In aquatic systems, CO₂ is not very soluble, is easily lost to the atmosphere at warm temperatures, and availability is pH-dependent, so it can indeed be limiting. The diffusion coefficient for CO₂ in water is only 10⁻⁴ times that found in air. The boundary layer between the moss and the flowing water reduces that availability even more. Aquatic bryophytes have high CO₂ compensation points (> 50 μl L⁻¹), higher than that of typical of C₃ tracheophytes (Bain & Proctor 1980).

Raven *et al.* (1998) indicate that stream mosses such as *Fontinalis antipyretica* (Figure 27) have very little CO₂ limitation because of the constantly flowing water that renews CO₂ and the reduced boundary layer resulting from water flow. On the other hand, in deep, quiet water, this species has much more difficulty getting CO₂, despite

higher concentrations, due to the increased boundary layer surrounding the moss.

Unlike many aquatic tracheophytes, mosses are apparently unable to use bicarbonates as a source of CO₂ (Bain & Proctor 1980; Allen & Spence 1981). Ruttner (1947) first demonstrated this limitation quantitatively in the mosses *Calliergon giganteum* (Figure 34), *Cratoneuron filicinum* (Figure 35), *Eucladium verticillatum* (Figure 36-Figure 37), *Fissidens rufulus* (Figure 38-Figure 39), *Hylocomium splendens* (Figure 22-Figure 23), and *Neckera crispa* (Figure 40) and the thallose liverwort *Marchantia polymorpha* (Figure 19), and Steeman Nielsen (1947) found the same in *Fontinalis antipyretica* (Figure 27), even though *F. antipyretica* has the enzyme carbonic anhydrase needed for the conversion of bicarbonate to CO₂. Bain and Proctor (1980) further examined mosses from alkaline habitats, yet were unable to demonstrate any use at all of bicarbonates; Allen and Spence (1981) independently determined this once more for *Fontinalis antipyretica*.

Therefore, in aquatic systems at higher levels of pH, when the CO₂ equilibrium shifts toward bicarbonate or carbonate, CO₂ becomes unavailable. In these conditions, perhaps the CO₂ is transformed from bicarbonates in some taxa by lower pH values at the moss-water interface, but no experimental evidence has verified this hypothesis. Thus, the number of mosses growing in alkaline waters is limited, and it seems that many of the ones that do occur in alkaline waters are adapted to growing in the highly aerated water of waterfalls and rapids, as, for example, *Fissidens grandifrons* (Figure 41) (pers. obs.). Some grow in very cold glacial meltwater in which more CO₂ is soluble (Vitt *et al.* 1986). Others are restricted to the splash zone at the edge of the water, where CO₂ is trapped as the water moves through the air, as in *Cratoneuron* (Figure 42) species (Vitt *et al.* 1986; Glime & Vitt 1987).

When mosses live at great depths, light and temperature can be low. The ability of mosses to grow slowly reduces their need for CO₂ and light. In great depths of Lake Grane Langos, Denmark, *Sphagnum subsecundum* (Figure 43) and *Drepanocladus exannulatus* (Figure 44) grew faster in deep water than in shallow water! (Riis & Sand-Jensen 1997). Riis and Sand-Jensen concluded that this more rapid growth at greater depths was possible due to lower temperatures that permitted more CO₂ to remain dissolved, CO₂

supersaturation, and nutrient enrichment from the sediments below the thermocline.

Role of pH

In the aquatic system, pH is important in determining the chemical fate of the CO₂. Under acidic conditions, it remains dissolved as CO₂. But if the water is warm, the CO₂ gas is easily lost to the atmosphere.

At circum-neutral pH levels, the CO₂ in water is converted to bicarbonate. At least some tracheophytes are able to use bicarbonates, but studies on use by bryophytes are ambiguous. In basic waters, carbonates are formed and cannot be used by any of the plants.

In situations of higher pH, CO₂ can be present for a short time as it is released from sediments or trapped in turbulent water (Lovalvo *et al.* 2010). Bryophytes could take advantage of these ephemeral concentrations before they are converted to unusable forms.

Within the cell, the enzyme **carbonic anhydrase** converts bicarbonates to CO₂ in both bryophytes and tracheophytes (Steeman Nielsen & Kristiansen 1949; Arancibia & Graham 2003). Some tracheophytes use extracellular carbonic anhydrase to convert bicarbonates to free CO₂ (Allen & Spence 1981). There is no direct evidence that bryophytes can use bicarbonates (James 1928; Ruttner 1947; Steeman Nielsen 1947; Bain & Proctor 1980; Allen & Spence 1981; Osmond *et al.* 1981; Glime & Vitt 1984; Prins & Elzenga 1989; Madsen *et al.* 1993; Ballesteros *et al.* 1998; Raven *et al.* 1998); nevertheless, some bryophytes are able to live in the pH range of bicarbonates. I have an unconfirmed suspicion that bryophytes may convert limited amounts of bicarbonate to CO₂ at the leaf surface, perhaps by the presence of H⁺ released from exchange sites.

To further complicate the story, Farmer *et al.* (1986) found that the aquatic moss *Fontinalis antipyretica* (Figure 27) has no **PEP carboxylase** and uses only Rubisco for its fixation of CO₂ in photosynthesis, supporting the earlier conclusion of Steeman Nielsen (1947) that *F. antipyretica* cannot use bicarbonates from the water for its photosynthesis. Nevertheless, Harder (1921) had already shown that *F. antipyretica* increased its net assimilation from 0.01 to 0.64% when bicarbonate concentration was raised from 0.66 to 3.14 as HCO₃⁻. Later, Burr (1941) likewise demonstrated greater productivity in this species in water with more bicarbonate than in that with CO₂.

Steeman Nielsen and Kristiansen (1949) offered a possible explanation – that CO₂ might enter photosynthetic reactions in its hydrated form, *i.e.* as bicarbonate.

Bain and Proctor (1980) found that of the 20 aquatic species tested from a variety of habitats, all but the hornwort *Anthoceros husnotii* (Figure 45) with pyrenoids had pH compensation points in the range expected for CO₂-dependent C₃ plants. Nevertheless, many studies support the concept that all aquatic mosses are C₃ plants (Ruttner 1947; Allen & Spence 1981; Osmond *et al.* 1981; Salvucci & Bowes 1981; Raven 1991; Raven *et al.* 1987, 1994, 1998), despite some living in conditions that have CO₂ concentrations below the expected CO₂ compensation point.

Figure 45. *Anthoceros husnotii*, a species with pyrenoids, giving it a different pH compensation point from that of non-hornworts. Photo from Earth.com, with permission.

Peñuelas (1985) demonstrated what appeared to be use of NaHCO₃ (sodium bicarbonate) by *Fontinalis antipyretica* (Figure 27) as a carbon source. During photosynthesis by this species, the pH increased to 9.6, indicating a CO₂ compensation point of 1.1 mM m⁻³ CO₂. This photosynthetic rate was higher than could be explained by CO₂ alone and when HCO₃⁻ levels were increased, the photosynthetic rate likewise increased, even though CO₂ levels in the water were held constant. In fact, photosynthesis continued until the pH reached 11.8-12.0 for *F. antipyretica* and 10.10 for the alkaline-tolerant *Fissidens grandifrons* (Figure 41). But to further confuse the issue, in a different stream, Peñuelas found that *F. antipyretica* could not use HCO₃⁻ to photosynthesize, suggesting either different physiological races or different acclimation to conditions. We know that there are genetic differences among populations of this highly variable species (Shaw & Allen 2000). Even if these genetic differences are expressed as a physiological mechanism to use bicarbonate, we still do not understand what that mechanism might be!

Bogs

Hummocks present unique habitats, and their CO₂ relations are no exception. Rydin and Clymo (1989)

described their upper parts as obtaining CO₂ from air rather than water between the *Sphagnum* (Figure 28) plants, depending on high CO₂ concentrations in the **acrotelm** (living layer of peat) water. In fact, they found that the CO₂ concentration in that layer was twice that in the outside atmosphere (Rydin & Clymo 1989; Smolders *et al.* 2001).

As the atmospheric levels of CO₂ rise and N deposition provides critical and often limiting nutrients, the composition of plant communities changes. This is particularly true in *Sphagnum* (Figure 46-Figure 51) bogs (Berendse *et al.* 2001). In this case, we expect productivity of tracheophytes to increase as they benefit from greater CO₂, often decreasing the competitiveness of the bryophytes and causing tracheophyte expansion. *Sphagnum* is one of the most important groups of plants to serve as a carbon sink in the Northern Hemisphere, facilitated by its slow decomposition. But when Berendse and coworkers studied the effects of raised CO₂ and N on *Sphagnum* and other plants in four locations in Western Europe, the elevated CO₂ had no effect on *Sphagnum* biomass increase. N, on the other hand, caused a decrease in *Sphagnum* growth due to competition.

In a bog in the Netherlands, *Sphagnum divinum* (previously in *S. magellanicum*; Figure 46) benefitted from elevated CO₂ by exhibiting increased growth in height in the second and third growing seasons (Heijmans *et al.* 2001). Tracheophytes that grew close to the more rapidly growing *S. divinum* were affected negatively by the increased *Sphagnum* height. Mitchell *et al.* (2002) found that on one harvested peatland the initial colonizer was *Polytrichum strictum* (Figure 5). Under a treatment of added CO₂ (560 ppm), the later colonizer *Sphagnum fallax* (Figure 47) was able to successfully compete with the *P. strictum*.

Figure 46. *Sphagnum divinum*, a species that increases in height growth when living in higher CO₂ levels. Photo by David Holyoak, with permission.

Van der Heijden *et al.* (2000a) found that not all *Sphagnum* had the same response to elevated CO₂. *Sphagnum papillosum* (Figure 48), an oligo-mesotrophic species, benefitted in growth from elevated CO₂ (720 ppm). On the other hand, the ombrotrophic *S. balticum* (Figure 49) received no growth benefit, despite elevated sugar in stems and capitula in both species. Unlike many of the studies discussed in subchapter 8-1, in this case additional

N along with elevated CO₂ benefitted *S. papillosum*, but it had no effect on *S. balticum*. Doubling CO₂ without N addition cause lower N levels in both species.

Figure 47. *Sphagnum fallax*, a species that competes better in an atmosphere with higher CO₂. Photo by Michael Lüth, with permission.

Figure 48. *Sphagnum papillosum* with sundew. Photo by Michael Lüth.

Figure 49. *Sphagnum balticum*, a species that does not benefit when additional N accompanies elevated CO₂. Photo by Michael Lüth, with permission.

The response of *Sphagnum fallax* (Figure 50) may explain the elevated sugars (van der Heijden *et al.* 2000b).

Initially, elevated CO₂ stimulated photosynthesis, but after 3 days of exposure it was down-regulated to pre-elevation values. However, the elevated CO₂ continued to cause reduced dark respiration. At the same time there was a continuous increase in soluble sugar in the capitula. Doubling the CO₂ caused a decrease of N in the capitula, but not in the stems. This N reduction was coupled with a decrease in amino acids but did not affect soluble protein levels, causing a shift in N partitioning.

Figure 50. *Sphagnum fallax*, a species that stores elevated sugars when the CO₂ is elevated. Photo by Jan-Peter Frahm, with permission.

Not all *Sphagnum* grows in hummocks. *Sphagnum cuspidatum* (Figure 51) grows primarily submerged. When it was subjected to added CO₂ for 12 weeks, only the highest CO₂ concentration in the water caused increased growth in length and biomass (Paffen & Roelefs 1991).

Figure 51. *Sphagnum cuspidatum*, a submerged moss that is indifferent to added CO₂ until the levels are quite high. Photo by Michael Lüth, with permission.

In addition, some bryophytes may be able to tap into a source of carbon we usually don't consider in bryophytes. Rydin and Clymo (1989) have demonstrated that at least in *Sphagnum* the fixed carbon can be transported within the stem. Using ¹⁴C labelling on *Sphagnum papillosum* (Figure 48), they found almost the entire alcohol-soluble fraction moved from older parts to the apex, with little transfer of the insoluble fraction.

Methane

Methane (CH₄) is the product of **anaerobic** (no oxygen) bacterial breakdown. In several bogs of Canada, the highest emissions occurred in raised-bog and patterned-poor-fen pools where the peat is degrading (Bubier 1995). Methane is much more effective as a greenhouse gas compared to CO₂. And wetlands are the largest natural source for methane. Submerged *Sphagnum* (Figure 51) uses methane that is converted through symbiosis with partly endophytic **methanotrophic** (able to gain carbon from methane) bacteria, leading to highly effective *in situ* methane recycling (Raghoebarsing *et al.* 2005). These bacteria live in the hyaline cells and on leaves where they convert the methane to CO₂. This conversion provides 10-15% of the carbon source for these *Sphagnum* species.

CO₂ and Desiccation Tolerance

Syntrichia ruralis (Figure 21) is a common desiccation-tolerant moss. When subjected to elevated CO₂ it showed increased net CO₂ uptake in high CO₂ conditions by more than 30% (Tuba *et al.* 1998). Both desiccation-tolerant and non-tolerant plants, bryophytes included, show initial positive responses of photosynthesis to elevated CO₂, but both groups exhibit reduced or even reversed photosynthetic rates in the longer term (Tuba *et al.* 1999). This slightly later study implies that increased CO₂ levels will have little advantage for either group of bryophytes.

Translocation

Rydin and Clymo (1989) found that carbon is transported within *Sphagnum* (Figure 50) plants. This could provide a physiological mechanism that moves older carbon compounds from deeper parts of the peatlands upward. This could dilute the ¹⁴C pool within the living plant and change both the location and the proportions of ¹²C, ¹³C, and ¹⁴C. If *Sphagnum* is able to take in carbon from deep sediments and move it upward in the water column, this would result in false readings for carbon dating. Might the moss be preferentially moving ¹²C upward from older peat and thus reducing its proportion of ¹⁴C? If so, we need to re-evaluate our methods for dating peat.

By contrast, it appears that mosses like *Grimmia* (Figure 52) that receive their water from above can actually move carbon as photosynthate from the tip of the plant to the base and even to underground parts, much as we would find in a tree (Alpert 1989). Lacking any specialized conducting cells, this moss presents a puzzle as to its mechanism of movement, although as we shall see later in this chapter, it uses the source-sink principle used by tracheophytes.

Importance of Bryophytes in C Cycling

Porada *et al.* (2013) estimated that the terrestrial net uptake of carbon by bryophytes and lichens is 0.34 to 3.3 Gt yr⁻¹ (gigatons). This appears to be small until you consider bogs and polar habitats where bryophytes dominate the vegetation. In those locations, the bryophytes are significant carbon sinks.

Turetsky (2003) noted that bryophyte growth and metabolism have a direct influence on the carbon flux into the ecosystem. She found that annual accumulations of C in the bryophytes are a better measure for understanding the carbon cycle. Growth of such species as those of *Sphagnum* (Figure 46-Figure 52) can range from ~19-1,656 g m⁻² yr⁻¹, with carbon comprising about 48% of this biomass. Feather mosses in the boreal forest have a net primary productivity ranging 24-80 g C m⁻² yr⁻¹. In the Antarctic, *Polytrichum juniperinum* (Figure 53) has a net primary productivity of 213-350 g m⁻² yr⁻¹, whereas *Chorisodontium aciphyllum* (Figure 54) living there has 162 g m⁻² yr⁻¹ (Fenton 1980). Nevertheless, Turetsky noted with surprise that the bryophyte net primary productivity (NPP) of polar, boreal, and temperate regions were comparable.

Flushing contributes loss of carbon from plant and litter layers, particularly following desiccation (Turetsky 2003). Soluble organic compounds are lost as membranes become distended and cannot continue to retain the soluble contents. During rewetting, these leaked compounds can become leached to the environment (Proctor 1982; Wilson & Coxson 1999). Mats of the boreal/alpine moss *Hylocomium splendens* (Figure 22-Figure 23) released a pulse of organic carbon equivalent to -15 kg ha⁻¹ following rain events (Wilson & Coxson 1999). The soluble C from living *H. splendens* was 23-75% of that released. Tropical epiphytes can release equivalent to 122 kg ha⁻¹ yr⁻¹ of soluble sugars (Coxson *et al.* 1992).

The carbohydrate leachates from the boreal forest moss *Pleurozium schreberi* (Figure 55) can support the growth of mycorrhizal fungi and can even reach *Pinus contorta* (Figure 56) through this pathway (Carleton & Read 1991). Similarly, soluble carbohydrates can penetrate to deeper layers of peatlands and wetlands where they are taken up by microbes (Charman *et al.* 1999; Chasar *et al.* 2000). They further influence this activity by providing suitable habitat for invertebrates (Gersen 1982; Merrifield & Ingham 1998) that break up the bryophytes into smaller pieces that provide more surface area for the microbes to colonize. Microfungi associated with the bryophytes can decompose organic carbon (Tsuneda *et al.* 2001; Thormann *et al.* 2002). Any of this released carbon can also be exported to streams and lakes (Schindler *et al.* 1997; Carpenter *et al.* 1998; Elder *et al.* 2000).

Figure 56. *Pinus contorta*, a species that can benefit from mycorrhizae that use carbon leachates from mosses. Photo by Walter Siegmund, through Creative Commons.

The bryophytes have physical effects on the return of carbon from other plants. They can reduce soil temperature and increase soil moisture, thus affecting the rate of decay and carbon cycling (Van Cleve *et al.* 1983; Sveinbjornsson & Oechel 1992; Eckstein 2000). Their external capillary action enhances the possibilities for decomposition (Turetsky 2003).

Climate Change – an Antarctic Problem

Bryophytes in the Antarctic must contend with large temperature fluctuations within a single day. Pannewitz *et al.* (2005) note the importance of understanding the effects of climate change on the bryophyte component in order to predict the effects of climate change on vegetation there. Their results from variations in temperature, light, moisture content, and CO₂ suggested that it would be very difficult to predict the effects of climate change on these communities. Increases in temperature are likely to cause increases in CO₂ as long-standing dead portions begin to decay. They found that there was a large response to increases in CO₂ by two of the three bryophytes they tested [*Bryum pseudotriquetrum* (Figure 57), *B. subrotundifolium* (Figure 58)], with increasing temperatures causing a greater response. CO₂ saturation wasn't reached at the 20°C temperature tested. *Bryum pseudotriquetrum* exhibited no saturation up to 2000 ppm CO₂ at 20°C. *Bryum subrotundifolium*, however, became saturated above 1000 ppm. Thus CO₂ was limiting for both species at the ambient CO₂ of 360 ppm.

Figure 57. *Bryum pseudotriquetrum*, a species whose CO₂ saturation is above 2000 ppm. Photo by Hermann Schachner, through Creative Commons.

Figure 58. *Bryum subrotundifolium*, an Antarctic bryophyte in which CO₂ saturation is reached when CO₂ exceeds 1000 ppm. Photo by Rod Seppelt, with permission.

On the other hand, *Hylocomium splendens* (Figure 22-Figure 23) (Sonesson *et al.* 1996) and Arctic tracheophytes (Oechel *et al.* 1997) demonstrated that such enhancement of photosynthesis could be short-lived. This short-term enhancement could be the result of rapidly reaching nutrient limitation (Oechel & Billings 1992). However, in the Antarctic nutrients are rarely limiting (Kappen & Schroeter 2002), at least in part due to the rich guana deposits (Green *et al.* 2000a, b). Nevertheless, Pannewitz and coworkers (2000) concluded that increased CO₂ in the atmosphere would probably not have long-term effects because the ambient levels might already be high in the Antarctic. On the other hand, I would expect that increased temperatures there would increase the very slow rate of decomposition, thus potentially causing great increases of CO₂ for the bryophytes at the ground level where they live.

Bryophytes and tracheophytes might respond differently to CO₂ and climate change. Green *et al.* (1998) found that the relationships between the electron transfer rate (ETR) and CO₂ in photosynthesis of bryophytes differs from that found in tracheophytes. Dark respiration responds strongly to cause substantial changes in CO₂ exchange rates. In Antarctic populations of *Bryum argenteum*, there is a strong linear relationship between gross photosynthesis and the electron transfer rate, an unusual response exhibited by the C₃ bryophytes compared to that of C₃ tracheophytes. This relationship varied with temperature; Green and coworkers suggested that light suppression of dark respiration might be involved.

Summary

The early atmosphere had considerably more CO₂ than the current one. However, in the last 60 years, CO₂ concentrations have risen from 315 to 404 ppm in the atmosphere.

Soils release CO₂ through respiration by bacteria, fungi, and other soil organisms. Bryophytes are able to trap much of this CO₂ before it reaches the atmosphere.

Thallose liverworts may have a spongy interior with pores to facilitate exposure of internal photosynthetic cells to CO₂. Mosses are C₃ plants that benefit from high CO₂ concentrations and cool to moderate temperatures (up to 25°C). They have difficulty obtaining CO₂ when they are wet and the presence of cuticular waxes in species such as *Polytrichum* spp. and *Saelania glaucescens* facilitates the absorption of CO₂ by repelling water. *Sphagnum* keeps its photosynthetic cells moist on 2-3 sides while permitting 1-2 sides to be exposed to the atmosphere.

Hornworts may have pyrenoids that concentrate CO₂ around the enzyme Rubisco, facilitating photosynthesis. Some aquatic mosses may be able to concentrate CO₂ and this may be facultative, being enhanced on hot days. In acid conditions they use CO₂ dissolved in the water, but some evidence suggests that in the mid-pH range some species may be able to use bicarbonates.

Some bryophytes can use amino acids. At least some *Sphagnum* species use methane as a carbon source. And some species can move C up or down within the plant.

Bryophytes, especially in wet habitats, may be able to move water up from sediments, taking advantage of decompositional carbon. Others may move photosynthate from actively growing apical parts to lower parts for storage.

Bryophytes may serve as carbon sinks, especially in peatlands.

Acknowledgments

I appreciate the contributions of undergraduate Phil Gaudette and M. S. student Jennifer Jermalowicz Jones for their critical reading of the manuscript from the perspectives of students interested in nutrient relationships of bryophytes. Stephen Rice helped to clarify the carbon discussion.

CHAPTER 8-3

NUTRIENT RELATIONS: NITROGEN

Figure 1. *Physcomitrella patens* growing on previously flooded soil. Note the nitrogen-fixing blue-green bacterium, *Nostoc*, at the arrow. Photo by Michael Lüth, with permission.

N Forms

Nitrogen is available in many forms. The most abundant of these, N_2 gas, cannot be used by plants or animals and must be converted by **Cyanobacteria** or bacteria before plants can use it. Animals can only obtain it by eating other organisms that have already placed the N into amino acids. Other forms of N that plants can absorb include **ammonium** (NH_4^+), **nitrite** (NO_2^-), **nitrate** (NO_3^-), and organic forms such as **amino acids** and **urea**. As we shall soon see, not all bryophytes have the same ability to use these forms and some are toxic to most taxa.

Nitrate and Ammonium

Plants, including bryophytes, can take in and use both NO_3^- (nitrate) and NH_4^+ (ammonium). The form of nitrogen needed by bryophytes varies with species and habitat. Aquatic higher plants use nitrogen in three inorganic forms: NO_2^- (nitrite) (Schwoerbel & Tillmanns 1964, 1977), NO_3^- , NH_4^+ (Schwoerbel & Tillmanns 1972; Rudolph & Voigt 1986). Bryophytes usually absorb NH_4^+ more easily than they absorb NO_3^- (Schwoerbel & Tillmanns 1974; Simola 1975; Miyazaki & Satake 1985;

Schuurkes *et al.* 1986). Cation vs anion exchange sites may determine the use of nitrate (anion) vs ammonium (cation), causing *Sphagnum* to have a strong preference for ammonium because of its extensive cation exchange sites (Wanek & Pörtl 2008).

Vanderpoorten (2000) reported that NH_4^+ N is one of the best factors to explain differences in aquatic *Amblystegium* (Figure 2) distributions in river systems. Frahm (1975) found that the brook moss *Fontinalis antipyretica* var. *gigantea* (Figure 3) had a low tolerance for NH_4^+ , but Schwoerbel and Tillmanns (1974, 1977) found conflicting evidence showing that this species uses NO_3^- and NH_4^+ , with NH_4^+ being taken up first if provided together with NO_3^- . In fact, it is unable to uptake NO_3^- in the dark (Schwoerbel & Tillmanns 1974). To show the complexity of the N relationships, growth on a nitrate medium requires the bryophytes to convert it to ammonium ions before they can assimilate it (Brown 1982). It is possible that various strains have developed within species that have different tolerance levels for some of their nutrients.

Figure 2. *Amblystegium fluviatile*, an aquatic moss sensitive to ammonium levels. Photo by Michael Lüth, with permission.

Figure 3. *Fontinalis antipyretica* var. *gigantea* dry, a moss with mixed responses to ammonium as its nitrogen source. Photo by Janice Glime.

Physiology of Nitrate and Ammonium

Assuming that bryophytes operate as do **tracheophytes** (lignified vascular plants), NO_3^- , once in the plant, is converted to NH_4^+ . In leaves, the intermediate product, NO_2^- , is reduced by **nitrite reductase** (enzyme that facilitates addition of hydrogen and loss of oxygen from NO_2^- during photosynthetic electron transport process). No intermediate product is released and the final product is NH_4^+ . Since photosynthesis provides the **NADH** (nicotinamide adenine dinucleotide + H , the active coenzyme form of vitamin B_3) and **ferredoxin** needed for conversion of nitrogen oxides to NH_4^+ , the conversion process is enhanced by the same things that enhance photosynthesis – high light and warm temperatures (Salisbury & Ross 1978). Thus, more ammonium is produced.

Morphological Anomalies

Brown (1982) suggested that the pH or alkalinity affects availability of N for plants, with NO_3^- being more available in neutral or alkaline soils and NH_4^+ in acidic soils and water. But NH_4^+ is usually toxic to plants in any appreciable quantity. Sironval (1947) found that NH_4^+ ions caused degeneration of the **caulonema** (part of protonema from which buds arise) of *Funaria hygrometrica* (Figure 4) and Southorn (1977) found they caused morphological abnormalities in the same species. Killian (1923) likewise found morphological abnormalities in the leafy liverwort *Scapania* (Figure 5). On the other hand, Burkholder (1959) found that cultured bryophytes did equally well on both NO_3^- and NH_4^+ salts.

Figure 4. *Funaria hygrometrica* protonema showing caulonema, a stage that seems to degenerate when ammonium ions are added. Photo by Janice Glime.

Figure 5. *Scapania undulata*, an aquatic leafy liverwort that exhibits morphological abnormalities when ammonium concentrations are too high. Photo by David T. Holyoak, with permission.

An interesting consequence of pH differences was suggested by Machlis (1962). In *Sphaerocarpos texanus* (Figure 6), male plants are smaller than females in the field. Machlis attributed this to the ability of male plants to absorb NH_4^+ ions more readily than females, causing them to have a lower pH , which could suppress growth. He supported this suggestion by growing the plants on potassium, which caused no pH change, and likewise no reduction in the size of male plants.

Figure 6. *Sphaerocarpos texanus*, a thallose liverwort in which male plants absorb NH_4^+ ions more readily than do females, causing males to have a lower pH, possibly accounting for growth suppression and smaller males. Photo by Martin Hutten, with permission.

Benefit or Detriment?

In a study designed to determine the effects of various forms of N on bryophyte function, Alghamdi (2003) studied the popular, fast-growing aquarium moss *Taxiphyllum barbieri* (Java moss, Figure 7). He found that the benefit to the moss depends on what parameter you measure (Figure 8). For example, dry biomass increase was greatest in high NO_3^- concentrations ($30 \text{ mg L}^{-1} \text{ N}$), whereas the greatest increase in length occurred in high NH_4^+ concentrations ($30 \text{ mg L}^{-1} \text{ N}$). This difference resulted in the least biomass increase per stem length in high NH_4^+ concentrations, despite the relatively high increase in length in that treatment. The overall appearance of the mosses in high NH_4^+ , then, was to appear long and thin compared to those in other treatments, but not dissimilar to the plants in the control (standard nutrient solution but with no N source). Based on the lower growth in the NH_4NO_3 media, Alghamdi reasoned that in the presence of NH_4^+ , the NO_3^- became unusable because of the inhibition of nitrate reductase by NH_4^+ (see Syrett & Morris 1963; Orebanjo & Stewart 1975). At the same time, the lower concentration of NH_4^+ ($15 \text{ mg L}^{-1} \text{ N}$) in combination compared to NH_4^+ alone ($30 \text{ mg L}^{-1} \text{ N}$) reduced the growth. This relationship was consistent with much greater growth at $30 \text{ mg L}^{-1} \text{ N}$ than at $10 \text{ mg L}^{-1} \text{ N}$ as NH_4^+ (Figure 8).

Figure 7. *Taxiphyllum barbieri*, an aquarium moss subjected to high ammonia concentrations from fish waste products. Photo by Tan Sze Wei, Aquamoss website <www.aquamoss.net>, with permission.

NO_2^- caused only modest improvements in biomass and length over N-free controls (Figure 8), but caused considerable increase in chlorophyll *a* (Alghamdi 2003; Figure 10). The chlorophyll *a:b* ratio was highest in the high NO_3^- treatment, due to mosses in that treatment having the least chlorophyll *b* per biomass of moss, a concentration even lower than that of controls (Figure 10). In fact, effects of inorganic N form on chlorophyll *b* resulted in either no improvement over N-free controls, or depressed levels of chlorophyll *b*. However, chlorophyll *a* was higher in nearly all nitrogen treatments than in controls. Baxter *et al.* (1992) found a similar but slight decrease in total chlorophyll concentration in *Sphagnum cuspidatum* (Figure 9), typically a submersed species, with increasing levels of NH_4^+ , but in Alghamdi's experiments, *Taxiphyllum barbieri* (Figure 7) actually had total chlorophyll increase, although not statistically significant, with increase from 1 to $30 \text{ mg L}^{-1} \text{ N}$ as NH_4^+ (Figure 10).

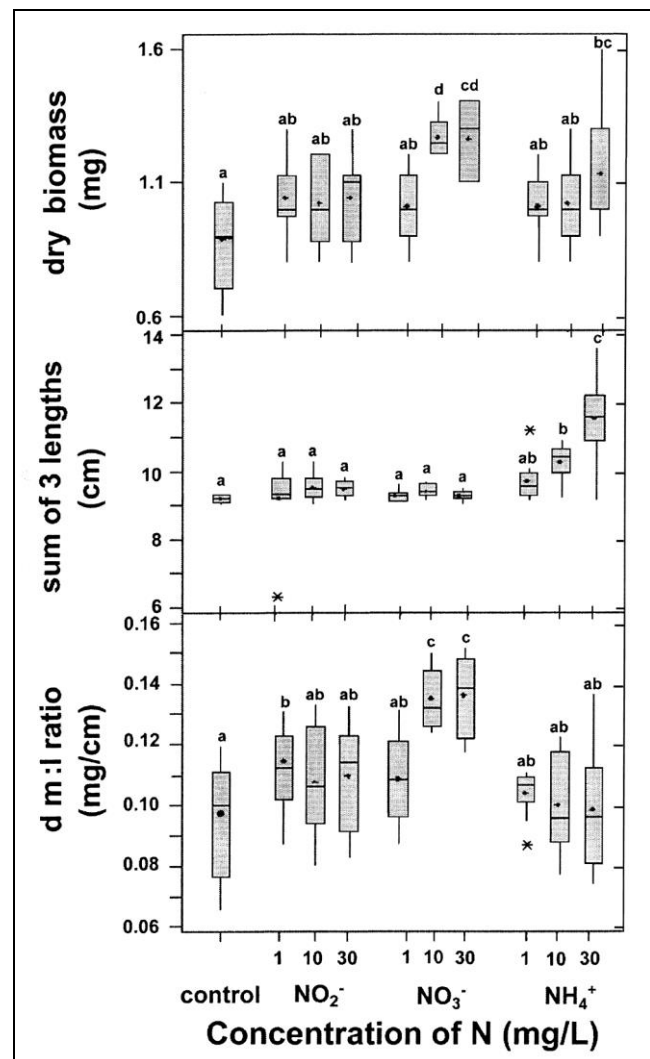

Figure 8. Effects of various forms of inorganic N (control = no N) on growth in length (l) and biomass (d m) of *Taxiphyllum barbieri*. Box mean (dot) and median (horizontal line); bottom of box is first quartile and top is third quartile. Whiskers represent lowest and highest observations still inside region defined by lower limit $Q1-1.5 (Q3-Q1)$ and upper limit $Q3+1.5 (Q3-Q1)$; *represents outliers that extend beyond whiskers; $n=15$ sets of 3 stems. Means with same letters are not significantly different from each other (DNMRT, $\alpha = 0.05$). Based on Alghamdi 2003.

Figure 9. *Sphagnum cuspidatum*, an aquatic species that has a decrease in chlorophyll with an increase in ammonium ions. Photo by Jonathan Sleath, with permission.

Figure 10. Effects of various forms of inorganic N (control = no N, NO₂⁻ = nitrite, NO₃⁻ = nitrate, NH₄⁺ = ammonium) on chlorophyll *a* and protein concentrations of *Taxiphyllum barbieri*. Notation as in Figure 8; n = 15 sets of 3 stems. Based on Alghamdi 2003.

Protein concentrations in *Taxiphyllum barbieri* (Figure 7) showed a very different picture from other measurements, with little difference among treatments except at 10 and 30 mg L⁻¹ NO₃⁻ (Figure 10; Alghamdi 2003). In *Sphagnum cuspidatum* (Figure 9) Baxter *et al.* (1992) found the addition of NH₄⁺ (as NH₄Cl) generally caused an increase in amino acids, at least within the first 15 days, in both locations studied, with arginine increasing the most at the unpolluted site and actually decreasing at the NH₄⁺-polluted site. The latter study suggests that *Sphagnum cuspidatum* may acclimate to a higher level of NH₄⁺ in a way that it eventually requires higher levels than populations not continuously exposed to such high levels. Clearly the uses of the various forms of N in bryophytes are complex and one cannot give a simple answer as to which form is best.

Species Differences

In *Sphagnum* (Figure 18, Figure 33-Figure 23), differences exist among the species. *S. flexuosum* (Figure 11) is apparently unable to utilize NO₃⁻ (Schuurkes *et al.* 1986), and Touffet (1971) found that NO₃⁻ actually reduced the growth of *Sphagnum* and was less effectively utilized than NH₄⁺ when it was the only N resource. Nevertheless, in many *Sphagnum* species nitrate reductase, an inducible enzyme (Deising 1987), permits use of NO₃⁻. High levels of NH₄⁺ inhibit nitrate reductase, and hence reduce growth, by inhibiting NO₃⁻ uptake (Rudolph *et al.* 1987). Rudolph and Voigt (1986) demonstrated that 322 µM was a favorable concentration of NO₃⁻ in *S. magellanicum* (Figure 12), whereas at 225 µM NH₄⁺ the chlorophyll content decreased. At 600 µM NH₄⁺, nitrate reductase activity was reduced by as much as 20%. These factors most likely limit mosses in particular habitats.

Figure 11. *Sphagnum flexuosum*, a species that is unable to use nitrate. Photo by Michael Lüth, with permission.

Figure 12. *Sphagnum magellanicum*, a species that benefits from added nitrate. Photo by Janice Glime.

Growth is promoted by added nitrate and ammonium in *Sphagnum fallax* (Figure 13), a species of hollows and lawns (Twenhöven 1992). *Sphagnum magellanicum* (Figure 12), typically a hummock species, exhibits no benefit with the same treatments. In fact, both species on hummocks exhibit reduced growth in added nitrate and

ammonium. On the other hand, growth is reduced in levels that are lower than the levels resulting from the present atmospheric inputs, suggesting that these bogs were originally N limited. This changes the competitive status of these two species. *Sphagnum fallax* is typically competitive, whereas *S. magellanicum* is stress tolerant. When N deposition is elevated in previously N-limited conditions, *S. fallax* is able to outcompete *S. magellanicum*.

In the sub-Antarctic on Marion Island, increased NH_4^+ caused an increase in CO_2 assimilation for four moss species, but NO_3^- had a greater effect. Cl^- added with the NH_4^+ may have caused the lesser increase with NH_4^+ additions (Smith 1993). These increases are significant in this habitat with such low soil nutrient levels.

Long Term Effects

The negative effects of elevated nitrate and ammonia in fens are demonstrated in Dutch fens (Paulissen *et al.* 2004). These researchers found that *Scorpidium scorpioides* (Figure 14) and other brown mosses declined, whereas *Sphagnum squarrosum* (Figure 15) and *Polytrichum commune* (Figure 16-Figure 17) increased, lowering the pH. *Scorpidium scorpioides* did best on nitrate; ammonium nitrate decreased its growth somewhat, and ammonium itself was very toxic. *Sphagnum squarrosum* and *Polytrichum commune* experienced little affect from the N treatment.

Organic Nitrogen

Most agricultural plants seem to absorb their nitrogen in the form of NH_4^+ or NO_3^- , but it seems that bryophytes have more options. *Sphagnum* (Figure 18, Figure 23, Figure 33) is able to use urea (along with phosphate) in the

Alaskan wetlands, resulting in an increase in biomass compared to controls (Sanville 1988). In nature, amino acids likewise can be abundant, present as breakdown products of plant and animal wastes, litter, and corpses. Yet few culture studies or field tracer studies have included these organic forms until recently. Is it possible that bryophytes can use this organic N as their primary source? If so, they may benefit from organic leachates in early stages of litter decomposition of a soil environment.

In bogs and poor fens, NH_4^+ seems to be the predominant form of available N (Rosswall & Granhall 1980). NO_3^- is often lost through denitrification (Hemond 1983). Not surprisingly, some studies show that *Sphagnum* seems to require most of its inorganic N as NH_4^+ (Schuurkes *et al.* 1986). But Simola (1975, 1979) showed that *Sphagnum nemoreum* (= *S. capillifolium*; Figure 18) and *S. fimbriatum* (Figure 19-Figure 20) both could use amino acids. Simola (1975) examined the effects of common peat amino acids – those most likely to be available to the *Sphagnum*. For *Sphagnum nemoreum* NH_4NO_3 proved to be the best N source, with the ammonium ion being used more effectively than nitrate. The amino acids arginine and alanine as the only N source proved to provide satisfactory growth. On the other hand, this species made no use of the amino acids leucine, lysine, isoleucine, or methionine. Lysine actually inhibited growth. This species is more tolerant to organic nitrogen than are tracheophytes, especially of the non-proteinogenic amino acid hydroxyproline. More recently, McKane (1993), using tracer studies, found that for *Sphagnum*, *Aulacomnium palustre* (Figure 21), and *Hylocomium splendens* (Figure 22), the amino acid **glycine** was actually the preferred form of nitrogen over NH_4^+ and NO_3^- .

Figure 18. *Sphagnum nemoreum*, a species that can use amino acids as a nitrogen source. Photo by Michael Lüth, with permission.

It appears that in Arctic ecosystems, organic nitrogen (amino acids, especially glycine) may actually be the preferred source of N for some bryophytes, including *Sphagnum rubellum* (Figure 23) (Kielland 1997). Even amino acids with higher molecular weights, such as **aspartate** and **glutamate**, can be absorbed at higher rates than inorganic N. Kielland suggested that the high capacity for absorbing amino acids might be an adaptation to the low inorganic N availability in the Arctic.

Figure 22. *Hylocomium splendens*, a species that "prefers" glycine over ammonium and nitrate. Photo by Michael Lüth, with permission.

Figure 23. *Sphagnum rubellum*, a species that exhibited decreased growth when receiving elevated ammonium nitrate. Photo by Michael Lüth, with permission.

The Arctic is not the only place where amino acids can provide N for bryophytes. *Hylocomium splendens* (Figure 22) in the boreal forest can utilize glycine (Forsum *et al.* 2006). When ammonium, nitrate, and glycine were applied in spray solutions similar to the concentrations in precipitation, this moss took up the greatest labelled N compared to other concentrations. This included a 17% contribution from amino acid N.

Even floodplain bryophytes can use amino acids. Schuler *et al.* (1955) found that in culture the thallose liverwort *Sphaerocarpos texanus* (Figure 6) grew more typically on a mix of amino acids than it did on NH_4NO_3 alone.

Burkholder (1959) examined the effects of 20 amino acids (0.0001 M AA to 0.0016 M AA) with and without the addition of NH_4NO_3 on the color and growth of *Atrichum undulatum* (Figure 24). Glycine, L-cystine, L-cysteine, and L-tyrosine were the only treatments with amino acids alone in which the moss retained its green color. Others were yellow-green, brown-green, or brown (in DL-serine and DL-tryptophan). When grown in combination of each of these 20 amino acids with NH_4NO_3 , plants in all treatments grew more than in any of the amino acids alone except in the highest concentration (0.0016 M) of DL-tryptophan. Growth was generally greatest in the lower concentration of amino acid (0.0001 M) plus NH_4NO_3 .

Figure 24. *Atrichum undulatum* with capsules, a species that is able to use some amino acids, but not others. Photo by Andrew Hodgson, with permission.

The report of amino acid utilization by the aquatic Java moss (*Taxiphyllum barbieri*, Figure 7) (Alghamdi 2003), seems unusual among the aquatic mosses and may somehow relate to its ability to live in aquaria and tropical streams where most other bryophytes seem unable to survive. Could this in some way relate to the higher annual temperatures of its tropical habitat? Or is the lack of evidence for amino acid usage in many other species simply a lack of testing?

Alghamdi (2003) chose common soil water-soluble amino acids (glycine, methionine, serine, arginine, and alanine) to compare their effects on growth, branching, chlorophyll, and protein on the aquatic moss *Taxiphyllum barbieri* (Figure 7). He found that four of these amino acids induced branching, relative to the controls, but no branching appeared in any of the methionine treatments (Figure 25).

Figure 25. Effects of water soluble amino acids on number of branches in the Java moss, *Taxiphyllum barbieri*. cont = control, gly = glycine, meth = methionine, ser = serine, arg = arginine, ala = alanine. From Alghamdi 2003.

Methionine proved to be inhibitory to growth in length whereas serine caused an increase in both dry biomass and length relative to controls (Figure 26;

Alghamdi 2003). **Arginine** as the only N source at 1, 10, and 30 mg L⁻¹ caused a striking increase in the biomass and ratio of dry biomass to length, but maintained a length somewhat less than that of the N-free controls (Figure 26). This resulted in unusually short, wide plants, combined with high protein concentrations but below normal chlorophyll concentrations at the lowest level applied (1 mg L⁻¹; Figure 27).

Figure 26. Effect of water soluble amino acids on the biomass, length, and robustness (wt:length) of the Java moss, *Taxiphyllum barbieri*. Cont = control, Gly = glycine, Meth = methionine, Ser = serine, Arg = arginine, Ala = alanine. Length and biomass represent sum of 3 stems; n = 10 sets of 3 stems. Notation as in Figure 8. Based on Alghamdi 2003.

Methionine likewise caused an increase in biomass and decrease in length growth with concentration increase (1, 10, 30 mg L⁻¹). **Alanine** caused an increase in both length and biomass with concentration, with the overall effect being one of a more robust plant at higher concentrations, having a higher biomass to length ratio than that of the controls. The mosses responded to 1 mg L⁻¹ **glycine** much as they did to the N-free medium, but at higher concentrations (20 and 30 mg L⁻¹) their length and biomass both increased considerably over that of controls.

Alghamdi (2003) then compared the effects of glycine, which seemed to produce the "healthiest" plants, to those of the inorganic forms of N. This aquatic moss did less well on the inorganic forms NH₄NO₃ or NO₃⁻ than on NH₄⁺ alone or NH₄⁺ + the amino acid **glycine** and did best on glycine alone, producing more biomass, longer stems, and

more branches (Figure 28, Figure 29). In fact, glycine seemed to induce branching (Table 1).

Figure 27. Effect of water soluble amino acids on the protein content and total chlorophyll concentration of the Java moss, *Taxiphyllum barbieri*. cont = control, gly = glycine, meth = methionine, ser = serine, arg = arginine, ala = alanine. n = 10 sets of 3 stems. Notation as in Figure 8. From Alghamdi 2003.

In the same series of experiments, Alghamdi (2003) examined the effects of inorganic N and glycine on the chlorophyll and protein content of *Taxiphyllum barbieri*. Glycine, both alone and in combination with NH₄⁺, resulted in the highest protein concentrations (Figure 30). The effects on chlorophyll were less clear, but the highest total chlorophyll occurred in the highest glycine concentration (Figure 30). NH₄⁺ at 20 mg L⁻¹, however, produced similar chlorophyll concentrations, but at 30 mg L⁻¹ the chlorophyll content decreased.

Figure 28. Effect of N source as nitrate (NO₃⁻), ammonium (NH₄⁺), glycine (gly), and combinations at two concentrations on number of branches in *Taxiphyllum barbieri*. The combinations have half the total N from each source. From Alghamdi 2003.

Figure 29. Effect of nitrate (NO_3^-), ammonium (NH_4^+), glycine (gly), and combinations on the increase in biomass (d m) and length (l) and robustness (wt:length) of the Java moss, *Taxiphyllum barbieri*. Notation as in Figure 8; n = 10 sets of 3 stems. From Alghamdi 2003.

Table 1. Effect of various N forms on moss branching in *Taxiphyllum barbieri*. From Alghamdi 2003.

Treatment	Moss Branching
glycine	long with many short branches
NO_3^-	short and no branches
NH_4^+	long and few short branches
glycine + NH_4^+	long with many short branches and slightly thin
NH_4NO_3	short, thin and few short branches

Other organic compounds, such as nucleic acids, are also released from organism tissues as they decay. Based on his data showing that *Atrichum undulatum* (Figure 24) had good growth in a medium with yeast nucleic acids as its N source, Burkholder (1959) tested growth of this species on the nucleic acid bases. Growth of leafy shoots was good in **adenine** and **guanine**, but there was no growth

in uracil or thymine. Growth in xanthine, uric acid, and cytosine was less than that in NH_4NO_3 .

Figure 30. Effects of inorganic N compared to glycine on the protein and chlorophyll content of Java moss (*Taxiphyllum barbieri*). Notation as in Figure 8; n = 10 sets of 3 stems. From Alghamdi 2003.

Both uracil (in the presence of NH_4NO_3) and aspartic acid caused *Sphagnum squarrosum* (Figure 15) to become thalloid (resembling its protonema), as did hydroxyproline + glycine, occasionally (Burkholder 1959). Not all mosses responded in the same way. Growth of *Leptobryum pyriforme* (Figure 31) and *Splachnum sphaericum* (Figure 32) and others was "excellent" on a medium with NH_4NO_3 plus **uracil**, but was poor in *Sphagnum squarrosum*. On the other hand, while growth of *Leptobryum pyriforme* was good with **uric acid** and **cytosine**, *Splachnum sphaericum* had poor growth. The ability to use nucleic acids, amino acids, and other organic N compounds could permit bryophytes to take advantage of partially decomposed litter in which these nitrogen sources leak from the dead tissues.

