MEGALOPTERA – Alderflies, Dobsonflies and Fishflies

This is a small order and most are aquatic as larvae. Nevertheless, some members of the Corydalidae (dobsonflies) pupate under mosses, a stage lasting about two weeks (Needham et al. 1901). These species include Chauliodes pectinicornis (Figure 1-Figure 2), C. rastricornis (Figure 3-Figure 4), and Nigronia serricornis (Figure 5-Figure 6).
Barnard (1931) reported pupae of alderflies (Sialidae) from Sphagnum and other wet or aquatic mosses that grew near or in streams and waterfalls in South Africa. These alderflies required that the mosses be wet.

NEUROPTERA – Lacewings

Not many members of Neuroptera use bryophytes, but Richards and Davies (1977) reported that lacewing larvae search for prey in mosses.

Osmylidae

The larvae of Osmylus (Figure 7) live in the mosses on the banks of woodland streams (Elliott 1996). Even the adults are typically found near these small streams that have mossy banks suitable for larval development. In Great Britain, the larvae can be found in these mosses throughout the year. In the winter they migrate deep into the moss rhizoids where they hibernate.

The female Osmylus fulvicephalus (Figure 7) lays about 30 eggs 2-3 days after mating (Elliott 1996). These often are laid in small groups. When deposited on mosses they are laid singly or in pairs on the undersides of leaves and near the water (Lestage 1920; David 1936; Ward 1965). The eggs are cylindrical and slightly flattened. These white eggs darken to brown within a few days, making them less obvious than the white version. Eggs hatch in 4-22 days, depending on the temperature (Withycombe 1923; David 1936; Ward 1965).

When the larvae of the giant lacewing, Osmylus fulvicephalus (Figure 7), emerge, they burrow into the mosses (Elliott et al. 1996) and live among damp mosses in the splash zones of river banks and streams (Plant 1994; Roper 2001). These larvae are only 5 mm when they hatch, but reach 15 mm by the third (final) instar from which they develop into pupae (Elliott 1996).

In this moss habitat Osmylus fulvicephalus (Figure 7) larvae are able to eat small arthropods (Elliott et al. 1996). They strike at movement and inject enzymes that paralyze the prey. When they hatch, the first instar larvae eat mites and Collembola, but second and third instars switch to
eating larvae of small Diptera. The common Chironomidae (midges) are paralyzed in 10 seconds by the enzymes. They then suck the contents out of the prey. The larvae may dive into the water to find prey, but if they are forced to remain submersed they die within 8-28 days (Ward 1965).

The third (and final) larval instar overwinters in diapause and is able to withstand total immersion during flooding (Elliott et al. 1996). When spring arrives, the larvae make a cocoon, incorporating some of the moss in the cocoon, then pupate for 10-14 days before cutting their way out with their mandibles. They then emerge as adults (Figure 8) without further feeding. The adults fly about over the water surfaces in their woodland homes in the evening (crepuscular) (Elliott 1996).

Chrysopidae

The Chrysopidae don’t live among bryophytes, but they sometimes wear them. The larvae attach various pieces of debris, including bits of mosses and lichens, on their backs (Figure 9) (Skorepa & Sharp 1971; Slocum & Lawrey 1976; Eisner et al. 2002; Pérez-de la Fuente et al. 2012; Anonymous 2015; Newman et al. 2015). This cloak provides camouflage that hides them from both predators and prey.

Larvae of the green lacewing Leucochrysa pavida (Figure 10-Figure 13) (Slocum & Lawrey 1976) and the brown lacewing (Anonymous 2015) take their camouflage with them. They make packets of lichen fragments, bark, pollen grains, fungal spores, and moss fragments that they attach to spines on their backs (Slocum & Lawrey 1976). Likewise, immature brown lacewings use lichen and moss coverings to camouflage and protect them from predators and to disguise themselves from their prey (Insects 2014).

**Hallucinochrysa diogenesi** (Figure 14) is a fossil lacewing that attached plant fibers, bark, leaves, algae, mosses, snail shells, and corpses of its food prey on its back (Pérez-de la Fuente et al. 2012). These were held in place by the bristles on the backs of the larvae.

**Summary**

The **Megaloptera** and **Neuroptera** are small orders. Hence there are few bryophyte dwellers. Some members of **Megaloptera** pupate under mosses. In the **Neuroptera**, the best known bryophyte-dwelling genus is **Osmylus**. *Leucochrysa pavida* makes packets of camouflage that include moss fragments among other objects.