Figure 31. *Leptobryum pyriforme*, a species that grows well with uric acid and cytosine. Photo by Michael Lüth, with permission.

Figure 32. *Splachnum sphaericum* with capsules, a species with good growth on NH_4NO_3 plus uracil, but poor growth with uric acid and cytosine. Photo by Michael Lüth, with permission.

When N (as NH_4NO_3) was added to a mire in central Sweden, *Sphagnum fuscum* (Figure 33), *S. magellanicum* (Figure 12), and *S. rubellum* (Figure 23) exhibited increased concentrations of amino acids in the capitulum (Nordin & Gunnarsson 2000). But the growth in length decreased at the same time. The researchers demonstrated that when the amino acid N concentrations exceeded 2.0 mg N g^{-1} dry mass, growth was negatively affected. The amino acid N concentrations did not serve as a good measure of N deposition rates when the deposition rates were less than $1.0 \text{ g m}^{-2} \text{ yr}^{-1}$.

Brown (1982) suggested that in low N environments the mosses may be able to move organic molecules containing N from dying and dead cells to the growing apex. It is very likely that these molecules would be amino acids, as well as dipeptides and other organic compounds.

Some amino acids, leaking into the environment from decaying vegetation, could cause developmental anomalies leading to abnormal growth forms in bryophytes. For example, amino acids, such as **hydroxyproline**, can cause desuppression in the development of underleaves in liverworts (Basile & Basile 1980; Basile *et al.* 1988), causing them to look like normal leaves. In the moss *Atrichum* (Figure 24), amino acids inhibited leafy shoot development (Burkholder 1959). This might be another example of the **Gaia hypothesis** (Lovelock, 1988), wherein the ecosystem behaves like a superorganism and species depend on other species for their biochemical needs during development. The N relationships of bryophytes are proving to be more complex than we previously thought.

Figure 33. *Sphagnum fuscum*, a species that exhibited decreased growth when receiving elevated ammonium nitrate. Photo by Jutta Kapfer, with permission.

Nitrogen Uptake

With the variety in forms of N used by various species, we might expect sites and mechanisms of uptake to vary as well. Atmospheric deposition of N serves as the major source of N for many bryophytes (Soares & Pearson 1997). These researchers raised concerns about the ability of increased levels of these N sources in pollution to inhibit nitrate reductase and affect cation, total N, and organic acid concentrations.

Using *Racomitrium lanuginosum* (Figure 34), *Rhytidiadelphus loreus* (Figure 35), and *Philonotis fontana* (Figure 36) and a single field misting with $3 \text{ mol m}^{-3} \text{ NH}_4^+$ and NO_3^- Soares and Pearson (1997) found a 20% increase in tissue N after 48 hours. Labelled N experiments on *R. lanuginosum* revealed N partitioning, with the highest N uptake in the upper stem and leaves. High concentrations of N resulted in reduced N uptake efficiency. The ammonium decreased nitrogen reductase activity and caused organic acids and cations to decline. However, nitrate treatments cause the opposite response.

Figure 36. *Philonotis fontana*, a species that rapidly takes up added N in the first 48 hours. Photo by Michael Lüth, with permission.

What controls the rate of uptake in various species? Jauhiainen *et al.* (1998) found that among seven *Sphagnum* species, the greatest uptake rate was by individuals (not species) that had the largest capitula and a high number of ion exchange sites. These species were the lawn species *S. pulchrum* (Figure 37), *S. fallax* (Figure 13), *S. papillosum* (Figure 38), and *S. magellanicum* (Figure 12). However, when compared on the basis of dry mass, the most effective species were the hummock species *S. fuscum* (Figure 33) and *S. rubellum* (Figure 23). These species were also the most effective ones in retaining available nitrogen.

Figure 37. *Sphagnum pulchrum*, a lawn species with a large capitulum and high nitrogen uptake. Photo by Michael Lüth, with permission.

Kopáček and Blažzka (1994) examined ammonium uptake in alpine streams of the High Tatra Mountains, Slovakia. Maximum uptake rates of ammonium N by bryophytes ranged 6-11 mg m⁻² h⁻¹. The uptake rate did not seem to relate to pH during 3- to 5-hour testing periods. Nevertheless, nitrification of ~50% of the NH₄⁺-N added occurred in non-acidified streams, but was negligible in acidified streams.

In the aquatic liverworts *Jungermannia vulcanicola* (Figure 39-Figure 40) and *Scapania undulata* (Figure 5,

Figure 41), uptake activities were similar (Miyazaki & Satake 1985). Uptake was greatest at the plant tips and decreased toward the base. Uptake of ammonium at the tip was between 1.9 X 10⁻⁵ and 5.8 X 10⁻⁵ g N g dry wt⁻¹ h⁻¹. Nitrate uptake was less than that of ammonium.

Bryophytes have a variety of options for obtaining N. In the Antarctic, *Bryum pseudotriquetrum* (Figure 42-Figure 43) and *Sarconeurum glaciale* (Figure 44) are able to retain more of the N from precipitation than does the dry soil of the fellfields where they live (Greenfield 1992). The N forms are retained by ion exchange and chelation, enabling them to supplement the low nutrient levels in the rocks and poor-nutrient soils.

Bryophytes are diverse in their abilities and physiologies. We have often assumed that they are unable to take N from the soil. However, Ayres *et al.* (2006) demonstrated clearly that mosses are able to derive N from the soil. In fact, they suggested that uptake from soil might be common among mosses, but this prediction needs to be tested.

Nitrogen Fixation

With 78% of our atmosphere being composed of nitrogen and only about 5% of biomass being nitrogen, one would expect this element to be no problem for living systems to obtain. But unlike phosphorus, it cannot normally be obtained from bedrock. And just as you and I can make no use of the free, gaseous nitrogen we breathe, most plants can't either. Instead, plants require their nitrogen fixed into ammonium (NH_4^+) or nitrate (NO_3^-) salts (or converted to amino acids) before they can obtain and convert it to specific amino acids and proteins they need.

Nitrogen fixation is the process of trapping atmospheric nitrogen and converting it to NH_4^+ and in some cases, converting it to NO_3^- . Elbert *et al.* (2012) estimated that cryptogamic covers, including **Cyanobacteria**, algae, fungi, lichens, and bryophytes, account for nearly half of biological N fixation in terrestrial communities. Bryophytes play a crucial contributor in many communities by providing suitable habitat for the N-fixers.

N fixation by **Cyanobacteria** associations with bryophytes may be important in many ecosystems where it has hardly been recognized (Cullimore & McCann 1972; Madhusoodanan & Dominic 1996). Nitrogen fixation is a major source of usable nitrogen for bryophytes, particularly in bogs and fens. Like many tracheophytes, bryophytes can use N released by N fixation from associated bacteria and **Cyanobacteria**. The **heterocysts** (large, transparent, thick-walled cell in filaments of some **Cyanobacteria**; site of nitrogen fixation; Figure 45) of **Cyanobacteria** make them a rich source of amino acids as a result of their **nitrogen-fixing** activity. That is, they are able to convert atmospheric N to a form usable by other living organisms.

Figure 45. *Anabaena* (**Cyanobacteria**) showing heterocyst in middle lower part of picture. Photo by Janice Glime.

In the process of nitrogen fixation in **Cyanobacteria**, the simple CH_2O group from sugars, fixed by cells adjacent to the heterocyst, is moved into the heterocyst (Figure 46). Atmospheric nitrogen (N_2) enters adjacent cells and is passed to the heterocyst. In the heterocyst **nitrogen reductase** (enzyme that catalyzes addition of H^+ to N to form NH_4^+) catalyzes the transformation of N_2 to the reduced NH_4^+ with H^+ obtained from the CH_2O group.

Figure 46. Nitrogen fixation in **Cyanobacteria**, with atmospheric nitrogen entering an adjacent cell and being transferred to the **heterocyst**, where it is converted to ammonium (NH_4^+). The ammonium is then moved to the adjacent cell where it is converted into organic compounds, typically amino acids. Diagram by Janice Glime.

Many studies have shown that some bryophytes, especially peatland bryophytes, obtain N through N fixation processes of surface-dwelling **Cyanobacteria** (Figure 47) as well as other bacteria (Cullimore & McCann 1972; Granhall & Selander 1973; Alexander *et al.* 1974; Basilier *et al.* 1978; Smith & Ashton 1981; Smith 1984; Nakatsubo & Ino 1986, 1987; Bentley 1987; Given 1987; Bergman *et al.* 1993; Madhusoodanan & Dominic 1996). In the **Cyanobacteria**, the most significant contributions come from taxa such as *Nostoc* (Figure 1, Figure 48), *Anabaena* (Figure 49), and *Calothrix* (Figure 50) that have the special cells called **heterocysts**. These cells provide a "safe" environment for nitrogen fixation because they lack the oxygen-generating reactions of photosystem II. The enzyme **nitrogen reductase** is unable to make the conversion in an aerobic environment, hence requiring a location where photosynthetic oxygen is not available. Since only the **Cyanobacteria** and some true bacteria are able to use the abundant atmospheric nitrogen, this conversion makes a significant contribution to usable nitrogen in the ecosystem.

Figure 47. **Cyanobacteria** on *Campylopus* at geothermal vent in New Zealand. Photo by Janice Glime.

Figure 48. *Nostoc*, a typical N-fixing **Cyanobacterium** that can be found associated with bryophytes. Note the enlarged heterocysts. Photo by Janice Glime.

Figure 49. *Anabaena*, a common N-fixing symbiont that lives among bryophyte leaves. Photo by Yuuji Tsukii, with permission.

The **Cyanobacteria** fix more nitrogen than is essential for their own needs and release the excess to their environment. Significant contributions of N through N fixation by **Cyanobacteria** occur in grasslands (Vlassak *et al.* 1973), boulder communities (Snyder & Wullstein 1973a, Jones & Wilson 1978), tropical forests, especially in

epiphyllous communities (those growing on a leaf) (Bentley 1987), poor *Sphagnum* (Figure 18, Figure 23, Figure 33) mires (Basilier 1979), boreal forests (DeLuca *et al.* 2002; Gundale *et al.* 2011), and polar turfs (Alexander 1975; Alexander *et al.* 1978).

Figure 50. *Calothrix*, a nitrogen-fixing **Cyanobacterium** that can live in association with *Phaeoceros*. Note the heterocyst at the base of each filament. Photo by Yuuji Tsukii, with permission.

In the terrestrial moss *Hymenostylium recurvirostre* (Figure 51), association with *Nostoc* (Figure 48) is common. Labelled ^{15}N from N_2 gas, converted by *Nostoc*, resulted in the highest concentrations in the new rhizoids, then new shoots, then old shoots and old rhizoids (Jones & Wilson 1978). Jones and Wilson suggest that these locations indicate the nitrogen is being translocated from old to young tissues. Not only is free NH_4^+ available, but also large quantities of extracellular amino acid leakage is associated with this *Nostoc*. In view of the discussion above on bryophyte use of amino acids, it is likely that the moss and its neighbors might be using these amino acids as part of their N source.

Figure 51. *Hymenostylium recurvirostrum* with capsules, a species that commonly has *Nostoc* associates. Photo by Michael Lüth, with permission.

In some of the liverworts and hornworts, **Cyanobacteria** seem to behave symbiotically (Saxena 1981), but more frequently it seems to be only a matter of suitable habitat. For example, in the moist Pacific northwest, approximately 85% of the sampled epiphytic leafy liverwort *Porella navicularis* (Figure 52-Figure 53)

harbors *Nostoc* (**Cyanobacteria**; Figure 48) in distinct colonies under the leaf curled margins and in other plant crevices (Dalton & Chatfield 1985). Nitrogen fixation is measured by the acetylene reduction method, and the product C_2H_2 is used as the measure of fixation. The production of fixed N on *P. navicularis* resulted in a mean of $53.5 \text{ nmol C}_2\text{H}_2 \text{ g}^{-1} \text{ d m h}^{-1}$ and reached up to $316 \text{ nmol C}_2\text{H}_2 \text{ g}^{-1} \text{ d m h}^{-1}$. Dalton and Chatfield (1985) at first thought the *Porella* association was symbiotic, but the low number of heterocysts (3-7%) is typical of free-living *Nostoc*; symbiotic ones typically have a frequency of 30-40%. In either case, the effect is the same; by providing a suitable habitat for **Cyanobacteria**, the mosses facilitate an increase of available N in the system.

Temperate bryophytes often have associated **Cyanobacteria**, especially *Nostoc*. Soil associations with bryophytes can benefit the ecosystem in several ways. Not only do they provide additional usable N to the ecosystem, as in the *Hymenostylium recurvirostre* (Figure 51) association in Upper Teesdale (Wilson 1975), but they also provide a buffer against erosion and leaching of nutrients already in the upper soil layers.

Few studies have quantitatively addressed the role of micro-organisms in bryophyte communities, particularly in peatlands where their role is significant (Gilbert *et al.* 1999). Nevertheless, these micro-organisms are undoubtedly key players in nutrient cycling through the microbial loop.

Table 2. Comparison of N fixation rates by **Cyanobacteria** associated with bryophytes in various habitats. Rates converted to nmol N using the 3:1 ratio of reduced acetylene to fixed N given by Nakatsubo and Ino (1987) and Vlassak *et al.* (1973). gfm = grams fresh mass; gdm = grams dry mass. Table compiled by Medora Burke-Scoll.

Arctic, Antarctic, and Alpine

In bryophyte-Cyanobacteria associations in the Antarctic (Smith & Russell 1982; Smith 1984; Nakatsubo & Ino 1987; Line 1992; Pandey *et al.* 1992), Arctic (Alexander *et al.* 1978), and alpine/subalpine zones (Lambert & Reiners 1979), N fixation may be a very important contribution of this limiting nutrient to the nutrient-poor ecosystems (Smith & Ashton 1981). Although Smith and Ashton failed to show much acetylene reduction to indicate fixation activity in the field on sub-Antarctic Marion Island at ~0°C, they considered that during the warm summer, fixation by **Cyanobacterial** flora of bryophytes could approach that exhibited in the lab at ~20°C, thus contributing significantly to the available N in the ecosystem. In a 48-hour field incubation with an air temperature of -1.7°C and moss moisture of 300-1500%, only the moss *Ditrichum strictum* associations had any positive acetylene reduction (1.17 & 1.21 µg g⁻¹ 48h⁻¹). The more protected, but nevertheless very cold, *Clasmatocolea humilis* and *Cryptochila grandiflora* (= *Jamesoniella grandiflora*; Figure 54) associations failed to demonstrate any fixation.

Arctic and Subarctic

In the Arctic soils of Svalbard, Norway, N fixation by both Free-living and bryophyte associations of **Cyanobacteria** is the only significant source of N input to the soil ecosystem (Solheim *et al.* 1996). The most important bryophytes for harboring such associations were *Calliergon richardsonii* (Figure 55) and *Sanionia uncinata* (Figure 56). An interesting factor in the fixation was grazing by geese (Figure 57). Grazed areas had a 10-fold maximum fixation (693.6±1.5 nmol C₂H₄ h⁻¹ gdm⁻¹) compared to ungrazed areas (65.3±16.6 nmol C₂H₄ h⁻¹ gdm⁻¹), perhaps because in these areas the **Cyanobacteria** also occurred on the grass. The transfer of fixed N to the plants supported high plant productivity. On the other hand, where birds harbored under cliffs, the concentration of bird droppings inhibited N fixation.

Increased levels of UV-B radiation in the sub-Arctic could have an effect on the rate of nitrogen fixation in bryophyte-*Cyanobacteria* associations (Solheim *et al.* 2002). These researchers found that it causes a 50% decrease in N-fixation potential in the dominant lichen *Peltigera aphthosa* (Figure 58), a species with *Nostoc* as its N-fixing symbiont. Furthermore, the moss *Sanionia uncinata* (Figure 56) in vegetation exposed to experimentally enhanced levels of UV-B for 3 and 4 years in the high Arctic in Svalbard exhibited a 50% reduction in N-fixation potential compared to controls after 3 years. *Hylocomium splendens* (Figure 22) failed to show a reduction in N fixation potential after seven years of exposure to increased UV-B. In that same experiment, a 50% increase in precipitation caused a 6-fold increase in N fixation potential.

Nitrogen fixation by *Cyanobacteria* seems to have been important in the colonization of Surtsey, a subArctic island south of Iceland, formed by volcanic eruptions from 1963-1967 (Henriksson *et al.* 1987). By 1987 it had extensive colonies of mosses [*Bryum argenteum* (Figure 59-Figure 60), *Ceratodon* (Figure 61), *Racomitrium* spp.

(Figure 62)] that had *Cyanobacteria* associates capable of N-fixation, primarily *Nostoc calcicola*. *Racomitrium canescens* (Figure 62) exhibited an unidentified N-fixing *Nostoc* species living **inside** its cells.

Antarctic and SubAntarctic

Like Surtsey, the Antarctic lacks litter, so bryophytes have little litter source for N. Without litter, making soil is a slow process. Hence, having an N-fixing partner is often an essential part of life (Smith & Ashton 1981; Smith & Russell 1982).

In support of the suggestion that contributions to N in the summer may be significant, Nakatsubo and Ino (1987) found that approximately 330 mg N m⁻² was fixed per growing season in some areas of the Antarctic. Fogg and Stewart (1968) found that most N fixation occurs at temperatures above 10°C, thus explaining the lack of activity in the Smith and Ashton (1981) study. Temperatures in the moss-*Cyanobacterial* associations in summer in the maritime Antarctic typically are in excess of 10°C, often reaching 20°C during midday (Huntley 1971). Smith (1984) found that the fixation rate increased at temperatures from -5°C to a maximum at 25-27°C, decreasing sharply after that. Saturation occurred at ~1000 μmol m⁻² s⁻¹ photon flux density, decreasing at higher levels. Once suitable temperatures were available, moisture seemed to be the most important criterion, causing an increase in fixation up to the highest water content measured: 3,405%! The chemical conditions suitable for

fixation seem to be restrictive, with an optimum pH in this system of 5.9-6.2 and a negative response to the addition of P, Co, or Mo (Smith 1984). Hence, under warmer conditions, fourteen out of nineteen bryophyte associations did indeed exhibit fixation, with values increasing as moisture content increased (Smith & Russell 1982). Rates ranged from 0.36 to 310.57 nmol C₂H₂ g⁻¹ dw h⁻¹ (acetylene reduction as indirect measurement of N fixation) among the fourteen with measurable fixation. Surprisingly, in their study, temperature and radiation seemed to have no effect on the rate.

Alpine and Subalpine

The alpine zone likewise is nitrogen limited due to the slow decay rate and limited organic layer. *Cyanobacteria* are important in binding the soil and in providing reduced N. In the subalpine zone of the White Mountains of New Hampshire, USA, the moss *Plagiomnium cuspidatum* (Figure 63) provides a suitable habitat for *Cyanobacteria* (Lambert & Reiners 1979). Nevertheless, in an association under the subalpine forest, the *Sphagnum* (Figure 15) association was the only one with significant N fixation activity. Lambert and Reiners attributed the activity, in the capitulum, to bacteria, although they considered *Cyanobacteria* to be a possibility.

Figure 63. *Plagiomnium cuspidatum*, a species that hosts *Cyanobacteria* in the White Mountains, northeastern USA. Photo by Hermann Schachner, through Creative Commons.

On Mt. Fuji, the moss communities of the dry SW slope are nearly devoid of N-fixing activity, but on the moist NE-facing cliffs they exhibit high activity, especially with *Nostoc* colonies (Nakatsubo & Ohtani 1991), again demonstrating the importance of moisture. In the somewhat less severe climate of the Alaskan blue spruce taiga system, feather mosses such as *Pleurozium schreberi* (Figure 64) and *Hylocomium splendens* (Figure 22) are important substrates for N-fixing aerobic and facultative anaerobic bacteria (Billington & Alexander 1983). Here the mosses were quite important, exhibiting daily June and July rates of 74, 119 and 109 μg C₂H₄ m⁻² d⁻¹ of N fixation, respectively, for 3 years of study.

Peatland Associations

Sphagnum (Figure 18, Figure 23, Figure 33) is highly colonized by a variety of *Cyanobacteria*, both on its surface (Hooper 1982), and in its hyaline cells (Figure 65- Figure 66; Granhall & Hofsten 1976; Granhall & Lindberg 1978), especially by *Nostoc* (Figure 48) and *Hapalosiphon* (Figure 67) (Sheridan 1991). In bogs and fens, *Cyanobacteria* on bryophyte surfaces can contribute considerable usable N to the ecosystem (Alexander *et al.* 1974; Basilier *et al.* 1978, Basilier 1979; Lambert & Reiners 1979; Rosswall & Granhall 1980, Hooper 1982). Chapman and Hemond (1982) determined that the contribution was greater than that from the only other known input, bulk precipitation (as NO_3^-). Three types of *Sphagnum* (Figure 18, Figure 23, Figure 33) N-fixing associations fix N: epiphytic *Cyanobacteria*, intracellular *Cyanobacteria*, and N-fixing bacteria (Granhall & Selander 1973, Granhall & Hofsten 1976).

Figure 67. *Hapalosiphon*, a common member of *Cyanobacteria* that occurs on bryophytes. Photo by Jason Oyadomari, with permission.

Basilier (1979) reported N-fixation activity by *Cyanobacteria* on *Sphagnum* (Figure 18, Figure 23, Figure 33), *Drepanocladus* (Figure 68), and *Calliergon* (Figure 55) in phosphorus-rich environments. Basilier and coworkers (1978), as well as Granhall and Selander (1973), found that the highest N fixation rates in their studies occurred on species of the mosses *Sphagnum* and *Drepanocladus* (s.l.), with a mean value of $9.4 \text{ g m}^{-2} \text{ yr}^{-1}$. In fact, *Cyanobacteria* associated with *Sphagnum* can have higher N fixation per heterocyst than do free-living *Cyanobacteria* in the same condition (Basilier 1980). Granhall and Lindberg (1978) reported a total rate of $0.8\text{--}3.8 \text{ g fixed N m}^{-2} \text{ yr}^{-1}$ in wet *Sphagnum* communities in a mixed pine and spruce forest in central Sweden. Zimicki (1976) and Basilier *et al.* (1978) have estimated N fixation in various sites for *Sphagnum riparium* (Figure 69) to be $0.5\text{--}6.4 \text{ g m}^{-2} \text{ yr}^{-1}$.

Basilier *et al.* (1978) found that the fixation rate in the *Sphagnum riparium* (Figure 69) association was strongly light dependent, but that pH in the range of 4.3 to 6.8 had little effect. Maximum fixation occurred around noon with the middle of the growing season exhibiting the highest rates. Interestingly, they found that rates on the apical

portions and non-green portions of the *Sphagnum* were lower than other green parts, and that the highest rates occurred on the periphery of the moss community. On the other hand, using ^{15}N as a tracer, Basilier (1980) later found that enrichment of N from *Cyanobacteria* fixation appeared within two hours in the apex of *Sphagnum*. It appears that habitat comparisons need to be made to determine where the highest rates might occur – and why.

Figure 69. *Sphagnum riparium*, a substrate for N-fixing *Cyanobacteria*. Photo by Michael Lüth, with permission.

Once the *Cyanobacteria* convert the N to NH_4^+ and amino acids, these are available not only for the bryophytes they occupy, but also for the tracheophytes rooted among them. In Thoreau's Bog in Massachusetts, N fixation exceeded atmospheric N deposition (Hemond 1983), and Hemond concluded that microbial N fixation provides sufficient quantity of N that N may never be limiting to primary productivity in a bog (or poor fen) ecosystem.

Boreal Forests

The boreal forest productivity is limited primarily by available soil N. Bryophytes on the forest floor serve as C and N pools. Recently, researchers have realized the role of N-fixation by *Cyanobacteria* in association with bryophytes in the boreal forest. DeLuca *et al.* (2002) reported that N-fixation reached only $0.5 \text{ kg N ha}^{-1} \text{ yr}^{-1}$. On the other hand, they found that *Nostoc* (Figure 48) living in association with *Pleurozium schreberi* (Figure 64) fixes $1.5\text{--}2.0 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ in Scandinavian and Finnish boreal

forests. They suggest that previous estimates of N-fixation in boreal forests may be too low.

Pleurozium schreberi (Figure 64) is able to modulate its N content based on the amount of N input. With N addition, the N-fixation per unit moss mass and per unit area decreases sharply (Gundale *et al.* 2011). This causes the N pool in the moss to remain stable except at very high additions. This effect on the bryophytes provides at least part of the explanation for the constancy of N acquisition by woody plants up to $12 \text{ kg ha}^{-1} \text{ yr}^{-1}$ additional N. The researchers suggested that bryophytes limit the acquisition of anthropogenic N by woody plants in the boreal forest.

Egorov (2007) found that the nitrogen regime of most of the moss species in the Khibiny Mountains of Eurasia was self-supporting. He attributed this to nitrogen fixation by the epiphytic *Cyanobacteria* on the mosses, accounting for 28% of the total N in the mosses during the growing period.

Hylocomium splendens (Figure 22) is another important feather moss in the boreal forest. And like *Pleurozium schreberi* (Figure 64) it is a major contributor to the conversion of N to a usable form by providing a suitable substrate for *Cyanobacteria* (Zackrisson 2009). It is interesting that both of these feather mosses contribute greater N-fixation rates at northern latitudes ($64\text{--}69^\circ \text{ N}$) than at the more southern latitudes. This is mostly accomplished by species of *Nostoc* (Figure 48) and *Stigonema* (Figure 70) as the *Cyanobacteria* N fixers. Of further interest is the greater tolerance to N pollution in *Hylocomium splendens* when compared to *P. schreberi*. Consistent with its tolerance to N pollution, *H. splendens* exhibited a somewhat higher N-fixation rate at high fertility sites. But *Hylocomium splendens* contributed about 50% less to the total N than did *P. schreberi*. Together, these two species contribute $1.6 \text{ kg fixed N ha}^{-1} \text{ yr}^{-1}$.

Figure 70. *Stigonema turfacea*, member of a genus that is common on bryophytes as a nitrogen fixer. Photo by Jason Oyadomari, with permission.

Temperate Forests

Lindo and Whitely (2011) pointed out that we know about the symbiotic *Cyanobacteria*-bryophyte associations that contribute significantly to the nitrogen levels on the forest floor through nitrogen fixation. But contributions of this process in the canopy are poorly understood. Older trees can contribute bio-available nitrogen to the ecosystem through the *Cyanobacteria*-bryophyte associations where

atmospheric nitrogen is fixed in the canopy, potentially making a major contribution to the nitrogen dynamics of the forest. This seems to be especially true in the temperate rainforest. Lindo and Whitely (2011) found that *Cyanobacteria* density was significantly greater in epiphytic bryophytes compared to mosses on the forest floor, with the highest rates ($0.76 \text{ kg N ha}^{-1} \text{ yr}^{-1}$) at 30 m in the canopy compared to the forest floor ($0.26 \text{ kg N ha}^{-1} \text{ yr}^{-1}$). Thus this relationship is important in the canopy of large, old trees in a coastal temperate rain forest with high epiphytic bryophyte biomass.

Tropics

Although associated *Cyanobacteria* are best known from bryophytes in northern habitats, they also exist in the tropics. In the cloud forest on a volcano in the French West Indies, *Sphagnum erythrocalyx* is substrate for the N-fixing *Cyanobacterium Hapalosiphon flexuosus* (see Figure 67) (Sheridan 1991). The mean rate of methane production caused by N reduction was $19.1 \text{ nmol C}_2\text{H}_4 \text{ gdw}^{-1} \text{ h}^{-1}$ with an annual contribution of N by N fixation of $4.02 \text{ kg N ha}^{-1} \text{ yr}^{-1}$. The production in the uppermost green capitula was 4.5X that in the basal portions.

Epiphylls

Epiphylls are those organisms that live on leaves. These are common in warmer climates where the leaves remain on the plant for more than one year. In rainforests, epiphyllous liverworts provide the moist microhabitat needed for high rates of nitrogen fixation by associated bacteria and *Cyanobacteria* (Bentley & Carpenter 1980; Bentley 1987; Carpenter 1992), which may be transferred to the host leaves (Bentley & Carpenter 1984).

At least some micro-organisms living in association with epiphyllous liverworts are able to transfer this fixed nitrogen directly to their host plants (Figure 71; Bentley & Carpenter 1984), thus constituting a loose arrangement that benefits the tracheophyte as well as the bryophyte. In the palm *Welfia georgii*, 10-25% of the N in the leaf was derived from the micro-organisms harbored there among the leafy liverwort cover.

Liverwort Symbiosis

Several attempts have been made to explain the high degree of N fixation in liverwort associations. In an early attempt, Griggs (1937) grew liverworts from Katmai volcanic ash on N-free sand for three years to determine their success compared to that of liverworts on the same medium, but with the addition of $4 \text{ mg L}^{-1} \text{ NH}_4\text{NO}_3$. During that three-year period, the ones with the additive grew no better, but toward the end of the three years, the N-free cultures became pale and unhealthy. When $4 \text{ mg L}^{-1} \text{ NH}_4\text{NO}_3$ was added to the N-free cultures, they promptly revived. Griggs took this as evidence that no N fixation had occurred.

Nevertheless, at least the thallus of the liverwort *Blasia pusilla* (Figure 72) has symbiotic *Cyanobacteria* that do perform N fixation (Rodgers 1978; Peters 1991). In fact, there are many genetic strains of *Nostoc* (Figure 48) associated with *Blasia* (West & Adams 1997; Costa *et al.* 2001). The presence of *Nostoc* induces both structural and metabolic changes within the *Blasia* thallus (Kimura & Nakano 1990; Meeks 1990).

Figure 71. Means and standard errors of 5 hrs of production of fixed nitrogen in leaves of the palm *Welfia georgii* incubated alone (with epiphylls removed) and leaves with intact epiphylls, indicating a much greater transfer of new N to the leaf when epiphylls are present. Redrawn from Bentley & Carpenter 1984.

Nostoc (Figure 48) is only capable of invading the liverwort when the *Nostoc* is in its mobile stage (Kimura & Nakano 1990). That is, when the segments (called **hormogonia**) of a filament separate, they are mobile by a gelatinous sol-gel transformation that permits them to

slither and glide. In this stage they are able to invade the thallus of *Blasia pusilla* (Figure 72) and induce the morphological changes that permit the partnership to work. At the same time, the *B. pusilla* signals the *Nostoc* by producing two **auricles** (earlike lobes), each with an enclosed chamber housing a slime papilla that fills the chamber with mucilage (Renzaglia 1982a). The mucilage attracts the *Nostoc*, which then takes up residence in the chamber (Figure 73). Once the *Nostoc* arrives, the auricle increases in size and closes its opening. Following the invasion, the surrounding cells of the *Blasia* thallus have attenuated growth and produce branched filaments from hyaline cells that penetrate the *Nostoc* colonies (Kimura & Nakano 1990). These filaments form a labyrinth of wall ingrowths into the *Nostoc* cells, suggesting that they may have the role of transfer cells for exchanging metabolites (Ridgway 1967; Duckett *et al.* 1977). Once it has settled into its thallus home, the *Nostoc* produces numerous heterocysts, which are essential for the N fixation.

Figure 73. *Blasia pusilla* *Nostoc* colony, the site of N fixation. Photo by Dick Haaksma, with permission.

When the *Nostoc* (Figure 48) grows deeply embedded within the liverwort thallus, it no longer has access to dissolved CO₂. Stewart and Rodgers (1977; 1978) determined that the *Nostoc* obtains its carbon through transfer from the *Blasia* (Figure 72) thallus to *Nostoc*, suggesting that this is really a **mutualistic** relationship (one in which both partners benefit). Within the thallus the *Nostoc* requires a higher light intensity and higher temperature (above 17°C) for maximal activity compared to those living alone (max activity above 12°C) (Rodgers 1978). Hence, the liverwort provides a safe compartment that will remain moist much longer than the external environment, and even provides the needed carbon source for its symbiont.

The ability to colonize rapidly, symbiont intact, is facilitated in *Blasia pusilla* (Figure 72) by the production of two types of gemmae (Figure 74-Figure 75). These gemmae permit the symbiont to travel with the gemma and easily renew the partnership arrangement upon germination (Renzaglia 1982b; Duckett & Renzaglia 1993). Taxa that depend on spores for their dispersal would not benefit from this convenience.

Figure 75. *Blasia pusilla* gemmae "star" gemmae. Photo by Dick Haaksma, with permission.

As already noted, the epiphytic leafy liverwort *Porella navicularis* (Figure 52-Figure 53) provides a suitable substrate for *Nostoc* (Figure 48) in western North America (Dalton & Chatfield 1985). This association is present in a broad geographic range. The presence of these *Nostoc* (Figure 48) symbionts in liverworts seems to be restricted to taxa that are pioneers (Schuster 1992a, b), living in temporary or poorly colonized habitats that are likely to be low in usable N.

Hornwort Associations

Hornworts (**Anthocerotophyta**) are well known for their symbiotic associations with **Cyanobacteria**, especially *Nostoc* (Figure 48) in association with *Phaeoceros* (Figure 76) and *Anthoceros* (Figure 77) (Peirce 1906; Ridgway 1967; Enderlin & Meeks 1983; Steinberg & Meeks 1987). A wide diversity of *Nostoc* strains infect these hornworts (West & Adams 1997), and it appears that *Anthoceros* harbors a *Nostoc* that is unique from that of *Blasia* (Figure 72) (Leizerovich *et al.* 1990). But *Phaeoceros* also hosts the filamentous *Calothrix* (**Cyanobacteria**; Figure 50) (West & Adams 1997). This multiplicity of symbiotic genera is apparently unusual; Rai

et al. (2000) indicate that typically only one genus will infect a particular taxonomic group of plants.

Figure 76. *Phaeoceros carolinianus* showing bluish green color typical of plants with *Nostoc* inhabitants. Photo by Michael Lüth, with permission.

For the association to begin, the *Nostoc* (Figure 48) must form **hormogonia** (portions of filament in **Cyanobacteria** that become detached and reproduce by cell division) that can break away and move through the environment to reach the hornwort (Wong & Meeks 2002), just as in *Blasia* (Figure 72). But it seems that the hornwort makes certain that this occurs, if there is *Nostoc* in the vicinity. Free-living *Nostoc* rapidly forms hormogonia when in the presence of *Anthoceros punctatus* (Figure 77), or even in the presence of agar preconditioned with *A. punctatus* (Campbell & Meeks 1989), indicating a diffusible substance from *A. punctatus* that stimulates this response.

Figure 77. *Anthoceros punctatus*, a species that stimulates formation of hormogonia in *Nostoc*. Photo by Jonathan Sleath, with permission.

Both *Nostoc* (Figure 48) and the hornwort seem to be modified physiologically once joining in symbiosis (Joseph & Meeks 1987; Campbell & Meeks 1992). Before the partnership can work, the *Nostoc* must form heterocysts (large, transparent, thick-walled cells found in filaments of certain **Cyanobacteria**; sites of N fixation) (Wong & Meeks 2002). This is where the enzyme **nitrogenase**, needed for the N fixation, is located in both free-living and

symbiotic strains (Rai *et al.* 1989). When mutants of *Nostoc punctiforme* (Figure 78), unable to form **heterocysts**, were introduced to *Anthoceros punctatus* (Figure 77), the partnership formed, but no N fixation occurred; the mutants did not produce any nitrogenase.

Figure 78. *Nostoc punctiforme*, a species that does not fix N when it cannot form heterocysts. Photo by Thibul, through Creative Commons.

As in the *Blasia* (Figure 72) symbionts, the nitrogenase of the *Nostoc* (Figure 48) must have an anaerobic environment in which to fix nitrogen. Campbell and Meeks (1992) demonstrated this by showing that the symbiont could produce fixed N only under anaerobic conditions when grown outside its host. However, when it grew in its *Anthoceros punctatus* (Figure 77) host, it could be grown anaerobically; the special cavities where it grew on the host provided the anaerobic conditions needed.

Perhaps one explanation for the success of N fixation within the host lies in the structure of the symbiont heterocyst, contrasting with that of the free-living *Nostoc* (Figure 48) strains. When growing inside the host, the *Nostoc* heterocyst lacks the outer polysaccharide layer typical that in of free-living *Nostoc* (Campbell & Meeks 1992). Rather, it appears that when the *Nostoc* grows in the cavities of *Anthoceros punctatus* (Figure 77), the cavities replace that wall function. *Anthoceros* also mediates the nitrogenase activity, suppressing it in the presence of NO_3^- (Campbell & Meeks 1992) and NH_4^+ (Steinberg & Meeks 1991). The end product of the *Nostoc* fixation is NH_4^+ , accounting for 75% of the introduced radioactive N after 0.5 min, but only 14% after 10 minutes of incubation (Meeks *et al.* 1985), indicating a rapid transformation to something else. Glutamine and glutamate are quickly synthesized via the glutamine synthetase-glutamate synthase pathway, preventing the toxic buildup of NH_4^+ . Thus one end result of the symbiosis is that the intracellular levels of NH_4^+ are low compared to those of symbiont-free *Anthoceros*.

Only 10% of the NH_4^+ is assimilated into the *Nostoc* (Figure 48); 1% is lost to the medium; *Anthoceros* (Figure 77) incorporates the remainder (Meeks *et al.* 1985). Prakasham and Rai (1991) demonstrated that there is a specific methylammonium transport system in the symbiotic *Nostoc*, which may account for the reduced NH_4^+ levels and rapid transfer to the host. In symbiont-free *Anthoceros* supplied with high levels of NH_4^+ , the glutamate dehydrogenase system is functional, permitting

an NH_4^+ buildup (Meeks *et al.* 1983). Therefore, it appears that the *Nostoc* partner provides a very effective and safe source of NH_4^+ for the *Anthoceros* host (Meeks *et al.* 1985).

As in the *Blasia* (Figure 72) partnership, *Nostoc* (Figure 48) living within the hornwort gets its carbon primarily from its host plant (Stewart & Rodgers 1977). In fact, *Nostoc* isolated from *Anthoceros punctatus* (Figure 77) had only 12% of the Rubisco activity of free-living strains, with an equal reduction in CO_2 fixation (Steinberg & Meeks 1989; Rai *et al.* 1989). However, the distribution and levels of Rubisco were similar in the two strains (Rai *et al.* 1989), with 4.3% and 5.2% of the protein as Rubisco in symbionts and free-living *Nostoc*, respectively (Steinberg & Meeks 1989), suggesting that there is regulation of the Rubisco activity and not an alteration at the gene transcription level. This could be related to the fact that the structure of the chlorophyll complex differs somewhat; the *Nostoc* contains the typical cyanophycean granules, but it lacks **phycobilisomes**, the cellular organelle located on the surface of the thylakoids of the chlorophyll complex and in which the biliprotein pigments (**phycocyanin**, **phycoerythrin**) are present (Honegger 1980).

Because the *Nostoc* (Figure 48) has reduced ability to fix its own carbon, this transfer of fixed carbon from *Anthoceros punctatus* (Figure 77) to *Nostoc* is necessary for the fixation of N_2 . When the *Nostoc*-hornwort association was deprived of light for 28 hours, the rate of acetylene reduction (as a measure of N fixation) declined by 99%, but resumed up to 64% of its illuminated activity when supplied with glucose in the dark (Steinberg & Meeks 1991), indicating the need for light and photosynthetic activity for the partnership to work. These researchers found that photosynthates produced immediately by the **Cyanobacterium** can supply at least one-third of the reductant needed for nitrogenase activity in the short-term for the symbiosis to work. When gametophytes were deprived of light, but sporophytes were provided with light, nitrogenase activity continued (Stewart & Rodgers 1977), suggesting a transfer of sugar from the sporophyte to the gametophyte, then to the *Nostoc*. These factors suggest that the *Nostoc*, living in the reduced light of the interior of the hornwort thallus, may be dependent upon the hornwort for glucose or similar carbohydrate as an energy source in order to continue its N fixation, thus completing a true mutualistic relationship with its host.

The local sites of the host plants act as islands that effectively keep the *Nostoc* (Figure 48) strains in isolation. Even within a single host plant there may be a great diversity of cyanobacterial strains, and these strains seem to be restricted to one site (Costa *et al.* 2001). Nevertheless, some host plants shared strains of *Nostoc* that could be found growing 2000 m away. Furthermore, strains found in *Blasia* (Figure 72) could also be found in the lichen *Peltigera neopolydactyla* (Figure 79). Although different cavities can easily host different strains in both *Blasia* and the **Anthocerotophyta**, a single cavity seems only to host one strain.

Lunar Rocks

Liverworts were among the few organisms to grow successfully on lunar rocks. But why? The thallose

liverwort *Marchantia polymorpha* (Figure 80) exhibited a tremendous increase in growth following being sprinkled with Apollo 11 or 12 lunar rock material. Hoffman (1974) followed up on this observation by testing the effects of basalt from Minnesota and C-horizon substrate from the Valley of Ten Thousand Smokes, Alaska. In both cases, the growth of *M. polymorpha* was significantly increased. But what caused this surge of growth? Nitrogen was absent in any form in both the lunar material and the basalt, and neither P nor K was abundant, so the three typical fertilizer nutrients seem not to be the cause. The macronutrients Ca, Mg, and S were all more abundant in basalt than in the C-horizon soil, but the C-horizon soil caused the greater stimulation. Iron remains a possibility, being abundant in all three substrata. We already know that it stimulates the growth of *Funaria hygrometrica* (Figure 4) (Hoffman 1966). And it is also known to stimulate N fixation in Cyanobacteria (Mills *et al.* 2004; Moore *et al.* 2009). On the other hand, no data were gathered on the pH, which could affect the solubility, and therefore availability, of all the nutrients. Some have speculated that survival of the liverwort was possible due to partnering **Cyanobacteria** that could trap and convert the atmospheric nitrogen. Perhaps we need to look for soil and rock components that foster the N fixation reaction.

Other Stressful Habitats

In **cryptogamic crusts** (*i.e.* soil crusts of algae, lichens, bryophytes, fungi, and micro-organisms; Figure 81) of prairies, deserts, and grasslands, **Cyanobacteria** are able to maintain an active state longer when water is held by the bryophytes. This increases their contribution to the usable N in the soil (Vlassak *et al.* 1973; Giddens 1982; Belknap *et al.* 2001). The crust itself is vital to maintaining both water and nutrients in the soil during and following heavy storms.

In geothermal fields and following fires, bryophytes again provide the moist environment needed to maintain N-fixing micro-organisms (Brasell *et al.* 1986). Hence, we must ask if the bryophytes are net users of nitrogen, or do they facilitate a net gain to the system. At least in some habitats they definitely facilitate a gain by providing the right habitat for fixation to occur, accompanied by leakage of the new N products.

Figure 81. Cryptogamic crust with the moss *Syntrichia inermis*. Photocourtesy of Lloyd Stark.

Likewise, bryophyte-Cyanobacteria associations are important in the colonization of volcanic lava. **Cyanobacteria** are common on bryophytes of dry lava fields (Englund 1976) as well as on the moist, warm bryophyte surfaces near steam vents (Broady *et al.* 1987). Both *Anabaena variabilis* (= *Tricormus variabilis*; Figure 82) and *Nostoc muscorum* were associated with *Funaria hygrometrica* (Figure 4) on the newly formed volcano Surtsey off the Icelandic coast (Rodgers & Henriksson 1976). Although the *Funaria* did not directly affect the fixation rate, growth of both the *Funaria* and the **Cyanobacteria** benefitted by the association, and the N content of *Funaria* also increased as a result of the cyanobacterial N fixation.

Although moss associates are responsible for most N fixation in Arctic and subarctic ecosystems, legume associations are considered the predominant N fixers in temperate ecosystems (Stewart 1967). Nevertheless, in some temperate habitats bryophytes are the only plants able to occupy the habitat. For example, on granite outcrops, bryophytes, especially *Grimmia/Schistidium* (Figure 83), are well known for their role in accumulating soil and nutrients and holding the moisture needed for tracheophyte establishment. Microbial nitrogen fixation on these bryophytes is part of this successional story (Snyder & Wullstein 1973a; Jones & Wilson 1978).

Nitrogen Translocation

We know that N is needed in amino acids, proteins, nucleic acids, and ribonucleic acids. But where do they go in the plants? Eckstein and Karlsson (1999) compared their locations in the boreal forest moss *Hylocomium splendens* (Figure 22) and the wet habitat moss *Polytrichum commune* (Figure 16-Figure 17). They demonstrated that both **endohydric** (having internal conduction) and **ectohydric** (using external conduction) species were able to move N compounds from one **ramet** (attached branch serving like a separate organism) to another. Current-year segments of both species appeared to be strong **sinks** for nitrogen, as demonstrated by their considerable increase in the labelled N pool during the season. **Sinks** are locations where something, such as plant nutrients, organic pollutants, or metal ions, is stored and immobilized through natural processes.

In the period of June to September, *Polytrichum commune* (Figure 16-Figure 17) lost labelled N from all segments (Eckstein & Karlsson 1999). The researchers attributed this to transfer of N to underground structures (sinks). However, in *Hylocomium splendens* (Figure 22), the one-year-old segments had increased labelled N, whereas the older segments lost 50% of the labelled N they had absorbed. This ability to transfer nutrients from one

part to another is especially beneficial in nutrient-poor environments.

N Sequestering

Sinks can be seasonal, with actively used nutrients moving from locations such as leaves to storage locations as winter approaches or simply be storage of excess. Once incorporated into the bryophytes, nutrients, including N compounds, can either be sequestered or recycled. In some cases they are moved to young, growing tissues. In the tropics, epiphytic bryophytes can sequester inorganic nitrogen from atmospheric deposition. Clark *et al.* (2005) estimated that the epiphytic bryophytes and epiphytic assemblages retained 33-67% of the inorganic N deposition from cloud water and precipitation, retaining 3.4 kg N ha⁻¹ yr⁻¹, accounting for 50% of the inorganic N in atmospheric deposition. This effectively removes 50% of the suitable N sources and sequesters them in the bryophyte tissues.

In the boreal species *Hylocomium splendens* (Figure 22) in a subarctic birch woodland, retention of labelled N varied from three to ten years, depending on the method used (Eckstein 2000). The ability to transport the N compounds to other locations in the plant and a relatively long life span for the growth segments could explain the long residence time of the labelled N. This species uses **acropetal** (from base upward) transport, thus minimizing losses from by the environment by storage in older segments.

Some nutrients are lost to grazing, and in the Arctic, Snow Geese (*Chen caerulescens*; Figure 84) contribute to this herbivory (Kotanen 2002). But mosses can play a role in this goose scenario. Tissues of grasses and sedges that are eaten by the geese are not compensated for their losses, with tissue N responding poorly to N additions. Kotanen suggests that the abundant mosses in these freshwater wetlands sequester the added N, preventing it from reaching forage plants and returning to the ecosystem through feces. But in tracer studies, Kotanen found that mosses did not prevent the grasses and sedges from likewise taking up ammonium and nitrate at or below the moss surface. Nevertheless, most of the added N was absorbed by the mosses before it reached the soil, diverting N away from the forage plants and sequestering it in the moss peat.

Figure 84. *Chen caerulescens* grazing on grass that competes with mosses. Mosses, however, take up added N. Photo by Walter Siegmund, through Creative Commons.

N Deficiency Effects

For agricultural plants we know all the symptoms of deficiency. Even the house plant owners are often aware of deficiency symptoms. But for bryophytes, we know little.

One of the symptoms of nutrient deficiency in crop plants is presence of red coloration in the leaves. When the thallose liverwort *Marchantia polymorpha* (Figure 80) was grown without nitrate and phosphate, the ventral cell layers developed a red-violet color in the cell walls (Voth & Hamner 1940).

We know that some algae use diminishing N availability in their medium as a signal to go into a sexual phase and produce resting zygotes (Trainor 1959; Singh & Chaudhary 1990; Matsuda *et al.* 1992). Do any bryophytes also use any nutrient signal to become sexual?

In the thallose liverwort *Marchantia* (Figure 80), a low ratio of N to C stimulates production of sexual branches (Lockwood 1975). In seeming contrast, the liverwort *Fossombronia brasiliensis* produces more gametangia when N is supplied as nitrate than when it is supplied as ammonium (Chin *et al.* 1987). In *Bryum argenteum* (Figure 59-Figure 60), reduced nutrient levels stimulate the production of sex organs (Joenje & During 1977), but it wasn't clear which nutrient(s) deficiency might be critical for the reproduction.

Several species of the thallose liverwort *Riccia* (Figure 85) produce archegonia and antheridia in response to limiting nitrates (Selkirk 1979). On the other hand, urea not only increased archegonial production significantly in *Riccia crystallina* (Figure 85) but also increased growth (Sood 1974). It is more interesting that in this species the amino acids hydroxyproline, serine, threonine, asparagine, glutamic acid, alanine, and leucine increased archegonia production, whereas glycine, tryptophan, aspartic acid, and valine increased production of antheridia.

Figure 85. *Riccia crystallina*, a species that produces more archegonia and grows more when given urea. Photo by David T. Holyoak, with permission.

In other cases, organic N compounds alter the photoperiodic induction of gametangia. In the leafy liverwort *Cephalozia lunulifolia* (= *C. media*; Figure 86), the amino acids arginine, cysteine, and tryptophan plus kinetin can override photoperiodic control (Lockwood 1975). And these amino acids had similar negating effects over the photoperiodic short-day initiation of gemmae.

Furthermore, adding inorganic N as nitrate or ammonium did not override the effects of the amino acids.

Low levels of N can also reduce gemma production in the thallose liverwort *Marchantia polymorpha* (Figure 80) (Wann 1925; Duckett & Pressel 2009). This seems also to explain the loss of gemma production in this species two years following a fire (Duckett & Pressel 2009). On the other hand, *Ceratodon purpureus* (Figure 61) and *Funaria hygrometrica* (Figure 4) on bonfire sites have early gemma production, as do *Bryum* (Figure 59-Figure 60) species in arable fields (Duckett *et al.* 2004; Pressel *et al.* 2007). Ball (2010) reported that nitrate levels go up following a fire, and that these results are persistent. The charcoal resulting from the fire stimulates the conversion of ammonia to nitrates through the action of bacteria. This suggests that some of these bryophytes may benefit differently from different forms of nitrogen.

Figure 86. *Cephalozia lunulifolia*, a liverwort in which the amino acids arginine, cysteine, and tryptophan plus kinetin can override photoperiodic control of gametangia and gemmae initiation. Photo by Hermann Schachner, through Creative Commons.

N Enrichment

The unusual way in which bryophytes respond to nitrogen addition has interesting effects in the ecosystem. As already noted, increases in nitrogen often result in a reduction of bryophyte cover and diversity or replacement of one species by another. But even though the bryophyte productivity decreases as N deposition increases, the stored N can increase within the bryophyte (Gundale *et al.* 2011).

This has interesting implications for the ecosystem, because it buffers the N reaching the tree roots, at least in boreal forests (Gundale *et al.* 2011). Predictably, N fixation by associated *Cyanobacteria* decreases as N fertilization increases. In the boreal feather moss *Pleurozium schreberi* (Figure 64), the tissue concentrations of nitrogen increased but the biomass decreased with increasing nitrogen addition. Because feather mosses provide considerable biomass on the boreal forest floor, they can have considerable impact on the nitrogen that is able to reach the trees, trapping nitrogen from precipitation, providing niches for *Cyanobacteria*, and sequestering nitrogen from airborne dust.

Many studies in peatlands have included enrichment of N to determine effects on bryophyte productivity. In an Arctic heath community, where N and P are colimiting, Gordon *et al.* (2001) found that applications of N (0, 10, & 50 kg ha⁻¹ yr⁻¹) and P (0 & 5 kg ha⁻¹ yr⁻¹) caused a decrease in lichen cover; applications of 10 kg ha⁻¹ yr⁻¹ resulted in a higher proportion of physiologically active bryophyte shoots. Nevertheless, individual bryophyte species responded differently, suggesting that we cannot draw generalizations from limited fertilization experiments.

Added N can affect different life stages differently. In Wales populations of *Racomitrium lanuginosum* (Figure 34), growth was stimulated initially with the highest N addition level (60 kg N ha⁻¹ yr⁻¹) (Jones *et al.* 2002). However, after 6 months, all concentrations (20, 40, & 60 kg N ha⁻¹ yr⁻¹) caused decreased growth compared to the control with no N addition. By contrast, optimum regeneration from fragments occurred at 20-40 kg on bare soil, but under a canopy of the grass *Festuca ovina* (Figure 87) it was best at 0-20 kg N.

Figure 87. *Festuca ovina*, a grass that benefits the growth of *Racomitrium lanuginosum* fragments on the soil at its base. Photo by J. C. Schou (BioPix), with permission.

Thus we have seen that N enrichment, including that from atmospheric pollution, can be detrimental to bryophytes, especially in some conditions. This has resulted in the disappearance of some species (Strengbom *et al.* 2001). Strengbom and coworkers found that in a boreal forest after fertilization had been stopped for nine years, there were no signs of bryophyte recovery. Mycorrhizal fungi produced more sporocarps on the formerly fertilized plots than on those still receiving N, but the species composition was very different from that of never-fertilized controls. After 47 years of no fertilization, the mosses *Brachythecium reflexum* (Figure 88) and *Plagiothecium denticulatum* (Figure 89) showed enhancement from the previous N fertilization. On the other hand, the common moss *Hylocomium splendens* (Figure 22) was still less abundant than in the controls that were never treated with N. These changes were in contrast to the constancy of tracheophyte composition during and after cessation of N treatments.

Figure 88. *Brachythecium reflexum*, a species that showed enhancement of coverage 47 years after N fertilization ceased. Photo by Michael Lüth, with permission.

Figure 89. *Plagiothecium denticulatum*, a species that showed enhancement of coverage 47 years after N fertilization ceased. Photo by Hermann Schachner, through Creative Commons.

In a boreal forest of northern Sweden, simulated N deposition had no short-term effects on the above- or below-ground biomass of the understory (Nordin *et al.* 1998). The recovery increased with the N dose. In the plots with 0.5 kg N ha⁻¹ the highest concentrations of labelled N occurred in the bryophytes [*Dicranum majus* (Figure 90) and *Pleurozium schreberi* (Figure 64)], whereas in higher applications the grass *Deschampsia flexuosa* (Figure 91) exhibited the highest levels. The elevated N also resulted in greater herbivory on the blueberry *Vaccinium myrtillus* (Figure 92). This raises the as-yet unanswered question of how increased N affects herbivory on bryophytes.

The reduction of bryophyte productivity with increased N deposition is a recurring theme (Koranda *et al.* 2007). Koranda and coworkers sought an explanation for this reduced productivity. Using fragments of *Thuidium tamariscinum* (Figure 93) and *Hylocomium splendens* (Figure 22), they assessed the effects of ammonium nitrate (30 kg ha⁻¹ yr⁻¹) for 80 days. In this experiment, there was no growth change in *T. tamariscinum*, whereas *H. splendens* showed growth reduction. The latter also exhibited a significant increase in N concentration, whereas only *T. tamariscinum* had a significant increase in amino

acid N. Both species exhibited a reduction in lipid concentration, accompanied by strikingly enhanced turnover rates of carbon storage pools in the fertilized plants. Koranda and coworkers interpreted these results to indicate that the depressed growth of *H. splendens* may be caused by enhanced synthesis of N-containing organic compounds, most probably of cell wall proteins. Disturbance of the cellular carbon metabolism may also contribute.

In a nutrient-deficiency condition, with 10 weeks of watering with distilled water daily, *Pseudoscleropodium purum* (Figure 94) grew faster than did *Brachythecium rutabulum* (Figure 95) (Bates 1994). When those populations were subjected to a nutrient pulse of 8 daily additions of KH_2PO_4 and NH_4NO_3 , followed by 10 weeks of no nutrient additions, growth of *P. purum* was significantly stimulated, whereas that of *B. rutabulum* was not. *Pseudoscleropodium purum* increased its uptake of P, less so of N, and conserved these more effectively in nutrient-deficient conditions than did *B. rutabulum*. Cation exchange appears to be important in sequestering nutrient cations. These results can explain differences in habitat – *P. purum* lives where nutrient inputs are unpredictable, coming as wet deposition; *B. rutabulum* lives in a more continuous nutrient supply, apparently coming from the soil.

Figure 94. *Pseudoscleropodium purum*, a species that conserves N and P in nutrient-deficient conditions. Photo by Phil Bendle, with permission.

Sphagnum magellanicum (Figure 12) has a different set of habitat conditions and illustrates differences in ammonium and nitrate enrichment effects. As noted earlier, this species was favored by nitrate concentrations up to $322 \mu\text{M}$, whereas ammonium concentrations $\geq 255 \mu\text{M}$ caused decreases in chlorophyll content and growth (Rudolph & Voigt 1986). At $600 \mu\text{M}$ of added ammonium there was a 20% reduction in nitrate reductase activity and net photosynthesis.

Calliergonella cuspidata (Figure 96) in a calcareous fen in the mountains of Switzerland showed no observable morphological changes due to increased N levels, whereas the same species showed a number of morphological changes in higher light intensities created by cutting of the tracheophyte vegetation (Bergamini & Peintinger 2002).

Figure 96. *Calliergonella cuspidata*, a species that does not change morphology in response to increased N levels. Photo by Michael Lüth, with permission.

In a different set of experiments, Heijmans *et al.* (2001) elevated the nitrogen levels ($5 \text{ g N m}^{-2} \text{ year}^{-1}$ as ammonium nitrate) in a bog in The Netherlands for three years, added at 3-week intervals during the growing seasons. As one might expect, the tracheophyte biomass increased. But for the *Sphagnum* (Figure 18, Figure 23, Figure 33), growth was significantly reduced in the third growing season. It is likely that this was the result of encroaching tracheophyte cover.

Can we expect a different response from a submersed species of *Sphagnum*, such as *S. cuspidatum* (Figure 9)? In a culture experiment lasting 12 weeks, this species was grown at various levels of ammonium (Paffen & Roelefs 1991). In highly enhanced CO_2 , this species had increased growth in length and biomass, both with and without ammonium enrichment, but with only ammonium enrichment there was no increase in biomass.

Bryophytes have often been used as monitors. In terrestrial habitats, the moss bag became popular. In aquatic habitats, bryophytes can be used *in situ* or as transplants. The aquatic moss *Fontinalis antipyretica* (Figure 97) has been used to assess a variety of pollutants. Mosses such as this have the advantage of accumulating pollutants rather than representing the momentary levels found in chemical assays. For understanding its indications as a biomonitor for NH_4^+ , it was necessary to understand the pattern of uptake and the way in which high concentrations could alter physiological performance (Vieira *et al.* 2009). These researchers learned that the concentrations that had significant impact on membrane permeability were the same as those that caused a significant lowering of photosynthetic capacity. As time passes in those higher concentrations, the damage threshold is lowered.

Habitat Relations

Surprisingly, some of our best studies on canopy bryophytes are from the tropics. Clark *et al.* (1998) estimated the N accumulation of epiphytic bryophytes in a tropical montane forest in Costa Rica to be $1.8\text{--}3.0 \text{ g N m}^{-2} \text{ yr}^{-1}$. N release from bryophyte litter in the canopy and on the ground was initially rapid, with $\sim 30\%$ released. Release from green shoots on the forest floor was greater, with $\sim 47\%$ of the initial N released in the first 3 months. The researchers found no evidence for net N immobilization by either litter or green shoots, but the remaining N in the litter, as already seen above in other species, was **recalcitrant** (substance that degrades at extremely slow rate if at all when released into environment). The epiphytic bryophytes retained $0.8\text{--}1.3 \text{ g N m}^{-2} \text{ yr}^{-1}$. The ability of these epiphytes to retain inorganic N from atmospheric deposition gives them a major role in converting mobile forms of N to highly recalcitrant forms.

Previous research at this site indicated that epiphytic bryophytes retain inorganic N from atmospheric deposition to the canopy (Clark *et al.* 1998). Therefore, they play a major role in transforming N from mobile to highly recalcitrant forms in this ecosystem.

In a study of layer differences in a wooded meadow, Kull *et al.* (1995) found that upper layers have the best access to light and the lower layers have higher N-use efficiency and/or better ability to acquire N. The herbaceous layer has the highest level of foliar nitrogen compared to the tree and moss layers. However, the herbaceous layer is co-limited by light and nitrogen, whereas the moss layer is limited only by light.

On Signy Island in the Antarctic, the dry turf had lower total N concentrations per dry weight (0.79%) than did the wet carpet (2.17%) (Christie 1987). In December, the meltwater and pools of the dry turf had $230 \mu\text{g N L}^{-1}$ while $165 \mu\text{g N L}^{-1}$ was present in the wet carpet. *Nostoc muscorum* was present at both sites and exhibited high levels of nitrogen fixation. Biological N fixation accounted for $45.9 \text{ mg m}^{-2} \text{ yr}^{-1}$ in the dry turf and $192.4 \text{ mg m}^{-2} \text{ yr}^{-1}$ in the wet carpet. Christie attributed additional inputs to penguin activity.

Throughout this chapter we have seen differences both among species and among habitats. We have barely scratched the surface in understanding these differences and why they occur.

Nitrogen Cycling

In those habitats where bryophytes form a major component of the ecosystem, their role in N cycling can be important. This is particularly true in cold biomes and tropical rainforests (Cornelissen *et al.* 2007). As we have seen, bryophytes host N-fixing bacteria and **Cyanobacteria** that contribute significant usable N to the soil. They furthermore modify the soil climate through control of hydrology and temperatures. They provide safe sites to soil organisms that contribute to litter breakdown.

Temperature plays an important control on the rate of breakdown in the Alaskan tundra. Warming from 4° to 10° significantly increases the rates of nitrogen mineralization, causing a significant effect on the rate of N cycling in litter and tundra soils (Hobbie 1996). Among the growth forms, graminoid litter had the fast rate, whereas moss and deciduous shrub litter had the slowest decomposition rates. This is largely due to the placement of bryophyte nutrients into recalcitrant forms (Hobbie 1996; Cornelissen *et al.* 2007). Decomposition will be discussed further in a separate chapter of this volume.

Summary

Nitrogen is available to bryophytes as **ammonium** (NH_4^+), **nitrite** (NO_2^-), **nitrate** (NO_3^-), and organic forms such as **amino acids** and **urea**. Nitrite, however, is generally toxic. Ammonium can lower internal pH and suppress growth. Nitrite can cause an increase in chlorophyll *a*, whereas nitrate can cause a decrease in chlorophyll *b*, both causing an increase in the *a/b* ratio. But effects on amino acid and protein concentration vary among species and among habitats. In the Arctic, amino acids and urea are utilized by both bryophytes and tracheophytes. *Sphagnum* species often seem to benefit more from amino acids than from ammonium.

Much of the nitrogen uptake is from precipitation; some is from the soil. But our knowledge of nitrogen uptake mechanisms is meager, and the mechanisms

differ among species. These include ion exchange sites and chelation and can be affected by pH, iron and phosphorus concentrations, and temperature.

Some, perhaps many, bryophytes solve the nitrogen problem through symbiotic partners, especially **Cyanobacteria**, that carry out **nitrogen fixation**. This process seems to be especially important in the polar and alpine regions under warmer summer conditions up to ~25°C. But more xeric conditions such as among **epiphyllous** tropical bryophytes and associated with prairie and grassland cryptogamic crusts also benefit from N fixation. In all of these habitats, bryophytes have an **important role** in maintaining the moisture necessary for the fixation to occur.

Peatlands have a high N fixation rate, and **Cyanobacteria** are common in association with *Sphagnum*. They have a wider pH tolerance range (4.3-6.8) than the **Cyanobacteria** in the cold habitats (5.9-6.2).

The liverwort *Blasia pusilla* provides a special chamber in each **auricle** where it is moist with mucilage and the **Cyanobacteria** enter and grow. It then seals the chamber and produces filaments that penetrate the *Nostoc* colonies. Finally the *Nostoc* produces numerous heterocysts. The *Nostoc* even travels with the gemmae.

Anthoceros punctatus forms a similar partnership, as do most of the hornworts, but it even stimulates the *Nostoc* to form hormogonia, permitting it to slither toward the hornwort. In both liverwort and hornwort partnerships, the ammonium produced by the cyanobacterial heterocyst is quickly converted to glutamine and glutamate to avoid the buildup of toxic ammonium. The *Anthoceros* gets almost 90% of the fixed N and provides fixed C to its **Cyanobacteria** partner.

Moon rock, and rock taken from volcanic areas on Earth, stimulate the growth of bryophytes, but we don't know why. One possibility is the high concentration of iron; another is that symbionts thrived on these rocks, providing N fixation.

It appears that bryophytes play a major role as a substrate for N fixation in many nutrient-poor habitats, making than essential component of those ecosystems.

Nitrogen content varies with species, habitat, season, type of N available, and concentration of N in the ecosystem. It can be sequestered in slowly decaying tissues or translocated to growing regions.

N deficiency, or the wrong form of N (e.g. NH_4^+), can cause bryophytes to become long and thin, appearing etiolated. **Glycine**, **serine**, **arginine**, and **alanine** can induce branching. **Methionine** not only did not induce branching, but it also inhibited growth. Glycine caused the greatest weight and length gain of these amino acids in Java moss. Even nucleic acids are usable N sources, with good leafy shoot growth in **adenine** and **guanine**, but no growth in **uracil** or **thymine** in some species and good growth in others. In *Sphagnum squarrosum* **uric acid** and **cytosine** caused the plant to become thalloid.

N enrichment can have initial stimulating effects followed by long-term negative effects, in some case

because of competition from other kinds of plants. These differences vary by species and habitat.

Nitrogen cycling among bryophytes is not well understood. We do know that they can release it when dry tissues are rehydrated, but they can also sequester it, serving as sinks, or expose it in recalcitrant forms as tissues decay.

Acknowledgments

I appreciate the contributions of undergraduate Phil Gaudette and M. S. student Jennifer Jermalowicz Jones for their critical reading of the manuscript from the perspectives of students interested in nutrient relationships of bryophytes. Medora Burke-Scoll prepared the table on N contributions by **Cyanobacteria**.

CHAPTER 8-4

NUTRIENT RELATIONS: UPTAKE AND LOCATION

Figure 1. Drops of "steam" from geothermal vents resting on the wire-like leaves of *Campylopus holomitrius* and providing a source of nutrients and a means of trapping airborne nutrients. Photo by Janice Glime.

Uptake

The **role** of bryophytes in nutrient uptake within ecosystems is generally ignored because of their small stature. Weetman and Timmer (1967) showed that the common feather moss *Pleurozium schreberi* (Figure 2) in a black spruce (*Picea mariana*; Figure 3) forest took up only 23-53% of N, P, K, and Mg taken up by trees. Nevertheless, that is a non-trivial figure. But bryophyte contributions to sequestering nutrients can be substantial. Yet we have little concept of whether their net contribution is beneficial or detrimental in those ecosystems where they abound.

Figure 3. *Picea mariana* forest in Northern Alberta, Canada, with *Pleurozium schreberi* and *Hylocomium splendens*. Photo by Richard Caners, with permission.

General Considerations

Sources

First we need to recall that the sources of nutrients for bryophytes include precipitation, dust, and to a limited extent, substrate. Brown (1982) explains that bryophytes absorb mineral nutrients over their entire surface (Figure 1). This ability is promoted by two characteristics of bryophytes: a large surface area to volume ratio, and a low surface resistance, relative to **tracheophytes** (lignified

vascular plants), due to the limited development of cuticle. This is further enhanced within the bryophyte by typically having leaves of only one cell layer in thickness, hence exposing every leaf cell directly to the nutrient supply immediately. Based on what we know thus far, actual entry into the cell is most likely similar to that of tracheophytes.

Site of Uptake

Their typical differences in site of uptake would seemingly remove the bryophytes from competition with tracheophytes for soil nutrients. Due to lack of vessels and tracheids, we have assumed that uptake of nutrients by bryophytes is primarily through their leaves. Even in the endohydric *Polytrichum* (Figure 4), water entry is gained primarily at the tips of the plants by water that has travelled upward through external capillary spaces (Trachtenberg & Zamski 1979). Hence, we can expect that most nutrient entry is not through rhizoids, but through leaves, and at least in some mosses may be greater at the tips than in lower parts of the plant. Brown and Wells (1990) remind us that despite their small size, the bryophytes have intricate surface areas that are effective at trapping both dust and moisture that can subsequently enter the bryophyte (Figure 1). The ratio of surface area to volume in bryophytes is enormous compared to that of trees and other tracheophytes.

Figure 4. *Polytrichum commune*, a moss with internal conduction, but that transports nutrients externally through capillary spaces. Photo by Michael Lüth, with permission.

Rhizoids

Even if bryophytes were to use their rhizoids to gather some nutrients, the soil penetration by these structures is generally shallow and well above the zone occupied by most fine roots of tracheophytes, especially trees. Instead, we have assumed that bryophytes typically rely largely on dust on their surfaces and on nutrients dissolved in rainfall. In forests, these arrive primarily through leachates acquired in canopy throughfall. This is a quite different strategy from that of tracheophytes, although in *Polytrichum commune* (Figure 4) it does appear that some nutrients might enter through the rhizoids (Chapin *et al.* 1987). On the other hand, *P. commune* and other forest floor mosses in the black spruce forest (Figure 3) lose nutrients to the black spruce fine roots through *mycorrhizae* (fungal associates).

Growth Form

Growth form affects nutrient trapping and subsequent uptake. Taylor and Witherspoon (1972) found that

Dicranum (Figure 5), which grows in a relatively tight clump, retains more particles than do open lichens such as *Cladonia/Cladina* (Figure 6), even though these lichens display considerable surface area. Hence, we should expect such tight cushions to be more effective at trapping than more open bryophytes like *Brachythecium* (Figure 7) or *Mnium* (Figure 8). On the other hand, Shacklette (1965) found that bryophytes were significantly contaminated with soil particles, including insoluble ones such as Al, Be, Fe, Si, and Zr. But, it would appear that even deeper soil is not immune to moss nutrient scavenging, perhaps through a combination of capillary action and concentration gradient.

Figure 7. *Brachythecium rutabulum*, showing open growth form that traps less dust than the more cushiony forms like *Dicranum*. Photo by Janice Glime.

Figure 8. *Mnium hornum*, an open bryophyte that may trap less dust than cushion forms. Photo by Tim Waters, through Creative Commons.

Age

Bryophyte uptake can relate to **age**. In studying the Alaskan black spruce (*Picea mariana*) forest (Figure 3), Chapin *et al.* (1987) found that in three of the moss taxa studied, the phosphate absorption capacity increases with age of green tissue, but decreases with age of brown tissue.

In the aquatic moss *Warnstorfia fluitans* (Figure 9), an **acidophile** (preferring acid habitats), iron (Fe) **accumulates** in the cell wall (Satake 2000). The highest concentrations are in the base, increasing toward the tip. In addition to the biological accumulation within the walls, iron is held on the mosses in crystal form.

Figure 9. *Warnstorfia fluitans*, a species that can accumulate iron in its cell walls. Photo by Michael Luth, with permission.

Nutrient Concentration

Lou *et al.* (2013) found that the content of the heavy metals Pb, Cr, and Cu in the moss *Haplocladium microphyllum* (Figure 10) correlated with the concentrations in the medium. Iron (Fe), on the other hand, increased in a similar manner until the concentration in the medium reached 400 mg L⁻¹ as Fe⁺⁺. Below that level the iron facilitated uptake of other nutrient ions. The absorption capacity for these metals follows the order

Fe>Cr>Cu>Pb. Like most things in nutrient relationships, the amount matters. At low concentrations, both lead and copper ions, as with iron, promote the absorptive capacity of other nutrient elements. At high concentrations the same metals decrease uptake of other nutrient elements. Chromium is an exception, inhibiting absorption capacity of the nutrients P, K, Ca, S, Fe, and Cu even when the Cr concentrations are low. Lou and coworkers found that Pb and Cr are stored primarily in the peripheral cortex of the moss stem in *Haplocladium microphyllum*. It is not clear how this affects uptake of other ions.

Figure 10. *Haplocladium microphyllum*, a species in which uptake is dependent on concentration. Photo by Robin Bovey, with permission through Dale Vitt.

Water Source

The standing or flowing water habitat of *Sphagnum* fen (Figure 11) species contrasts sharply with the rainfall source of many other bryophytes. Although species occupying raised bogs with no ground water input may rely almost entirely on rainfall, those mosses in fen situations undoubtedly get nutrients from the ground water as well. In a study of 21 species of *Sphagnum* (Figure 21-Figure 29) in Poland, this genus demonstrated its ability to accumulate N, P, and K in the upper parts of the plant through active uptake, whereas Ca, Mg, and Na accumulated through passive **cation exchange** (Wojtun 1994; see below), suggesting an arrangement of nutrients within the plant similar to that of the tracheophytes.

Figure 11. Rich fen showing marl deposits (Ca⁺⁺) on plants. Photo by Janice Glime.

A number of researchers have concluded that **cryptogamic crusts** (soil crusts of algae, Cyanobacteria, fungi, lichens, and bryophytes) that live on the soil in areas with low rainfall increase the availability of essential elements, such as N, Cu, K, Mg, and Zn, thus benefitting seeds, seedlings, and mature tracheophyte plants (Harper & Pendleton 1993; Belnap & Harper 1995; Harper & Belnap 2001). This is most likely due to a combination of trapping airborne nutrients and preventing loss due to erosion and leaching from the soil. We are only beginning to understand the extent and role of bryophytes in nutrient trapping, sequestration, and release in various habitats.

Cation Exchange

Once we understand external transport, we must examine how the nutrients actually enter the moss. Are all nutrients equally capable of entry? Most likely not, but how is that controlled? And can these bryophyte leaves function as well as roots of tracheophytes in the absorption of nutrients?

Brown and Buck (1985) considered the **cation exchange capacities** (CEC; see below) of bryophyte cell walls to be important in their uptake and sequestering ability. Potassium (K) can be held on exchange sites, then remain in solution once it enters the plant. These researchers warned that it was important to know the locations of minerals within and on the bryophytes because ions such as those of Ca and Pb can remain on exterior exchange sites whereas Mg and Zn can be both internal and external.

Dainty and Richter (1993) identified two classes of weak-acid binding sites. One had a low pK (2-4) and the other a high one (>5). pK is the pH at which equal concentrations of acidic and basic forms of a substance are present; it is the negative \log_{10} of the dissociation constant of the electrolyte. The binding sites are related to the uronic, amino, and phenolic acid contents of the cell walls. Dainty and Richter concluded that "valence-dependent reductions in cation activities in the wall phase are an important contributor to the differences in the pK estimates."

The ability of bryophytes to take up nutrients from weak solutions (Babb & Whitfield 1977) permits them to grow in situations that may be limiting to tracheophytes. We know that many (perhaps all) bryophytes sequester nutrients on exchange sites (Clymo 1964; Craigie & Maass 1966; Wells & Brown 1990; Bates 1997), but that the exchange capacity varies among species (Büscher *et al.* 1983).

Polyuronic Acids and CEC

In bryophytes, **cation exchange** is the process in which positively charged ions in the environment are able to replace H^+ ions at the surface of the cell walls, particularly those of leaves. **Cation exchange capacity** (CEC) is due to high concentrations of non-esterified **pectates**, mostly **polyuronic acids**, within the cell walls (Clymo, 1963; Craigie & Maass, 1966) and seems to be the first step in uptake of nutrient cations (Koedam & Büscher 1983). Fine roots of tracheophytes use this method as the first step in obtaining cationic nutrients from their surroundings. Koedam and Büscher (1983) demonstrated that CEC in mosses, typically much higher than in tracheophyte roots (Table 1; Knight *et al.* 1961), was

related to soil preference and carbonate content of the bryophytes.

Table 1. Mean cation exchange capacity of cell walls of tracheophyte roots compared to that of bryophyte gametophores. Tracheophytes from Klein & Horst 2005; bryophytes from Bates 1982b.

	$\mu\text{g g}^{-1}$ dry mass

yellow lupine	422.0	527.4
barley	106.8	59.1
rye	63.1	65.5

The **uronic acids** are important in creating cation exchange sites. Popper and Fry (2003) have demonstrated that bryophytes (including hornworts, thalloid and leafy liverworts, and basal mosses) have higher concentrations of **glucuronic acid** in their primary cell walls than any of the other land plants. Basal mosses have higher concentrations than more advanced mosses, and the highest occurs in *Sphagnum* (Figure 21-Figure 29). *Anthoceros* (Figure 102-Figure 103) was unique in having a repeat-unit of glucuronic acid- $\alpha(1\rightarrow3)$ -galactose, a substance nearly lacking in other kinds of plants in the study. **Galacturonic acid** is known as a subunit in some **xyloglucans**, a group of hemicellulose cell wall compounds (Peña *et al.* 2012). In particular, Peña *et al.* (2008) found that mosses and liverworts have **xyloglucans** that contain galacturonic acid, making them distinctly different from those xyloglucans demonstrated in both hornworts and tracheophytes. Popper and Fry (2003) considered that the cell wall xyloglucans may have been pre-adaptive substances that permitted early colonization of land, permitting rapid acquisition of nutrients during periods of short-lived surface water availability.

The role of cation exchange in nutrient uptake in poor nutrient habitats is further supported by the greater ability of *Sphagnum* (Figure 21-Figure 29) to exchange Ca^{++} and Mg^{++} ions for H^+ ions, providing them with a mechanism to obtain the very limited nutrients in their habitats. For example, Temple *et al.* (1981) reported the exchange capacity of *Sphagnum* to range 0.9 to 1.5 meq per gram dry biomass, whereas that of other mosses generally ranges 0.6-1.1. Figures in meq on tracheophytes were hard to

find; I was able to find that wheat (*Triticum vulgare*) has a low CEC of 0.02 meq per gram dry biomass of roots, with the highest in that study of 0.2 meq in cress (*Lepidium sativum*) (Wiersum & Bakuma 1959).

On the other hand, if the Ca^{++} content of the habitat is too high, *Sphagnum* will bind so much Ca^{++} to its leaf surfaces that it will eventually kill the moss (personal observation). Although this cation exchange process is beneficial in obtaining nutrients, it can also result in accumulation of high levels of heavy metal pollutants (Brown 1984) such as Cd because the moss lacks sufficient selectivity in either binding or uptake of these non-nutrients (Brown & Bates 1990).

The Mechanism

As early as 1961, Knight *et al.* found a correlation between **uronic acid** contents and cation exchange capacity. *Sphagnum* (Figure 21-Figure 29), in particular, has extensive binding sites through its use of the **polyuronic acid** known as **galacturonic acid** (Clymo 1963). Through this capability, *Sphagnum* is able to outcompete tracheophytes. By creating an "intense nutrient impoverishment" for other plants, *Sphagnum* gains a competitive edge (Van Breemen 1995). It can impede growth of peatland shrubs such as leatherleaf (*Chamaedaphne calyculata*; Figure 12) (Bartsch 1994) by sequestering nutrients the shrubs need for growth.

Figure 12. *Chamaedaphne calyculata*, a species that must compete with *Sphagnum* for nutrients. Photo by Uleli, through Creative Commons.

Polyuronic acids such as galacturonic acid have a **carboxyl group** (COOH^+) protruding on the outer surface of the cell wall. This carboxyl group freely exchanges its H^+ for other cations in its surroundings (Figure 13). Hence, when cations such as K^+ , Mg^{++} , and Ca^{++} filter through the bryophyte layer, these ions are often bound on these bryophyte cell wall exchange sites.

Seemingly all bryophytes have a large number of exposed exchange sites, compared to those even of roots of tracheophytes (Knight *et al.* 1961). These exchange sites are essential to the uptake of nutrients in non-*Sphagnum* bryophyte taxa as well. For example, *Pseudoscleropodium purum* (Figure 14) ceased absorbing Mg^{++} and lost intracellular Mg when the exchange sites were saturated with CaCl_2 , suggesting adherence to exchange sites may be a necessary prerequisite to Mg^{++} uptake (Bates 1989). Addition of both K^+ and Ca^{++} greatly increased their

concentrations in the exchangeable fraction of the cell but significantly reduced the concentration of Mg^{++} . Malmer *et al.* (1992) found that the concentrations of Mg^{++} and Ca^{++} in Canadian mire species [three *Sphagnum* species and *Tomentypnum nitens* (Figure 15), all from hummocks] correlated with the surface water concentrations. It is interesting that when Ca^{++} is increased, the brown mosses are more competitive than are *Sphagnum* species. And there is evidence that brown mosses as well as *Sphagnum* can lower the pH, but that they typically do it at a higher level of pH (Figure 16) (Glime *et al.* 1982).

Figure 13. View of leaf cross section of *Sphagnum* (left) with two enlarged chlorophyllous cells and hyaline cell on right. Enlargement shows **carboxyl groups** (COOH^+) of the **polyuronic acid** and one Ca^{++} that will exchange for two H^+ ions in cation exchange. Drawing by Janice Glime.

Cation Competition

So how does competition between cations happen? Divalent cations such as Ca^{++} and Mg^{++} require two binding sites. When there are many of these ions in the environment, they compete for binding sites, occupying two of them in paired sites. Other ions that require two sites then have more difficulty finding the pair of sites they need to bind.

Because plants have a finite number of exchange sites, ions must compete with each other for those locations. Thus, if one cation is in excess, it can cause cellular deficiency of other cations that are unable to gain access to these exchange sites. Based on their experiments with *Hylocomium splendens* (Figure 19) and *Sphagnum*, using artificial precipitation, Gjengedal and Steinnes (1990) considered that cations such as Na^{+} and Mg^{++} in the precipitation may occupy exchange sites and affect the uptake of other ions by this competition. They found that uptake of Zn and Cd were pH dependent and that increasing temperatures increased the uptake for all four of the metals tested (Ca, Cu, Pb, Zn).

Figure 19. *Hylocomium splendens*, a species in which cations such as Na^{+} and Mg^{++} in the precipitation may occupy exchange sites and affect uptake of nutrient cations. Photo by Michael Lüth, with permission.

Figure 20. *Calliergonella cuspidata*, a species whose growth is inhibited at high Ca concentrations. Photo by Michael Lüth, with permission.

Complexing reactions with anions such as Cl^{-} may also interfere with uptake. When Bates and Farmer (1990) applied $CaCl_2$ to three bryophytes, their responses varied by habitat. *Pseudoscleropodium purum* (Figure 14) and

Calliergonella cuspidatum (Figure 20) from chalk soil exhibited significantly reduced growth at high Ca concentrations ($5 \text{ mol CaCl}_2 \text{ m}^{-3}$), whereas *P. purum* and *Pleurozium schreberi* (Figure 2) from acidic clay were unaffected by the additions. The mosses from the chalk soil had lower initial tissue levels of K and Mg, suggesting that the additional CaCl_2 caused deficiencies in these nutrients through exchange site competition.

Ions in the external solution will first establish equilibrium with the exchange sites (Brown 1982). This physical process is completed very rapidly in the lab, but may require days in the field (Brown & Bates 1990). Once that is established, the remaining ions are available for uptake to the interior of cells (Pickering & Puia 1969). Hence, high concentrations of minerals will ultimately increase the uptake.

The number of exchange sites seems to be adaptive, at least in *Sphagnum*. *Sphagnum* section *Acutifolia* (Figure 21), which inhabits drier locations, has more exchange sites per unit of biomass than do members of section *Cuspidatum* (Figure 22), which are wet hollow species (Brown 1982). Both Clymo (1963) and Spearing (1972) showed that the number of exchange sites correlated positively with height above water of the optimum habitat for *Sphagnum* species. This permits hummock species to hold nutrients on their cell surfaces until they are needed without having to wait for rainfall to provide a new source.

Monovalent ions have little effect on CEC for divalent ions (Brehm 1968). But CEC of monovalent cations drops to 0.025 - 0.14 times capacity when in company of divalent cations, presumably due to double binding of divalent ions, much like doubling the strength of a magnet.

Brehm found that dead and living material have the same CEC on a dry weight basis. Nevertheless, living *Sphagnum* (Figure 21-Figure 29) cells contain most of the K^+ and Na^+ , Ca^{++} is mostly on the external exchange sites, and Mg^{++} is on both locations. On the other hand, branches and stems of *Sphagnum* have very different CEC. The living *Sphagnum* is able to maintain a relatively constant cellular content of cations, even when the concentrations of the medium varies widely.

The ability of an exchange site to hold a given positively charged ion depends not only on the valence (charge) of the ion, but also on concentration. When there is a flood of H^+ ions, these will replace the other, more rare and higher mass cations. Again, this is like a magnet; it is harder for a magnet to hold something heavy than something light (like H^+). Hence, basic cations from the bryophyte surface are released into the soil (Foth & Ellis 1997). A striking example of this phenomenon is the case of acid rain making a *Sphagnum* (Figure 21-Figure 29) peatland alkaline and causing the *Sphagnum* to die! (Kilham 1982). The acid rain caused the release of alkaline positive ions from the surrounding hillside, which ultimately washed into the peatland. Although *Sphagnum* is equipped to bind such ions and make its surroundings more acid, it was not equipped to handle the large concentration that resulted from the uphill release. Instead, cations such as Mg^{++} and Ca^{++} accumulated on the surface of *Sphagnum* and eventually killed it. In forested ecosystems, cations released from soil exchange sites become available to roots, may be leached from the organic layer into deeper layers, or may be lost through runoff.

Heavy Metal Relationships

Several bits of information suggest that heavy metals like cadmium use cation exchange of low valence ions to aid their uptake. For example, in the thallose liverwort *Dumortiera hirsuta* (Figure 23), pretreatment with 80 mM KNO_3 causes higher Cd^{++} uptake, suggesting that potassium is able to strip exchange sites of competing cations, allowing higher valence cadmium to then strip some of those sites and enter cells (Mautsoe & Beckett 1996).

Figure 23. *Dumortiera hirsuta*, a liverwort that uses cation exchange to take up heavy metals. Photo by Li Zhang, with permission.

The heavy metals, in turn, influence uptake of potassium and magnesium – two essential nutrients (Carballeira *et al.* 1999). The researchers suggested that loss of K, a very soluble nutrient, from the cells might be due to the effect of the heavy metals on the cell membranes, changing their permeability. The cation Mg^{++} was most likely displaced from the cation binding sites by the heavy metals.

In one experiment, three aquatic bryophytes were exposed for 60 minutes to solutions of 0, 1, 10, 50, 100, and 200 ppm each of Cd, Co, Cu, Ni, Pb, and Zn (Carballeira *et al.* 1999). Locations of these metals plus K and Mg were determined. Most metals remained on extracellular locations, rather than intracellular. On the other hand, only negligible amounts appeared in the particulate fraction. The relationship between water concentration and extracellular concentration could be modelled with a **Michaelis-Menten** equation:

$$v = \frac{d[P]}{dt} = \frac{V_{\max} [S]}{K_M + [S]}$$

v = reaction rate

$[S]$ = concentration of substrate S

P = product

t = time

V_{\max} = max rate achieved at saturating substrate concentration

K_M = substrate concentration at which reaction rate is half of V_{\max}

$d[P]/dt$ = change in product per change in time

But the three aquatic species in this study by Carballeira *et al.* (1999) differed markedly. In *Scapania undulata* (Figure 24-Figure 25), the extracellular cation-binding sites demonstrated high metal affinity. On the other hand, *Fissidens polyphyllus* (Figure 26) has relatively low affinity. Nevertheless, *F. polyphyllus* had the highest internal concentrations of these metals at the end of the experiment. The uptake priorities were the same for all three species.

In these aquatic bryophytes, *Fontinalis antipyretica* (Figure 27), *Scapania undulata* (Figure 24-Figure 25), and *Fissidens polyphyllus* (Figure 26), the extracellular compartment held more metals than did the intracellular compartment (Vázquez Castro *et al.* 1999). The extracellular cation-binding sites of *S. undulata* had a high metal affinity, whereas it was relatively low in *F. polyphyllus*. On the other hand, *F. polyphyllus* after the incubation in the metal solutions had the highest intracellular metal contents. All three species had the same ranking of metal uptake.

Uptake of heavy metals in these aquatic bryophytes led to considerable losses of intracellular K (probably due to effects on plasma membrane properties) (Carballeira *et al.* 1999). Similarly, Mg^{++} cellular contents decreased, but it was apparently due to competition by the metals on the binding sites, limiting uptake. Species differences were again interesting. *Scapania undulata* (Figure 24-Figure 25) exhibited the highest losses of K from internal cell sites, followed by *Fontinalis antipyretica* (Figure 27). On the other hand, *S. undulata* had the lowest losses of Mg from its extracellular exchange sites. These experiments help to explain competition among nutrients and locations in the short term, but long-term effects could be different, as seen in Chapter 8-3 on nitrogen.

Much of what we know about uptake of minerals into plants comes from studies on these heavy metal pollutants. Cadmium, a common pollutant in areas with agricultural fertilizers and other human uses, moves from extracellular sites of the bryophytes to intracellular sites. In *Rhytidiadelphus squarrosus* (Figure 28) cadmium altered photosynthetic rates (Wells & Brown 1987). Its activity at the **plasmalemma** (cell membrane) may exercise control over other ions, affecting their accumulation within the cell, and *vice versa*.

Differing Affinities

Breuer and Melzer (1990a) contributed to the explanation of ion competition using *Sphagnum* (Figure 21-Figure 29) from a high moor. They found that when two or more ions are present, there is an order to the binding success: $Pb^{++} > Cd^{++} \geq Ca^{++} > Mg^{++} > K^{+} > Na^{+} \geq NH_4^{+}$. Hence, those with higher binding affinities were able to suppress the binding of the lower affinity ions.

Breuer and Melzer (1990b) commented that *Sphagnum* (Figure 21-Figure 29) "shows behaviour of a relatively ideal ion exchanger." And, while species differ in their capacity, the coefficients of selectivity are independent of species. These bound cations can readily be displaced if another cation is present at a higher concentration, has a larger hydrated atomic radius, or has a higher valency (Bates 2000).

In *Sphagnum* (Figure 21-Figure 29) Hájek and Adamec (2009) found the exchangeable cation content decreased in the order of $Ca^{++} \geq K^{+}$, Na^{+} , $Mg^{++} > Al^{+++} > NH_4^{+}$, whereas the intracellular element content demonstrated the order of $N > K > Na$, Mg , P , Ca , Al . While Ca occurred primarily on exchange sites, Mg , Na , and especially K , Al , and N occurred inside the cells. Vertical position in the bog influenced the nutrient uptake and location. Hummock species have a higher cation exchange capacity (CEC) and accumulate more exchangeable Ca^{++} . By contrast, the hollow species have a lower CEC and accumulate more exchangeable Na^{+} , especially among the lower dead shoot segments. Intracellular N and P were consistently lower in the dead portions, indicating their translocation to growing upper portions. *Sphagnum magellanicum* (Figure 29) has about 40% lower N content in its cells compared to other species, suggesting its inability to compete for N . This can cause it to lose competition to other species (Hájek & Adamec 2009), but its drought tolerance aids it in occupying tops of hummocks (Li *et al.* 1992). This leaves us wondering why it has such a low N content.

Figure 29. *Sphagnum magellanicum*, a species with low N content. Photo by Michael Lüth, with permission.

Rühling and Tyler (1970) demonstrated the order of binding affinity of several heavy metal cations using *Hylocomium splendens* (Figure 19): $Cu \cong Pb > Ni > Co > Zn \cong Mn$. In a two-hour experiment, these heavier cations preferentially bound to the exchange sites even when lighter cations of Ca^{++} , K^{+} , Mg^{++} , and Na^{+} were present in high concentrations. However, this sequence changed when the elements were supplied individually. Other researchers also demonstrated differences from this sequence in *Rhytidiadelphus squarrosus* (Figure 28) (Brown & Beckett 1985), *Brachythecium rutabulum* (Figure 7) (Brown & Buck 1978), and *Pohlia nutans* (Figure 30) (Webster 1985). These differences may relate to damage by some of the elements, such as cell membrane damage by mercury in some of the experiments,

concentration differences, and possible contamination from soil particles (Brown & Wells 1990).

Figure 30. *Pohlia nutans*, a species of exposed, low-nutrient habitats. Photo by Michael Lüth, with permission.

In the moss *Rhytidiadelphus squarrosus* (Figure 28), competition occurs in the order of $Cd \cong H > Ca > Mg \gg K$ on the extracellular sites (Wells & Brown 1990), suggesting that the low weight of H compensates for the higher valency of Cd. However, affinity of the intracellular Cd transport site occurred in the order of $Ca > Cd > Mg \gg K$. Thus, internally calcium was a competitor for cadmium, but magnesium was not. Cadmium experienced maximum uptake at pH 5.6 and was very sensitive to pH. Potassium had no competitive ability against these ions. This presents another interesting question. How do internal differences in pH affect uptake, transport, and storage of ions? And what are the extent and locations of those pH differences?

Nieboer and Richardson (1980) found a divalent metal ion selectivity binding order of $Pb > Cu > Cd > Co \cong Fe > Ni > Zn > Mn$, although Rühling and Tyler (1970) found a slightly different order for *Hylocomium splendens* (Figure 19): $Cu \cong Pb > Ni > Co > Zn \cong Mn$, an order that seems to be widespread in bryophytes (Bates 2000). However, once the sites are nearly fully occupied, this preferential binding is no longer the strongest force, possibly accounting for differences illustrated here. Isolated binding sites are only able to bind one position on the cation, hence eliminating the advantage for higher valency ions. In fact, at this stage, the isolated sites are more likely to bind univalent ions than divalent ones and more likely to bind divalent ones than trivalent ones (Richter & Dainty 1990). This is because divalent and trivalent ions require adjacent binding sites, whereas monovalent ions can utilize isolated sites. It is also likely that in systems with lower pH, more sites are occupied by H^+ ions, creating more isolated sites. This would favor the binding of lower valency ions such as K^+ and account for the high selectivity at a low pH.

Habitat Differences

Cation exchange sites can serve two conflicting purposes: bind the cations against further uptake, or concentrate them for absorption sites (Büscher *et al.* 1990). These roles have rarely been discussed for terrestrial bryophytes. This affects the bryophyte tolerance of various substrates. Using the **acidicline** (preferring soils with pH <5) species *Atrichum undulatum* (Figure 31), *Leucobryum glaucum* (Figure 32, *Mnium hornum* (Figure

33), and *Polytrichum formosum* (Figure 34, and the **neutrocline** (preferring pH close to neutral, *i.e.* >5) species *Homalothecium sericeum* (Figure 35) and *Plagiomnium undulatum* (Figure 36), Büscher *et al.* found that **acidophilous** and **acidicline** taxa generally have lower CEC and are more able to tolerate the toxic aluminium (Al) levels, but not high levels of Ca. **Neutrocline** taxa instead avoid habitats with aluminium in the substrate and thrive on high calcium levels. (But what is the mechanism causing the avoidance?) They concluded that cation exchange properties do not protect mosses against potentially toxic ions, including aluminium, by sequestering them. But they did conclude that the exchange sites could increase the availability of cations. High CEC favored fixation of Al ions over Ca ions, indication that a low CEC is needed for taxa to tolerate acid soils.

Figure 35. *Homalothecium sericeum*, a **neutricline** species with higher numbers of cation exchange sites. Photo by Michael Lüth, with permission.

Bates (1992) found that in epilithic and woodland soils the cation exchange capacity decreases with decreasing Ca content, and likewise with decreasing pH of the substrate. This change might help to protect the bryophytes against the toxic aluminium that increases in concentration in acidic solutions, *e.g.* soils polluted by acid rain.

Figure 36. *Plagiomnium undulatum*, a **neutricline** species with higher numbers of cation exchange sites. Photo by Michael Lüth, with permission.

Calcareous rocks, inhabited by **calcicoles** (Ca-preferring species), typically have Ca^{++} concentrations 16-17 times that found in species from non-calcareous rocks (**calcifuges** – species avoiding Ca) (Bates 1982a). The calcicoles exhibit 3-4 times as many cation exchange sites as the calcifuges. Bates suggested that the calcicole mosses may require greater Ca^{++} concentrations to maintain cell membrane integrity.

Uptake Rate

Uptake of these nutrients is very rapid when concentrations are high. Half the maximum extracellular uptake can be achieved in 4.45 ± 1.03 minutes in $100 \mu\text{mol L}^{-1}$ Cd (Brown & Beckett 1985). This rate is concentration dependent and at lower (more natural) concentration levels it can take several days to reach equilibrium (Mouvet 1987). Release of the cations from the exchange sites when the element is removed from the medium takes even longer, as shown in the aquatic liverwort *Chiloscyphus polyanthos* (Figure 37-Figure 38) (Maurel-Kermarrec *et al.* 1985). The uptake ability varies between clones that grow within meters of each other (Wells & Brown 1987; Wells 1988). This can result from differences in light/moisture availability in the open vs under shrubs, as demonstrated in *Rhytidiadelphus squarrosus* (Figure 28) (Wells & Brown 1987). This difference could have been caused by thicker cell walls in the higher light population of *R. squarrosus*.

Figure 37. *Chiloscyphus polyanthos* in a typical habitat. Photo from <www.aphotofauna.com>, with permission.

Figure 38. *Chiloscypus polyanthos*, a leafy liverwort with cation exchange. Photo by Michael Lüth, with permission.

In summary, nutrient uptake into the moss is initially dependent on available exchange sites, but then it depends on affinity of a particular nutrient for appropriate transport sites of cell membranes, presence of competing elements, and turnover rate of the uptake site (Brown & Bates 1990), and perhaps cell wall thickness (Wells & Brown 1987).

Desiccation and Loss

Brown and Brumelis (1996) found that desiccation and duration of drought affected cellular location of elements in *Hylocomium splendens* (Figure 19), a boreal forest floor species. Rehydration partially reversed these effects.

When bryophytes become desiccated, nutrients leave the cells through leaky membranes (Bewley 1979). But Bates (1997) has shown that in *Brachythecium rutabulum* (Figure 7) and *Pseudoscleropodium purum* (Figure 14), leaked K^+ ions are able to remain on leaf surfaces (Figure 14), held there on exchange sites, and are re-absorbed upon hydration. Like tracheophyte roots, bryophytes utilize cation exchange sites to hold nutrients at their surfaces until those nutrients are moved into the plant.

Anion Uptake

Bryophytes also have exchange sites for **anions** (negatively charged ions), but these are far less abundant and likewise their role is less well understood (Clymo 1963). Even now, little is known about anion uptake. Wells and Richardson (1985) found that only living shoots of *Hylocomium splendens* (Figure 19) were able to accumulate arsenate and selenite, both **anions**. Arsenate uptake is inhibited by phosphate (anion) competition when both are supplied at the same time. On the other hand, if plants were incubated in phosphate before providing arsenate and selenite, it had no effect on their uptake. It appears that arsenate and selenite are accumulated by separate transport systems in this species and that these systems may be the ones responsible for phosphate uptake. pH was important, with arsenate uptake optima occurring between 3 and 5, whereas selenate was optimal at pH 3.

Polytrichum commune (Figure 4) has a well-developed conducting system and was the only bryophyte one study that had more uptake in brown portions than in green ones (Chapin *et al.* 1987). *Sphagnum* species were the only ones with significant P uptake in the current growth. But in seeming contradiction, the anionic form of N (nitrate) was preferred by *Sphagnum* over the cationic

ammonium source of N (Rudolph *et al.* 1982). This preference likewise contradicts the results of Wanek and Pörtl (2008) who concluded that *Sphagnum* (Figure 21-Figure 29) prefers ammonium because of its numerous cation exchange sites. But it does coincide with the inhibition of nitrogen reductase by ammonium (Syrett & Morris 1963; Orebamjo & Stewart 1975). Furthermore, Wanek and Pörtl (2008) found that amino acids contributed a significant fraction of the N used by *Sphagnum* from the lowland rainforest in Puerto Rico.

Brown (1982) suggested that anion adsorption is probably especially low in mosses because they have low iron and aluminium content and high cation exchange capacity (Clymo 1963; Chapin *et al.* 1987). Phosphorus, as the phosphate anion, is taken up primarily from the mineral substrate (Bates 1992). Chapin *et al.* (1987) concluded that accumulation of the phosphate anion, as they observed in mosses of the Alaskan black spruce (*Picea mariana*, Figure 3) forest, was therefore by active absorption similar to that of higher plants. In these forests, mosses hold 17% of the phosphorus pool, despite accounting for 75% of the annual P accumulation. The mosses have a greater ability to absorb phosphate than do fine roots of the black spruce.

Proton Pumps

After ions have reached the surface of the cell, they require energy to enter the cell. In tracheophytes, the **proton pump** is well known in such activities as bringing nutrients into root hairs, opening and closing guard cells, closure of the Venus flytrap, and growth, to name only a few. In bryophytes, the proton pump has likewise been demonstrated, and like that of tracheophytes, it uses ATP to "pump" H^+ ions out of a cell (Figure 39). This leaves the cell with a negative charge that attracts cations into the cell (Raven *et al.* 1998). The resulting negative charge provides the force needed to bring in K^+ , NH_4^+ , Mg^{++} , Ca^{++} , sugars, and amino acids, and probably other cations that have not yet been confirmed experimentally.

Cotransport

As a positively charged ion enters the cell, it typically brings along an associated anion by **cotransport**. The pump, at the same time, regulates the pH within the cell to about 7.3-7.6. In bryophytes, the leaf cell surface and interstitial spaces between the cells provide sites where adhering cations are able to enter the cell through the proton pump mechanism.

Figure 39. Known transport processes through the plasmalemma of a bryophyte cell. Diagram based on Raven *et al.* 1998.

As a result of ion movement through CEC and the proton pump, the bryophyte most likely has an influence on the **rhizoidosphere** (soil space immediately surrounding rhizoids) similar to that of tracheophytes on the rhizosphere (Raven *et al* 1998), although in the case of bryophytes, leaves may contribute to the alteration of conditions even more than the rhizoids. The rhizoidosphere is acidified in the process of cation exchange and proton pumping to bring nutrient cations into the cells, creating positive charges within the cells and accumulating organic anions in the cell vacuoles.

Pinocytosis

Pinocytosis results when a cell ingests a liquid by budding small vesicles inward from the cell membrane, thus containing the droplet. The droplet of liquid then is incorporated into the cell cytoplasm. Gullvåg *et al.* (1974) observed this mechanism in *Rhytidiadelphus squarrosus* (Figure 28) when it was treated with lead-rich particles in the lab. When they tested mosses that were exposed to lead pollution in the field, they found that the lead was bound within the nucleus. The importance of pinocytosis for incorporating nutrients into the cells of bryophytes seems to lack study.

Nanoparticles

The concept of nanoparticles is a relatively new idea in bryophyte ecology. Canivet *et al.* (2014) found, for the first time, that nanoparticles of iron in a mineral water suspension could penetrate the leaves of the moss *Physcomitrella patens* (Figure 40). In follow-up experiments Canivet *et al.* (2015) further demonstrated the penetration of iron nanoparticles into the moss *Physcomitrella patens*. Using concentrations of 5 ng, 50 ng, 500 ng, 5 µg, and 50 µg per plant, they found no effect on ATP concentrations, reactive oxygen species, malondialdehyde, or glutathione, suggesting that the plants had not been physiologically harmed at any of these concentrations. The role of nanoparticles in providing essential nutrients or harming the plants seems to thus far lack exploration.

Figure 40. *Physcomitrella patens*, a moss that can take up nanoparticles of iron. Photo by Michael Lüth, with permission.

Influence of Cellular Structures

Many studies have treated cellular influences as if the cells were homogeneous (Brown & Wells 1990). First, the nutrient must cross the cell membrane. But in fact, once inside the cell, the nutrient may be held in solution, like K, or bound into amino acids and proteins, like some of the N and P. The chlorophyll molecule can take Mg out of play. When these binding compounds take the nutrient out of solution, they affect the concentration gradient from outside to inside the cell, affecting the concentration gradient used for the nutrient to cross the cell membrane and enter the cell. Others are bound to intracellular binding sites, again altering uptake rate.

Pickering and Puia (1969) described three phases of element uptake against time, an "unusual" process compared to that in algae and tracheophytes (Brown & Wells 1990). The first phase is the initial rapid uptake as the ions diffuse into interstitial spaces in the tissues (Pickering & Puia 1969). Then the uptake is controlled by equilibration with cell wall exchange sites. The final phase is a slow, linear increase of intracellular uptake. This third phase does not occur in dead material. As demonstrated in *Rhytidiadelphus squarrosus* (Figure 28), carriers can be used to transport the element across the membrane (Brown & Beckett 1985; Wells & Brown 1987). Specificity of these carriers determines how much inter-element competition there is for the intracellular uptake. This in turn affects the rate of uptake.

Location Is Important

As already noted, location of nutrients on and in the bryophytes is important (Brown and Buck (1985). The method used can present a bias that is misleading regarding normal nutrient concentrations. A nutrient adhering to the cell wall is not immediately available to the cells and may not be representative of the needs of the cells. Others may be held in the spaces within the walls. To fully understand the nutrient physiology, we must understand where these nutrients are located on and in the bryophyte plants (see Table 2).

Table 2. Element locations in bryophytes. Based on Brown 1982.

- in particles trapped by leaves
- in solution on exterior & in matrix of cell wall
- as ions bound to external exchange or chelating sites & on plasma membranes
- in solution in cytoplasm & vacuoles
- as insoluble substances in cytoplasm & vacuoles
- in leptome (especially Polytrichaceae)

New Growth

When new branches are formed and expand in the absence of additional nutrients, these nutrients must be obtained from existing tissues. In some cases, this is through **acropetal** (base to tip) transfer, as seen in *Rhytidiadelphus squarrosus* (Figure 28) (Wells 1988). Potassium, a very soluble nutrient, declines in lower portions as the apex grows. Calcium, on the other hand, is

not soluble and is taken from the initial apical segment, not transported from older tissues. Magnesium exhibited a somewhat similar response, but all segments lost Mg from intracellular sites as the apex grew.

Specificity

Some nutrients are taken up more easily than others. Leblond (2004) examined the uptake of heavy metals in the moss *Pseudoscleropodium purum* (Figure 14). The nutrient elements manganese and potassium had the highest retention. Non-nutrient ions of sodium, aluminium, and silica had the least retention. Youngest tissues accumulated the most nutrients, but internal redistribution occurred. Leblond found that soluble materials were taken in more easily than those deposited as particulates.

We know that cation exchange sites selectively bind higher valency cations (Richter & Dainty 1990). But at least in *Sphagnum russowii* (Figure 41-Figure 43) there are two classes of exchange sites. The well-known one is associated with polygalacturonic acids and accounts for more than 50% of the cation exchange capacity (Richter & Dainty 1989). In addition to that, **phenolic acids** account for about 25%, whereas **amino acid**, **sulfate ester**, and **silicate deposits** in the cell wall contribute to a lesser degree.

When studying aquatic bryophytes, Burton and Peterson (1979) found that 33% of the cell-wall-bound Zn could be removed by the enzyme **pronase** (mix of enzymes that break down proteins), suggesting that a considerable portion of its binding might be due to protein binding. Richter and Dainty (1989) found a small number of binding sites that are more specific to small valency cations such as potassium. If these sites include phenolic compounds, one can presume that such binding sites might be widespread in bryophytes, wherein phenolic compounds are common (Mues & Zinneister 1988; Liao 1993; Basile *et al.* 1999). Is this yet another use for these presumed "secondary" compounds? If so, what does it mean for cycling of potassium if it can be bound to the cell walls? Does this help the plant to retain its valuable potassium when cell membranes, damaged by desiccation, permit potassium to leak from the cell? Such a mechanism could contribute to the survival of bryophytes after desiccation and permit them to become a long-term sink for this and other ions.

We know that cation exchange is a somewhat selective process. Higher valency ions are bound preferentially over lower ones because they occupy more than one exchange site. Cations have binding preferences (Nieboer & Richardson 1980, 1981). **Class A** includes K, Ca, Mg, and S. These elements prefer oxygen-rich ligands, such as carboxylic groups. **Class B** elements such as Ag, Cu, H, Hg, Pb, and Au are toxic and prefer ligands that are rich in sulfur and nitrogen. The third group is a borderline class that includes Cu^{++} , Ni^{++} , Pb^{++} , and Zn^{++} . Hence, the quantity of any element bound to the cell wall will depend on concentration in the medium (precipitation, water, soil), its affinity for type of exchange site, and the total number of suitable exchange sites.

Dead cells may actually have more exchange sites than live ones due to shrinkage of cell membranes that cover them on the inside. On the other hand, Wells (1988) found that when the cells are killed by a strong acid, the exchange capacity decreases, a phenomenon he attributed to loss of cytoplasm.

Hence, the quantity of any element bound to the cell wall will depend on concentration in the medium (precipitation, water, soil), its affinity for type of exchange site, and the total number of suitable exchange sites. Dead cells may actually have more exchange sites than live ones due to shrinkage of cell membranes that cover them on the inside. On the other hand, Wells (1988) found that when

the cells are killed by a strong acid, the exchange capacity decreases, a phenomenon he attributed to loss of cytoplasm.

Fortunately, bryophytes seem to have uptake specificity for things they need over things they do not. For example, the thallose liverwort *Dumortiera hirsuta* (Figure 23) preferentially took up Ca, Mg, and Zn over Cd (Mautsoe & Beckett 1996). When KNO₃ was used to pretreat the plants, Cd uptake occurred, suggesting that the high concentration of K⁺ removed the competing ions from the exchange sites and they were subsequently replaced by Cd. Light and increased temperatures also stimulated Cd uptake. Even *Sphagnum* (Figure 21-Figure 29, Figure 41-Figure 44), the champion of cation exchangers, distinguishes among ions in ways that do not seem to depend strictly on valence. It accumulates Al and Mn, but excludes Cu and Zn, accumulating much less of these than the concentrations in the surrounding fen water (Li & Glime 1990).

Shimwell and Laurie (1972) found that ectohydric and mixohydric mosses differ in their absorption, retention, and excretion of heavy metals. During droughts, **ectohydric** (having external conduction) mosses excrete such heavy metals as Zn and Pb, forming surface crusts containing up to 6% Pb and 1-5% Zn. In **mixohydric** (having both external and internal conduction) mosses, on the other hand, the metals generally are located at the base of the moss carpet in the older growth, suggesting their accumulation in older tissues and lack of internal transport.

Seasons

Since most bryophytes gain most of their nutrients from precipitation, we might assume that most nutrient uptake therefore occurs when it rains. Yet the relationship is most likely not so simple. Francez and Loiseau (1999) found that *Sphagnum fallax* (Figure 44) was more efficient at intercepting applied N (as NH₄NO₃) in August than in June, even though August had the lowest rainfall. Dust accumulation can benefit bryophytes that are able to absorb nutrients in early morning dew and even on humid nights when there is no benefit for tracheophytes.

Figure 44. *Sphagnum fallax*, a species that takes up more N in August than in June. Photo by Michael Lüth, with permission.

Bates (1992) considered that in rapidly growing species such as *Brachythecium rutabulum* (Figure 7) the

seasonal deposition of tracheophyte litter is especially important. In the slower-growing species such as *Pseudoscleropodium purum* (Figure 14), wet deposition may be the most important.

Turner and coworkers (2003) found that rates of acid phosphatase activity in moss apices differed markedly among species, but most taxa had the most activity in winter and least in summer. Nevertheless, tissues maintained relatively constant N and P concentrations throughout the year. A negative correlation between phosphatase activity and P concentration in the tissues suggests that the enzyme may become active in response to phosphorus needs and serves to indicate nutrient stress.

Núñez-Olivera *et al.* (2001) found that seasonal differences in several aquatic bryophytes [*Fontinalis antipyretica* (Figure 27), *F. squamosa* (Figure 45, *Jungermannia eucordifolia* (Figure 46), and *Pellia endiviifolia* (Figure 47)] did not mimic the seasonal differences in their native streams. Rather, the concentrations depended on the interactions of internal and external factors. The elements that had the most persistent annual cycle were mostly essential nutrients: N, P, and Fe, plus the non-essential Na. The lowest concentrations occurred in spring and the highest in autumn. Concentrations were lowest during periods of growth.

Glucose Uptake

External glucose can enhance growth of at least some bryophytes (Jennings 1918). *Ceratodon purpureus* (Figure 48) grew 4-5 times as much when provided with glucose on nutrient agar compared to nutrient agar without glucose. This implies that organic sources of carbon that may be available in the substrate are suitable carbon sources for at least some mosses. Vujičić *et al.* (2009) found that the best conditions for axenic culture of the moss *Dicranum scoparium* (Figure 49) was in MS medium enriched with sucrose at 1.5% at 18-20°C.

Figure 48. *Ceratodon purpureus*, a species that grows faster when external glucose is supplied. Photo by Michael Lüth, with permission.

Bryophytes can store their carbohydrates as sucrose and fructan, as exhibited in *Porella platyphylla* (Figure 50) and *Sphagnum flexuosum* (Figure 51-Figure 52) (Marschall 2010). Galloway and Black (1989) demonstrated that the bryophytes they tested have the necessary enzymes for sucrose to enter cellular metabolism by the sucrose synthase pathway. Adding glucose, fructose, and sucrose to the medium causes these bryophytes to down-regulate photosynthesis when the bryophytes are kept either in the dark or in the light (Marschall 2010). On the other hand, when no

carbohydrates were added, darkness had little influence on total carbohydrates, suggesting that they maintain a well-regulated carbohydrate pool.

Sugars differ in their effects on bryophyte development (Sabovljevic *et al.* 2005). In *Bryum argenteum* (Figure 53), added sugars have a positive effect on development of the protonema and multiplication of the shoot. On the other hand, all tested sugars had a negative effect on both of these developmental stages in *Atrichum undulatum* (Figure 31).

Figure 53. *Bryum argenteum*, a species for which added sugars have a positive effect on development. Photo from India Biodiversity Images, through Creative Commons.

Not only do bryophytes store sugars, but as we might expect as a consequence, they also release them (Coxson *et al.* 1992). In the tropical montane rainforest of Guadeloupe, frequent wet-dry cycles cause the epiphytic bryophytes to accumulate 950 kg ha^{-1} of sugars and polyols. These are released during rewetting, contributing to sugars available to other organisms in the canopy. The canopy leafy liverwort *Frullania atrata* (Figure 54) stored 17% of its dry biomass as sugar and polyol reserves, whereas the lower canopy species *Phyllogonium fulgens* (Figure 55) stored less than 6%. On the other hand, it was the lower canopy bryophytes that released the most sugars and polyols (0.9 g m^{-2}) during rewetting, compared to 0.3 g m^{-2} for the upper canopy. This release yielded an estimated 122 kg ha^{-1} from the upper canopy. These sugars

contribute significantly to nutrient cycling by providing an energy source for the decomposer organisms.

Fungal Connections – Mycorrhizae?

One mode of uptake by bryophytes has largely been ignored by ecologists until recently, potentially causing researchers to be looking in the wrong places or not all important places for bryophyte effects on ecosystem nutrient budgets. That mode is by means of **mycorrhizae** (fungal associations that function in transfer of nutrients to roots or rhizoids) or similar partnerships with **fungi**.

In 1976, Kottke and coworkers recognized that the ability of mosses to compete was affected by differential growth stimulation of the mosses by fungi. Still, little attention was paid to moss-fungal interactions from an ecosystem perspective, but bryologists began noticing that many mosses seemed to have fungal hyphae associated with their underground parts. Meanwhile, the tree physiologists were recognizing that fungal partners were critical to the nutrient and water uptake of trees. And orchid growers recognized that the native fungi must be kept with the orchids for successful growth. Now, fungi are recognized as essential to the nutrient uptake of tree

roots, and stories about their partnerships with roots are replacing the traditional teaching emphasis on root hair mechanisms of uptake.

Ecologists estimate that 95% of all plant species are in genera that form mycorrhizal associations (Sylvia *et al.* 2004). In temperate and boreal forests, up to 95% of the short roots of trees form **ectomycorrhizae** [form of symbiotic relationship that occurs between a fungal symbiont and the roots (or rhizoids) of various plant species]. Mycorrhizae are critically important to most forest trees, which depend on them to increase surface area and contact nutrients in a much greater volume of soil than the tree is able to reach. Bryophytes, likewise, are able to take advantage of this partnership to reach sources otherwise unavailable to them. Even in the Antarctic, such fungal relationships can be important, as in the leafy liverwort *Cephaloziella exiliflora* (Figure 56) (Williams *et al.* 1994; Chambers *et al.* 1999). There are also indications that nutrients are transferred from the moss mat to the tree roots through mycorrhizae (Chapin *et al.* 1987). But we know little of the extent of these relationships.

Figure 56. *Cephaloziella exiliflora*, a leafy liverwort with fungal associations in the Antarctic. Photo by Tom Thekathyl, with permission.

Although Boros reported a unique parasitic fungus on mosses in 1926, most botanists considered the bryophytes to be almost immune from fungal attack; even less attention was paid to the possibility of any sort of fungal partnership. In 1970, Kamal and Singh reported on the **rhizoidosphere** fungal flora of bryophytes. In 1975, Pirozynski and Malloch offered the theory that mycorrhizae were an essential part of the invasion of land by the original bryophyte-like plants, helping them to survive in an environment that was poor in nutrients and sustained frequent periods of desiccation. But actual proof of a mycorrhizal partnership, extant or extinct, was not forthcoming.

Finally, in the 1980's, reports of bryophyte mycorrhizal (shouldn't it be mycorrhizoidal?) associations began to appear in the literature (Parke & Linderman 1980; Rabatin 1980; Pocock & Duckett 1985a; Iqbal *et al.* 1988a, b; Ligrone 1988). These have included associations with *Funaria hygrometrica* (Figure 57) (Parke & Linderman 1980; Iqbal *et al.* 1988a), *Sphagnum palustre*

(*cymbifolium*) (Figure 58-Figure 59), *Polytrichum commune* (Figure 4) (Iqbal *et al.* 1988a), and in *Marchantia emarginata* (= *M. palmata*, Figure 60) both rhizoids and the ventral thallus (Iqbal *et al.* 1988b).

Ligrone and Lopes (1989) demonstrated **vesicles** and **arbuscules** ("little trees"; branched structures formed by fungi within plant cells; Figure 61) in both rhizoids and parenchyma cells of the thallose liverwort *Conocephalum conicum* (Figure 62), suggesting a true mycorrhizal association. The arbuscules are thought to be the site of nutrient exchange (Harrison 1999), at least in roots. Even *Phaeoceros laevis* (Figure 63), a member of the **Anthocerotophyta** and host of a *Nostoc* (**Cyanobacteria**; Figure 64-Figure 65) symbiont, has a fungal associate that appears to be mycorrhizal (Ligrone 1988). When *P. laevis* is infected, the plastid forms a networking structure, the vacuole mass decreases, and the organelle density increases, all modifications suggestive of a partnership.

In 1985, Pocock and Duckett (1985b) investigated the rhizoids of 206 of the 284 British liverworts. They found that swollen rhizoids occurred in 33 species of the Jungermanniales and were always associated with fungal hyphae. Swollen and branched rhizoids were particularly well developed in the **Lepidoziineae** (Figure 66) and **Cephaloziineae** (Figure 94) and often occurred on flagelliform shoots, but were better developed on the

underground axes. Duckett *et al.* (1991) later described the highly specialized associations between ascomycetous fungi, known for their ectomycorrhizal partnerships, and 46 species of British liverworts. They found the majority of these ascomycetous fungi to occur with the leafy liverwort suborders **Lepidoziineae** and **Cephaloziineae**. [Ascomycetous associations are found in a relatively small number of families of leafy liverworts (Read *et al.* 2000)]. Strikingly, 33 of these 46 British liverwort taxa form flagelliform axes (Duckett *et al.* 1991). These axes have elongate parenchyma cells with abundant plasmodesmata in their transverse end walls. Their apices are mucilaginous and the subapical amyloplasts appear to act in detecting gravity, much as they do in protonemata. In addition to serving as perennating structures, these axes appear to be major organs of assimilation. Is this facilitated through a mycorrhizoidal partnership?

In all these leafy liverwort cases, the fungi infect the individual rhizoids independently, but most of these 46 taxa nevertheless have abundant fungi-infected rhizoids that extend 20-30 cm into the peaty substrate (Duckett *et al.* 1991). What an extension for a tiny bryophyte! In the liverworts *Lepidozia* (Figure 66), *Kurzia* (Figure 67), and *Telaranea* (Figure 68), but known in no others, the rhizoids swell prior to fungal infection. In *Cladopodiella* (Figure 69), the fungi form a pseudoparenchymatous sheath around the swollen rhizoidal tips.

Figure 66. *Lepidozia reptans*, a species in which rhizoid tips swell prior to fungal association. Photo by Michael Lüth, with permission.

Figure 69. *Cladopodiella fluitans*, a species in which fungi form a sheath around rhizoid tips. Photo by Kristian Peters, with permission.

By 1988, Boullard had presented evidence that the fungal symbiotic relationship with the liverworts was evolutionarily very old. Yet, in 1990, During and van Tooren pointed out that "in only very few cases have these interactions been analysed functionally."

Other associations have been documented in the field. Although not truly mycorrhizoidal because they lack the composite structure definitive of this relationship, bryophytes now are known to enter into partnerships. Even buried wood, inoculated with ^{32}P , was able to provide P for the living tips of *Hypnum cupressiforme* (Figure 70-Figure 71) through a saprotrophic fungus, *Phanerochaete velutina* (Figure 72), that connected to the older parts of the moss (Wells & Boddy 1995).

Figure 72. *Phanerochaete velutina*, a fungal associate of *Hypnum cupressiforme* on wood. Photo by James K. Lindsey, with permission.

The fungal association may in some small way benefit the neighboring plants, and they in turn the bryophyte (Duckett & Read 1995). As noted earlier, Chapin *et al.* (1987) have found an association that may indeed benefit the trees. In an Alaskan forest they found that the mycorrhizal fungi of the black spruce (*Picea mariana*, Figure 3) stimulated the moss carpet above to release phosphorus to the tree roots! When the mycorrhizae were inhibited, more P remained with the mosses and less escaped from the plots, where it presumably went to tree roots.

Rhizoids of at least some leafy liverworts in the **Lepidoziaceae** (Figure 66), **Calypogeiaceae** (Figure 73), **Cephaloziaceae** (Figure 94), and **Cephaloziellaceae** (Figure 56) can be infected by the same fungus, *Hymenoscyphus ericae* (Figure 74), an ascomycetous fungus, that infects members of the Ericaceae such as *Calluna* (Figure 75), *Erica* (Figure 76), *Rhododendron* (Figure 77), and *Vaccinium* (Figure 78-Figure 79) (Duckett & Read 1995). So far, there appears to be no evidence of a transport pathway from moss to fungus to ericaceous plant or vice versa, but the presence of one of these host plants would enhance the opportunities for the fungus to grow there and thus provide greater opportunities for the fungus to join with the other host. This is similar to the

partnership between *Monotropastrum humile* (an achlorophyllous flowering plant; Figure 80), a fungus, and a beech tree (*Fagus crenata*, Figure 81) (Kasuya *et al.* 1995). The fungus in the *F. crenata* appears to be the same as that in the *M. humile*, and evidence implies that the fungus joins the two tracheophytes. In this way, the *M. humile* could take advantage of the sunlight reaching the canopy of *Fagus crenata* by receiving carbohydrates from the canopy transferred through the fungus to the *M. humile*. The fungus appears to be a member of the Russulaceae (Figure 82) (Yamada *et al.* 2008; Matsuda *et al.* 2011).

Cryptothallus mirabilis

It appears that the fungi may be to some liverworts what the mycorrhizae are to the grape fern *Botrychium* and to many of the saprophytic forest floor flowering plants – a means of getting sufficient energy when the canopy is blocking an extensive portion of the light. Such a relationship is essential to the thallose liverwort *Cryptothallus mirabilis* (Figure 83), a European species known as ghostwort. It occurs nestled in mires and lacks chlorophyll. Certainly for it, a partnership is essential. But this liverwort has a **Basidiomycota** fungus as its ectomycorrhizal partner (Ligrone *et al.* 1993). They concluded that this liverwort is a **parasite**! It was thought that its fungal partner joined it to a species of *Betula* (birch), from which it ultimately obtained its carbohydrate energy source (Wiehle 1988; Pocock & Duckett 1984; Frey & Kürschner 1991; Read *et al.* 2000), much like the parasitic flowering plant *Monotropa uniflora* (Figure 84), the Indian pipe. However, Ligrone *et al.* (1993) disagree. They found that the fungi in *Betula* roots had a different morphology from those in the associated *C. mirabilis*. It appears that the association of *C. mirabilis* is more like that of the goblin fern *Botrychium mormo*, wherein the fungus derives carbon from decomposing litter and transfers some of it to the fern, permitting it to live in low light (Gundale 2002). But could it also be that the form of the fungus depends on the host, thus differing between that of the *C. mirabilis* and that of the *Betula*?

Bidartondo *et al.* (2003) determined that *Cryptothallus mirabilis* (**Basidiomycota**; Figure 83-Figure 86) is an **epiparasite**, depending on a species of the fungus *Tulasnella* (Figure 85-Figure 86). This fungus forms **ectomycorrhizal** (symbiotic relationship between fungal symbiont and roots of plant species) associations with surrounding trees. It is able to transfer labelled ^{14}C from birch (*Betula*) seedlings in the lab, and presumably from tree roots in the field. Species of this same genus are also associated with *Aneura pinguis* (Figure 87) (Kottke *et al.* 2003) and some orchids (Clements & Ellyard 1979; Roche *et al.* 2010).

Figure 87. *Aneura pinguis*, a species with chlorophyll and that is closely related to *Cryptothallus mirabilis*. Photo by Michael Lüth, with permission.

When it develops, the *Cryptothallus mirabilis* (Figure 83) fungus (Figure 88-Figure 91) forms large, intracellular coils in the liverwort (Ligrone *et al* 1993). Then the liverwort cytoplasm proliferates and the starch content of its plastids decreases. As the hyphae die back and aggregate into large masses, the liverwort cells senesce. In *C. mirabilis*, the fungal hyphae contain abundant glycogen and occasionally amyloid deposits. It is interesting that the fungal partner in *C. mirabilis* is identical to the one in *Aneura pinguis* (closely related but photosynthetic; Figure 87) from alpine sites but different from the fungus in *A. pinguis* from a chalk pit and sand dunes. In *C. mirabilis*, net carbon transfer is to the liverwort, and it is likely that there is transfer from the fungus to the liverwort in *A. pinguis* as well. In addition to the morphological similarities, further support for this hypothesis in *A. pinguis* is that spores of both liverwort species fail to develop beyond a few cells in *axenic* (sterile) culture.

Bidartondo and Duckett (2010) concluded that most of the thalloid liverworts contain **Glomeromycota** (Figure 92) that form arbuscular mycorrhizae with them. Many leafy liverwort species and members of the thallose **Aneuraceae** have a relationship with **Basidiomycota**. Whereas the **Aneuraceae** associate almost exclusively with species of *Tulasnella*, eight leafy liverwort genera predominately associate with members of *Sebacina vermifera* (**Basidiomycota**; see Figure 93). *Sebacina* species have a habit of surrounding plants, so some of them may envelop the plants and prevent photosynthesis. It is interesting to note that when multiple species of bryophytes occur together, they rarely share the same fungal species. Furthermore, the bryophyte symbioses are not like those of the tracheophytes.

Underground and Other Partnerships

It appears that *Cryptothallus* (Figure 83) is not the only liverwort capable of living below ground with an **Ascomycota** fungal partner (Duckett *et al.* 1989). In bog communities, the leafy liverworts (**Jungermanniales**) *Cephalozia* (Figure 94), *Cladopodiella* (Figure 69), *Kurzia* (Figure 67), *Lepidozia* (Figure 95), *Odontoschisma* (Figure 96), and *Telaranea nematodes* (Figure 68) can all develop extensive underground stem systems with numerous rhizoids that have swollen, fungus-containing tips. These liverworts can produce new shoots down to 24-30 cm in peat and to 10 cm in rotten logs (*Lepidozia reptans*, Figure 95).

In Malaysia, members of the leafy liverwort family **Lepidoziaceae** (Figure 95) can produce such axes down to 1.5 m in the peaty soil of the upper montane rainforest (Duckett *et al.* 1989). When these develop in the dark, they retain their partnership morphology, but when the shoots are exposed to light they regenerate into leafy shoots and lose their gravitropic response. This loss of fungal partnership morphology appears to be related to the disappearance of subapical amyloplasts, known to have a gravimetric response. Duckett and coworkers suggest that these liverworts may be acting as alternative hosts to ericaceous mycorrhizae, particularly in places like Malaysia. In Great Britain, less than 20% of the **Jungermanniales** (Figure 94-Figure 95) have rhizoidal fungi, whereas in the montane forests of Malaysia, where ericaceous shrubs are extensive, the percentage may be as high as 80-90%.

As the search continues, more and more fungal taxa are being described in bryophyte associations, but not all are mycorrhizal (Khan *et al.* 1997; Döbbeler 1997; Brouwer 1999). In fact, a number appear to be parasitic; others are just coexisting, perhaps benefitting from the modulated temperature and moisture. Nevertheless, approximately 300 species of **Ascomycota** appear to grow obligately on bryophytes (Döbbeler 1997). More than 40 species of **Ascomycota** in six orders occur on the **Polytrichaceae** alone, primarily on *Polytrichum* s.l. (Figure 4, Figure 34) and *Dawsonia* (Figure 97) (Felix 1988). Some fungi, for example *Lemprospora* (Figure 98) and *Octospora* (Figure 99), are known only from bryophytes (Döbbeler 1997; Brouwer 1999); in other cases, the bryophyte has never been found without its fungal associate (Döbbeler 1997). *Octospora* and other genera infect the subterranean rhizoids of **Polytrichaceae** (Figure 4, Figure 34, Figure 97), while others occupy the spaces between the vertical leaf lamellae (Felix 1988). In fact, 20 different **Ascomycota** species are known to occupy that unusual habitat without apparently having any effect on the moss.

Raspe and De Sloover (1998) suggested that the discomycetous fungus *Mniaecia jungermanniae* (Figure 100-Figure 101), which lives exclusively on leafy liverworts in the **Jungermanniales** (Figure 100), might have achieved the first step toward mutualism. This destructive parasite grows inside the bryophyte rhizoids but

does not seem to afford any direct benefit to the liverwort. It appears it has a long way to go to reach mutualism.

We have noted several times that bryophytes obtain phosphate, and possibly other nutrients, from the bedrock. It is likely that at least in some cases fungi contribute to this nutrient source. Calling them "**rock-eating mycorrhizae**," Schöll *et al.* (2008) demonstrated that tunnels occur in mineral grains. They attributed these to hyphae from ectomycorrhizae that can dissolve mineral grains. Whether these fungi are directly associated with bryophytes, or they use litter or other plants for their carbon source, these fungi permit phosphates and other nutrients to enter nutrient cycling, potentially making some of them available to the bryophytes.

Arbuscular Mycorrhizae

Harrison (1999) reported that arbuscular mycorrhizae, restricted to the fungal order **Glomales** (**Zygomycota**, more recently named **Glomeromycota**; Figure 92), infected some bryophytes. Schüßler (2000) reported that a member of this order, *Claroideoglossus claroideum* (Figure 92), formed a mycorrhiza-like symbiosis with the hornwort *Anthoceros punctatus* (Figure 102-Figure 103). Following inoculation with spores, Schüßler found branched hyphae within the thallus within 20 days. This was the first definite experimental establishment of an arbuscular mycorrhiza-like association between a member of the **Glomales** and a bryophyte, although Felix (1988) had reported mycorrhiza-like associations in a number of taxa (Table 3). In 2003, Jakucs *et al.* found vesicles of a glomalean fungus in the moss *Hypopterygium* (Figure 104), suggesting that there might indeed be a mutualistic relationship in which the fungus also benefits, but that hypothesis still awaits verification.

There is a certain degree of specificity among the bryophyte species that have fungal associations. Russell and Bulman (2004) found that *Marchantia foliacea* (Figure 107-Figure 109) from two locations in New Zealand supported *Glomus* (Figure 109) (*n.b.*, many species of *Glomus* are now placed in *Claroideoglomus*; Figure 92) arbuscular fungi internally (Figure 109), but that *M. polymorpha* (Figure 110) did not. Every *M. foliacea* thallus they examined contained this *Glomus* species in the parenchyma tissue around the midrib. The fungus invaded the thallus through the smooth rhizoids and grew upward through the thallus, forming arbuscules only in the upper portion of the thallus. The hyphae crossed directly through the cell walls of the liverwort. This same fungus forms mycorrhizal associations with the conifer, *Podocarpus* (Figure 111), and it may be that this fungus is shared by both plants. Unfortunately, we still have no evidence if this relationship between the fungus and the liverwort is truly symbiotic.

The specificity of some of the groups for specific plant phyla is fascinating. For example, **Zygomycota** (Figure 112) colonize members of **Anthocerotophyta** (Figure 102) and **Marchantiophyta** (Figure 110, Figure 113), but not **Bryophyta** (Figure 104) (Read *et al.* 2000). On the other hand, members of the **Glomales** (Figure 92) isolated from

the flowering plant *Plantago lanceolata* were able to colonize the thallose liverwort *Pellia epiphylla* (Figure 113) and produce arbuscules and vesicles.

These fungal-bryophyte associations form structural associations similar to those of vesicular-arbuscular mycorrhizae of tracheophytes. Despite the large number of associations recognized between bryophytes and fungi, Read and coworkers (2000) still stressed the "need for analysis of the functional attributes of these symbioses." They presented further evidence that these fungal associations were ancient, being important to the first plants to colonize land. This contention is supported by fossil evidence of glomalean fungal structures associated with early bryophytes in Ordovician sediments that are 460 and 400 million years old (Remy *et al.* 1994; Redecker *et al.* 2000).

Beneficial or Harmful?

The fungal associates are not always beneficial to the bryophytes. Zobel *et al.* (1999) treated a sub-Arctic forest community with fungicide and found that the bryophytes and dwarf shrubs increased in biomass relative to the control. Could it be that the fungi are frequently stealing from the bryophytes and making nutrients available to trees?

Summary

Unlike tracheophytes, bryophytes take up nutrients over their entire surface. With leaves only one cell thick in most taxa every leaf cell is thus exposed to environmental sources of nutrients. The three most limiting nutrients (N, P, K) accumulate in the upper parts of the plants through active uptake, whereas Ca, Mg, and Na accumulate through passive **cation exchange**. Bryophytes have high **cation exchange capacity** (CEC) due to **polyuronic acids** in their cell walls. Once ions are bound on exchange sites, a **proton pump** removes H^+ ions from the cell, creating a **charge gradient** that brings in positive ions. These bring along negative ions by **cotransport**. It appears that bryophytes have two, perhaps more, types of exchange sites, permitting differential binding of ions. They also seem to have specificity for things they need over things they do not. Anion exchange sites can contribute

to phosphate uptake. Abundance of cation sites compared to anion sites can account for the preference of ammonium (cation) over nitrate (anion).

Further active processes are able to distinguish ions formed by N, P, and K from more exchangeable cations such as those of Ca^{++} or Mg^{++} , and they are generally able to maintain relatively constant levels of these essential nutrients despite changes in environmental concentrations. Increasing temperatures increase the uptake, which is also pH-dependent. Some uptake occurs through **pinocytosis** and entry of **nanoparticles**.

Fungi are often associated with the rhizoids of bryophytes. It may be that a large number of bryophytes are afforded the advantages of fungal partner relationships, providing them with considerably more surface area for acquiring nutrients. The thallose liverwort *Cryptothallus mirabilis* has a fungal partner (*Tulasnella*) that provides carbohydrates for this non-chlorophyllous plant.

Many bryophyte-fungal associations have been discovered, but the types of interaction lack our understanding. We know that glomalean fungi are frequently associated with bryophytes, but the association has not been clearly described. This could be a very fruitful area for further research.

Acknowledgments

I appreciate the contributions of undergraduate Phil Gaudette and M. S. student Jennifer Jermalowicz Jones for their critical reading of the manuscript from the perspectives of students interested in nutrient relationships of bryophytes. Dana Richter made many helpful suggestions on the fungal section. Simon Bulman helped me to locate Julia Russell to obtain her mycorrhizae pictures. Jean Faubert made suggestions to improve the chapter. Many photographers have contributed their images through Creative Commons or have given me permission.

CHAPTER 8-5

NUTRIENT RELATIONS: TRANSLOCATION AND TRANSPORT

Figure 1. *Bazzania trilobata* and other bryophytes growing together. Note the dead tissue in the lower right part of the clump, where nutrient sinks can be mobilized to supply growing apical tissues. Such clumps can play a significant role in the distribution of forest nutrients. Photo by Michael Lüth, with permission.

Translocation and Transport

One of the most poorly understood abilities of bryophytes by "vascular" botanists is the ability of bryophytes to transport nutrients within the plant. Understanding that transport of nutrients occurs through specialized vascular tissue (xylem and phloem), they have sometimes assumed that the "non-vascular" bryophytes are unable to move substances from one part of the plant to another. Hence, the assumption has been that as bryophytes die (Figure 1), decomposition will return the component nutrients. But while bryophytes lack tracheids, vessels, and sieve cells, they do not lack the ability to transport substances from one part of the plant to another, *i.e.* **translocation**. In some cases, such as *Polytrichum* (Figure 17), they actually transport substances through their **leptoids** (phloem-like cells; Figure 2) and **hydroids** (xylem-like cells; Figure 2). Those mosses such as

Polytrichum with well-developed leptoids form a **leptome**, similar to the cylinder of phloem in a tree trunk. The collective hydroids in the center of the stem form the **hydrome**, also known as the **hydrom**. But it is clear that lack of even these special conducting cells is no deterrent to transport or to translocation in bryophytes. Hence, we can find nutrient elements in a number of locations within and upon the plant (see subchapter 8-4).

One aid to the transport of substances from cell to cell is the presence of **plasmodesmata** in the cell walls (Mahmoud 1965; Oliver & Bewley 1984). These connecting threads permit substances to move from cell to cell without traversing cell membranes, although the movement is undoubtedly slower than that of the movement of water in the interstitial capillary spaces of cell walls.

Figure 2. Cross section of *Polytrichum juniperinum* and longitudinal section of *Atrichum undulatum* stem to illustrate parts of central strand (leptoids and hydroids) and stem structures. Drawings by Margaret Minahan, based on Héban (1977).

Duckett and Ligrone (2003) list several specific examples in their note "What we couldn't have done if we'd stayed in Europe: Selection and serendipity in the Southern Hemisphere." They demonstrated the presence of "food-conducting cytology" (*i.e.* food conducting cells) in the widespread groups of **Hookeriaceae** (Figure 3), **Neckeraceae** (Figure 4), **Orthotrichaceae** (Figure 5-Figure 6), and **Sphagnum** (Figure 7-Figure 11), as well as in most caulonemata and rhizoids. Furthermore, this food conducting organization is present in the axes of the primitive moss *Takakia* (Figure 12-Figure 13) and the moss-like leafy liverwort *Haplomitrium* (Figure 14-Figure 15), as well as being widespread in Marchantialian thalli.

We have seen that bryophytes move water about internally as well as externally. There is ample evidence that they likewise move nutrients, hormones, and photosynthate within the plant, and of course, nutrients get moved externally with capillary water as well. Within stems, leptoids may serve to enhance nutrient movement; Héban (1974) demonstrated that "sieve elements" (**leptome**) of *Polytrichum commune* (Figure 16-Figure 17) exude liquid. **Polytrichaceae** have highly specialized leptoids with polarized cytoplasmic organization within the axis. In the endohydric moss *Polytrichastrum alpinum* (Figure 18), labeled ^{14}C supplied as CO_2 travelled at the rate of 7.5 cm h^{-1} within the stems of a population in Point Barrow, Alaska, whereas in some tracheophytes, the rate may be little more than 1 cm per hour for water movement. In other mosses, including *Sphagnum* (Figure 7-Figure 11), less specialized parenchyma cells of the stem and seta carry out similar functions.

Figure 16. *Polytrichum commune*, a moss with extensive internal conduction. Photo by Michael Lüth, with permission.

It does not require the sophisticated structures of *Polytrichum* (Figure 16-Figure 17) to move substances within mosses. Alpert (1989) demonstrated that photoassimilate moved from the leaves to the stem bases and even underground stems in *Grimmia laevigata* (Figure 19), a predominantly ectohydric moss, but he was unable to demonstrate any movement of mineral nutrients in this way (see stem of a related species, Figure 20).

Movement from Older to Younger Tissues

Consider the impact on our thinking when we discovered that even *Sphagnum* (Figure 7-Figure 11) moves nutrients from older, dead portions to younger tissues. Among these, it appears that in *Sphagnum* cellular N and P move to shoot segments, but that metallic elements do not (Hájek & Adamec 2009). Such ability permits it to live in extremely low nutrient habitats, yet have sufficient nutrients to sustain life and growth for centuries. Particularly in habitats such as true bogs, where all nutrients arrive through precipitation, the *Sphagnum* is able to trap and hold 50-90% of the deposited N (Li & Vitt 1997). This leaves little for tracheophytes, and Aldous (2002) found that the tracheophytes received less than 1% of that N supply.

Rydin and Clymo (1989) had already demonstrated that *Sphagnum* (Figure 7-Figure 11) is able to move both P and C upward through 7 cm of stem length. If the *Sphagnum* holds and relocates its N within its own tissues, the tracheophytes have little ability to compete for the limited supply of N they so greatly need. For example, Aldous (2002) demonstrated that *Sphagnum capillifolium* (Figure 21) translocates its N supply to growing tissues within the capitulum. In a relatively clean site in Maine, it moved 11-32% of its N and in an N-polluted site, it moved 64-83% within the 2-cm segments examined. Gerdol (1990) found that N, P, and K in *Sphagnum* of ombrotrophic bogs in the Alps were directly absorbed in the chlorophyllose cells (Figure 22), but also partly recycled from ageing tissues to the growing capitulum.

Figure 22. *Sphagnum papillosum* leaf cells showing network of green chlorophyllose cells and transparent hyaline cells. Note that the hyaline cells are long with spiral wall thickenings. These cells have pores what expose the inside cation exchange sites. Photo by Ralf Wagner <www.drralf-wagner.de>, with permission.

Potassium is a highly soluble nutrient. Garciadeblas *et al.* (2007) demonstrated that *Physcomitrella patens* (Figure 23) expresses the same potassium and sodium transport systems as that found in flowering plants. Hence, we find that potassium is able to move from older to young tissues.

Bakken (1995) suggested that the reason the acrocarpous moss *Dicranum majus* (Figure 24) has a low N demand and persistence of N in young tissues at sites with high N is that it moves N from older to younger tissues. *Pleurozium schreberi* (Figure 25), a large, pleurocarpous, feather moss with no central strand or special conducting cells, is even able to move its nutrient supply about. And it is selective about it. It is able to move the soluble K^+ and Mg^{++} from plant base to apex, but, as in tracheophytes, the insoluble Ca^{++} is non-translocatable (Bates 1979). In fact, the concentration of Ca^{++} increases with distance from apex, assumedly reflecting its longer

time to accumulate there. As a component of the cell wall, the concentration of Ca^{++} would increase as the cell sap was lost after death. But that is not the full explanation of its increasing concentration there. Ca^{++} supplied below the *Pleurozium* mats moves up the stems externally, taking advantage of the exchange sites and capillary movement of water (Bates & Farmer 1990). If it behaves like *Sphagnum* (Figure 21-Figure 22), broken cells will expose more exchange sites on the insides of cells, permitting Ca^{++} to be bound there.

Directional Differences

Wells and Brown (1996) demonstrated internal movement in the moss *Rhytidiadelphus squarrosus* (Figure 26). By collecting the moss and depriving it of any external nutrient supply, they were able to determine that apical growth continued, facilitated by **acropetal** (base to tip) transfer of cations (K^+ , Mg^{++} , and Ca^{++}) from basal segments in proportion to that cation pool. When the mosses were pretreated with these three cations, the status of the shoots did not influence the elements that arrived in the newly grown shoots. Rather, acropetal transfer of externally bound cations occurred.

Figure 26. *Rhytidiadelphus squarrosus*, a species with internal nutrient transport that seems to depend on living cells. Photo by Michael Lüth, with permission.

Surprisingly, even the heavy metals travel. Rühling and Tyler (1970) found that in *Hylocomium splendens* (Figure 27-Figure 28) metals such as Cu, Fe, and Mn are taken in by the young tissues and moved to the older ones. Could this be a means of sequestering them where they are less dangerous to the moss?

Figure 27. *Hylocomium splendens* on spruce forest floor. Photo by Janice Glime.

Species Differences

It seems that bryophytes differ among species in their nutrient mobilities, and in which nutrients go where. Eckstein and Karlsson (1999) compared the movement of N in the pleurocarpous moss *Hylocomium splendens* (Figure 27-Figure 28) and the acrocarpous *Polytrichum commune* (Figure 16-Figure 17), both common in boreal forests. In both species, the current year of growth served as a sink for N. In *P. commune* the older segments showed a net loss of N from June to September, a loss the authors interpreted as resorption of N to the subterranean rhizome.

Figure 28. *Hylocomium splendens* stem cs, showing central parenchyma cells. Photo by Botany Website, UBC, with permission.

By contrast, in *Hylocomium splendens* (Figure 27-Figure 28), the one-year-old segments, like the youngest segments, increased in N, whereas the older segments lost 50% of the N initially measured there (Eckstein & Karlsson 1999). All the N lost from the older segments could be identified in the two youngest segments. Thus, as the three-year-old segments of *H. splendens* died and became brown, N moved upward in the plant to younger segments. It is interesting that one species (*P. commune*, Figure 16-Figure 17) behaved as trees do in the fall, moving the N downward, whereas the other (*H. splendens*) behaved as trees or crop plants do in spring, moving it to the new growth.

Even the aquatic mosses behave like tracheophytes in their transfer of nutrients from older to younger segments. The soluble N, P, and K are concentrated in the apical regions of *Fontinalis squamosa* (Figure 29) and *F. antipyretica* (Figure 30-Figure 31), whereas the less soluble Ca, Mg, and Fe increase toward the base (Mártínez Abaigar *et al.* 2002). However, there are two possible explanations for this: N, P, and K are moved from older to younger tissues, just as they are in tracheophytes, or younger, more active tissues actively uptake these three nutrients. Márínez Abaigar and coworkers considered both factors to be contributing.

Mechanisms of Transport

Source to Sink?

This evidence of movement leads us to the question of how movement occurs. One possible mechanism is the **source to sink** phenomenon. In this case, a substance moves from an area of higher concentration (**source**) to one of lower concentration (eventual **sink**). But for this movement to continue, the final destination (**sink** – site of accumulation) must metabolize or store the substance in an insoluble form so that the recipient tissues become a sink and concentration gradients can continue from the source. For example, carbon moved as sucrose can be converted to starch or cellulose, or other constituent, causing the concentration of sucrose to continue to be higher at the source (see discussion under Sporophyte Conduction below).

In *Rhytidiadelphus squarrosus* (Figure 26) the rate of movement from old to young tissues is inversely related to the pool size, so that small segments move proportionally more nutrients to the developing tissues (Wells & Brown 1996), following a source-to-sink principle. When side branches were removed from *Hylocomium splendens* (Figure 27-Figure 28) to adjust the nutrient pool, loss of those branches led to lower concentrations of K^+ , Mg^{++} , Ca^{++} , and Zn^{++} in the young shoots, indicating the importance of movement from older to younger tissues in this boreal forest feather moss (Brümelis & Brown 1997). These young segments did, however, produce more branches when branches on mature segments were removed. It seems that nothing is ever simple.

It appears that *Pleurozium schreberi* (Figure 25) could be a nitrogen **sink**. *Pleurozium schreberi* absorbs N in quantities apparently beyond its needs (Raeymaekers 1987; Raeymaekers & Glime 1990). And as might be expected, K^+ is easily leached out of the moss under stress of simulated acid rain and desiccation (Raeymaekers & Glime 1990). Thus, it appears that this moss that can provide 100% cover in Jack pine (*Pinus banksiana*; Figure 32) and other northern and boreal forests could have a major impact on nutrient flux. As an accumulator of N, it could become a sink, or it could release its excess load slowly over time. With its propensity for losing K^+ when suffering membrane damage from desiccation, *P. schreberi* and other bryophytes could be a means of sequestering K^+ from throughfall and dust, then releasing it later, perhaps hoarding it until rain comes, releasing it to tracheophyte roots at a time when the K^+ is most vulnerable to loss from the roots by leaching and runoff. This seemed to be the case for loss from *Sphagnum* when it was released near the end of the growing season, a result of rainfall that ended summer drought in a forested fen (Leary & Glime unpublished data). On the other hand, does *P. schreberi* the very presence of its thick mat could prevent or diminish runoff loss, slowly releasing the K^+ to the soil as the rainfall event progresses. Our understanding of this process of bryophyte storage and later release to roots is as yet too limited to know the net impact.

Enrichment Effects

When the moss is enriched with a nutrient, the translocated load can likewise be enriched. When input of N as $^{15}\text{NH}_4^{15}\text{NO}_3$ was compared at low and high levels, *Sphagnum capillifolium* (Figure 21) increased its annual N translocation from 11% to 80% (Aldous 2002). Aldous (2002) estimated that translocation contributes 0.5-11% of the annual N budget of the moss. This observation is consistent with the observation that N translocation is higher in the high N deposition Adirondack sites than in the low deposition Maine sites in the northeastern USA. However, the Maine sites had a low water table and severe drought during the year of measurement and thus we cannot assume that the greater movement in the Adirondacks was due to the greater concentration of N.

Internal Transport

Internal conducting cells are present in some members of both liverworts and mosses, but are unknown in hornworts (Ligrone *et al.* 2000). In mosses, they can be present in both generations, whereas in liverworts they are present only in the gametophyte. This is predictable in that liverworts form their setae after the capsule matures and is ready for dispersal. Thus, any conducting tissue would be of little value, and furthermore have little time to develop.

Structural Facilitation

Mosses also have the ability to conduct nutrients through **symplastic** transport in rhizoids and caulonemata, and similarly in the thallus parenchyma of liverworts (Ligrone *et al.* 2000). The **symplast** is the living protoplasm of the cells that is interconnected between cells,

and substances can move through it following a concentration gradient.

In *Takakia* species (mosses), **Calobryales** (liverworts) and **Pallaviciniaceae** (liverworts) the water-conducting cells have perforated walls with pores derived from plasmodesmata. In the bryoid mosses, the water conducting cells (**hydroids**) are imperforate. In the **Polytrichaceae** (Figure 2, Figure 16- Figure 18) the **leptoids** (in this family they are highly specialized food-conducting cells) the cytoplasmic organization is polarized and has a distinct axial system of microtubules. In *Sphagnum* (Figure 7-Figure 11) and other mosses there are less specialized parenchyma cells in the leafy stem and seta.

Rydin and Clymo (1989) considered that the dominant understanding of *Sphagnum* (Figure 33) was that the lack of any anatomical specialization in the stem (Figure 34-Figure 35) caused those mosses to rely instead on external conduction in the capillary spaces. However, in their experiments they demonstrated that this thinking was wrong. Instead, internal transport is both "rapid and quantitatively important." In fact, when labelled ^{32}P and ^{14}C were supplied below the tips of *S. recurvum* (Figure 33), both moved to the top of the plant regardless of the direction of external mass flow. High concentrations of the labelled P and C were in the stem. Furthermore, if the stems were steamed above and below the point of application, the labelled P and C failed to move, suggesting that live cells were needed for the transport. *Sphagnum recurvum* has a central mass of parenchyma that is 20-50 cells across. These cells have end walls with perforations of about 100 nm and a density of 7-13 μm^{-2} , providing a single cell wall with ~1500 perforations.

Figure 33. *Sphagnum recurvum*, a species that transports P and C internally. Photo by Malcolm Storey, <www.discoverlife.com>, through Creative Commons.

It is likely that most bryophytes have some sort of conduction specialization within the stem. *Sphagnum* (Figure 33-Figure 35) has revealed its internal system within the central portion of the stem (Ligrone & Duckett 1998). This system is manifest by the absence of large central vacuoles, presence of a spindle-shaped nucleus with prominent axial system of endoplasmic microtubules, membrane-bound tubules and vesicles, and a high frequency of plasmodesmata in the crosswalls, all characteristics that are common to food-conducting cells. These same characters are also known in the food-

conducting cells of **Bryopsida** and suggest an organization specialized for symplastic transport. They are also known in rhizoids and caulonemata of mosses and in thallus parenchyma cells of liverworts (Ligrone *et al.* 2000).

Figure 35. *Sphagnum* stem cs showing large outer cortex cells and small cells in central strand. Photo from Botany Website, UBC, with permission.

Leptome Transport

In tracheophytes, we tend to think of the phloem as transporting sugars downward, but other substances are transported there as well, and the direction of flow may at times be reversed. In bryophytes, the same is true.

Trachtenberg and Zamski (1978) determined that in addition to photosynthate, the **leptome** of *Polytrichum juniperinum* (Figure 36-Figure 37) moves ionic solutes such as sulfate and lead, whereas the chelated forms of iron and lead move in the **hydroids**. Ions from the moss surface are able to move across the cortex through the free space between the cells (**apoplastically** – see below). The

leptome actually acts much like the endodermis of a root in serving as a barrier between the hydrome and the cortex. Thus, it becomes a site where toxic ions accumulate and are not transported to the rest of the plant. In their experiments, Trachtenberg and Zamski found that lead (Pb) moved in this way, accumulating in the leptome, but no Pb was found within the cytoplasm of any cortex cells. The leptoids, on the other hand, had heavy deposits. Hence, it appears that an active **symplastic** mechanism controls the movement of solutes and heavy metals in much the same way as the endodermis of a root. It is interesting that the stem of a moss has developed this same safeguard.

Figure 36. *Polytrichum juniperinum*, a species that moves ionic solutes such as sulfate and lead in the **leptome**, but moves the chelated forms of iron and lead in the **hydroids**. Photo by Janice Glime.

Figure 37. *Polytrichum juniperinum* stem cs with central hydroids and surrounding leptoids. Photo from Botany Website, UBC, with permission.

To obtain the same toxicity with the EDTA (chelated) Cu and Zn requires 500X more concentrated solution than with the ionic form. The chelation changes the mode of translocation within the bryophyte, with bound (chelated) ions moving in the free space to the leptome. These observations are consistent with the structure of the leptoid cells, which have large nuclei and an abundance of endoplasmic reticula (Eschrich & Steiner 1967; Héban 1976), both permitting the cells to exercise high metabolic activity.

A similar phenomenon for copper and zinc has been seen in gemmae of *Marchantia polymorpha* (Figure 38) and protonemata of *Funaria hygrometrica* (Figure 39- Figure 40) (Coombes & Lepp 1974). Copper was more toxic than zinc to both species at levels above 8 mg L⁻¹. Protonemata did not grow and spores did not germinate in *Funaria hygrometrica*. Even at 1 mg L⁻¹, few buds formed in *Funaria*. In zinc, it produced rounded protonemal cells that could be interpreted as brood cells, known to occur as a response to unfavorable conditions (Van Andel 1952). In *Marchantia*, rhizoid formation on gemmalings was inhibited at 1 ppm copper. Zinc did not cause any noticeable changes. In these bryophytes, there was a delicate line between essential levels and toxic levels of copper, with levels above 0.5 mg L⁻¹ being deleterious to development.

Figure 39. *Funaria hygrometrica*. Photo by Michael Lüth, with permission.

Carbon Transport

We know that the **leptome** (that part of the stem of some mosses composed of **leptoids**, Figure 41) conducts assimilates, and that sucrose applied to the outside of the plant ends up in the leptoids (Trachtenberg & Zamski 1978). In tracheophytes, many other substances can travel in the phloem, the tracheophyte counterpart of the leptome. But, in a bryophyte, how does one examine what is travelling in a tube so small it cannot be seen without a microscope, for which preparation is likely to disrupt the whole process?

Figure 40. *Funaria hygrometrica* spore with developing protonema. Zinc and copper are toxic to both the spore and the protonema. Photo by Janice Glime.

One of the most fascinating techniques (to me at least) in all biology is the use of aphids to determine what travels in conducting tissues. Well, even bryophytes can have aphids! And Thomas and Lombard (1991) have taken advantage of this fascinating tool to determine just what travels in the leptoids of *Polytrichum commune* (Figure 16-Figure 17). The aphid, *Myzodium modestum* (Figure 42), a moss aphid and thus quite small, inserts a needlelike stylet into the moss conducting tissue (leptoids) to get nutrients. Thomas and Lombard found that when *P. commune* leaves are treated with ¹⁴C-sucrose, 17-34% of the labelled carbon can be detected in 2-15 aphids within four hours. In fact, these aphids are so efficient at removal that the movement of sucrose to other parts of the plant and to shared underground rhizomes is reduced from its normal 4% to 1% or less.

Figure 41. Cross section of *Polytrichum* stem. Photo courtesy of Isawa Kawai.

Figure 42. *Myzodium modestum* adult, a species that taps into the "sap" in leptoids of *Polytrichum*. Photo from CBG Photography Group, through Creative Commons.

In *Polytrichum commune* (Figure 16-Figure 17), labelled ^{14}C from sucrose applied externally quickly appeared in the growing stem apex, young leaves, bud initials, and underground axes, all sinks for this C source (Reinhart & Thomas 1981). It appears that the C is more likely to move **acropetally** (toward the tip) than **basipetally** (toward the base). Nevertheless, labelled C travels from the leaves both acropetally (Eschrich & Steiner 1967) to the growing shoot apex and basipetally to underground rhizomes (Collins & Oechel 1974). The movement of externally applied sucrose requires ATP as an energy source for uptake, followed by movement from the **apoplastic** free space (see below) into the leptome, similar to **phloem loading** in tracheophytes (Reinhart & Thomas 1981).

The movement of externally applied labelled ^{14}C in *Polytrichum commune* (Figure 16-Figure 17), and by implication also the plant's own photosynthate, reaches several other leaves within two hours and reaches the rhizome within 72 hours or less (Reinhart & Thomas 1981). Experiments using radioactively labelled ^{14}C demonstrate that C moves in mosses in a **source-to-sink** fashion, as it does in tracheophytes. Furthermore, movement to the underground axis in this and other mosses allows translocation to neighboring members of a clone (Thomas *et al.* 1988, 1990), either directly through rhizomatal connections or indirectly through carbohydrates that escape into the soil/moss medium and can be absorbed. The carbon is both used and stored, with labelled carbon appearing in starches and cell wall polysaccharides one week and six weeks later, respectively (Thomas *et al.* 1988).

As you might expect, the patterns of translocation will vary between species of bryophytes, even in the same ecosystem. For example, near Fairbanks, Alaska, in a *Picea mariana* forest (Figure 43), *Polytrichum commune* (Figure 16-Figure 17) retained the most of labelled ^{14}C after 2 hours, while *Sphagnum subsecundum* (Figure 44) retained the least (Skré *et al.* 1983). However, after 35 days, it was *Sphagnum subsecundum* that had the highest fraction of radiolabelled ^{14}C in the brown tissues, with *Polytrichum commune* coming in second. The two pleurocarpous feather mosses, *Hylocomium splendens* (Figure 27-Figure 28) and *Pleurozium schreberi* (Figure 25), had no consistent pattern of translocation after 2 hours or 35 days. All four species exhibited high loss of labelled ^{14}C to respiration (presumably photorespiration) during the first 2 hours, which coincided with the peak of the growth season.

Sphagnum papillosum (Figure 9-Figure 11) translocated ^{14}C in the soluble fraction from older parts of the moss to the apex, with very little transfer into the insoluble fraction, to neighbors, or into the gas phase (Rydin & Clymo 1989). In fact, the transfer of ^{14}C to the capitulum from lower portions of the plant was about equal to that lost from the capitulum through respiration. The capitulum also transferred about twice as much ^{14}C to the insoluble fraction and about half as much to its neighbors. After 22 weeks, about 25% of the remaining labelled carbon was incorporated into new tissues.

Apoplastic Transport

Cell walls and extracellular spaces form the **apoplast** of a plant, including any bryophyte. Because the apoplast provides capillary spaces, it facilitates the movement of water and solutes across the plant tissues (Figure 45). Even the cell wall is composed of cellulose fibers that provide minute capillary spaces (Figure 46). But little seems to be published about apoplastic transport in bryophytes. (See above under Leptome Transport and under Carbon Transport; below under Sporophyte Conduction).

Figure 45. Apoplastic and symplastic pathways through cells. Note that such large vacuoles are not common in healthy bryophytes. Image by Jackacon, through public domain.

Figure 46. Cellulose SEM showing spaces among the fibers. Photo by Guiotoku *et al.* 2012, through Creative Commons.

David Hanson (Bryonet) has raised the interesting question about apoplastic movement of sugars in bryophytes. Would this sugar excretion that is beneficial to bacteria and fungi be less favorable in flowing water? I might add, would it instead facilitate the proliferation of the microbial community in the water, providing a nearby source of CO₂ for the CO₂-limited aquatic species? There is much to learn about nutrient relationships of bryophytes.

Desiccation Effects

Few studies have addressed the effects of desiccation on internal transport in bryophytes. In particular, the specialized food conduction cells (**leptoids**) of desiccation-tolerant mosses like *Polytrichastrum formosum* (Figure 47-Figure 48) undergo numerous changes during dehydration (Pressel *et al.* 2006). The endoplasmic microtubules disappear; the plastids, nucleus, and mitochondria become rounded and lose their longitudinal alignment of organelles. Instead of the typical stacks of endoplasmic reticulum of hydrated tissues, membranous tubules arranged at right angles to the main cellular axis appear. Small vacuoles fill the internal cytoplasm. The plasmalemma forms labyrinthine tubular extensions that outline newly deposited cell wall ingrowths. Leptoids become plugged with electron-opaque material while nearby parenchyma cells are depleted of their starch deposits. However, upon rehydration the leptoids return to their normal cytology within 12-24 hours. When the toxic oryzalin is provided to the plants, it prevents this recovery, indicating the importance of processes of living cells. Pressel and coworkers interpreted this to indicate a key role of the microtubular cytoskeleton in the recovery of the leptoids.

External Translocation

It is well known that water moves externally in mosses (and also internally to varying degrees). Nutrients in the solution move with the water, and nutrients adhering to the leaves can be carried with the water as well. Even soil nutrients can be moved upward this way.

As mosses die, especially those with an upright habit, ions can be moved externally from basal portions to upper portions rather easily (Brehm 1971; Brown 1982). Dead and dying lower tissues release ions that go into solution in the external surface film. Evaporative loss of water (**transpiration**) from the capitulum of *Sphagnum* (Figure

7-Figure 11) and from apices of **Bryopsida** causes water to move upward through the external capillary spaces. As it does, it carries with it the ions leaked from dead and dying cells. These can then be absorbed on the exchange sites of the apex. Brown (1982) considered that the higher concentrations of Ca⁺⁺, K⁺, and Mg⁺⁺ in *Mnium hornum* (Figure 49) in higher light intensities (Thomas 1970, in Brown 1982) could be the result of increased transpiration. But is it moved internally or externally? It has a well-developed internal conduction system (Figure 50).

Sporophyte Conduction

As we have already seen for water, the sporophyte gets nutrients, hormones, and an energy supply from the gametophyte through the sporophyte **foot** (Figure 51-Figure 53) (Courtice *et al.* 1978). Some of the evidence for this transfer is indirect. For example, in *Polytrichastrum formosum* (Figure 47-Figure 48), a decrease in the amino acid arginine in the gametophyte is coincidental with an increase in the sporophyte (Whel 1975). Whel suggested that this parallels the tracheophyte movement of N from a mature to young organ.

Figure 51. *Marchantia polymorpha* (thallose liverwort) capsule ls showing location of the foot next to gametophyte tissues. Photo from Botany Website, UBC, with permission.

Figure 52. Liverwort (*Pellia*) young sporophyte. Photo by Paul Davison, with permission.

Figure 53. *Sphagnum* capsule ls showing foot imbedded in pseudopodium (gametophyte) tissue. Photo from Botany Website, UBC, with permission.

The internal structure reveals **transfer cells** at the gametophyte-sporophyte junction (Figure 54; Lal &

Chauhan 1981). The transfer cells are found in the foot of the sporophyte and in the adjacent gametophyte tissue and are endowed with an extensive and complex wall labyrinth. Ligrone and Renzaglia (1990) demonstrated that the hornwort *Dendroceros tubercularis*, as in other hornworts, is endowed with dense protein deposits in the vacuoles of both gametophyte transfer cells and the sporophyte foot. The structure of the transfer cells suggests a function in the movement of metabolites from the gametophyte to the sporophyte by their numerous mitochondria and intense enzyme activity, especially of phosphatases and some respiratory enzymes (Lal & Chauhan 1981).

The junction cells are the first to differentiate in the young sporophyte (Kwok & Rushing 1999). The transfer cells on both sides of the junction have plastids and starch content, with numerous small vacuoles and lipid deposits in the junction cells, further supporting the role of this region in transfer of nutrients to the sporophyte.

Caussin *et al.* (1983) demonstrated that sporophytes of *Polytrichastrum formosum* (Figure 47-Figure 48) absorb the amino acids glycine, threonine, and α -aminoisobutyric acid through the **haustorial** (absorptive) foot, using the transfer cells. Removal of the haustorial foot significantly reduced the absorption of these amino acids into the sporophyte.

Figure 54. Transfer cell showing wall labyrinth. Computer-drawn from photo in Lal and Chauhan (1981).

Chevallier *et al.* (1977) demonstrated that radioactive orthophosphate moved from the gametophyte to the capsule and eventually to the spores in *Funaria hygrometrica* (Figure 55). However, once the capsule turned from green to brown, indicating maturity, the original 18% transfer rate turned to zero. But this is not the only potential means for the sporophyte to get its nutrients. It is, at least in *Funaria hygrometrica*, able to absorb nutrients directly through its capsule, hence opening the possibility that it gets some sporophyte nutrients from dust and rainwater.

It appears that K^+ moves into the developing sporophyte rapidly, whereas Ca^{++} , which is generally immobile, moves more slowly (Brown 1982). In Brown's study, as the gametophyte senesced, its K^+ diminished and the concentrations of Ca^{++} and Mg^{++} increased, presumably due to movement of K^+ from the senescing gametophyte to

the young sporophyte, followed by Ca^{++} and Mg^{++} occupying the vacated exchange sites on the gametophyte.

Figure 55. Capsules of *Funaria hygrometrica*. Photo by Janice Glime.

Marsh and Doyle (1981) demonstrated that sugars are transported actively by the transfer cells. A more startling discovery is that the sporophyte of *Anthoceros punctatus* (Figure 56) transfers sugars from the photosynthetic sporophyte to the thallose gametophyte, where it is used by its *Nostoc* (Figure 57) partner (Stewart & Rodgers 1977)!

Figure 56. Thallus of *Anthoceros punctatus* with young sporophytes. Photo by Des Callaghan, with permission.

Figure 57. *Anthoceros punctatus* *Nostoc* colonies (dark area). Photo by Des Callaghan, with permission.

As nutrients cross the **placenta** (gametophyte-sporophyte interface) into the sporophyte, there is another opportunity for nutrient discrimination. Basile *et al.* (2001) found that the gametophyte accumulated much greater quantities of Pb and Zn than did the sporophyte in *Funaria hygrometrica* (Figure 55). These two elements accumulated in the placental **transfer cells** on both gametophytic and sporophytic sides. When the two metals were applied in the lab, Basile and coworkers found that the two generations had different accumulation quotients.

The size of the sporophyte seems to play a role in determining the rate of transfer of carbon in the photosynthate from the gametophyte to the sporophyte (Browning & Gunning 1979). In *Funaria hygrometrica* (Figure 55), labelled gametophyte photosynthetic products were transported to the sporophyte at a linear rate for up to 12 hours after treatment with $^{14}\text{CO}_2$. Movement from the **haustorium** (nutrient exchange area in foot of sporophyte) to the capsule, through the seta, occurs at the slow rate of $1\text{--}3\text{ mm h}^{-1}$. And larger sporophytes received the photosynthate at a faster rate than did smaller ones. Does this mean that there is a source-sink movement, with larger capsules forming a larger sink? Or is there a transpiration stream involved in which larger capsules lose water faster, hence drawing water up from the gametophyte much like a tracheophyte water stream? Both water stress and lack of light inhibited transport, but if only the sporophyte was darkened, it had no effect. This again suggests the possibility of a source-sink movement, with the source (gametophyte) becoming depleted of photosynthate in the dark. But it is also possible that a transpiration stream could be involved, as suggested by the loss of movement under drought stress. Both could contribute.

In members of *Polytrichum s.l.* (Figure 58-Figure 59), transport of carbon from the gametophyte to the sporophyte is especially important (Renault *et al.* 1992). The calyptra completely covers the capsule and is fortified with dense hairs, limiting photosynthesis by the capsule. In *Polytrichastrum formosum* (Figure 47-Figure 48) sucrose serves as the primary soluble sugar for both the sporophyte and gametophyte. However, in the **apoplast** (capillary spaces in cell wall) of the **vaginula** (bottom part of archegonium when calyptra separates; foot of sporophyte is imbedded in vaginula – Figure 60) the sugars are primarily hexoses, with the conversion from sucrose to hexose facilitated by a cell wall **invertase** at pH of 4.5. The highest concentration ($\sim 230\text{ mM}$) of soluble invertase occurs in both the haustorium and the vaginula, where a soluble invertase has its highest activity (pH 7.0). Glucose uptake is carrier-mediated, with little dependence on external pH. Once glucose is absorbed into the haustorium, it is converted to sucrose. Hence, sucrose is converted at the gametophyte-sporophyte interface to fructose and glucose, then converted back to sucrose after the haustorium cells absorb hexose. These changes may permit the sugar accumulation in the haustorium.

A more detailed anatomy of the gametophyte-sporophyte junction in the moss *Acaulon muticum* (Figure 61) may clarify some of the nutrient transfer (Rushing & Anderson 1996). This junction has the sporophyte foot imbedded in the gametophyte vaginula, with intervening placental space. The basal cell of the foot develops extensive wall ingrowths. Sporophyte cells that contact

that basal cell likewise develop ingrowths on their outer tangential and radial walls that contact the basal cell. These young sporophyte cells have numerous mitochondria, strands of endoplasmic reticulum, and dictyosomes, especially adjacent to areas of extensive wall development. The plastids contain abundant reserves of starch. The wall ingrowths continue to become more extensive on all walls of the sporophyte foot, but never occur on the upper wall of the basal cell where it contacts the remainder of the sporophyte. As the sporophyte develops, the plastids of the foot contain fewer starch reserves. The gametophyte vaginula does not exhibit wall ingrowths until the sporophyte foot is well developed. Rushing and Anderson suggested that the early development of the wall ingrowths in the sporophyte foot and especially the basal cell may facilitate the rapid movement of both water and nutrients from gametophyte to sporophyte.

There has been much recent speculation into the role of the stomata in the sporophyte of bryophytes. Haig (2013) suggests an important function in conduction. Once the calyptra has been "outgrown" by the capsule, leaving the lower part of the capsule exposed, the stomata may provide a transpiration stream that helps to draw resources from the gametophyte up to the sporophyte, much as the open stomata of tree leaves facilitate the transpiration stream of water and nutrients upward in trees. Haig contends that the seta serves to raise the capsule above the boundary layer, facilitating the movement of moisture from the moss to the air and coincidentally moving the nutrients upward from the gametophyte. Haig further suggests that the calyptra serves to protect the gametophyte from excessive transfer to the developing sporophyte.

Summary

While most bryophytes obtain their nutrients primarily from atmospheric dust and precipitation, acrocarpous mosses may also receive considerable input from the substrate through upward movement

externally and subsequent internal movement. Cation exchange sites hold nutrients on leafy surfaces and facilitate uptake and discrimination between ions. Further active processes are able to distinguish ions formed by N, P, and K from more exchangeable cations such as those of Ca^{++} or Mg^{++} , and they are generally able to maintain relatively constant levels of these essential nutrients despite changes in environmental concentrations. Bryophytes use pathways both through cells (**symplastic**) and between cells (**apoplastic**) to move internal substances, just as do the tracheophytes. And they may even have a filter similar to the endodermis, in the form of a **leptome**, at least in the **Polytrichaceae**. Leptome cells may become disfigured during desiccation, but they return rapidly to normal configuration following rehydration.

Many bryophytes also behave like tracheophytes in moving essential ions such as those formed by N, P, and K from older to younger parts, whereas less soluble ions like Ca^{++} remain in older tissues. Their ability to acquire ions from rainwater and hold them in their tissues makes them a sink for forest nutrients, but some, especially K^{+} , may be released in heavy rainfall following a dry period, returning the nutrients to the forest floor as a pulse. Heavy metals may be sequestered in older tissues or on external exchange sites. Movement may additionally occur through **source to sink** mechanisms or a transpiration stream.

Sucrose is transported in the **leptome**, as well as through stem parenchyma cells. Radiolabelled carbon quickly appears in the stem apex, young leaves, bud initials, and underground axes. Most of the movement is toward the apex (**acropetal**), but some also moves to the base (**basipetally**). Some reaches other stems in the clone. The **leptome** also moves ionic solutes, whereas the chelated forms move in the **hydroids**.

Sugars and nutrients move from the gametophyte to the sporophyte through the **transfer cells** in the sporophyte foot. But members of the **Anthocerotophyta** may transfer photosynthate from the green sporophyte to the gametophyte to nourish the *Nostoc* colonies. Stomata at the base of the capsule may create a transpiration stream that helps to move resources from the gametophyte to the sporophyte once the capsule is partially free of the calyptra.

Their ability to move nutrients from old to young tissues and to store them both externally and internally raises serious questions about their role in the nutrient cycling in the habitats where they are abundant. On the other hand, they may release potassium when roots need it the most.

Acknowledgments

I appreciate the contributions of undergraduate Phil Gaudette and M. S. student Jennifer Jermalowicz Jones for their critical reading of the manuscript from the perspectives of students interested in nutrient relationships of bryophytes.

CHAPTER 8-6

NUTRIENT RELATIONS: DEFICIENCY

Figure 1. *Dicranum spadiceum* in an alpine habitat where nutrients are typically deficient. Photo by Michael Lüth, with permission.

Nutrient-deficient Habitats

Tracheophytes have well-known adaptations to low nutrients. Among the herbaceous seed plants adapted for low nutrient habitats, a small growth form with narrow leaves or basal rosettes seems to predominate (Grime 1977). Evergreenness is common in both dry and wet habitats (bogs and fens), presumably affording the plant the opportunity of using their leaves for several years without having to provide the nutrients to grow a new supply. Like the shade plants, these plants possess an inherently slow growth rate.

Bryophytes in general seem to grow best in low-nutrient habitats (Figure 1). It is interesting that their productivity is no greater in extreme rich fens than in bogs and poor fens (Vitt 1990). Furthermore, the addition of nutrients to bryophytes in intermediate fens does not result in an increase in productivity. If we compare the bryophytes to the low-nutrient-adapted plants described by

Grime (1977), the bryophytes are likewise small, have narrow leaves, and are mostly evergreen (but not leathery). As discussed earlier, they are able to move soluble nutrients from older tissues to growing apices. Furthermore, bryophytes are able to survive in low-nutrient habitats despite their small size and slow growth rate. In nutrient-rich habitats, they have no chance of competing with the fast-growing tracheophytes.

In bogs and fens, *Sphagnum* seems to have its own way of "competing" for the limited supply of nutrients. In experiments where both *Sphagnum fuscum* (Figure 2) and *Drosera rotundifolia* (sundew, Figure 2) were fertilized with N, the *Sphagnum* was able to advance its growth (Svensson 1995), seemingly ready to outcompete the tiny *Drosera* plants for light. However, the *Drosera* tapped into the nutrients at a different depth in the system, elongated its vertical stem that connected two successive years of

growth, and hence kept up with the vertical growth of the *Sphagnum*. Interestingly, the *Drosera* made more but smaller leaves and increased its leaf thickness, thus not increasing its shading effect on the moss. Svensson concluded that the moss relocates the nutrients within itself, thus preventing their potential spread to tracheophytes.

Figure 2. Sundew (*Drosera rotundifolia*) (three round leaves) growing with *Sphagnum fuscum*. Photo by Michael Lüth, with permission.

Bryophytes can be deprived of nutrients in habitats that are rich in nutrients. This paradox results from nutrient competition for the binding sights. Calcium compounds such as CaCl_2 can raise both exchangeable and intracellular Ca^{++} concentrations and displace other exchangeable essential nutrients such as K^+ and Mg^{++} (Bates & Farmer 1990), both of which are often in limiting supply. But the interesting response to addition of CaCl_2 that Bates and Farmer found is that the low-nutrient mosses *Pleurozium schreberi* (Figure 3) and *Pseudoscleropodium purum* (Figure 4) from acidic clay were unaffected, whereas *Calliergon cuspidatum* (Figure 5) and *Pseudoscleropodium purum* from chalk (CaCO_3) soil suffered reduced growth, apparently due to the resulting K^+ and Mg^{++} deficiencies.

Figure 3. *Pleurozium schreberi*, a low-nutrient species that was unaffected by CaCl_2 . Photo by Janice Glime.

Ion concentrations in the substrate or in water can be misleading relative to nutrient availability. A low-nutrient substrate such as a rock in a forest might actually place the bryophyte in a position to obtain considerable nutrients from throughfall that has collected nutrients from the

canopy trees. And bryophytes dwelling in a stream with reasonably fast flow will have a continuous supply of new nutrients that can compensate for low concentrations (Birks & Dransfield 1970).

Nutrient Deficiency Symptoms

It takes nerve to title a section Nutrient Deficiency Symptoms when you are writing about bryophytes. This has apparently never been systematically studied for bryophytes in general! A search in Cambridge Abstracts brought one reference, a field study following fire: "Germination of *Ceratodon purpureus* (Figure 6) on all the burnt surfaces, and of *Funaria hygrometrica* (Figure 7) on the charred surfaces appeared to be nutrient or pH -limited. Growth of *C. purpureus* and *Dicranella heteromalla* (Figure 8) appeared to be nutrient- or pH -limited on some or all of the burnt surfaces." This 1994 study by Thomas *et al.* appears to be the only field study in recent years even to allude to nutrient deficiency symptoms in any context. And that one is merely a guess.

Figure 8. *Dicranella heteromalla*, a species that appears to be pH- or nutrient-limited when growing on burned substrata.

Culture studies for the purpose of keeping bryophytes alive are the most productive avenue for locating possible clues as to the response of bryophytes to limiting nutrients.

But, since bryophytes tend to have much lower nutrient requirements than do tracheophytes (Griggs & Ready 1934; Voth 1943; Burkholder 1959; Southorn 1977; Dietert 1979), most of the trial and error in culture experiments revolves around getting nutrient concentrations low enough that algae, fungi, and bacteria don't predominate. For whatever reason, the total nutrient content of bryophytes, indicated by what is left in dry matter ash content, is lower than that of any other group of plants, algae, bacteria, or fungi, except for the woody parts of trees and shrubs (Table 1; Larcher 1983, 1995).

Table 1. Comparison of mean dry matter ash content for various groups of organisms. From compilation of Larcher (1983, 1995).

Bacteria	8-10%
Fungi	7-8%
Planktonic algae without skeletal material	~5%
Diatoms	up to 50%
Seaweed	10-20%
Mosses	2-4%
Ferns	6-10%
Grasses	6-10%
Dicotyledonous herbs	6-18%
Geophytes	5-10%
Succulents	10-20%
Halophytes	10-55%
Cacti	10-16%
Tundra herbs	~5%
Swamp plants	5-15%
Ericaceous dwarf shrubs	
Leaves	3-6%
Shoots	1-2%
Broad-leaved trees	
Leaves	3-4%
Wood	~0.5%
Bark	3-8%
Conifers	
Needles	~4%
Wood	~0.4%
Bark	3-4%

In addition to ions that compete for exchange sites, another problem with nutrient solutions is that they may have higher osmotic values than those internal ones of the bryophytes, causing osmotic shock (Brown 1982). Furthermore, the slow growth of bryophytes permits them to call upon nutrient reserves for a considerable time before deficiency symptoms appear. If multiple nutrients are limiting, the result is likely to be simply retarded growth rate, at least in the short term.

In a study on the epiphyllous leafy liverwort *Radula flaccida* (Figure 9), Olarinmoye (1975) found that when grown in distilled water, these liverworts became chlorotic and brittle, but still demonstrated considerable growth extension, indicating they most likely were using nutrient reserves. They did best in a nutrient medium diluted to 10-20% of the normal strength bryophyte medium, a solution already dilute compared to that used for most tracheophytes.

N and P Deficiency

Nutrient deficiency, especially N and P, can reduce plant growth by hindering physiological and biochemical processes. Deficiency can reduce protein synthesis and photosynthetic rates, while increasing carbohydrate content. But are bryophytes typically nutrient deficient? There are numerous examples that suggest they typically are not. It appears that they require much lower concentrations of nutrients than do other plants, obtaining most of their nutrients from precipitation. For example, when the nutrients of rainwater near Fairbanks, Alaska, were amplified to 2-5 times their normal concentration, bryophytes showed no growth increase, and some responded negatively (Skré & Oechel 1979). Even the large moss *Pseudoscleropodium purum* (Figure 4) showed no response to increased nutrients in a field experiment (Bates 1987). Rather, although *P. purum* may exhibit a temporary increase in internal nutrient concentrations, those relatively quickly return to the concentrations typical under normal rainfall (Bates 1989).

Despite the lack of direct field evidence, Richardson (1981) recognized that inadequate nutrient supply can cause stress and reduce photosynthetic performance of mosses. On the other hand, some bryophytes such as *Ceratodon purpureus* (Figure 12) may alter their growth form under low nutrient conditions. In this moss, greater shoot initiation occurs on media deficient in N (Seppelt & Hancock 1991). Hmmm... Wouldn't that be maladaptive?

Few visible deficiency symptoms seem to have been documented for bryophytes, contrasting with the symptoms that are highly documented for tracheophytes. In tracheophytes, N deficiency causes plants to be light green with lower leaves yellow due to transport of N to growing tissues; stems are short and slender, and the root-to-shoot ratio is high (Salisbury & Ross 1992). Growth is directly related to N availability in feather mosses (Sveinbjörnsson 2002). P deficiency causes plants to become dark green, often with red-purple on the undersides of leaves. As in N deficiency, the stems are short and slender. For those bryophytes that have been studied, similarities in nitrogen and phosphorus deficiency symptoms exist, but bryophyte responses in general for these two deficiencies seem to be more distinct from each other than in tracheophytes. Development of chlorosis is a typical N deficiency symptom in both tracheophytes and bryophytes. *Funaria hygrometrica* (Figure 7, Figure 13) responded to absence of either N or P at the protonemal stage by producing few protonemata on the deficient agar, and those soon became chlorotic in the N-free medium (Hoffman 1966), failing to produce gametophores (Dietert 1979). *Atrichum undulatum* (Figure 14) had a similar response of gametophores becoming yellow (Burkholder 1959). Likewise, no new gametophores were produced in the P-free medium (Hoffman 1966). *Weissia* (Figure 15) also became chlorotic in the absence of N (Dietert 1979), the gametophore tissue soon became tough and fibrous, and the leaves were scalelike. In P-free media, the entire culture became dark brown.

When mature *Fontinalis antipyretica* (Figure 16) was cultured in a P-free medium for four weeks, all plants had dark green leaves, as in tracheophytes, although some had scattered chlorotic leaf tips (R. Marr & Glime unpub). In the N-free medium, all had pale green leaves, again being similar to symptoms of tracheophytes. By contrast, in experiments with excess N, *Fontinalis dalecarlica* (Figure 17) and *F. novae-angliae* became deep green (Glime unpub., Figure 18-Figure 19).

Although roots of tracheophytes are affected by nutrient deficiencies, there seem to be no studies that examine the effects on bryophyte rhizoids.

Phosphorus has been considered a major limiting factor for mire plant growth (Watt 1966; Small 1972; Moore & Bellamy 1974; Li & Glime 1990). On the other hand, mosses may be more competitive against tracheophytes under low P conditions; Richards (1959) reported that mosses can uptake most of the phosphate fertilizer when mosses and grasses are growing together. Apparently the phosphorus can be stored and used later in other locations; Rydin and Clymo (1989) reported the transport of phosphorus in *Sphagnum* (Figure 20-Figure 29), suggesting that it was being stored for use later.

Figure 20. *Sphagnum magellanicum*, a species for which growth is typically limited by inadequate P. Photo by Michael Lüth, with permission.

The greatest number of field studies on nutrient additions have been done on the genus *Sphagnum*, but

deficiency information is again based primarily on lab studies. Sanville (1988) and Aerts and coworkers (1992) found that *Sphagnum* production in the field increases in response to nutrient addition, suggesting that it has been growing under deficiency conditions. In support of this, Li and Glime (1990) used lab studies to demonstrate that low nutrient concentration is a major factor causing low productivity or death of parts of *Sphagnum*. Limiting P can limit the growth of mature *Sphagnum magellanicum* (Figure 20-Figure 21) and *S. papillosum* (Figure 22-Figure 23). Boatman and Lark (1971) found that P was likewise limiting for the protonema growth of *Sphagnum magellanicum* (Figure 21, *S. papillosum* (Figure 23), and *S. cuspidatum* (Figure 24).

Figure 24. *Sphagnum cuspidatum*, a species of peatland valleys and pools that has reduced protonema growth in media with low P. Photo by Michael Lüth, with permission.

Li and coworkers (1993) demonstrated that both high and low concentrations of P can cause *Sphagnum magellanicum* (Figure 25) to produce red pigments, a character common for this moss when it is in strong sunlight in nature (Rudolph 1963, 1964; Rudolph & Vowinkel 1969). What are the implications of this? Does absence of red color mean anything relative to P availability, or only that light is inadequate for pigment development?

Figure 25. *Sphagnum magellanicum* showing red pigments that are typical of bright light or low P. Photo by Jan-Peter Frahm, with permission.

Sphagnum (Figure 20-Figure 25) cell structure (Figure 26) and general morphology change in response to nutrient concentrations (Figure 30). Baker and Boatman (1989) found that the stem length between branch fascicles in *Sphagnum cuspidatum* (Figure 24) was positively related to the N content of the capitula, whereas the capitulum dry biomass was negatively related, suggesting that branches continued to develop somewhat normally, but expansion of the stem between these branches was reduced under N deficiency. Yet, there was no correlation between interfascicular length and capitulum dry biomass. Hintikka (1972) found that *Sphagnum fallax* (Figure 27) failed to develop hyaline cells in a medium high in NH_4^+ or organic N, but low in carbohydrates (Figure 28-Figure 29). Furthermore, Baker and Boatman (1992) found that hyaline cell length of branch leaves in *Sphagnum* is directly correlated with the CO_2 concentration, whereas it is inversely correlated with the N and P concentrations (Figure 30). As might be expected, the lengths of the hyaline and chlorophyllose cells were closely correlated with each other, but also correlated with leaf length. On the other hand, short leaves had few and poorly differentiated hyaline cells.

Figure 30. Arrangement of photosynthetic and hyaline cells in *Sphagnum capillifolium* leaves grown in high N & P/low CO₂ (ambient) treatment (upper) compared to those in low N & P/high CO₂ (5%) treatment (lower). Based on Baker & Boatman (1992).

Baker and Boatman (1992) suggested that the presence of well-differentiated hyaline cells in *Sphagnum* (Figure 26, Figure 28) provided a "scavenging system" for inorganic nutrient ions when they were in low concentration. The additional surface area on the interior of the cells, highly endowed with polyuronic acids, provides a large surface for binding and facilitating uptake. While this suggestion may be true, the notion of cause and effect is questionable. The plant can hardly make a decision that it needs more or longer of these cells in order to get nutrients.

How does this change in hyaline cells affect the desiccation tolerance of the moss? Perhaps one explanation is that bogs and fens are never N limited due to their Cyanobacteria flora, but that if the system is getting dry, little of the N is reaching the new leaves at the top because of the loss of capillary water. This would result in longer leaves and more hyaline cells, providing the hyaline cells needed to hold a water reservoir. But would the timing work? Would these young leaves get the signal soon enough to have the hyaline cells ready when they need them for maintaining hydration?

Liverwort deficiency studies are even more limited than those of mosses. Voth and Hamner (1940) reported that N deficiency caused a reduction in growth of *Marchantia polymorpha* (Figure 31) and the plants were stunted. Symptoms in *Marchantia polymorpha* more closely resembled those of tracheophytes. In cultures lacking N, P, or both, the midrib was darker (Figure 32) and scales, rhizoids, and the lower epidermis became red in about 10 days (Voth 1941). After 2 weeks, the N-free plants ceased growing and produced no gemmae cups; they produced few dichotomies and thalli remained narrow. Eventually the upper surface became chlorotic. Those plants lacking P likewise had a very dark midrib (Figure 32) and red underside, but contrasted sharply with the N-free plants in having frequent dichotomies with broad thalli, giving the thalli a rosette appearance, and producing numerous gemmae cups (Figure 33). As in the mosses, *Leucolejeunea clypeata* (see Figure 34) plants were light yellow to white in the absence of P (Fulford *et al.* 1947).

K Deficiency

Potassium is also a translocatable nutrient, the most easily moved – and lost – of all the nutrients in both tracheophytes and bryophytes due to its high solubility and low ionic mass. When deficient in K^+ , tracheophytes

exhibit mottled or chlorotic leaves with small spots of dead tissue, usually at the tips and between veins, and especially at the margins; stems are slender. In bryophytes older parts may exhibit leaf margin chlorosis somewhat similar to effects seen on tracheophytes.

When cultured in a liquid medium with no potassium for four weeks, all samples of *Fontinalis antipyretica* (Figure 16) remained bright grass-green in color, although some were slightly pale (R. Marr & Glime unpub). By contrast, *Marchantia polymorpha* (Figure 33) (on solid agar) exhibited tan coloration in its older thallus parts, especially along the wing margins near the tip (Voth 1941). In tracheophytes, K^+ is important in the regulation of guard cells. No connection has been made between K^+ and the cells surrounding *Marchantia* pores (Figure 35-Figure 36), but it is possible that K^+ is likewise involved in their tendency to close under dry conditions.

Ca Deficiency

Calcium is important in maintaining membrane integrity (Brown 1982) and in binding cells together. Brown suggests that Ca^{++} may be required in greater concentrations by mosses that grow in Ca^{++} -rich sites. These mosses can have 16-17X as much Ca^{++} as species from Ca^{++} -poor habitats (Bates 1982). Mosses in calcareous habitats have 3-4X as much Ca-exchange

capacity as mosses from Ca^{++} -poor habitats (Bates 1978). Brown (1982) reasons that the Ca^{++} may be used to maintain membrane integrity. He suggests that these **calciphilic** (Ca^{++} loving) bryophytes may have inherently leakier membranes at low Ca^{++} concentrations and that it is also more difficult for them to uptake ions such as K^+ . Jefferies (1969) reported that *Cephalozia connivens* (Figure 37) (a **calcifuge** – avoiding Ca) had maximal K^+ uptake at 0.1 mM Ca^{++} and pH 4, whereas *Mesoptychia turbinata* (calcicole – of Ca-rich habitats) did best at 3.0 mM Ca^{++} and pH 4-8. Nevertheless, K^+ efflux was unaffected by the Ca^{++} concentration in these two liverworts. Patterson (1946) suggested using a K:Ca ratio of 49:1 to maintain membrane integrity when using KCl to test osmotic potential. Osmotic tests that lack Ca^{++} should be suspect because they do not provide the Ca^{++} needed to keep the membrane intact.

Figure 37. *Cephalozia connivens*, a **calcifuge**. Photo by Michael Lüth, with permission.

Calcium deficiency is known to interfere with growth because the cell walls cannot cement together properly, lacking the Ca needed for the calcium pectate bonds. In algae, new crosswalls fail to form between newly divided nuclei (Reed 1907). This element has low solubility and is generally not translocatable, so it cannot be taken from older leaves to supply the growing tips. Thus, necrosis of leaf tips and margins and death of the stem apex are common in Ca-deficient tracheophytes, often preceded by chlorosis (Voth 1941). Bryophytes seem to be no exception. In *Marchantia polymorpha* (Figure 31), the Ca^{++} -deficient plants had less growth and biomass increase than controls (Voth 1941). Nehira (1973) also showed that Ca^{++} was required for rhizoid differentiation in *Marchantia*, with Ca^{++} accumulating at the rhizoid base.

In the leafy liverwort *Leucolejeunea clypeata*, the response is somewhat unusual, although perhaps only visible because of the one-cell-thick leaves. Growth in a medium with no calcium causes normally flat cells to become swollen (Figure 38; Geldreich 1948a), although it has no effect on already mature cells, suggesting weak or easily extended cell walls, consistent with insufficient Ca

pectate. However, these leaves still test positive for pectic substances, but negative for presence of calcium, indicating that some other element such as Mg or K has been used in place of Ca. Geldreich suggests that the rounding is the result of this substitution because magnesium and potassium do not have the hardening property of calcium pectate, thus permitting elasticity to the cell wall. This is an interesting result because some species of *Fissidens* [*F. cristatus* (Figure 39-Figure 40) vs *F. adianthoides* (Figure 41)] are separated based on this rounded cell character difference. Might this simply be an environmental expression of calcium deficiency? On the other hand, Geldreich did not find the cell difference witnessed by Fulford *et al.* (1947) on *L. clypeata* with this same treatment.

Figure 38. Effects of a Ca-deficient environment on leaf cells of *Leucolejeunea clypeata*. **Upper:** leaf grown on normal nutrient agar, showing distinct cell walls and flat surfaces. **Lower:** leaf grown on Ca-deficient agar, showing bulging cells. Photos retouched from Geldreich 1948a.

A second symptom of Ca^{++} deficiency in *Leucolejeunea clypeata* (Figure 38) is the configuration change in the oil bodies (Geldreich 1948a). In normal cells, the oil bodies are ovoid and typically one per cell. In the Ca^{++} -deficient leaves, the shape varied from globose to ovoid and they numbered up to seven per cell. This is

another trait change that could confound identification in some taxa.

Unlike the response of *Leucolejeunea clypeata* (Figure 38), wherein the protonema failed to develop on a Ca^{++} -free medium (Geldreich 1948b), *Funaria hygrometrica* protonemata (Figure 7, Figure 13) grew rapidly on Ca^{++} -free agar, but these were from already established transplanted cultures (Hoffman 1966). The gametophores that developed were small, a response typical of Ca^{++} -deficient tracheophyte sporophytes, with soft tissues that were easily torn; the entire culture turned black. In the chelated form, Ca^{++} becomes unavailable, at least for *Funaria hygrometrica* (Iwasa 1965), unlike the chelated form of iron, which is the more usable form, suggesting that on organic substrates this moss might suffer from a Ca^{++} deficiency. This should be explored as a possible cause of its preference for inorganic soil and ash and its disappearance when other plants arrive.

Marchantia polymorpha (Figure 31-Figure 33) likewise responded to reduced Ca^{++} supply (12 mg/L) by developing black tips (Voth 1941). The wings of the apical notches became black first, followed by the meristematic region. Then a V-shaped zone developed progressively back from the tip. Many of these blackened tips became watery, but by the end of the 32-day experiment many of the blackened tips were curled upward, dry, and brittle. This is similar to the response of the alga *Spirogyra*, in which the apical cell eventually contains a dark lecithin-like substance (Reed 1907). Voth (1941) showed that in *Marchantia*, early symptoms were internal, with maturing cells having larger vacuoles and fewer chloroplasts. One interesting response is that while dorsal cells are breaking down, the ventral cells surrounding the smooth rhizoids are persistent and become a source of regenerated thalli – tenacity to the end!

Mature *Fontinalis antipyretica* (Figure 16, Figure 43), on the other hand, responded to Ca^{++} deprivation by becoming pale yellow-green with a hint of brown (R. Marr & Glime, unpub).

Mg Deficiency

Deficiency of magnesium in tracheophytes results in lower leaves becoming mottled or chlorotic due to translocation of the Mg^{++} to developing apical tissues; leaves often become reddish; tips and margins turn up, causing the leaves to become cupped. Symptoms such as cupped leaves are more difficult to detect, if they exist, in bryophytes. The absence of veins might even make this trait unlikely. In some cases, lacking definitive studies among the bryophytes, deficiency symptoms can be inferred from the symptoms of excess from a competing nutrient. Most mosses need very little calcium, and calcium from limestone rock is more often detrimental than helpful to mosses. Clymo (1973) demonstrated that Ca^{++} coupled with high pH, at which it is most soluble, actually killed most *Sphagnum* species, with *Sphagnum squarrosum* (Figure 42) being the most tolerant in the study. *Sphagnum* is particularly sensitive to CaCO_3 , forming crusts on its branch tips and soon losing vigor. Hence, these crusts of CaCO_3 are symptomatic that the moss is likely to be deficient in the Mg^{++} and K^{+} that must compete for binding sites.

Figure 42. *Sphagnum squarrosum*, a species tolerant of high pH and Ca levels. Photo by Janice Glime.

The effects of Mg^{++} absence seem to be similar to those of Ca^{++} deficiency for *Funaria hygrometrica* (Figure 7, Figure 13) (Hoffman 1966). Protonemata grew well and new gametophytes formed, but like the Ca^{++} -deficient plants, these were smaller than those receiving the nutrient. In the culture study, the stems turned brown and eventually many entire gametophores turned brown. But other than the color changes, the leafy plants appeared to be quite healthy. When mature *Fontinalis antipyretica* (Figure 43) was cultured in a Mg^{++} -free medium for four weeks, all plants seemed to remain normal in appearance (R. Marr & Glime unpub). *Marchantia polymorpha* (Figure 31-Figure 33) likewise seemed to remain a healthy color, but had less area growth and dry biomass compared to controls (Voth 1941). This differs from tracheophyte symptoms in which the plants become chlorotic. Long-term absence or deficiency of Mg^{++} would undoubtedly cause chlorosis, and eventually death, because Mg^{++} is needed to form the chlorophyll molecule.

S Deficiency

Sulfur is rarely a limiting nutrient, even for tracheophytes, but soils in parts of Australia, Scandinavia, southwestern grain-producing parts of Canada, and northwestern U. S. A. can be sulfur deficient. Sulfur is used in the amino acids cysteine and methionine, thus is needed for building proteins. Sulfur is not readily translocated in plants, so deficiencies are exhibited by young tissues. In tracheophytes, the terminal bud remains alive, but young leaves and veins of older leaves become chlorotic (Salisbury & Ross 1992).

As with Ca^{++} deficiencies, *Funaria hygrometrica* protonemata (Figure 7, Figure 13) grew on S-free agar, developing gametophores (Hoffman 1966). But these gametophores were likewise small and they later became slightly chlorotic. Depriving mature *Fontinalis antipyretica* (Figure 43) of S for four weeks seemed to have no effect on its appearance (R. Marr & Glime unpub). Likewise, *Marchantia polymorpha* (Figure 31-Figure 33) growing on S-free agar showed no visible symptoms (Voth 1941). However, S in the atmosphere during the experiments may be sufficient to provide the needs for these low-nutrient, slow-growing plants.

Fe Deficiency

In the soil, high pH contributes to iron deficiency in plants, and in acidic soils Al can interfere with Fe uptake.

Furthermore, Fe needs to be in a chelated form for cells to absorb it across the membrane. Once delivered to the tissues, Fe is also immobile and cannot be moved easily from older to younger tissues. In tracheophytes its deficiency causes interveinal chlorosis similar to that for Mg^{++} deficiency, but in the case of Fe it is the younger leaves that become chlorotic. Although it is not required in chlorophyll, it is apparently needed by the enzymes used to synthesize chlorophyll and it is needed especially in the electron transport system.

In bryophytes, symptoms of Fe deficiency are poorly known and vary with species. When transplanted to agar with no iron, *Funaria hygrometrica* protonemata (Figure 7, Figure 13) grew rapidly, but produced very few new upright gametophores (Hoffman 1966). Those that were produced became chlorotic and the plants eventually turned brown. When mature *Fontinalis antipyretica* (Figure 43) was cultured without Fe for four weeks, the stems became bright red, especially near the base, and some leaves were likewise red at the base (R. Marr & Glime unpub). When unchelated iron was provided as $FeCl_3$, all *F. antipyretica* plants had yellow-brown leaves with bright green stems. Normally the stems of this species are brown. One must ask why the symptoms differed when unchelated iron was supplied. Did something in the medium or in the plant chelate it to a limited extent? What could account for the red coloration with no Fe?

Comparisons of the macronutrient deficiency symptoms in the mosses *Fontinalis antipyretica* (Figure 43) and *Funaria hygrometrica* (Figure 7, Figure 13) and thallose liverwort *Marchantia polymorpha* (Figure 31-Figure 33) are presented in Table 2.

Table 2. Deficiency symptoms in *Fontinalis antipyretica* (Figure 43) based on unpublished data of Robert Marr and Janice Glime, *Funaria hygrometrica* (Figure 7, Figure 13) based on Hoffman (1966), and *Marchantia polymorpha* (Figure 31-Figure 33) based on Voth (1941).

	<i>Fontinalis</i>	<i>Funaria</i>	<i>Marchantia</i>
N	pale green	few protonemata, chlorotic	midrib dark, scales & rhizoids red
P	dark green	few protonemata, no gametophores	midrib dark, scales & rhizoids red
K	no visible effect		tan coloration of older parts
S	no visible effect	small, chlorotic	no visible effect
Mg	no visible effect	small, stems brown many leaves brown	less growth
Ca	pale yellow-green	small, soft tissues	less growth black tips
Fe	stems bright red	few gametophores, chlorotic, brown	

Micronutrient Deficiency

It is difficult to deprive plants of micronutrients because the minute quantities needed can occur as contaminants. Any bryophytes brought from the field are likely to have sufficient quantities on their surfaces to last them for a long time. Even when grown on nutrient-

deficient agar (missing B, Cl, Cu, Mn, Mo, and Zn), *Funaria hygrometrica* (Figure 7, Figure 13) continued to produce protonemata (Hoffman 1966). Although gametophores developed, they remained stunted and their stems turned dark. The tissues were tough and difficult to tear, much like in the N-deficient cultures. When Marr and Glime (unpub) deprived mature *Fontinalis antipyretica* (Figure 43) of micronutrients for four weeks, most plants exhibited no symptoms, except that 8 apical pieces developed brown tips (in 4/5 replicate containers). On the other hand, when Cu was added to *Fontinalis dalecarlica* (Figure 44) in Lake Superior water, greener cells resulted.

Figure 43. *Fontinalis antipyretica* with brown tips (arrow) such as might be seen with a nutrient deficiency.

Figure 44. *Fontinalis dalecarlica* showing the greenest leaf cells at 1.0 mg copper per liter. Photo by Janice Glime.

Biochemical changes that affect the ability of the plant to tolerate stress may also occur. For example, in *Marchantia palacea* var. *diptera* (Figure 45) grown in copper-deficient media, the enzyme Cu/Zn-superoxide dismutase was inactivated (Tanaka *et al.* 1995). This enzyme group is important in maintaining membrane integrity (Dhindsa & Matowe 1981; Dhindsa *et al.* 1981; Gong *et al.* 1997). Therefore, its destruction or inactivation may result in greater membrane damage during desiccation, resulting in a loss of nutrients from the cell. Such losses can result in a multiplicity of symptoms because other nutrients have become deficient as well.

Figure 45. *Marchantia palacea* var. *diptera*, a species that disables the enzyme Cu/Zn-superoxide dismutase when grown in a copper-free medium. Photo by Janice Glime.

Oxygen Deficiency

One rarely considers plants in the context of oxygen deficiency, but apparently even some members of this oxygen-producing group can suffer from insufficient oxygen. When the aquatic leafy liverwort *Jungermannia exsertifolia* subsp. *cordifolia* (Figure 46) was cultured in a non-aerated solution, it accumulated considerably less phosphorus in the first three days, probably due to blockage of mitochondrial respiration, followed by a net loss of P, indicating probable membrane damage (Mártínez Abaigar 2002).

Figure 46. *Jungermannia exsertifolia* subsp. *cordifolia*, a species that seems to require oxygen to take in P. Photo by Michael Lüth, with permission.

Community Effects of Deficiencies

Although nutrient concentration often may not cause evident deficiency or excess symptoms in bryophytes, it can have a strong effect on community composition. Bryophyte-dominated peatlands provide a good example. Following an extensive literature survey, Bedford *et al.* (1999) suggest several generalizations regarding peatlands: "(1) plant community type changes across broad nutrient gradients; (2) species richness declines as various indicators of nutrient availability increase beyond some

threshold; and (3) rare and uncommon species are almost always associated with species-rich communities." Perhaps it is safer to agree with Bedford *et al.* (1999) in their conclusions that our "generalizations do not always hold within community types; for many community types, the threshold beyond which richness declines has not been established, and high or low diversity may occur below that threshold; and (4) the failure of many studies to include bryophytes precludes drawing strong conclusions about nutrient availability and diversity in peatlands."

Brunkman (1936) found that moss cover in other habitats seemed to have little to do with nutrients. Cover on clays and clay loams in Alberta, Canada, ranged from 7 to 92%, on sandy loams from 59 to 92%, and on Jack pine (*Pinus banksiana*) sand to sandy loams, from 3 to 71%. Brunkman found these data to be "confounding," and interpreted them to mean that the moss does not correlate with soil type, and by inference, probably does not correlate well with nutrients. He had to conclude that mosses were of little or no value as indicators of possible timber values and volumes because "the moss cover wanders all over the site values without any sequence . . ."

On the other hand, Epstein and Yeatman (2003) found that bryophytes increase when tracheophytes such as *Betula nana* resorb higher percentages of N, depriving other shrubs of the nutrient and thus favoring bryophytes. Thus, even if the bryophytes do not directly respond to the nutrients, they may respond because of the resulting change in competition from tracheophytes for space and light.

Nevertheless, Marczonek (1984) showed that *Conocephalum conicum* (Figure 47) population density is dependent on the soil levels of Ca^{++} and Mg^{++} . *Pellia epiphylla* (Figure 48) likewise has increased densities with increases of these two elements as well as N and K. *Meesia triquetra* (Figure 49) occurs where there is both a high pH and high concentration of Ca^{++} (Montagnes 1990). These are but few examples of the many pH and nutrient relationships that exist among the bryophytes. Many more will be discussed as we examine individual habitats later in this book. This surely is evidence that mosses and liverworts can and do get nutrients from the soil and that bryophytes do have minimal nutrient requirements, which they satisfy with either precipitation or substrate or both. The availability of these nutrients determines their growth and distribution, but not in isolation from other factors such as water availability and competition.

Summary

Bryophytes have low nutrient demands compared to tracheophytes, and this may permit them to thrive in habitats such as rock surfaces where they collect dust and throughfall, or in streams where a new supply of nutrients constantly flows by.

N and P deficiency can reduce protein synthesis and photosynthetic rates, while increasing carbohydrate content. N deficiency in bryophytes causes chlorosis and may result in tough, fibrous gametophores with scalelike leaves. In liverworts, at least, it causes a reduction in growth and gemmae cups. Liverworts also may develop red pigments in the absence of N, P, or both. In phosphorus-free media, mosses may become dark brown or may be dark green with only the tips exhibiting chlorosis. Low P limits growth. However, in the liverwort *Marchantia*, absence of P resulted in frequent dichotomies and broad thalli with numerous gemmae cups.

Carbohydrate deficiency, coupled with a high concentration of NH_4^+ or organic N can cause *Sphagnum* to fail to develop hyaline cells. These hyaline cells may provide a "scavenging system" for inorganic nutrient ions when they are in low concentration.

With **potassium** deficiency, older parts may exhibit leaf margin chlorosis somewhat similar to effects seen on tracheophytes. *Marchantia* likewise develops pale thallus margins.

Mosses growing in Ca^{++} -rich habitats may develop 3-4X as much Ca-exchange capacity as those from Ca^{++} -poor habitats. The Ca^{++} may be necessary to maintain membrane integrity and therefore would be important in retaining K^+ . Ca^{++} deficiency can result in reduced growth, lack of rhizoid differentiation, failure of protonemata to develop, black thallus tips, change in shape and increase in number of oil bodies in liverwort leaf cells, small gametophores, and soft tissues. If Ca^{++} is absent during cell development, the cell walls can become more elastic and appear rounded. Internal changes may include larger vacuoles and fewer chloroplasts.

Deficiency of Mg^{++} can result in smaller gametophytes with stems and leaves turning brown. Otherwise, Mg^{++} -deficient bryophytes seem to be healthy.

Sulfur deficiency symptoms are similar to those of Ca^{++} and Mg^{++} , with reduced gametophore growth and chlorosis, but few other symptoms. However, there is often sufficient S in the atmosphere to sustain the bryophytes.

Iron deficiency symptoms seem to vary among species. They include reduction in number of upright gametophores, chlorosis, red stems, red leaf bases, and bright green stems (with unchelated iron).

Micronutrient deficiency can result in stunted growth and dark-colored stems with tough tissues. Enzymes needed to maintain membrane integrity may fail, perhaps due to absence of the metal part of the enzyme.

In aquatic habitats, even oxygen can become limiting, resulting in inability to accumulate P.

Nutrient balance affects competition, and bryophytes often gain an advantage when tracheophytes are nutrient-deficient.

CHAPTER 8-7

NUTRIENT RELATIONS: FERTILIZATION

Figure 1. *Gymnostomum aeruginosum* growing on calcareous rock. Photo by Michael Lüth, with permission.

Fertilization Effects

We often learn about things in science by serendipity. And when it comes to learning about bryophytes in ecosystems, we often learn by what we do to their neighboring tracheophytes. Hence, when we fertilize our gardens or add fertilizers to restore impoverished land, the bryophytes respond, in their own way, along with the intended tracheophytic plants.

In general, fertilizers are detrimental to bryophytes. This is often because added fertilizers benefit tracheophytes that were unable to grow well in their absence and once being fertilized are able to overgrow the slow-growing bryophytes (Virtanen 2000), depriving them of light. One effect of fertilizers is that they frequently change the pH, often making it more alkaline; this is especially true for lime fertilizers. Few bryophytes are favored by high pH levels (Figure 1), and at the very least, the species composition is likely to change (Miles 1968; Miles 1973). Moreover, lime often has a desiccating effect, like that of chalk dust on your hands. However, some specific nutrients may be limiting and certain fertilizers may actually benefit the bryophytes.

Surprisingly, bryophytes in a polar semi-desert at Svalbard Arctic archipelago increased their cover as a benefit from applications of N, P, and K (with little effect by increased temperature), while there was a significant decrease in the cover of the flowering plants *Dryas octopetala* (Figure 2) and *Saxifraga oppositifolia* (Figure 3) (Robinson *et al.* 1998). A strong winter injury seemed to account for the ultimate decrease in *Dryas octopetala*. On

the other hand, *Hylocomium splendens* (Figure 4) and *Rhytidium rugosum* (Figure 5) exhibited significant reductions in growth in a combined temperature and fertilizer enhancement experiment in a subArctic-alpine community in Sweden (Jägerbrand *et al.* 2003).

Changes in nutrient concentrations can affect the lipid content of bryophytes, thus affecting their ability to tolerate cold and desiccation. In the Arctic, growing shoots contain more lipids than carbohydrates (Rastorfer 1972). The lipid content of *Sphagnum fuscum* (Figure 6-Figure 7) increases

during spring in the actively growing parts while decreasing in the senescent parts (Karunen & Salin 1981). *Dicranum elongatum* (Figure 8) uses lipids as storage material in its senescent parts (Karunen & Mikola 1980; Karunen & Liljenberg 1981). The conversion to carbohydrates may lower the freezing point, but I have not seen evidence to support this suggestion.

Figure 7. *Sphagnum fuscum* showing older (lower) parts where lipids decrease in spring, while increasing in the upper, growing parts. Photo by J. C. Schou, with permission.

Figure 8. *Dicranum elongatum*, a moss that stores lipids in its senescent parts (lower). Photos by Michael Lüth, with permission.

Al-Hasan *et al.* (1991) found that the addition of $\text{Ca}(\text{NO}_3)_2$ caused a shift in lipid content in the mosses *Ctenidium molluscum* (Figure 12), *Dichodontium pellucidum* (Figure 10), *Pogonatum urnigerum* (Figure 11), and *Tortella tortuosa* (Figure 12), with total lipids decreasing steadily with increasing concentrations of $\text{Ca}(\text{NO}_3)_2$ in the culture medium. At the same time, the proportion of the predominant polyunsaturated fatty acids also decreased [arachidonic acid (20:4) in *C. molluscum*, eicosatrienic acid (20:3) in *P. urnigerum*, and linoleic (18:2) and linolenic (18:3) acids in *D. pellucidum* and *T. tortuosa*].

Figure 10. *Dichodontium pellucidum*, a moss that shifts its lipid content with the addition of $\text{Ca}(\text{NO}_3)_2$. Photo by Michael Lüth, with permission.

Figure 11. *Pogonatum urnigerum*, a moss that shifts its lipid content with the addition of $\text{Ca}(\text{NO}_3)_2$. Photo by Michael Lüth, with permission.

Figure 12. *Tortella tortuosa*, a moss that shifts its lipid content with the addition of $\text{Ca}(\text{NO}_3)_2$. Photo by Michael Lüth, with permission. Photo by Michael Lüth, with permission.

Temperature also plays an important role in the storage of certain lipids and fatty acids. The content of triglycerides increases in *Dicranum elongatum* (Figure 8) plants photosynthesizing at low temperatures of 1-6°C (Karunen 1981).

N Additions

Because bryophytes receive much of their nutrient input directly from the atmosphere, their responses to added atmospheric inputs of such pollutants as NO_3^- and NH_4^+ can be rapid. If mosses are nutrient deficient, they should respond immediately and positively to these additions.

It appears that at least some bryophytes can use more N than they normally get. As noted in Chapter 8-6, *Fontinalis novae-angliae* (Figure 13) and *F. dalecarlica* (Figure 14) both became considerably darker green in response to higher N concentrations (Glime, unpubl.); *Dicranum majus* (Figure 15) likewise had its highest chlorophyll content from the highest N location (Bakken 1995).

Figure 13. *Fontinalis novae-angliae*, a species that attains a darker color in N concentrations much higher than their native streams. Photo by Janice Glime.

Figure 14. *Fontinalis dalecarlica*, a species that attains a darker color in N concentrations much higher than their native streams. Photo by J. C. Schou, with permission.

Figure 15. *Dicranum majus*, a species that increases its chlorophyll content in higher concentrations of N. Photo by Michael Lüth, with permission.

Muller (1997) compared N content of plants from a plot receiving low doses of NH_4NO_3 diluted in rainwater ($30 \text{ kg N ha}^{-1} \text{ year}^{-1}$) to plants from a control plot that received the same amount of rainwater without added N. The treatment simulated a tripling of the natural N deposition, while the added water represented only 7% of its annual precipitation. Although the N found in tracheophytes (0.7 mg N g^{-1}) in this study provided inconsistent results (Schleppi *et al.* 1999), the moss *Thuidium tamariscinum* (Figure 16) had a dry matter increase in N of 1.3 mg g^{-1} (7%) (Muller 1997). At the same time, treated *Hylocomium splendens* (Figure 4) tended to become brown (Muller 1997), while *Sphagnum nemoreum* (= *S. capillifolium*; Figure 17) seemed to have a reduction in photosynthetic pigments as a result of the added N (Schleppi *et al.* 1999). It appears that the mosses were harmed by the added N in this form, except for the greater storage of N in *Thuidium tamariscinum*. On the other hand, Heeschen and coworkers (1996) contended that N is a "critical nutrient" for bryophytes in raised bogs. But the form matters.

Figure 16. *Thuidium tamariscinum*, a moss that benefits from increased N input. Photo by Michael Lüth, with permission.

Figure 17. *Sphagnum nemoreum* (= *S. capillifolium*), a species that loses chlorophyll when N is added to its growing medium. Photo by Michael Lüth, with permission.

Li and Vitt (1997) in their experiments on nutrient applications in peatlands in Alberta, Canada, found that the added N increased the productivities of two dominant mosses, *Sphagnum fuscum* (Figure 6-Figure 7) in a bog and *Tomenthypnum nitens* (Figure 18) in a rich fen,

whereas the productivity of two dominant shrubs, *Rhododendron groenlandicum* (= *Ledum palustre* subsp. *groenlandicum*; Figure 19) in the bog and *Betula pumila* (Figure 20) in the rich fen, was unaffected. Furthermore, Nordin and Gunnarsson (2000), working with *Sphagnum fuscum*, *S. magellanicum* (Figure 21), and *S. rubellum* (Figure 22) from two mires in Sweden, found that addition of NH_4NO_3 actually caused decreased growth, but resulted in higher concentrations of amino acids in the tissues. When tissue amino acid concentrations exceeded 2 mg, growth in length decreased, suggesting the amino acids may have reached a toxicity level or that the feedback mechanism caused a toxic buildup of NH_4NO_3 .

Woodin *et al.* (1985) found that precipitation high in NO_3^- (as often found in acid rain) induces the nitrate reductase in *Sphagnum fuscum* (Figure 6-Figure 7). Eventually this causes a rise in ammonia, which in turn inhibits the nitrate reductase activity. Nitrate reductase is typically the limiting component in the conversion to amino acids, so it provides a control mechanism that attempts to moderate the concentration of NH_4^+ and amino acids in the plant:

But it is important to keep in mind several intervening factors. Bryophytes in bogs and poor fens typically have **Cyanobacteria** associated with them, and ammonium inhibits nitrate reductase, reducing the symbiotic N fixation by the **Cyanobacteria**. Furthermore, ammonium is more available in acid soils. (See Subchapter 8-3 for further discussion of these intervening factors.)

As one might expect, what is good for one bryophyte may destroy another. Dirkse and Martakis (1992) found that in Swedish forests, fertilization with NH_4NO_3 elicited a positive response from *Lophocolea heterophylla* (Figure 24) while causing a "distinctly negative" response from *Ptilidium ciliare* (Figure 24). In another experiment with the aquatic *Sphagnum cuspidatum* (Figure 37), Paffen and Roelofs (1991) were unable to demonstrate any response to added NH_4^+ unless the CO_2 concentration was increased simultaneously. This suggests that it is the usable C source (CO_2) that is limiting in that habitat, not the N source.

Nitrate reductase is formed only in the light in *Fontinalis antipyretica* (Figure 28) (Schwoerbel & Tillmanns 1974). If this is true in other bryophytes, it might explain why Fries (1945) was able to obtain only slight growth of *Leptobryum pyriforme* (Figure 25) and none in *Funaria hygrometrica* (Figure 26) when he cultured them on NO_3^- in the dark. In the light, on the other hand, *Funaria hygrometrica* and *Weissia controversa* (Figure 27) grew best on the NO_3^- source (Dietert 1979), but poorly even on a buffered NH_4^+ medium. And *Fontinalis antipyretica* grew best on NH_4^+ ions because of the suppression of nitrate reductase by NH_4^+ (Schwoerbel & Tillmanns 1974). Many bryophytes can reduce NO_3^- to NO_2^- in the dark, but light is required to stimulate conversion of NO_2^- to NH_4^+ (Brown 1982).

Figure 27. *Weissia controversa*, a species that grows best on nitrate and not on ammonium. Photo by Michael Lüth, with permission.

The aquatic moss *Fontinalis antipyretica* (Figure 28) responded to high levels of KNO_3 with a toxicity response that interfered with its physiological gas exchange (Stolz & Weise 1976). Its maximum sensitivity was in late spring, with minimal sensitivity in mid summer. High N levels can cause complete O_2 depletion in *Fontinalis*-colonized waters, interfering with P uptake. Total gas exchange of *F. antipyretica* increased 10-12 fold when air turbulence in the culture system increased from 25 to 45 L h^{-1} ; P uptake increased accordingly.

P Additions

Phosphorus typically comes from the mineral substrate, animal dung, and decomposition. The presence of *Funaria hygrometrica* (Figure 26) seems to correlate with the addition of phosphate fertilizer (O'Toole & Synnott 1971). Could this simply be tolerance, or is it a requirement? After all, this moss grows on charcoal, which typically binds ions, providing a low-nutrient habitat. In *Polytrichum formosum* (Figure 29), there seems to be a clear benefit; Vagts and Kinder (1999) reported an "exceptional stimulatory effect of NPK on this moss in a heathland."

Figure 29. *Polytrichum formosum*. Photo by Michael Lüth, with permission.

In an Alaskan study, addition of P in a stream resulted in an increase in cover of the mosses *Hygrohypnum alpestre* (Figure 30) and *H. ochraceum* (Figure 31-Figure 32), suggesting that these mosses had been P limited (Figure 33; Bowden *et al.* 1994). P concentrations are typically low in stream ecosystems and limit algal productivity as well.

Figure 33. Comparison of moss growth and biomass in unfertilized control reaches (0.05μM) and reaches fertilized by H₃PO₄ to a concentration of 0.3μM in the Kuparuk River, Alaska, USA. From Bowden *et al.* (1994).

In their study on a stream population of *Fontinalis antipyretica* (Figure 28), Stolz and Weise (1976) found that the incorporation of P is an active process and is temperature dependent. The RNA fraction was the cell fraction most sensitive to these concentrations.

N and P seem to act together in strange ways. In *Schistidium* (Figure 34) in Alaska, the addition of either N or P caused the cover to increase, but when both were added together the cover decreased (Gordon *et al.* 2001). In bogs and fens, the nutrient relationship can be quite complex. Thormann and Bayley (1997) found that when N or P was added to the water, net primary productivity of *Sphagnum fuscum* (Figure 6-Figure 7) decreased significantly and that water level was the primary limiting factor.

Figure 34. *Schistidium apocarpum* with capsules; members of *Schistidium* in Alaska respond positively to addition of either N or P, but not when they were added together. Photo by Christophe Quintin, through Creative Commons.

Ca and Mg Additions

Liming (CaCO₃) is a common practice for eliminating bryophytes from lawns and other areas where they are unwanted. ☹ One of the problems created by liming is desiccation. But Ca⁺⁺ from CaCO₃ can also harm bryophytes by competing with other nutrient ions by occupying too many exchange sites. This makes it difficult for other ions to bind to the cell walls and enter the bryophyte. But added Ca⁺⁺ is not always harmful to bryophytes. Helsper *et al.* (1983) found that repeated Ca⁺⁺ applications to a *Calluna*-dominated heathland in the Netherlands resulted in an increase in bryophytes.

The entry of Ca⁺⁺ and Mg⁺⁺ seem to interfere with each other, most likely through competition for exchange sites. The rich fen moss *Scorpidium revolvens* (Figure 35) responded to applications of MgCO₃ and CaCO₃ in relation to hardness (Tahvanainen 2004). At high Mg:Ca ratios and low hardness or at low Mg:Ca and high hardness, growth was suppressed, causing a bell-shaped response curve. In other words, growth increased, then decreased as Ca⁺⁺ increased (0-18 mg L⁻¹), but increased with the Mg level (0-12 mg L⁻¹).

Figure 35. *Scorpidium revolvens*. Photo by Michael Lüth, with permission.

Fe Additions

Iron can be a micronutrient or a macronutrient in plants and is needed in various enzymes. In oxygenated

water, iron forms iron oxides that are insoluble and precipitate out. However, in an aquatic system, deep water becomes **anaerobic** (lacking oxygen) and the iron then changes to its ferrous state and forms ferrous hydroxide, which is soluble. An interesting consequence of this relationship occurred in our study of a reservoir dam system (Glime & Keen 1984). The dam had the capability of providing outflow from four different depths. When the bottom depth was used, anaerobic water exited the reservoir and joined the shallow river below. The *Fontinalis duriaei* (Figure 36) in that river soon became covered with iron "pebbles." As the ferrous iron reached the photosynthesizing mosses, it changed to its ferric state and formed iron oxides with the photosynthetic oxygen. These ferric oxides adhered to the mosses as chunks or pebbles.

Figure 36. *Fontinalis duriaei*, a species that can become plated with iron when reduced iron meets oxygenated water and plants producing oxygen. Photo by Michael Lüth, with permission.

CO₂ Additions

When plants are submersed, CO₂ can easily be limiting. This seems to be especially true for *Sphagnum* as it enjoys the warmer temperatures of summer when CO₂ is quickly lost from the warm water. Addition of CO₂ to water in which *S. cuspidatum* (wet kitten moss; Figure 37) was growing caused strong increases in both biomass and length (Paffen & Roelofs 1991). Addition of NH₄⁺ without additional CO₂ had no effect on growth.

Figure 37. *Sphagnum cuspidatum* growing in water. Photo by Michael Lüth, with permission.

But once again, relationships are not so simple. When atmospheric CO₂ was increased to 700 ppm in combination with low levels of N deposition (6 g m⁻² yr⁻¹), *Sphagnum recurvum* var. *mucronatum* (Figure 38) responded with increased productivity, exhibiting a 17% increase in dry biomass (Heijden *et al.* 2000). But when N increased with the CO₂, no growth differences occurred. In fact, even at the highest N level coupled with the high CO₂ level there was a reduction of total N in the capitulum but not in the stems. This reduction in the capitulum coincided with reduced amino acids, but the soluble protein levels remained the same.

Figure 38. *Sphagnum recurvum* var. *mucronatum*, a species that benefits from added CO₂, but not when receiving added N at the same time. Photo by Jan-Peter Frahm, with permission.

Excess Nutrients

Some bryophytes require low nutrient conditions, and many simply cannot survive fertilization or high nutrient situations. The effect of high mineral concentrations has been a source of consternation for many bryologists who have attempted terrariums or culture of bryophytes. Standard nutrient concentrations usually need to be diluted to about 10% that used for tracheophytes and algae (Jeff Duckett, pers. comm. 23 February 2017), but as you will see in this chapter, that varies widely.

This problem of excess came to the attention of Bryonettors. Formation of a white crust on the tips of plants has attracted attention in a number of species. The discussion began when Caitlin Maraist (Bryonet 18 July 2016) cultured *Ceratodon purpureus* (Figure 39) on Turface (a clay that has been heated to improve absorption) moistened with DI water. The plants developed a white precipitate on their leaf tips. Timea Deakova (Bryonet 19 July 2016) reported having the same problem when culturing *Dicranum* species (Figure 8, Figure 15).

Figure 39. *Ceratodon purpureus* with capsules, a species that accumulates a white precipitate when grown on Turface. Photo by Michael Lüth, with permission.

Lars Hedenäs (Bryonet 19 July 2016) reported *Syntrichia ruralis* s.l. (Figure 40) as commonly having such a crust when growing in "strongly calcareous and periodically dry habitats... When dry, the upper leaf portions (hair-points and uppermost lamina) become brittle" with what appears to be a precipitated calcium compound.

Figure 40. *Syntrichia ruralis*, a species that precipitates a white crust at the leaf tips when it dries in strongly calcareous habitats. Photo by Michael Lüth, with permission.

When *Syrrhopodon texanus* (Figure 41) grows on mineral-rich sandstones, groups of plants can become white with salts accumulated on leaf tips, but adjoining species do not seem to have these accumulations (David Taylor, Bryonet 18 July 2016). This raises interesting questions about the various abilities of bryophytes to tolerate these salts. Why do some deposit them at their tips and others do not? How does this relate to internal vs external conduction? And what physiological adaptations permit some bryophytes to tolerate these salts without suffering from **exosmosis** (loss of water through the cell membranes due to the higher salt concentration on the outside of the cell)?

Fertilization and Community Structure

It is easy to see that, rather than benefit, mosses may suffer from increased fertilization both from acid rain inputs and from airborne farm fertilizers, as shown in many field experiments (Mickiewicz 1976; Brown 1982; Jäppinen & Hotanen 1990; Kellner & Mårshagen 1991). In industrialized areas, heavy metals, needed by the bryophytes in minute quantities, can further result in the decline of bryophytes when the industrial sources greatly increase the quantities of these pollutants. In some cases, this pollution fertilization may be beneficial to the bryophytes, as in the pine-heath system where nutrient levels are especially low. Under such circumstances, mosses including *Pohlia* (Figure 42-Figure 43) and *Pleurozium schreberi* (Figure 44) can replace lichens, including *Cladonia* spp., particularly if irrigation is supplied (Persson 1981). Skré and Oechel (1979) found that *Sphagnum nemoreum* (= *S. capillifolium*; Figure 17) also increased its productivity in fertilizer experiments, as did the litter-inhabiting species *Brachythecium oedipodium* (Figure 45) and *Plagiothecium laetum* (Figure 46) with higher N, P, or Mg (van Dobben *et al.* 1992). Increases in productivity and growth of bryophyte species can lead to changes in community structure.

Figure 45. *Brachythecium oedipodium* increased its productivity in fertilizer experiments with N, P, and Mg. Photo by Michael Lüth, with permission.

By contrast, Skré and Oechel (1979) found that *Hylocomium splendens* (Figure 4) and *Pleurozium schreberi* (Figure 44) in the black spruce (*Picea mariana*; Figure 47) forest near Fairbanks, Alaska, did not increase in cover with fertilizer additions, suggesting that nutrients were already more available than in the pine-heath system studied by Persson (1981) or that these populations were

adapted to lower nutrient levels. Jäppinen and Hotanen (1990) found that these common boreal species, also including *Dicranum* (Figure 48) and *Sphagnum* (Figure 52) species, were killed by fertilizer applications designed to improve timber yield, but that *Polytrichum commune* (Figure 49) seemed unaffected. The overall effect, then, of the addition of nutrients is that species that are typical of poor sites (lichens, Ericaceae, feather mosses) shift toward associations of species typical of rich sites (Poaceae and litter-inhabiting mosses).

On the other hand, disappearance of *Rhytidiadelphus squarrosus* (Figure 50) was not coupled with an increase in tracheophyte cover in either acidic or calcareous grassland (Morecroft *et al.* 1994). Rather, it appears to have responded to additions of NH_4NO_3 or $(\text{NH}_4)_2\text{SO}_4$ (ammonium sulfate) additions through disruption of its N metabolism (Bates 2000).

Figure 50. *Rhytidiadelphus squarrosus* with competing vascular plants. Photo by Michael Lüth, with permission.

Peatlands can respond differently in different geographic regions. Aerts and coworkers (1992) attributed the lower productivity of northern Swedish peatlands compared to those in southern Sweden to the 10X greater input of atmospheric N in the southern location. They supported this hypothesis by adding N and P at both sites. At the northern site, added N increased productivity 4-fold, but added P had no effect. Conversely, at the southern site, added N ($4 \text{ g m}^{-2} \text{ yr}^{-1}$) had no effect on productivity, whereas adding P ($0.4 \text{ g m}^{-2} \text{ yr}^{-1}$) increased productivity 3-fold. This trend is likewise supported by comparing a low and high deposition site in the Netherlands. Atmospheric N deposition there has been increasing, causing peatlands to increase in available N (Limpens *et al.* 2003). This increase in N seems to have coincided with an increase in *Sphagnum fallax* (Figure 52). However, Limpens *et al.* could find no evidence that *S. fallax* outcompeted any of the other five *Sphagnum* species in the area. Nevertheless, when N was added at a low deposition site, this species did expand its coverage. They determined that at the high deposition site *S. fallax* was limited by P. They concluded that when the capitulum N concentration is raised to 7 mg

L^{-1} or higher and the P concentration is 0.7 mg L^{-1} or higher, this species can increase and dominate.

Li and Vitt (1997) found that while moss productivity increased 4-300% with N enrichment ($3 \text{ g m}^{-2} \text{ yr}^{-1}$ as NH_4Cl), the productivity of the peatland shrubs *Betula pumila* (Figure 20) and *Rhododendron (=Ledum) groenlandicum* (Figure 19) did not. In fact, they concluded that the moss layer immediately retained nearly all of the added N. Likewise, Bayley *et al.* (1987) found that when N was added to a boreal peat system in the form of NO_3^- , 90% was taken up by the *Sphagnum* lawn (Figure 51) within 24 hours, resulting in a growth increase by the *Sphagnum*. No growth increase occurred in the tracheophytes, even after five years of experimentation (Vitt 1991). Sanville (1988) likewise found that *Sphagnum* production increased in response to nutrient addition.

Figure 51. *Sphagnum* lawn. Photo through Creative Commons.

Figure 52. *Sphagnum fallax*. Photo by Michael Lüth, with permission.

In the high Arctic heath, bryophytes are a major ecosystem component. When N and P were added to that system for eight years, there was no change in bryophyte cover, but physiological processes shifted in the bryophyte layer (Gordon *et al.* 2001). Only $10 \text{ kg ha}^{-1} \text{ yr}^{-1}$ of N increased the proportion of physiologically active bryophyte shoots while decreasing their capacity to assimilate NO_3^- . Effects of added P were even greater. When both nutrients were added, the species composition changed, with some bryophytes increasing in abundance

and others decreasing. Since N and P are both limiting in this Arctic system, increasing either will have an effect on the ecosystem. Thus, if mineralization increases as a result of global warming, we can expect shifts in the community structure of the Arctic ecosystems.

Predicting the behavior of tundra and peatland communities is not simple. Chapin and Shaver (1989) found that in Alaska the mosses (and lichens) had the greatest N and P use efficiency, but, unlike deciduous leaves, declined in N use efficiency with the addition of N plus P. Nevertheless, they can be efficient scavengers of available N, competing effectively with tracheophytes. In the Arctic tundra, Marion and coworkers (1987) found that litter recovered 1.3-16.3% and mosses 5.4-16.4% of labelled N, whereas above ground tracheophytes recovered only 2.6-5.0%. Although we tend to think of the tundra as being nutrient limited, it appears that it may not be nutrient limited for the mosses. Oechel and Sveinbjörnsson (1978) found that the addition of a dilute nutrient solution to the mosses there did not increase photosynthetic productivity or growth. One reason for this lack of response, or even decline in productivity, upon the addition of nutrients is that NO_3^- causes the induction of nitrate reductase activity, as shown for *Sphagnum fuscum* (Figure 6-Figure 7) by Woodin and coworkers (1985). Thus it appears that the feedback system controls the N levels in the mosses (see above under N Additions). Skré and Oechel (1979) likewise found that *Hylocomium splendens* (Figure 4) and *Pleurozium schreberi* (Figure 44) did not increase productivity after fertilizer additions, but surprisingly, *Sphagnum capillifolium* (Figure 17) did. Perhaps its position high in the hummock is less suitable than other locations for the N-fixing Cyanobacteria that maintain N levels in bogs and fens.

In some habitats, increasing the nutrient content can shift dominance from cryptogams, including mosses, to tracheophytes (van Dobben *et al.* 1992). When N (as NH_4NO_3) was added to a forest ecosystem in Sweden in an 18-year experiment, cryptogams, including the soil mosses *Pleurozium schreberi* (Figure 44) and *Hylocomium splendens* (Figure 4), and the heath family Ericaceae lost dominance to the grass *Deschampsia flexuosa* and **ruderal** (disturbed habitat) species. Both bryophytes were strongly "disfavored" by the addition of N at all levels. The other additions (P, K, Mg, S, and micronutrients) had similar effects but to a much smaller degree. *Pleurozium schreberi* was disfavored by S and micronutrients. Added P and N significantly stimulated the growth of *Pseudoscleropodium purum* (Figure 54), whereas *Brachythecium rutabulum* (Figure 53) did not respond (Bates 1994). The *P. purum* plants showed a greater uptake of P and to a lesser extent N than did the *B. rutabulum* while also conserving them more efficiently. Bates explained this difference in that *P. purum* depends on an unpredictable supply of nutrients from precipitation, whereas *B. rutabulum* probably obtains more of its nutrients from its substrate. Some nutrients are sequestered onto cell wall exchange sites of *P. purum* and taken up later as needed.

Figure 53. *Brachythecium rutabulum*. Photo by Michael Lüth, with permission.

Figure 54. *Pseudoscleropodium purum*, a species for which added P and N significantly stimulated the growth. Photo by Janice Glime.

Natural fertilizers have their effects too. Vanderpuye and coworkers (2002) suggest that fertilization by vertebrates may account for the type of moss tundra seen in Svalbard. Manuring of very cold ecosystems by seabirds (Figure 55) produces moss carpets characterized by a thin active layer over a thick accumulation of peat with no standing water. They suggest that in Sassendalen the role of the seabirds is replaced by reindeer (Figure 56) that create intense manuring in these favorable grazing areas.

Figure 55. Little Auks (*Alle alle*) on Svalbard, a source of manuring that provides nutrients for mosses. Photo by Alastair Rae, through Creative Commons.

Figure 56. Reindeer, large numbers that can contribute to manuring that provides nutrients for bryophytes. Photo by Roger S. Key, with permission.

In the boreal forest, it appears that effects of added nutrients on bryophyte community structure can be long lasting. Even 47 years after N fertilization ceased, the community structure had not returned to pre-fertilization composition (Strengbom *et al.* 2001). *Brachythecium reflexum* (Figure 57) and *Plagiothecium denticulatum* (Figure 58) had increased. On the other hand, the typically abundant *Hylocomium splendens* (Figure 4) had decreased relative to controls. At the same time, there seemed to be no difference in species composition of tracheophytes, but the sporocarp production of the N-sensitive mycorrhizal fungi had decreased.

Figure 57. *Brachythecium reflexum*, a species that increased following N fertilization. Photo by Michael Lüth, with permission.

Figure 58. *Plagiothecium denticulatum*, a species that increased following N fertilization. Photo by Michael Lüth, with permission.

Summary

Fertilizers typically harm bryophytes by benefitting their tracheophyte competitors. They can also raise the pH, creating conditions unfavorable for bryophytes. Only in the Arctic do fertilizers sometimes seem to benefit bryophytes, where nutrients are low and cool temperatures favor bryophyte growth. Fertilizers such as $\text{Ca}(\text{NO}_3)_2$ cause a decrease in the lipids that are needed for tolerance of cold and desiccation, whereas cold temperatures increase them.

Increases in N, especially as nitrate, increases the chlorophyll content in some species, such as *Thuidium tamariscinum*, while causing others, such as *Hylocomium splendens*, to turn brown. Peatland mosses often respond positively to N addition (as NH_4NO_3) while shrubs decrease. Ammonium is toxic, and the amino acid and nitrate balance must be such that it does not inhibit the conversion of NH_4^+ to amino acids. Light is needed for nitrate reductase to work, converting the nitrate to nitrite, which is then converted by nitrite reductase to ammonia and placed into amino acids. CO_2 is often limiting, making the addition of nutrients of little value. High N levels can also deplete the oxygen, preventing P uptake.

Added P seems to benefit aquatic mosses, at least in Alaska, causing an increase in bryophytic cover. Nevertheless, when N and P are added together, they can cause a decrease in productivity, even though each of these benefits when added alone.

Although Ca^{++} is an essential nutrient, it is usually harmful to bryophytes, interfering with uptake of other cations. Ca^{++} and Mg^{++} compete with each other for exchange sites and can reduce the uptake of K^+ .

CO_2 is especially limiting in aquatic environments, especially in warm weather. Under good photosynthetic conditions, iron can form iron oxide on the surface of bryophytes due to the high oxygen concentration resulting from photosynthesis.

Heavy metals, typically added from industrial air pollution, are usually detrimental to bryophytes, often causing loss of chlorophyll and brown tips.

Natural fertilization by seabirds and mammal dung favors the development of some species, especially in the tundra. On the other hand, added fertilizers in the boreal forest can depress bryophyte productivity for many decades.

Acknowledgments

I appreciate the contributions of undergraduate Phil Gaudette and M. S. student Jennifer Jermalowicz Jones for their critical reading of the manuscript from the perspectives of students interested in nutrient relationships of bryophytes.

CHAPTER 8-8

NUTRIENT RELATIONSHIPS: CYCLING

Figure 1. Nutrients may be tied up in bryophytes for decades, or recycle within months, in forests with abundant bryophytes, as in this forest with *Isoetes myosuroides*. Photo by Michael Lüth, with permission.

Storage and Release

Bryophytes are of particular importance in cold biomes and tropical forests (Cornelissen *et al.* 2007). In these ecosystems, they offer a number of important contributions:

1. They are substantial members of the above-ground biomass, often along with lichens.
2. They host N-fixing bacteria, thus providing a major soil N input.
3. They control soil chemistry and nutrient availability through their leakage of recalcitrant polyphenols, control of soil hydrology, and temperature modification.
4. They erode rocks but prevent soil erosion.
5. They provide food for animals.
6. They both protect and compete with tracheophytes.

In all of these roles, they influence the nutrient cycling of these ecosystems.

Few quantitative studies have addressed the role of bryophytes in ecosystem nutrient cycling (Brown & Bates 1990). Nevertheless, bryophytes may play a significant role in the retention and release of important limiting nutrients like nitrogen in many types of ecosystems (Figure 1). Nutrients collected from aerial dust and throughfall are returned to the ecosystem from bryophytes through leaching and decomposition. Bowden (1991) found that in primary succession on exposed **New Hampshire sands**, the rate of nitrogen accumulation in *Polytrichum* (Figure 2) was $10.1 \text{ kg ha}^{-1} \text{ y}^{-1}$. Even for this endohydric moss, he found that 58% of the annual input of nitrogen is from bulk precipitation. As suggested by this study, the bryological component of the ecosystem often plays a significant role in nutrient cycling (During 1990; Bates 1992; Nakatsubo 1997). When the *Polytrichum* was removed from the soil, nitrogen losses from the ecosystem temporarily exceeded

inputs, underlining the importance of the mosses in sequestering and holding nitrogen at the site. Lamontagne (1998) found that nitrification increased 13-fold under lichen and moss patches. In this case, the lichens did not fix atmospheric nitrogen and thus did not contribute directly to the nitrogen supply. Without the mosses (and lichens), the nitrogen from precipitation and throughfall can be lost to surface water that ultimately ends up in waterways and is carried from the local system. Furthermore, the mosses and lichens can contribute organic acids that leach nitrogen from the underlying bedrock, thus making it available to plants.

Figure 2. *Polytrichum commune*, a species that accumulates carbon in growing shoots and brown portions. Photo by Andrew Spink, with permission.

Only in **peatlands and the polar latitudes** have most ecosystem ecologists traditionally acknowledged the role of the bryophytes in storing or releasing nutrients. Nevertheless, bryophytes play several roles in the nutrient status of their native ecosystems. Whereas tracheophytes obtain nutrients only after mediation by the soil, most bryophytes obtain nutrients before they reach the soil.

The **boreal** feather moss *Hylocomium splendens* (Figure 3) in a subarctic birch woodland has a retention time of 3-10 years for N, transporting the N within the plant to the growing tips (Eckstein 2000). Such a retention can have a strong impact on the nutrient dynamics of a forest with 100% bryophyte cover on the forest floor.

Figure 3. *Hylocomium splendens*, a feather moss. Photo by Michael Lüth, with permission.

In the **Alaskan black spruce forest** (Figure 4), the bryophyte layer intercepts and accumulates more of every nutrient element but Ca^{++} than it receives from throughfall and litter (Oechel & van Cleve 1986), again suggesting that soil nutrients are also contributed. In the boreal forest, bryophytes are limited in biomass, but they nevertheless are major contributors to cover and primary productivity (Oechel & van Cleve 1986). They furthermore act much like a sponge in their ability to take up nutrients rapidly. Their further ability to modify the soil temperature and prevent permafrost makes them major ecosystem engineers for the nutrient regime.

Figure 4. Black spruce (*Picea mariana*) forest at Arctic Chalet, Inuvik, NT. Photo through Creative Commons.

Even in **tropical forests**, where trees can create up to five levels of canopy, the "insignificant" bryophytes can be significant in altering the nutrient regime. The bryophytes serve as filters for nutrients in rainfall, throughfall, and stemflow. This role is a complex one, differing among species of bryophytes, seasons, state of hydration, and types of nutrients (Glime 2001).

Working in **chalk grasslands**, During (1990) suggested that even when bryophytes are patchy they have a major impact on nutrients and tracheophytes associated with them, particularly during partial dieback and decomposition in the summer months. In chalk grasslands, bryophytes grow and absorb nutrients during autumn and winter, thus not competing with the inactive tracheophytes. They release nutrients by decomposition in spring and summer, hence serving to sequester nutrients in the ecosystem and provide them to the tracheophytes when nutrients are needed most for growth. It is clear that we cannot afford to ignore their potential role in ecosystem-level nutrient cycling.

Storage Locations

Many factors determine where nutrients are stored in bryophytes. External storage on exchange sites provides a ready supply as nutrients are used within the cells. Storage in underground stems can provide nutrients for new growth in spring. And many compounds are stored structurally, making them unavailable until the slow process of decomposition once again releases them.

Methodology Matters

Because of their tremendous surface area, bryophytes are typically "contaminated" with surface dust. This presents serious problems when trying to assess their nutrient content. While it seems obvious that washing would reduce the problem, it brings problems of its own. The success of washing mosses has rarely been quantified. Hence, degree of removal can vary widely between samples and researchers. And some species, with retentive sites such as boat-shaped leaves or clasping bases, will retain more soil particles than others. Furthermore, particulate matter may partially solubilize in the wash and could increase uptake. On the other hand, if the adhering dust contains sulfur or nitrogen oxides, the resulting acids could cause the loss of ions by leaching. The sudden change in ionic balance can have unpredictable influence on the adhering portion (*i.e.* those on exchange sites), causing a shift in the nutrient component of the bryophyte.

Published studies on the nutrient content of bryophytes have used a variety of methods, and one must assess the method to determine if the values given are appropriate for the interpretation needed. Lack of attention to bound ions on the moss surface can give misleading values.

Studies indicating locations of nutrient concentrations of bryophytes often do not provide a true picture of those constituents within the cells. Rather, they include the numerous ions located on exchange sites on the surfaces of the plant. Hence, in reviewing nutrient concentrations we must pay particular attention to the methods in separating the external from the internal components. Nevertheless, both internal and external storage have an impact on the nutrient cycling of the ecosystem.

Determining the positions of ions on and in bryophytes is largely a chemical process. Two different methods have revealed similar locations. Brehm (1968, 1970) found those located on the extracellular exchange sites by displacing the cations with 0.01N mineral acids. He followed this with formaldehyde to rupture the cells, releasing the internal soluble ions. The remaining cations were displaced with normal acid. Brown and coworkers used 1000 mg L⁻¹ Sr (Bates & Brown 1974) or Ni (Brown & Buck 1978a, b, 1979) to displace the bound extracellular cations, followed by boiling to release soluble ions, and then recovering residual material by a total digestion in concentrated HNO₃. Both groups found that Na⁺ and K⁺ occurred in the cytosol, while Ca⁺⁺ remained largely as an extracellular exchangeable form on plant external and intercellular surfaces. This makes sense because a major role of Ca⁺⁺ is in forming calcium pectate bonds to cement cell walls together. Mg⁺⁺ and Zn⁺⁺ showed intermediate patterns of location. Nevertheless, a complete understanding of affinities is necessary to interpret the concentrations. Brown and Bates (1972) used Ni to replace Pb, but later Brown (1982) pointed out that they had failed

to release all the Pb from exchange sites and that a concentration greater than 1000 mg L⁻¹ would be needed to remove elements like Pb that have a very high affinity for exchange sites.

Mineral Nutrients

Several studies have identified the locations where bryophytes store mineral nutrients. Brown (1982) states that in general the monovalent cations, *e.g.* K⁺, are concentrated near the apex and the divalent elements toward the base. We also know that in tracheophytes N, P, K, Mg, and Cl move easily due to greater solubility, whereas B, Ca, and Fe are relatively insoluble and immobile. One of the factors contributing to high concentrations of ions of such elements as Al, Ca, Fe, and Mn in older segments is that as cells die or other ions move to the apex, new binding sites are exposed, permitting more of these ions to accumulate there.

Brown and Buck (1985) likewise found that K⁺ resided in the cytosol of *Grimmia donniana* (Figure 5) and *Calliergonella cuspidata* (Figure 6), whereas Ca⁺⁺ and Pb⁺⁺ were in extracellular exchangeable forms. Mg⁺⁺ and Zn⁺⁺ seemed to be intermediate in behavior, with locations depending on the species and total element concentration.

Figure 6. *Calliergonella cuspidata*, a species in which K⁺ resides in the cytosol and Ca⁺⁺ and Pb⁺⁺ in extracellular locations. Photo by Michael Lüth, with permission.

What We Learned from Heavy Metals

Much of our knowledge of ion storage locations is derived from storage of heavy metal contaminants in the environment. For example, *Rhytidiadelphus squarrosus* (Figure 7) stores Pb in electron-dense regions of the plasma membrane, in vesicles, vacuoles, chloroplasts, and nuclei, and in the cell wall (Gullvåg *et al.* 1974; Ophus & Gullvåg 1974; Skaar *et al.* 1973). But *Hylocomium splendens* (Figure 3) in the same study only contained electron dense regions in the cell wall (Gullvåg *et al.* 1974). The researchers reasoned that the thicker cell wall of *H. splendens* might prevent entry.

Figure 7. *Rhytidiadelphus squarrosus*, a species that stores lead in its plasma membranes. Photo by Michael Lüth, with permission.

In the aquatic moss *Platyhypnidium riparioides* (Figure 8), Cu accumulates in three locations: intercellular in the cell wall free space, exchange sites on the cell wall, and residual within the cell (Mouvet & Claveri 1998). These three locations are those we should expect to hold most of the cations of a bryophyte, suggestion that heavy metals like Cu could compete with nutrients needed in greater quantity.

Figure 8. *Platyhypnidium riparioides*, a species that is able to store copper in the cell wall free space, on exchange sites on the cell wall, and residual within the cell. Photo by Michael Lüth, with permission.

Oil and Lipid Bodies

Oil bodies (isoprenoid essential oils; Figure 9-Figure 13) are well known in leafy liverworts, providing distinct diagnostic characters and provide distinctive odors, yet their function seems to remain unknown (He *et al.* 2013). Speculation includes protection from herbivores (Stahl 1888), pathogens, cold temperatures, excessive light (Hieronymus 1892), and UV radiation and desiccation (Gavaudan 1927; Chalaud 1931). These oil bodies are often associated with bryophytes that live in high light, but no physiological studies have demonstrated that they in fact make a difference. Perhaps the best argument for considering them to be food reserves is that most seeds store lipid droplets as a food reserve that is used for germination and subsequent growth (Huang *et al.* 2009).

Nevertheless, the oil bodies of liverworts seem to have an important function in cell metabolism (He *et al.* 2013). Understanding it may help us to understand how these plants tolerate their environment. But is that tolerance to light, desiccation, low temperatures, periods of low nutrients, herbivores, or something else?

More recently, Pressel *et al.* (2009) described the role of liverwort oil bodies in desiccation tolerance. These are well known to "disappear" when the liverworts are dried, thus disappearing in herbarium specimens. However, in their study, Pressel and coworkers found that instead they become unchanged in the dry state, but become flattened upon rewetting. Then, after 48 hours, they regain their normal morphology. Nevertheless, if they are dried too quickly, the oil bodies do indeed vanish upon rewetting and do not reappear. The abilities of these oil bodies to recover as flattened bodies under natural conditions, then regain their shape after 48 hours of recovery suggests that they may shift soluble carbohydrates or other important substances into the cytoplasm, permitting rapid recovery of the cell from drought.

Some mosses may also develop similar structures. Huneck (1984) reported that in mosses these are comprised of lipids, not oil drops. Jönsson and Olin (1898) reported that these lipids occurred only in certain taxonomic groups and exhibited seasonal variation. Among 50 species in Sweden, the contents varied widely, but they generally produced maximum concentrations in spring and autumn during their growth periods. These mosses furthermore lack the distinctive odors exhibited by many liverworts (Lorch 1931).

In mosses, the lipid drops occur in such varied locations as alar cells, basal laminal cells, upper laminal cells, and costa, sometimes occurring in all of these in the same leaf (Frahm 1994). But when present in the **Dicranaceae** (Figure 19), they consistently occur in basal laminal cells, but may also occur elsewhere. Frahm made one interesting discovery in the herbarium specimens he assessed – the lipid bodies tended to be most frequent in specimens collected in the cold season, at high elevations and Arctic regions. If you want to explore these further, they become more visible with a Fuelgen reaction using wet mosses treated with Schiff's reagent; this gives the lipid bodies a deep violet color.

Figure 19. *Dicranum scoparium* leaf base cells showing fat droplets. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Des Callaghan (Bryonet 30 July 2013) reported large oil droplets in the cells of the perichaetial leaf of *Diphyscium foliosum* (Figure 20-Figure 22). Ida Bruggeman (Bryonet 31 July 2013) reported that members of *Fissidens* will often produce several small, shiny droplets, a common occurrence in the *Fissidens* subgenus *Aloma* (Figure 23-Figure 24). Frahm (1994) reported that oil drops in laminal cells of **Dicranaceae** (Figure 19) were taxonomically important and considered these to serve as a means of storage in the species that had them. It is likely that all of these apparent "oil droplets" are in reality fat droplets.

Figure 24. *Fissidens exilis* leaf cells showing fat/oil droplets. Photo by Malcolm Storey, through Discover Life, with online permission.

Silvana B. Vilas Bôas-Bastos (Bryonet 31 July 2013) reported observing oil/fat droplets in the basal cells of the *Dicranella hilariana* (Figure 25). Rut Caparrós (Bryonet 8 August 2013) reported seeing large oil droplets in the vaginula of *Ulota* when the sample is crushed under the cover glass. Alison Downing (Bryonet 1 August 2013) saw what appeared to be oil bodies in *Chrysoblastella chilensis* (Figure 26-Figure 27), but was discouraged by colleagues who said mosses didn't have oil bodies. However, Matteri (1984) reported starch grains and what appeared to be oil drops in *C. chilensis* in the central tissue of tubers and postulated that they might serve as a means of perennation. She noted that these tubers do not readily separate from the stems and thus considered it unlikely that the tubers served in dispersal. Allan Fife (Bryonet 4 August 2013) described these tubers in New Zealand as common in axils of lower stems in this species.

As the bryophytes remain dry for longer periods of time, these oil/fat droplets gradually become smaller (Frahm 1994), disappearing rapidly in liverworts. In the *Dicranaceae* (Figure 19, Figure 35), however, they make take 8 years to completely disappear, slowly becoming smaller. In the leafy liverworts, the species that live in dry habitats manage to keep their oil bodies longer, making it possible to see them even in herbarium specimens.

Figure 27. *Chrysoblastella chilensis* leaf margin cells showing oil/fat droplets. Photo by Tom Thekathyl, with permission.

Rod Seppelt (Bryonet 31 August 2013) observed that when cutting stems of some species of *Bryum* (Figure 28), vast quantities of lipids were released – perhaps the same

as those substances being interpreted as oil droplets in moss leaves. It appears that we need help from the biochemists to determine what these substances are. Then we need ecophysiologists to determine their use to the bryophytes and ultimate role in nutrient cycling.

External Storage

Bryophytes do not need to store nutrients internally to have an impact on the ecosystem. Their ability to simply trap dust and retain it within the mat can be useful to some taxa while depriving others. Trapped soil and retained nutrients are apparently essential for some epiphytic taxa, especially in the tropics (Pocs 1982). This role has already been reported for orchids in Madagascar, where the moss *Leucoloma* (Figure 29) provides both the substrate and the nutrient source for epiphytic orchids (La Farge 2002).

Figure 29. *Leucoloma triforme* on bark, a moss genus that helps to support epiphytic orchids. Photo by Michael Lüth, with permission.

Rooting in epiphytic mosses is now known for trees! The koa tree (*Acacia koa*) in Hawaii produces nodules containing the N-fixing *Bradyrhizobium* (Figure 30) on adventitious roots (those arising above ground), but much larger and more abundantly, in the mosses growing in lofty places on the same tree (Figure 33-Figure 33; Leary *et al.*

2004)! These mossy habitats trap organic soils largely derived from decomposing heartwood and leaf litter of the host tree and contain significantly higher concentrations of exchangeable cations, total N, and significantly lower Al than the terrestrial soils. Is it the nutrients, the reduced Al, the moisture-holding capacity of the moss, or some moss exudate that stimulates these large nodules? Most likely it is the combination.

Bryophytes as Nutrient Sinks

Storage of nutrients in older parts or placing them in structural compounds can result in **nutrient sinks**. These serve as reservoirs that accumulate and store a nutrient; these sinks may result from continually transporting nutrients to new tissues, storing them in older tissues (Figure 34), or binding them in incalcitrant compounds. In any case, the sink makes the nutrient unavailable to other components of the ecosystem.

Figure 34. *Dicranum elongatum* showing brown senescent tissues where insoluble nutrients may remain for many years. Photo by Michael Lüth, with permission.

By trapping nutrients from the throughfall before they ever reach the soil, bryophytes serve as nutrient filters. This leads us to ask their role in parcelling out nutrients to the soil. Do bryophytes serve as nutrient sinks, and if so, do they eventually return their nutrient store to the forest soil? It may be too early to make generalizations, but let us consider some examples.

First of all, we know that bryophytes store their nutrients in structural compounds as well as within localized positions within the leaf cells. For example, Bakken (1995) pointed out that in *Dicranum majus* (Figure 35) N is stored in proteins and in chlorophyll. These organic components may be maintained within the moss for a long time, particularly while it is still alive. We have already seen that bryophytes move nutrients from old to

young tissues, thus depriving the soil of these nutrients through the pathway of decay.

Figure 35. *Dicranum majus*, a species that stores nitrogen in proteins and chlorophyll. Photo by Michael Lüth, with permission.

In an old-growth Douglas fir forest (*Pseudotsuga menziesii*; Figure 36), where bryophytes occupied only 0.13% of the total forest biomass, they contributed 20% to the biomass and 95% to photosynthetic tissue of the forest floor (Binkley & Graham 1981). Their biomass contribution of 1075 kg ha⁻¹ was composed of 92% *Eurhynchium oregonum* (Figure 37) and 7% *Hylocomium splendens* (Figure 3). The canopy throughfall contributed 3 kg ha⁻¹ yr⁻¹ N. By adding the moss component, Binkley and Graham added 10% to the estimates of understory N uptake.

Figure 36. *Pseudotsuga menziesii* forest. photo by Dave Powell, through Creative Commons.

Figure 37. *Eurhynchium oregonum*. Photo by Matt Goff <www.sitkanature.org>, with permission.

In an Alaskan black spruce (*Picea mariana*; Figure 4) forest, *Sphagnum* (Figure 64-Figure 66), *Hylocomium splendens* (Figure 3), and *Pleurozium schreberi* (Figure 38) have a higher capacity to absorb phosphate than do the fine roots of *Picea mariana* beneath them (Chapin *et al.* 1987). In boreal ecosystems, mosses can take up to three times as much N, P, and Mg as can *Picea mariana* (black spruce) (Figure 40; Oechel & van Cleve 1986) and add 5% to Ca^{++} and K^{+} uptake (Binkley & Graham 1981). Oechel and van Cleve (1986) contend that mosses have a major impact on both nutrient availability and soil temperature, competing with the trees and shrubs for available nutrients. But the question that remains is whether the mosses ultimately return them to the forest soil, thus serving as temporary sinks that release the nutrients when the mosses are dry and dormant. Since many bryophytes are dormant in the summer when the trees are growing, they may serve as reservoirs, providing nutrients at the most crucial time in the fall when the soil is depleted and rains return to leach the nutrients from the bryophytes. On the other hand, it appears that *Polytrichum*, perhaps through use of rhizoids for nutrient uptake, must compete with the fine roots near the surface and thus had the lowest P absorption rate of the four mosses studied in the spruce forest (Chapin *et al.* 1987). *Polytrichum commune* (Figure 39) exhibits translocation of nutrients to younger segments and ramets.

Figure 40. Comparison of annual nutrient uptake by mosses and black spruce trees (*Picea mariana*). Figure based on Oechel & van Cleve 1986, in Glime 2001.

In a different northern black spruce forest in Canada, feather mosses, primarily *Pleurozium schreberi* (Figure 38), sequestered 23-53% of the nutrient uptake estimated for their associated trees (Weetman & Timmer 1967). They prevented nutrient return to the tree roots by retaining those nutrients that reached the mosses as throughfall from canopy leachates. However, despite their sequestering of throughfall nutrients, Weetman and Timmer considered that the mosses were the major source of N for the trees because the mosses were able to accumulate nutrients on the shallow soils of these rocky sites. Weetman (1968) supported this hypothesis by demonstrating that there is a greater concentration of black spruce roots under the moss patches than elsewhere.

Weber and van Cleve (1984) demonstrated that feather mosses, primarily *Hylocomium splendens* (Figure 3) and *Pleurozium schreberi* (Figure 38), in the Alaskan black spruce (*Picea mariana*, Figure 4) forest can retain much of the N that enters the system and release it very slowly to the underlying organic layers, *i.e.* the root zone. But the return is very slow indeed. They found that the deeper layers of soil had incorporated little of the labelled N even three years later. It appears that N storage may work differently from that of other nutrients. In the two most common feather mosses, *Pleurozium schreberi* and *Hylocomium splendens*, 90% of the labelled N could still be recovered in the mosses 28 months after application (Weber & van Cleve 1981). One reason for such a high retention is that these species are able to move their N from older, senescing branches, to young ones (Eckstein & Karlsson 1999); 50% of the labelled N was missing from older branches, all of which could be accounted for in the younger branches.

Behaving in a manner similar to tracheophytes, *Hylocomium splendens* (Figure 3) in a dry pine forest in Latvia was able to move Mg^{++} , but not Ca^{++} , from brown and decaying segments toward the tips in autumn when it was dry (Brümelis *et al.* 2000). However, both elements were tightly held in green portions with no evidence of return to the environment through leaching. Such sequestering of N, Mg, and Ca would create a sink where

throughfall nutrients might not reach the forest floor for years or even decades, rather than days or weeks. Oechel and van Cleve (1986) suggest that in Alaska bryophytes have such great ability to immobilize nutrients that they can reduce tracheophyte productivity as succession proceeds from deciduous to coniferous woodland.

After 13 years of primary succession in a New Hampshire, USA, **sand pit** that had previously been a mature hemlock-maple-yellow birch forest (*Tsuga canadensis*-*Acer saccharum*-*Betula alleghaniensis*), there was a $10.1 \pm 1.9 \text{ kg ha}^{-1} \text{ yr}^{-1}$ N accumulation in 50-60 cm of soil beneath *Polytrichum* spp. (Figure 39) (Bowden 1991). The N content in the 50 cm of soil beneath the *Polytrichum* had increased from $98 \pm 7 \text{ kg ha}^{-1}$ in 1969 to $229 \pm 26 \text{ kg ha}^{-1}$ in 1982. Bowden reasoned that since the accumulation rate of N was probably much lower during early years in succession, it is likely that the accumulation rate later in succession was even higher than this. Surprisingly, the N content of living biomass of moss below ground was higher than that of above ground portions, with the soil portion accounting for ~55%. Presence of the moss seems to have accounted for a significant trapping and retention of N in the ecosystem, perhaps preparing the environment for success of larger and more N-demanding plants.

In the **chalk grassland**, bryophytes are able to absorb nutrients from the senescing autumn leaves. These nutrients would probably otherwise be leached from the system while the tracheophytes are inactive for the duration of winter (van Tooren *et al.* 1988). These leachates, incorporated into the bryophytes, are then released in the spring and summer from the decomposing bryophytes and used by the high-demand tracheophytes. Furthermore, bryophytes can act as sponges for the N in acid rain during winter when tracheophytes are unable to absorb it. We should expect that bryophytes in many temperate forests likewise are able to act as nutrient reservoirs, storing nutrients and releasing them in the hot, dry summer when availability is low due to tracheophyte demands.

In the **temperate forest**, bryophytes may be rare or abundant. In those forests where they are abundant, they could likewise play the role of a nutrient reservoir. However, the *Pseudoscleropodium purum* (Figure 41) in European **oak forests** demonstrates a different dynamic from that of the bryophytes in the boreal forest. Bates (1989b) found that the levels of cations within the moss component under an oak (*Quercus*; Figure 42) canopy were in dynamic equilibrium with the precipitation and/or throughfall (Bates 1989b; Brown & Bates 1990).

Figure 41. *Pseudoscleropodium purum*. Photo by Michael Lüth, with permission.

Figure 42. European oak (*Quercus*) forest understory habitat. Photo through Creative Commons.

The dominant and invasive moss *Pseudoscleropodium purum* (Figure 41) readily absorbed the natural leachates of K^+ , Ca^{++} , and Mg^{++} , particularly as the tree leaves were senescing in autumn (Bates 1989a, b). When sprayed with dilute solutions containing Ca^{++} , K^+ , and Mg^{++} , this moss absorbed most of the cations, but those that were not absorbed were released back to the ecosystem through the remaining growing season (Bates 1989a). The bulk of these were released during the next 10-15 days. Bates tracked P and K in *P. purum* for 74 days after application and found that only 6.3% of the P and 12.1% of the K were recovered in the moss throughfall, reaching the soil. But only 31% and 23%, respectively, remained in the moss tissues. Bates (1989a) suggested that the missing nutrients may have been incorporated by microorganisms or retained in litter. A likely consequence of this is rapid recycling of nutrients within the ecosystem.

Ecologists have theorized that bryophytes may behave like a slow-release fertilizer. They remove nutrients from the precipitation as it passes through them, then slowly release it during the succeeding weeks. This may be facilitated by the damage caused to membranes during drying. In other cases, cations bound to exchange sites may be released back to the ecosystem instead of being absorbed. This slow release mechanism can be beneficial to the ecosystem by reducing loss through leaching and providing a steady supply of nutrients as they are being removed by the roots. But there seem to be no data thus far to support or refute this hypothesis on a broad scale.

Just as in tracheophytes, we cannot generalize about bryophyte nutrient behavior because bryophytes exhibit differences as vast as those of tracheophytes, perhaps even more so. *Hylocomium splendens* (Figure 3), likewise a large moss, growing on a lime-contaminated site, did not release its excess Ca^{++} and Mg^{++} when moved to an uncontaminated site (Brümelis *et al.* 2000). Hence, bryophytes can serve as sinks, depriving the soil of nutrients returned by throughfall and stemflow. Since bryophytes tend to grow best, at least in deciduous forests, at the bases of trees where stemflow provides a concentrated pool of nutrients from leaves, branches, and atmosphere, this bryophytic filter could have considerable impact on both the nutrients supplied to the trees and on the herbaceous ground cover in the vicinity. Their presence at tree bases seems to be due to the slight rise in topography that reduces leaf litter accumulation, but could it also be due to the added nutrients?

In a North Wales oak (*Quercus petraea*; Figure 43) woodland, the dominant bryophytes were *Dicranum majus* (Figure 35), *Rhytidiadelphus loreus* (Figure 44), *Plagiothecium undulatum* (Figure 45), *Polytrichastrum formosum* (Figure 46), and *Thuidium tamariscinum* (Figure 47), occupying 90% of the ground vegetation standing crop (Rieley *et al.* 1979). These species were investigated to determine the effects of moss harvesting on the ecosystem. This moss layer readily absorbed the Ca^{++} , K^+ , and N leached from the canopy (Table 1). It is interesting that *Rhytidiadelphus* removed NO_3^- whereas *P. formosum* removed NH_4^+ . However, Mg^{++} suffered a net loss from the bryophyte layer to the soil. *Rhytidiadelphus loreus* actually returned more Mg^{++} to the soil than it intercepted, but removed Ca^{++} and K^+ , perhaps exchanging some of these for Mg^{++} on exchange sites.

Polytrichastrum formosum (Figure 46) seemed to have little effect on nutrient concentrations, with leachates from the moss equalling those in the canopy throughfall for Ca^{++} , K^+ , Mg^{++} , and Na^+ (Rieley *et al.* 1979). In any case, a large portion of these nutrients were returned to a pathway that would make them available to the root zone. This suggests once more the role of bryophytes as a reservoir for at least some nutrients, providing a slower

release than that of episodic throughfall, a role also supported in the Black Forest (Weetman 1968). Clearly, we need to understand the differences in nutrient retention among species and what causes those differences to be there.

Table 1. Bryophyte-related behavior of essential nutrients in a Welsh oakwood, in $\text{mg m}^{-2} \text{yr}^{-1}$, based on data from Rieley *et al.* 1979 in Longton 1984.

	Ca ⁺⁺	Mg ⁺⁺	K ⁺
Total input to bryophyte layer	3100	1810	2920
Bryophyte accumulation	410	390	1430
Excess input over bryophyte accumulation	2690	1420	1490

Weetman (1968) suggests that mosses may actually supply tree roots more directly. When he found that roots in a **black spruce forest** (Figure 4) were concentrated in decomposing mosses, he considered that mosses might serve as a collecting point for elements, especially N, absorbed by mosses from throughfall. Whether N was obtained from throughfall, soil, or airborne dust for *Hylocomium splendens* (Figure 3), a reservoir that is not easily leached and carried away by rainfall could be an asset to these N-poor forests (Tamm 1953). However, Berg (1984) provides conflicting information that suggests that N may be bound in phenolic compounds in the cell wall and essentially unavailable, even in dead tissue.

Chapin and coworkers (1987) found that mosses account for 75% of the P accumulated annually above ground in an **Alaskan *Picea mariana*** (Figure 4) forest, while they account for only 17% of the P pool in aboveground vegetation. In fact, *Sphagnum subsecundum* (Figure 48-Figure 49), *Hylocomium splendens* (Figure 3), and *Pleurozium schreberi* (Figure 38) have a higher capacity to absorb phosphate than do the fine roots of the black spruce beneath them. Again we beg the question, do they serve as a reservoir for slow release of P, or do they keep recycling it within their own tissues, moving it to growing parts, and depriving the roots?

Even those mosses that release some of their nutrients during senescence may hold them for many years. *Hylocomium splendens* (Figure 3) is an abundant feather moss in the **boreal forests and northern taiga**. In a subarctic birch woods, this species retained N for 3-10 years, depending on which measure was used (Eckstein 2000). Using ¹⁵N labelling, Eckstein found that the mean residence time (MRT) and annual nutrient production (ANP) for N were similar to values found in woody evergreen tracheophytes. These dominant feather mosses may retard the nutrient turnover in these forests first through their **acropetal** (base to apex) movement of nutrients and second by making unfavorable conditions in the forest floor. Eckstein suggested that such dominant taxa of bryophytes could act as ecosystem engineers to retard the nutrient turnover on the forest floor through production of acidic, nutrient-poor litter and depression of summer soil temperatures. These influences help to maintain a system more favorable for the mosses.

Longton (1992) contends that the humus contributed by moss may maintain soil fertility through chemical associations that retain the mineral ions and prevent loss through drainage. Some of these associations are of extraordinary duration. Dowding *et al.* (1981) determined that on Devon Island, Northwest Territories, Canada, 50% of the Ca in the **mesic tundra meadows** was bound in bryophytes with a decomposition time of 22 years.

Figure 49. *Sphagnum subsecundum*. Photo by Michael Lüth, with permission.

One mechanism by which bryophytes can create long-term nutrient sinks is through incorporation into less soluble organic compounds. N can be bound to phenolic compounds in the cell wall or retained in proteins bound by tannic acid compounds in the cell (Berg 1984). Furthermore, cation exchange sites can strongly bind divalent positive ions, rendering these ions unavailable to other ecosystem components, thus making the bryophytes effective competitors, much as they are in bogs and fens.

Soil and rock type also play a role in nutrient retention by bryophytes. For example, Simon and Szerényi (1985) demonstrated that the level of NH_4^+ and NO_2^- -N in soil under mosses increases from xerophytic to mesophytic species. CaCO_3 and pH seem to play a role in these differences, but nothing mechanistic can be inferred yet.

Even the **epiphytes** can make perceptible differences in nutrient cycling by intercepting and absorbing throughfall and stemflow nutrients, as demonstrated for Amazonian epiphytes (Herrera *et al.* 1978). But it appears they can also acquire nutrients that are in the vascular tissue of the main trunk! When ¹³⁷Cs was introduced into the stems of *Liriodendron*, 60% appeared in those bryophytes and lichens on the tree trunk and only 27% in soil bryophytes, with another 9% in bryophytes at the base of the tree (Hoffman 1972).

Luxury Nutrients

Most plants have the ability to store nutrients and use them later, at least to some degree. Tracheophytes transport the soluble nutrients from older, lower leaves to upper, growing ones, often leaving the older leaves chlorotic and eventually dying. Algae store luxury nutrients, using them later as supplies in the ecosystem dwindle, perhaps permitting them to accomplish a sexual phase that permits them to become dormant until better nutrient conditions prevail. Brown and Bates (1990), in investigating the moss *Pseudoscleropodium purum* (Figure 41), found luxury consumption and accumulation of some nutrient elements (K, Ca, and P) throughout the year, but other nutrients were retained poorly (Bates 1989b). However, they (Bates 1987; Brown & Bates 1990) found that *P. purum* had poor retention of these luxury nutrients, except for orthophosphate, with rapid transfer of the luxury elements to other parts of the nutrient cycle. Brown and Bates (1990) could find no evidence that these additional nutrient supplies could permanently enhance growth. It would seem that mosses are able to discriminate to a certain extent, maintaining required metabolic levels of N, P, and K, while excluding or excessively storing the ones that normally occur as trace amounts.

Brown (1982) also interpreted the work of Thomas (1970) on light intensity and nutrient concentrations in the moss plant to indicate luxury consumption of N and P. Thomas had found that concentrations of N and P in *Mnium hornum* (Figure 50) were negatively correlated with light intensity, whereas growth was positively correlated with intensity. This suggested to Brown that the faster-growing mosses in the light had sufficient nutrients and that therefore the higher concentrations in the slower-growing plants in lower light were luxury nutrients. Earlier work by Weetman and Timmer (1967) on *Pleurozium schreberi* (Figure 38) tends to support Brown's interpretation. They found that as the light intensity under the forest canopy decreased from 38% to 17% of full sunlight the nutrient concentration increased in the moss without any significant changes in total nutrient uptake. But one could also interpret the decreased concentrations in high light intensity to mean that the moss was using up its nutrient supply and moving nutrients from older tissues to actively dividing cells, consequently lowering the overall concentrations.

Figure 50. *Mnium hornum*, a species in which concentrations of N and P are negatively correlated with light intensity. Photo by Michael Lüth, with permission.

These additional nutrient supplies are not permanently retained within the new growth, but rather stored throughout the plant, as in tracheophytes. Li and Vitt (1997) reported preliminary results using ^{15}N that indicate mosses may be a major sink for applied N in peatlands, implicating luxury storage.

Martínez Abaigar and coworkers (2002) found that increased levels of KH_2PO_4 caused the leafy aquatic liverwort *Jungermannia exsertifolia* subsp. *cordifolia* (Figure 51) to accumulate significantly more P and K in its tissues. However, as exposure continued, the K concentrations fluctuated whereas P concentrations continued to increase. Concentrations of $20 \text{ mg L}^{-1} \text{PO}_4^{3-}$ seemed to saturate the liverwort at 0.53% dry biomass (DM). When tissue P concentration exceeded 0.45% DM, the net photosynthesis declined, suggesting toxicity. P enrichment did not affect the chlorophyll concentration, but the chlorophyll *a:b* ratio did decline, as did the ratio of chlorophyll to **phaeopigments** (non-photosynthetic pigments which are degradation products of chlorophyll pigments), likewise suggesting P toxicity.

Figure 51. *Jungermannia exsertifolia* subsp. *cordifolia*, a species that accumulates more P and K when treated with KH_2PO_4 . Photo by Des Callaghan, with permission.

Although bryophytes need only minute quantities of heavy metals, the ability to store metals in vesicles or bind them to the cell walls (abilities seemingly missing in tracheophyte leaves) permits bryophytes to store excessive amounts. Under the insult of atmospheric trace metal deposition, *Hylocomium splendens* (Figure 3) accumulated 14-24% more Cu, Fe, Pb, Ni, and V than did *Pleurozium schreberi* (Figure 38), but both mosses maintained similar concentrations of Cd, Mn, Zn, and Cr (Ross 1990), showing an inability to regulate those non-limiting ions. Nevertheless, it appears that bryophytes would accumulate most heavy metals, bound in vesicles or other locations, and release them to the cell if needed. At the very least, they could accumulate a heavy load in the cell walls. Burton (1979) found that *Fontinalis antipyretica* (Figure 52-Figure 53) maintained 80-90% of its accumulated Zn in the cell walls.

Figure 52. *Fontinalis antipyretica* showing its growth habit in a stream. Photo by Janice Glime.

Figure 53. *Fontinalis antipyretica* showing cell walls, where 80-90% of its uptake of zinc is stored. Photo by Janice Glime.

Carbon Sinks

In addition to the storage of mineral nutrients, bryophytes form carbon sinks. Storage of C as photosynthate, predictably, can be found in leaves, but labelled C soon accumulates in other places as well (Skré *et al.* 1983). In particular, in four boreal forest mosses [*Polytrichum commune* (Figure 2), *Hylocomium splendens* (Figure 3), *Pleurozium schreberi* (Figure 38), and *Sphagnum subsecundum* (Figure 48-Figure 49)] carbon accumulated in the growing shoot tips and in the senescent brown tissues. Large amounts were lost to respiration during the peak summer growing season.

The Vernal Dam

The **vernal dam hypothesis** predicts that spring herbs sequester nutrients during the spring when they have maximum growth, thus serving as sinks that retain nutrients that might otherwise be lost during runoff (Tessier & Raynal 2003). In their original hypothesis, Muller and Bormann (1976) considered the forest floor herbs to be sinks that would store nutrients in the spring when the trees were still dormant, then release these in the summer when the herbs were dormant and the trees were active (Rothstein 2000). Although this theory has been widely accepted, its basic assumptions have never been tested: 1. nutrients would otherwise be lost from the system in the spring; 2. forest floor herbs release nutrients to the system in the spring. In their study of a northern hardwood forest in the

Catskill Mountains, New York, USA, Tessier and Raynal (2003) found that evergreen, wintergreen, and deciduous plant species do indeed sequester nutrients during the spring. Soil microbes, on the other hand, seem to remain the same or decrease in their nutrient content during that same period. In forests, a burst of growth occurs in the spring, and nutrient sequestering can occur among spring herbs near the surface while trees are tapping nutrients at lower depths. The high sunlight available while the trees are still barren of leaves permits numerous spring herbs to grow and bloom, slowly resorbing their nutrients to underground organs during the remainder of the year. But do these nutrients ever get released? And would they have been lost otherwise?

Eickmeier and Schussler (1993) have traced the parameters affecting the activity of the spring herb, *Claytonia virginica* (Figure 54), in the forest. They found that shading reduced its biomass, while enhancing its tissue nutrient concentration. This resulted in both reduced specific leaf weight and RUBISCO activity. Fertilization with 192 kg ha⁻¹ total N, P₂O₅, and K₂O caused an increase in above ground vegetative biomass and increased tissue concentrations of N and P, but K concentrations were not affected. In conditions of high irradiance, RUBISCO activity increased, but it was unaffected under shaded conditions. Eickmeier and Schussler have interpreted these results to mean that *Claytonia virginica* is unable to acclimate to low irradiance and therefore depends on the brief period before leaf out to achieve its growth. Thus, it does indeed sequester nutrients that it could not obtain if it did not have this brief period of growth before leaf out. But does this support the vernal dam? It seems that it does. Under low light of summer, *C. virginica* lacks the capacity to store significant quantities of nutrients (Anderson & Eickmeier 1998). However, in brighter light, such as might be found before canopy leaf out, Anderson and Eickmeier (2000) found that *C. virginica* is able to increase the amount of N and P stored in its tissues when fertilized, and it lacks large storage organs such as those found in some spring ephemerals. Rather, it retains many nutrients in its above ground tissues and does indeed release them later in the summer rather than storing them.

Figure 54. *Claytonia virginica*, a species that takes advantage of the brief period before leaf out in spring to bloom, only releasing its nutrients later in summer and therefore creating a **vernal dam**. Photo by Janice Glime.

In sharp contrast, Rothstein (2000) found that the clonal forest herb *Allium tricoccum* (Figure 55) and other forest floor species in one northern hardwood forest did not

take up significant quantities of NO_3^- and that removal of the spring ephemerals did not affect the leaching rate of NO_3^- . In fact, many spring ephemerals resorb their nutrients and store them in underground parts (Anderson & Eickmeier 2000). Rather, Rothstein found that microorganisms took up eight times as much N as did the spring herbs. Furthermore, there was no decrease in summertime N mineralization when spring ephemerals had been removed, supporting the earlier study by Zak *et al.* (1990). Thus, in his study, Rothstein (2000) found that it was the microbes and forest floor litter that dominated the spring sink and created the vernal dam.

Figure 55. *Allium tricoccum*, a spring ephemeral that does not take up NO_3^- . Photo by Hardyplants, through public domain.

But what would occur if this litter were predominantly conifer litter supporting a forest floor that was covered with bryophytes? What is the behavior of bryophytes as the leaves fill the canopy and reduce their light? Certainly in northern ecosystems where the bryophytes are the dominant forest floor vegetation, this question is worthy of consideration. Patterson and Baber (1961) have found that many temperate mosses are dormant in late summer and autumn. Schwabe (1976) found that long days and elevated temperatures often induce dormancy, a phenomenon that can protect them against effects of desiccation during the summer.

Might shade-adapted bryophytes also experience a vernal dam? Light is most available in early spring, and with their C_3 photosynthesis, the bryophytes are well adapted to the low temperatures following snow melt. The melting snow has provided a continuous supply of moisture, and at least some light penetrates the thin layer of lingering snow. Spring would also seem to be a season of nutrient pulse for the bryophytes with nutrients provided by the melting snow as well as through aerial cleansing by the spring rains. Summer, with few showers, may be a nutrient-poor period, although the rains that occur will surely bring a good nutrient supply from the leachates and dust accumulations of the forest canopy leaves. Summer light availability, coupled with the high temperatures, would logically seem like a period appropriate for dormancy of most bryophytes. But few studies have considered the role of sunflecks in enhancing bryophyte photosynthesis. With no stomata to open and direct contact with the atmosphere, bryophytes would seem to be even better suited than C_3 tracheophytes at taking advantages of these brief pulses of light and processing the captured

energy while awaiting the next pulse. Such activity has been reported for tracheophytes and is discussed in the chapter on light.

This leaves us with the questions of when do the bryophytes need the most nutrients, when do they retain them best, and when might they release them, making them available to the soil below, and hence to the tracheophytes rooted beneath them. We can hypothesize that they would be most likely to release them when they are first wet after a period of drought, losing them before their membranes are repaired. But how long does that last, and how much is lost? Do their numerous exchange sites retain most ions, awaiting the time when the cell can once again bring them in through active transport? Is potassium preferentially lost because other ions compete for the exchange sites, making this very soluble low valence ion the most easily leached away from the plants? It appears that at least in some ecosystems bryophytes might indeed be vernal dams. The role of bryophytes in nutrient cycling is one of which we know very little.

Release during Desiccation/Rehydration

Seasonal events are very much the product of the types of seasons of a given area and what differs among them. Temperature, which folks in the temperate zone seem to consider almost exclusively as a seasonal indicator, may not be the factor most important to the bryophyte nutrient regime. Rather, seasonal differences in precipitation and moisture availability may be the primary controlling factors. This seems to be the case with nutrient release in the feather moss *Hylocomium splendens* (Figure 3) in a subalpine spruce-fir forest (Wilson & Coxson 1999), a phenomenon known as **pulse release** because it accumulates (some) nutrients over time, then releases them suddenly. During rehydration, nutrients and C leaked from the desiccated cells is released from the cell surfaces in a pulse release to the throughfall from the mosses. Organic C release to the forest soil can reach up to 1544 mg m^{-2} under these conditions. Experiments comparing this release to that of an inert mulch layer indicated that 23-75% of that pulse release originated in the moss mats. Release of both C and K is increased when drying is rapid. Wilson and Coxson compared the mosses to capacitors, storing low concentrations of nutrients from dust and minor rainfall events, then releasing them in higher concentrations during high rainfall events. Such a release would put the nutrients into the soil when it was most usable to the tracheophyte plants through uptake of the abundant water.

Buck and Brown (1979) likewise found that seasonal releases were tied to dehydration-rehydration processes in *Fontinalis antipyretica* (Figure 53) and *Plagiomnium undulatum* (Figure 45). Both K^+ and Mg^{++} were lost from dry cells, but clung to the extracellular exchange sites. Although K^+ in these plants had much higher concentrations in the intercellular spaces than on the exchange sites, the quantities on the extracellular sites also rose during desiccation, accounting for the losses suffered following desiccation and the pulse release to the soil during rehydration. Scafione (unpubl data) found that a pulse of K^+ is released from *Sphagnum russowii* (Figure 56) in the autumn at the time it is most beneficial for the tree roots in preparation for winter. In ecosystems where the bryophyte cover is typically significant it could play a

crucial role in the preparation of forest conifers for winter. This relationship might be of considerable importance for management of these forests to survive the occasional extreme winter.

Figure 56. *Sphagnum russowii*, a species that releases a nitrogen pulse in the autumn. Photo by Michael Lüth, with permission.

Bryophytes affect the decomposition rates on the forest floor. Decomposition rates under mosses were more rapid than those under lichens (Sedia & Ehrenfeld 2006), presumably due to higher moisture content.

Canopy Releases

In the **montane forest of the tropics**, and probably elsewhere, epiphytic bryophytes accumulate considerable N, much of which is fixed from atmospheric N by microbes (Clark *et al.* 2005). The epiphytic bryophytes, along with the full epiphyte assemblage, retained 33-67% of the nitrogen that was deposited by cloud water and precipitation, with the equivalent of a 50% annual accumulation of the nitrogen in the atmosphere. The bryophytes convert the soluble, highly mobile inorganic forms to organic forms that are retained in the canopy community, potentially being released during dehydration/rehydration cycles.

Even the **cloud forest** canopy experiences pulse release of nutrients from the canopy bryophytic epiphytes (Coxson 1991). During episodes of drying and rewetting, nutrients are leached from the newly rehydrated bryophytes. This leaching is greatest for the ions that normally reside in the intracellular pools. Coxson found that effluxes from stem segments of bryophytes from the Guadeloupe tropical montane rainforest could reach 80.1 kg ha⁻¹ yr⁻¹ for K, 1.4 kg ha⁻¹ yr⁻¹ for P, and 11.8 kg ha⁻¹ yr⁻¹ for N, although efflux rates from intact bryophyte mats were considerably smaller: 28.7 kg ha⁻¹ yr⁻¹ for K and 0.2 kg ha⁻¹ yr⁻¹ for P. Coxson surmised that the lower rate in the field reflected recycling of the leached nutrients within the moss mat. Nevertheless, the through flow loss provides a significant input to the forest floor below and to epiphylls on the leaves below them.

Coxson *et al.* (1992) estimated that more than 30% of the days cause these epiphytes to experience severe desiccation. These wet-dry cycles cause the canopy bryophytes to accumulate 950 kg ha⁻¹ of sugars and polyols. These sugars are then released in pulse form during rewetting episodes and subsequently translocated by through flow precipitation within the canopy. But the upper canopy leafy liverwort *Frullania atrata* accumulates

sugars and polyols equivalent to 17% of its dry weight, whereas the lower canopy moss *Phyllogonium fulgens* (Figure 57) accumulates less than 6%. Wet-dry cycles cause the release of fructose, mannitol, glucose, erythritol, glycerol, and sucrose into the throughfall. Despite the smaller storage levels of the lower canopy moss, bryophytes at that level released more (0.9 g m⁻²) compared to the upper canopy bryophytes (0.3 g m⁻²). Coxson and coworkers concluded that this release of carbon sources has a significant impact on nutrient cycling by providing suitable carbon for the microbes that carry out decomposition and non-symbiotic nitrogen fixation in these forests.

Figure 57. *Phyllogonium fulgens*, a lower canopy species in the Neotropics that accumulates less sugars and polyols than bryophytes in the upper canopy. Photo by Michael Lüth, with permission.

Hölscher *et al.* (2003) compared nutrient fluxes in three successional stages in an **upper montane rainforest** of Costa Rica. All three sites had *Quercus copeyensis* (Figure 58) as a dominant species, with various other species mixed in. The epiphyte litterfall of bryophytes and lichens differed greatly, with the highest values in the old-growth forest, which likewise had the greatest epiphyte abundance. Nevertheless, total nutrient throughfall and stemflow differed little among the three successional stages. Potassium in stemflow was only 5% in the old-growth forest, whereas it was 17% in the early successional forest and 26% in the secondary forest. Hence, in old-growth canopies the bryophytes retained the most potassium, releasing it almost entirely in throughfall.

In a **montane moist evergreen broad-leaved forest** in Yunnan, China, moss litter (including *Homaliodendron scalpellifolium* (Figure 59), *Symphiodon perrottetii*, *Herberta longifoliosa* sic (= *Herbertus longifolius* or *H. longifissus*?), and *Bazzania tridens* (Figure 60) had the slowest decay rate (0.22) compared to canopy tree leaf litter and bamboo (Liu *et al.* 2000). Bryophyte decomposition rates were less correlated with nutrient composition and lignin concentration in their initial mass

than were the tracheophyte rates (trees 0.55, bamboo 0.4). Whereas the turnover time for tree leaves was 1.5-2.50 years, it was 4.55 for the bryophytes.

Bogs and Fens

In **black spruce** (*Picea mariana*; Figure 4) stands, bryophytes are the major source of N for the trees (Weetman & Timmer 1967). But the cation exchange ability of *Sphagnum* (Figure 64-Figure 66) continues even after *Sphagnum* dies, making nutrient release by dead plants slow, at least in forested peatlands (Brock & Bregman 1989), while competition for nutrients continues by means of exchange on the newly exposed walls of dead cells. Exacerbating this problem is the slow rate of organic mass loss during decomposition, as is known for *Sphagnum recurvum* (Figure 61), although the release of N, P, and K was larger than that of organic matter (Brock & Bregman 1989). But even after 12 months of decay, a large proportion of the original N and P remained associated with the peat. This slow decomposition process is supported by the poor colonization by organisms and almost total absence of damage to the dead cells.

Figure 61. *Sphagnum recurvum*, a species with slow decomposition. Photo from Biopix, through Creative Commons

The same cation exchange ability that permits *Sphagnum* (Figure 64-Figure 66) to compete with trees for nutrients can also aid competition by facilitating toxicity to the root zone (Klinger 1988). The peat mosses can trap heavy metals in the root zone, making them more toxic due to the acid conditions; they can create anaerobic conditions in the rooting zone; and their chelation of cations can accelerate iron hardpan formation.

Despite our many studies on nutrients in peatlands, Bedford and coworkers, in a 1999 publication, state that the high variances in plant and soil N:P ratios of wetlands suggest it may be necessary to understand nutrient limitations at both the species and the community level before we can predict the effects of nutrient enrichment. If this need still exists for wetlands, it exists a hundred-fold for non-wetland bryophyte systems.

Bogs and fens are rapidly diminishing on our planet as development fills them in and at best puts a water hole somewhere else for wetland replacement. It is unlikely that any new wetland will become a bog or *Sphagnum* fen, and even if it does, it will be decades to centuries before there is even any evidence it will ever happen. Yet we continue to create conditions unfavorable for these diminishing habitats. Bergamini and Pauli (2001) have shown that fertilization of any sort is likely to destroy these fragile

systems that are not adapted for high nutrient input. In their study, after only 1.5 years, fertilized peatland plots contained 39% less bryophyte biomass on the N-fertilized plots and 53% less on the NPK-fertilized plots than the unfertilized controls. Likewise, bryophyte species diversity diminished. Competition for light by tracheophytes accounted for only part of the decline. Yet, in this ecosystem bryophytes play a crucial role in nutrient cycling and availability, both directly (Rieley *et al.* 1979) and indirectly, through their water-holding capacity (Mägdefrau & Wurtz 1951) and their ability to control water content of the uppermost soil layers (van Tooren *et al.* 1985).

Scheffer *et al.* (2001) compared decomposition rates in a *Sphagnum*-dominated (Figure 62) and a non-*Sphagnum* (Figure 63) fen. In both habitats, the sedge (*Carex*) litter had the highest decomposition rate compared to that of *Sphagnum papillosum* (Figure 64) and *S. squarrosum* (Figure 65-Figure 66). But in the *Sphagnum* site, all litter types exhibited net mineralization, whereas in the sedge-dominated site, there was net immobilization. The researchers postulated that nutrient availability and adaptation of the microbial communities might account for the decompositional differences in the two sites.

Turetsky *et al.* (2008) found that moss species were more important than micro-environmental conditions in determining the early stages of decomposition in four peatland types in boreal Alberta, Canada. *Sphagnum* (Figure 64-Figure 66) species partitioned resources into metabolic and structural carbohydrates. Hummock species decomposed slowly, but the hummock microhabitat itself corresponded to a rapid decomposition rate. This is at least

partly due to the pore structure created by the mosses. The mosses form tissues that resist decomposition, suggesting that they may stabilize losses of carbon from peatlands as the climate warms.

Figure 67. Concentrations of soluble components of moss litter (5 *Sphagnum* and 3 non-*Sphagnum*) collected from Canadian peatlands, including hot water-soluble carbohydrates, hot water-soluble phenolics, and soluble nonpolars (lipids). Data are means \pm one standard error. Same letter superscripts denote non-significant comparison of means (one-way ANOVA; species $p < 0.05$). Redrawn from Turetsky 2003.

pH Effects

Nutrient availability is limited by the ability of that nutrient to dissolve in water, reach the plant, then enter the plant. Most nutrients become more soluble at low pH and may be totally unavailable at higher pH levels. At the same time, toxic metals such as Al become more soluble at low pH and can harm the plants.

Riccia discolor has better growth in the range of pH 3-5 than at any other pH (Patidar & Kaul 1984). The restriction of various taxa of *Sphagnum* (Figure 64-Figure 66) to specific somewhat narrow pH ranges accounts in part for the successional pattern of bogs and fens. *Sphagnum* taxa that require lower pH ranges tend to occur higher on the hummock where the water level is unable to dilute the effects of cation exchange and its release of H^+ ions.

The species that always surprises me is *Calliergonella cuspidata* (Figure 6). This species grows in the contrasting-moisture habitats of **chalk grasslands and fens**. There it grows best at a pH of 7.5 and 5 ppm Ca^{++} , whereas at pH of 6.0 growth stops even with 5 ppm or more of Ca^{++} (Streeter 1970). These pH differences most likely reflect the differences in uptake ability of Ca^{++} and other nutrients.

In rivers, taxa seem likewise to be limited by pH. The availability of free CO_2 only at lower pH (Figure 68) levels severely limits productivity for mosses, whereas many, perhaps all, aquatic tracheophytes can utilize bicarbonates. Several attempts to demonstrate use of bicarbonates by aquatic bryophytes have failed, presenting a clear picture of CO_2 limitation (Bain & Proctor 1980, Allen & Spence 1981). Field studies in streams have revealed that the leafy liverworts *Scapania undulata* (Figure 69) and *Nardia compressa* (Figure 70) occur mostly in the pH range of 5.2-5.8, whereas the moss *Fontinalis squamosa* (Figure 71) occurs mostly at 5.6-6.2 (Ormerod *et al.* 1987), suggesting that these bryophytes have somewhat different abilities to acquire CO_2 . *Jungermannia vulcanicola* (Figure 72-Figure 73) survives the low pH of acid streams (1.9-4.7) in Japan (Satake & Miyasaka 1984; Yokouchi *et al.* 1984; Satake *et al.* 1990). *Leptodictyum* (Figure 74) can grow at a pH of 3.4 in organic lakes of Japan (Satake 1980). *Warnstorfia fluitans* (Figure 75) can live in acidic lakes with the low pH range of 3.4-3.8 (Satake 2000). In aquatic habitats, these pH differences affect the uptake of N forms and the ability to obtain CO_2 for photosynthesis, as well as affecting toxicity of pollutants.

Figure 68. Distribution of carbonate species as a fraction of total dissolved carbonate in relation to solution pH. Note that H_2CO_3 represents CO_2 dissolved in water; HCO_3^- is bicarbonate, and CO_3^{2-} is carbonate. Modified from Soil Chemistry 5-1 < <http://lawr.ucdavis.edu/classes/ssc102/Section5.pdf> >.

Figure 75. *Warnstorfia fluitans*, a species of acidic lakes with the low pH range of 3.4-3.8. Photo by Michael Lüth, with permission.

In an 18-year study of a **pine forest** stand in central Sweden, van Dobben and coworkers (1992) found that *Pohlia nutans* (Figure 76) experienced a 10-fold increase when acidified, whereas *Pleurozium schreberi* (Figure 38) almost disappeared.

Figure 76. *Pohlia nutans*. Photo by Michael Lüth, with permission.

In **geothermal** areas, as we will discuss later, distribution by pH is pronounced, whether by competition leading to more narrow realized niches, or by real limitations imposed by the acidity, and perhaps the accompanying sulfur. The low pH, and in some cases high pH, can affect nutrient solubility and may make certain ions toxic or, in high pH, make them unavailable.

Although many mosses seem to survive at low pH levels, competition from tracheophytes and limited nutrients can severely limit their abundance. In a **grassland** experiment, Virtanen *et al.* (2000) found that virtually no mosses were present on plots with a soil pH of 3.3-4.5. Rather, bryophyte biomass and diversity increased with soil pH.

Indicator Species

Despite the limited ability of bryophytes to use soil nutrients, soil characters can still limit their distribution,

making some of them suitable indicators. Some of this may be that they have greater ability to take up soil nutrients than we have imagined, perhaps through mycorrhizae, and some may result from airborne dust derived from the soil. For example, *Ceratodon purpureus* (Figure 77) is able to tolerate high N content (Dierssen 1973), although this widespread moss seems to be able to tolerate roadside gravel and rock ledges where one would expect N content to be low. On the other hand, *Aulacomnium palustre* (Figure 78), *Pleurozium schreberi* (Figure 38), *Pogonatum urnigerum* (Figure 79), and *Polytrichastrum alpinum* (Figure 80) indicate low N. Such mosses as *Funaria hygrometrica* (Figure 81), *Pohlia cruda* (Figure 82), and *Leptobryum pyriforme* (Figure 83) indicate good base saturation, whereas poor base saturation is indicated by good growths of *Psilopilum laevigatum* (Figure 84).

Use of mosses for prospecting was popular for a time during mining exploration, but their short penetration into the soil made them of limited value. Copper mosses – *Mielichhoferia* (Figure 85-Figure 86), *Dryptodon* (see Figure 87), *Scopelophila* (Figure 88-Figure 89) to be discussed in the Habitats volume – seem to be reliable indicators of the presence of copper (Persson 1948; Shacklette 1967), although it may actually be the sulfur

associated with the copper that encourages their growth (Hartman 1969). They are unknown in the copper-rich area of the Keweenaw Peninsula of Michigan, where the copper occurs as pure copper with no associated sulfur (pers. obs.). Nevertheless, their tolerance for the ore is higher than that of other mosses.

Needed Research

In 1992, Bates summarized our needs for understanding the physiology of nutrient uptake, translocation, and loss in bryophytes. We have made considerable progress since that time, but we still are unable to make sweeping generalizations. To understand clearly the ecosystems in which bryophytes form a significant ground cover or a significant epiphytic element, we must understand the role of the bryophytes in nutrient uptake and sequestering. We still have little understanding of what makes the various species differ in their ability to subsist on low nutrients. We likewise lack understanding of the effects nutrient deficiencies or excess may have on the morphology of the species. And we are only beginning to understand how long nutrients might remain within the bryophyte before being returned to the ecosystem. We have learned that, contrary to the perception of tracheophyte ecologists, the bryophytes move essential nutrients from older tissues to younger ones, often being recalcitrant toward returning anything to the soil unless the whole plant dies. But we don't know how widespread this phenomenon is in the many ecosystems where bryophytes form a significant ecosystem component. We have barely realized that bryophytes obtain their nutrients from the soil as well as the rain, but we can add little to the hypothesis

put forth by Bates (1992) that rapidly growing species may depend on the substrate and slower growing species mostly on precipitation. The nutrient role of bryophytes in ecosystems has come of age – we know that it is significant, and now it demands our attention.

Summary

Bryophytes can play a significant role in nutrient cycling in many kinds of ecosystems. Their ability to bind nutrients on their cell walls permits them to take these in when they become hydrated. They intercept atmospheric input and often hold it, preventing it from reaching the forest floor. In some locations, under conditions of wetting and drying, they can release nutrients during the first few minutes of rehydration when adhering inorganic and organic molecules dissolve in the throughfall. However, once their membranes are repaired, they tend to hold the nutrients on their surface exchange sites or within cells, or even between cells.

Nutrient concentration studies must be interpreted with caution due to the ability of bryophytes to hold dust readily on their surfaces. But even so, this is a role in the ecosystem that prevents this dust from reaching other plants or that releases it at some later point in time.

Mosses may have a limited capacity to retain **luxury nutrients** such as K, Ca, and P, but most of the essential macronutrients seem to be regulated to a relatively constant level. Heavy metals, on the other hand, tend to accumulate to high levels.

In boreal forests, feather mosses retain nutrients and move the soluble ones to young, growing tissues. Hence, nutrients may be bound within the mosses for decades. Nevertheless, spruce roots seem to flourish under the mosses, suggesting that mosses may accumulate nutrients that become available to the roots. *Polytrichum* seems to compete with the fine roots and therefore has a low absorption rate for P. For some reason, perhaps because the N is moved to underground portions, N is able to accumulate under *Polytrichum*.

In chalk grasslands, bryophytes trap and retain leachates from the autumn leaves, then release them in the summer when demand is highest for tracheophytes. Other nutrients, such as N, are retained in bryophytes as organic compounds that are bound in cell walls or retained in proteins. And the level of $\text{NH}_4^+\text{-N}$ and of $\text{NO}_2^-\text{-N}$ in soil under mosses increases from xerophytic to mesophytic species, but we don't know why.

At least some epiphytic mosses even seem to obtain nutrients from the vascular tissue of tree trunks. Epiphytic mosses in the tropics can provide a suitable habitat for legume nodule formation, for example *Bradyrhizobium* in the *Acacia koa* tree in Hawaii, providing a significant contribution to the overall N budget.

Seasonal behavior can, as in the case of *Sphagnum russowii*, release nutrients such as K^+ in the autumn when the trees need it in preparation for winter. But some bryophytes hold to their nutrients tenaciously at exchange sites, again depriving the soil. *Sphagnum* in bogs and fens can be destroyed by nutrient enrichment,

but even dead plants can retain the nutrients already stored. These mosses can also trap heavy metals and retain them in the soils, making the root zone toxic for trees. Because of their movement of nutrients to young tissues and incorporation into incalcitrant compounds, bryophytes can serve as nutrient **sinks**.

Low pH makes nutrients more soluble, but some bryophytes cannot survive, in some cases due to competition from tracheophytes, but in others most likely because the pH change disrupts the normal balance of nutrient uptake. High pH levels, especially accompanied by high concentrations of Ca^{++} , can result in competition for exchange sites that are needed for nutrient uptake. In aquatic systems, high pH reduces the available CO_2 , thus limiting photosynthesis. Some bryophytes serve as indicator species because of their ability to tolerate or not tolerate such conditions as high Ca^{++} or low pH.

Having learned how mosses gain, use, and lose nutrients, we must ask ourselves how these plants are able to subsist on such low concentrations of nutrients. In addition to their efficient absorption of nutrients in low concentrations, they benefit from their generally slow growth habit, thus greatly reducing their requirements per units of time and space.

Their ability to move nutrients from old to young tissues and to store them both externally and internally raises serious questions about their role in the nutrient cycling in the habitats where they are abundant.

Acknowledgments

I appreciate the contributions of undergraduate Phil Gaudette and M. S. student Jennifer Jermalowicz Jones for their critical reading of the manuscript from the perspectives of students interested in nutrient relationships of bryophytes.

CHAPTER 9-1

LIGHT: THE SHADE PLANTS

Figure 1. Bryophytes growing in deep shade, with *Frullania tamarisci* hanging in the foreground. Photo by Michael Lüth, with permission.

Bryophytes Are Shade Plants

As in tracheophytes, bryophytes become light limited at low light intensities (Tixier 1979). For example, epiphyllous bryophyte cover increased fourfold in a clearing in Costa Rica compared to that in the dark understory (Monge-Nájera 1989). Nevertheless, bryophytes exist in places with very low light intensities (Figure 1). The atmosphere, canopy, and surrounding ground cover all contribute to diminishing the light reaching the moss surface (Figure 2), and latitude reduces the radiation reaching bryophytes near the poles.

It is their ability to make a net gain from photosynthesis at very low light intensities that permits bryophytes to live in places inhospitable to other plants.

For example, herbaceous plants of a rich forest floor can retain 43-72% of the light that manages to penetrate the canopy, thus making the potential bryophyte substrate below very low in light indeed (Bodziarczyk 1992). Such total coverage becomes a competitive inhibitor for young seedlings, and even few bryophytes can tolerate such low light. But forests create an even greater toll on the light available to the soil substrate. They drop leaf litter that totally obscures the soil, making it uninhabitable for any bryophyte, and, most bryophytes seem unable to occupy the surface of this constantly changing leaf substrate. Thus, they are excluded from most of the deciduous forest floor by this inevitable litter-caused light limitation.

Figure 2. Irradiance at the moss surface - - - and total solar irradiance — in PAR units for three consecutive days in central Alaska in a black spruce forest. Figure redrawn from Skré *et al.* 1983.

Compensation Point

Net photosynthetic gain is that net carbon which is stored; it reflects net loss of carbon as CO_2 in respiration and photorespiration. Think of it like your paycheck. Your gross income is much greater than that on your paycheck because you have taxes subtracted from it. Think of respiration as the tax and the paycheck as net photosynthesis. The level of light at which CO_2 gain by photosynthesis just equals that lost by respiration is referred to as the **light compensation point**, *i.e.*, the light level at which net photosynthesis is zero. The mean annual light input must be above that level for the plant to maintain positive carbon gain. The highest intensity at which net photosynthesis increases is referred to as the **light saturation point**. And some bryophytes, especially some aquatic taxa, have very low light compensation and light saturation points.

In the bamboo forests (2200-3200 m asl) of Central Africa the bryophytes dry out in the daytime and regain moisture from the vapor-saturated atmosphere at night (Lösch *et al.* 1994). The mountain sites (2200-3200 m asl) had six times higher daily sums of PAR, temperatures 10-25°C, and relative humidities 60-100 %. Nevertheless,

photosynthetic optima of lowland (rainforest) species were somewhat higher than that found for bryophytes at the mountain sites. The light compensation points were smaller (3-12 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$) in the lowland than in the highland species (8-20 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$). On the other hand, the slopes of the curves in the low light range of the lowland species were distinctly steeper than in the high light range. Bryophytes in the rainforest (800 m asl) receive extremely high ambient CO_2 due high decomposition. This CO_2 advantage, coupled with their low light requirements and optimal temperature and humidity conditions provide sufficient photosynthetic conditions for them in this dark environment. Those from the higher elevation bamboo forests and tree-heat environments can take advantage of the higher light conditions despite variable temperatures and humidities.

Light Quality

Light quality differs among habitats. In the open, plants experience the full spectrum of sunlight in what we call white light. However, in the forest, the green canopy absorbs much of the red light, reflecting and transmitting green light. These differences in wave lengths and their respective differences in energy are important in a number of plant functions, with photosynthesis being among those affected.

Federer and Tanner (1966) demonstrated these differences in various habitats. The light quality differs even between hardwoods (most deciduous trees) and softwoods (conifers). Furthermore, light quality differs between clear and cloudy days. Light among all species groups tested had an energy maximum at 550 nm, a minimum at 670-680 nm, and a very high maximum in the near infrared. The light within the canopy is both beam solar radiation and diffuse sky radiation and these are both reflected and scattered.

But how do these differences in light quality affect the bryophytes? In *Physcomitrella patens* (Figure 3), no inhibition was present under high light illumination (Cerff & Posten 2012). These researchers found that a combination of red and blue light is most effective in reaching high growth rates and chlorophyll formation rates.

Figure 3. *Physcomitrella patens*, a species that has good photosynthetic output in a combination of red and blue light. Photo by Janice Glime.

Light Measurement

Light has been measured in a variety of units, and unfortunately, most of them are not directly interconvertible because they measure different things. These different aspects of light also play different roles in physiology of bryophytes. Light wavelengths that stimulate photosynthesis are restricted to those that activate chlorophyll, whereas short wavelengths of ultraviolet light can bleach and damage chlorophyll. Other wavelengths stimulate red and yellow accessory pigments. Yellow pigments (**cryptochromes**) help plants measure the duration of light and respond to different wavelengths.

Traditionally, light was measured in **foot candles** – the intensity of light from one candle on a square foot of surface one foot from the candle. This English unit is, fortunately, easily convertible to metric units of **lux (lumens per sq meter)** – the intensity of light from one candle on one square meter of surface that is one meter from the candle. Thus, one lux is less bright than one foot candle, and to convert from foot candles to lux, one must multiply by 10.764.

PAR (= PhAR) units measure only **photosynthetically active radiation** and are based on measurements in sunlight. In general, about 45% of incoming sunlight lies within the spectral range of 380-710 nm (Larcher 1995), the range used by photosynthesis, thus the range of PAR. Ultraviolet light waves are shorter (UV-A at 315-380 nm; UV-B at 280-315 nm) and have no role in photosynthesis; they do, however, cause chlorophyll and DNA damage. Light available for photosynthesis (PAR) has been reported as photosynthetic photon flux density (**PPFD**), expressed as $\mu\text{mol m}^{-2} \text{s}^{-1}$, or as **watts** per meter square (W m^{-2}). The light reaching the Earth's outer atmospheric limits is 1360 W m^{-2} (the solar constant). By the time it reaches Earth's surface, only 47% remains, thus making full sunlight $\sim 640 \text{ W m}^{-2}$. This varies considerably across the face of the Earth due to reflectance, scattering, cloud cover, and global position.

At sea level, maximum intensity can reach $\sim 1 \text{ kW m}^{-2}$, with PAR intensities of $\sim 400 \text{ W m}^{-2}$. Full sunlight ranges $\sim 70,000$ - $100,000$ lux (or 7,000-10,000 foot candles), with the higher number when there is a highly reflective white sand near the equator at midday or a complete snow cover on a sunny day. The generally-accepted value of maximum light is 680 lumens per watt of radiant power (Commission Internationale de l'Eclairage, Paris 1970). Fortunately, it is possible to provide a rough equivalent of PPFD at full sunlight of $1800 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ because we know the spectral quality of sunlight. However, when light is measured in shade, where leaves filter out red light and transmit green, or under water, or other places where the full spectrum of sunlight is not represented in the same proportions, such a conversion is not directly possible.

Table 1 gives approximate conversions under several more predictable conditions.

Having said all this, we have only looked at one end of the spectral effect – the light source (McCree 1973). Once light strikes the leaf, it encounters not only chlorophyll pigments (actually two chlorophylls in the plant kingdom, *a* and *b*), but it also encounters accessory pigments of various mixes of yellow, orange, and red (Figure 4) occurring in cell walls, cytoplasm, and plastids. Furthermore, cell shape

can bend and focus or scatter light, depending on cell wall structure.

Figure 4. Top: Absorption spectra of chlorophylls *a* and *b*, dissolved in diethyl ether. Middle: Absorbance spectra of lutein and β carotene in ethanol. Bottom: Action spectra of 22 species of crop plants. From Salisbury & Ross 1978.

Thus, our measurements of light are biased representations of light from the perspective of humans and not that of a plant leaf that must use that energy to activate the photosynthetic pathway. But, alas, it is the best we can do at present. This is not all bad, because the differences in response of various plants to the same measured light output give us indirect indications of differences in adaptations to light capture and cause us to probe further

for causes. Unfortunately, lumens and lux tell us even less because we have no measure of the wavelengths being received by the plant and thus know less about what sorts of adaptations to examine. It is like a human looking at a flower that reflects UV. We don't see what the bee sees.

Table 1. Conversions between PAR (PhAR) units or Klux (400-700 nm) units to μM photons $\text{m}^{-2} \text{s}^{-1}$ for light under ~predictable spectral conditions. (From McCree 1981; Larcher 1995).

To convert from: Multiply by factor in column to obtain $\mu\text{M} \text{m}^{-2} \text{s}^{-1}$	W m^{-2} (PAR)	Klux
daylight (sunny)	4.6	18
daylight (diffuse)	4.2	19
metal halide lamp	4.6	14
fluorescent tube (white)	4.6	12
incandescent lamp	5.0	20

Adaptations to Shade

Just what is it that permits bryophytes to succeed where light levels are so low, particularly when compared to tracheophytes? Certainly simple structure is one factor. Tracheophytes are actually adapted to protect themselves from high light intensity by having a thick, waxy cuticle and an epidermis. And the palisade layer in many taxa protects spongy mesophyll from light by using chlorophyll and other pigments to absorb much of it before it reaches the photosynthetically adapted spongy tissue. Bryophytes, on the other hand, have none of these adaptations and expose their photosynthetic cells directly to the light by having only one leaf cell layer in most cases (Figure 5). Only thallose liverworts like *Marchantia* (Figure 6) have an arrangement somewhat similar to spongy mesophyll (Figure 7), and a few mosses like the **Polytrichaceae** have a folded-over leaf margin surrounding leaf lamellae (Figure 8, lower), somewhat resembling palisade tissue of a tracheophyte. In fact, knowing the structure of a bryophyte, we must ask ourselves instead how they survive in the sun.

Most bryophytes are physiologically adapted to low light intensities and therefore have low chlorophyll *a:b* ratios (1.0-2.5:1, Mishler & Oliver 1991) compared to tracheophyte sun plants ($C_3 = 3:1$, $C_4 = 4:1$, Larcher 1983). Marschall and Proctor (2004) examined 39 moss and 16 liverwort species and determined that despite considerable variability, chlorophyll values were typical of shade plants. Median values of total chlorophyll were 1.64 mg g^{-1} for mosses and 3.76 mg g^{-1} for liverworts. Mosses had a chlorophyll *a:b* ratio of 2.29 and liverworts of 1.99, suggesting that liverworts are more shade-adapted than mosses. The reduced chlorophyll *a:b* ratio is due to increased levels of chlorophyll *b*, a typical shade adaptation that permits more trapping of photons that are then transferred to chlorophyll *a*. Even in those bryophytes that are sun species, the ratio tends to be low and the optimum light level likewise low. For example, *Plagiochasma intermedium* (Figure 9) has its optimum light intensity at 3500 lux with a day length of 10 hours (Patidar & Jain 1988); *Riccia discolor* has the same intensity optimum (Gupta *et al.* 1991). But full sunlight can be 70,000-100,000 lux.

Figure 9. *Plagiochasma intermedium*, a species with an optimum light intensity of only 3500 lux and 20-hour days. Jan-Peter Frahm, with permission.

Marschall and Proctor (2004) found that the PPFD (photosynthetic photon flux density) at 95% saturation had a median of $583 \mu\text{mol m}^{-2} \text{ s}^{-1}$ for mosses and $214 \mu\text{mol m}^{-2} \text{ s}^{-1}$ for liverworts, again suggesting that liverworts are adapted to a lower light regime. Not surprisingly, two *Polytrichum* (Figure 10) species had the highest values. Their system of lamellae (Figure 8) provides them with considerable surface area to exchange gas and enhance their photosynthetic capability. Other bryophytes appear to be limited by their lack of sufficient surface area for CO_2 uptake. Green and Snelgar (1982) report that in the thallose liverwort *Marchantia foliacea* (Figure 11) the internal air chambers do little to facilitate photosynthesis compared to *Monoclea forsteri* (Figure 12) which has a solid thallus. Rather, the spaces facilitate water retention and the authors suggest that *Marchantia foliacea* would fare better photosynthetically if it had a solid thallus in very moist environments. Presumably this would afford it more photosynthetic tissue for light capture.

Figure 10. *Polytrichum commune*. Two *Polytrichum* species have the highest photosynthetic values. Photo by A. J. Silverside, with permission.

Figure 11. **Upper:** *Marchantia foliacea* thallus. **Lower:** Cross section of thallus of *Marchantia foliacea* showing the nearly solid nature of the thallus. Tuba (1987) explains that because poikilohydric plants must depend on atmospheric moisture to regulate their internal water content, they are most likely to photosynthesize during early morning hours when there is dew, and during rainstorms, since those are the only times

their cells are hydrated sufficiently. These plants are most likely to be desiccated during periods of high light levels. Thus, it is logical that their chlorophyll is adjusted to low light levels and that their light compensation (Table 4) and light saturation points are low when compared to those of most flowering plants (Table 2). Nevertheless, the light compensation points seem to be slightly higher than those of shade-adapted flowering plants (Table 2), suggesting that bryophytes may benefit from occasional **sunflecks** (patches of light due to movement or gaps among the canopy leaves), or that we have insufficient data thus far to be making these generalities!

Table 2. Comparison of light compensation and saturation points for photosynthetic organisms from various habitats. From Larcher 1983, compiled from various authors.

Plant group	Compensation light intensity I_k in Klux	Light saturation I_s in Klux
Land plants		
Herbaceous plants		
C ₄ plants	1-3	>80
Agricultural C ₃ plants	1-2	30-80
Herbaceous sun plants	1-2	50-80
Herbaceous shade plants	0.2-0.5	5-10
Woody plants		
Winter-deciduous foliage trees and shrubs		
Sun leaves	1-1.5	25-50
Shade leaves	0.3-0.6	10-15
Evergreen foliage trees and conifers		
Sun leaves	0.5-1.5	20-50
Shade leaves	0.1-0.3	5-10
Understory ferns	0.1-0.5	2-10
Mosses and lichens	0.4-2	10-20
Water plants		
Planktonic algae		(7) 15-20
Tidal-zone seaweeds	1-2	10-20
Deep-water algae		1-2
Seed plants	<1-2	(5) 10-30

We do know that bryophytes are able to adjust to low light levels by increasing their number of chloroplasts, as demonstrated for *Funaria hygrometrica* in Figure 13.

Figure 13. *Funaria hygrometrica* cells from dim light (left) and strong light (right). Photos by Winfried Kasprick.

Compensation Points

Certainly some bryophytes are able to grow over a relatively wide range of light intensities, increasing their growth rate as the intensity increases. For example, in *Marchantia palacea* var. *diptera* (Figure 9), this growth increase occurs from 5.4 to 60 W m⁻² (Taya *et al.* 1995). However, above that level, there is a significant and rapid decrease in growth.

Figure 14. Thalli and archegoniophores of *Marchantia palacea* var. *diptera* from Japan. Photo by Janice Glime.

Compensation points suggest that there is indeed adaptation within the bryophytes to both low and high light levels (Table 3-Table 4). For example, in Antarctic lakes, *Drepanocladus* (*sensu lato*) (Figure 15) has a light compensation point similar to that of algal communities (0.11 W m⁻², $\approx 0.5 \mu\text{M m}^{-2} \text{ s}^{-1}$), whereas *Calliergon* (Figure 16), which occurs in shallower water, has a compensation point of 0.64 W m⁻², $\approx 2.9 \mu\text{M m}^{-2} \text{ s}^{-1}$ (Priddle 1980). *Fissidens serrulatus* (Figure 17) could maintain a positive net photosynthesis down to 7 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ (Gabriel & Bates 2003). This is not surprising for a species that occupies caves and the deep shade of forest ravines. *Hylocomium splendens* (Figure 18), typical of conifer forests, required 30 $\mu\text{M m}^{-2} \text{ s}^{-1}$ to reach its compensation point at natural concentrations of CO₂ of 400-450 ppm (ppm = mg L⁻¹) (Sonesson *et al.* 1992).

A low compensation point and a low light saturation value are typical for C_3 plants, and thus for bryophytes (Table 2). The low light compensation point in tracheophytes is in part due to the ability of C_3 plants to open their stomata quickly to take advantage of CO_2 exchange whenever sufficient light is available. However, lacking stomata, bryophytes are not limited by stomatal opening speed, so response time to take in CO_2 should not impose the same kinds of limits it does in tracheophytes. On the other hand, higher levels of CO_2 permit photosynthetic gain at high light intensities by increasing

the light saturation point. For light energy to be used in photosynthesis, there must be sufficient CO_2 for the fixation of photosynthetic product. Otherwise, excess excitation energy can damage the photosynthetic apparatus. Therefore, we should expect to find a higher light saturation point when the CO_2 concentration is higher, as already seen for *Hylocomium splendens* (Figure 18) ($100 \mu\text{mol m}^{-2} \text{s}^{-1}$ at a CO_2 concentration of $400\text{--}450 \text{ mg L}^{-1}$) (Sonesson *et al.* 1992). This is a relatively high level of CO_2 (but a reasonable level at the soil interface) and likewise a high level of light saturation. We will see shortly that such a high light saturation level in this CO_2 -enriched environment will permit the plants to take advantage of bursts of light (**sunflecks**; Figure 19) reaching the forest floor. Again, it would appear that lacking stomata, bryophytes are positioned to be able to make immediate use of these short bursts and have the physiological apparatus to accommodate them.

Figure 19. *Leucobryum glaucum* with sunflecks. Photo by Janice Glime.

Sunflecks

Importance of sunflecks (patches of bright light due to movement or gaps among the canopy leaves; Figure 19) for forest floor tracheophytes is well known. However, bryophyte usage of these bursts of light has been largely ignored (Kubásek *et al.* 2014). These researchers suggest that the anatomy of bryophyte gametophytes would allow a more rapid induction of photosynthesis due to the one-cell thickness, lack of stomata that must be opened, and only thin cuticle. They compared 10 moss species from sun and shade sites. By providing light after dark acclimation, they found that the moss photosynthesis did indeed induce much faster than observed in tracheophytes, reaching 50% of maximum gross photosynthesis in only 90 seconds. Maximum photosynthesis occurred in only 220 seconds, compared to 500–2000 s for most tracheophytes. Shade-grown mosses had a photosynthetic capacity comparable to that of sun grown plants. *Hypnum cupressiforme* (Figure 20–Figure 21) from shade induced photosynthesis slightly faster than did those from sunnier forest gaps (Figure 22). This high photosynthetic capacity permits these forest mosses to make efficient use of sunflecks.

Figure 20. *Hypnum cupressiforme* in an open habitat on rock. Photo by Michael Lüth, with permission.

Figure 21. *Hypnum cupressiforme* in a shaded habitat on a log. Photo by Michael Lüth, with permission.

Figure 22. Comparison of induction rates (IT50 and IT90) and time needed to reach net carbon uptake ($T_{A=0}$) of four gap and four shade samples of the forest moss *Hypnum cupressiforme*. One hour of dark acclimation with ambient CO_2 ($400 \mu\text{mol mol}^{-1}$) was followed by saturating irradiance of $1200 \mu\text{mol m}^{-2} \text{s}^{-1}$. Means are \pm SEM, $n=4$. All means comparing gap and shade groups differ at $P<0.025$. Modified from Kubásek *et al.* 2014.

Bryophyte photosynthetic capacity may be higher than is usually understood (Kubásek *et al.* 2014). For example, the sun species *Bryum argenteum* (Figure 23) under saturating light had $9 \mu\text{mol m}^{-2}$ of projected area s^{-1} under ambient CO_2 and $20 \mu\text{mol m}^{-2}$ of projected s^{-1} under 2000

ppmV of CO₂. This is similar to the photosynthetic capacities of many understory tracheophytes.

Figure 23. *Bryum argenteum*, a sun-tolerant moss made whitish by hyaline tips of overlapping leaves. Photo by George Shepherd, through Creative Commons.

Some tracheophyte physiologists have expressed surprise that shade-grown mosses do not have significantly lower photosynthetic capacity than gap-grown mosses (Jiri Kubásek, pers. comm. 5 April 2007). But consider the adaptations that cause tracheophytes to have less ability to take advantage of sunflecks. First they must open stomata, the slowest process in the induction of photosynthesis. Then, they have layers of cells to protect them from the high light intensity. And often they have a thick cuticle that reflects the sun, whereas it is thin in bryophytes. Bryophytes have none of these constraints and therefore can respond quickly to the short duration of sunfleck light.

Typically, however, light saturation points for bryophytes are low compared to those of tracheophytes. Gabriel and Bates (2003) found that most of the species they examined from an evergreen laurel forest had a saturation point less than 30 $\mu\text{mol m}^{-2} \text{s}^{-1}$, although the lowest among the seven species they studied was 20 $\mu\text{mol m}^{-2} \text{s}^{-1}$. The highest was for *Myurium hochstetteri* (Figure 24-Figure 25), which was saturated at 68 $\mu\text{mol m}^{-2} \text{s}^{-1}$. See also Chapter 9-2 for further discussion of Sunflecks.

Light Effects on Morphology

Sometimes added light can give unexpected results. Such is the case with *Calliergonella cuspidata* (Figure 26). In experiments where tracheophytes were cut, creating more exposure in a calcareous fen in the Swiss mountains, the moss *Calliergonella cuspidata* exhibited a number of morphological differences (Bergamini & Peintinger 2002). It had smaller increments in length on the main axis, shorter offshoots, greater branching density, higher number of offshoots, and greater biomass per unit length. On the other hand, there were no observable effects of increased N supply.

Figure 26. *Calliergonella cuspidata*, a species that has longer leaf intervals when shaded by tracheophytes. Photo by Michael Lüth, with permission.

Summary

In general, bryophytes are adapted to low light, relative to other land plants. They do well in forests as long as they are not buried by leaf litter. Most taxa have a low **light compensation point** and a low **light saturation point**. Light is usually measured as **photosynthetically active radiation (PAR)**, but this ignores the ability of accessory pigments to trap other wavelengths and transfer the energy to chlorophyll *a*.

Most bryophytes are adapted to capture of low light intensities due to their one-cell-thick leaves and lack of well-developed cuticle. Responses of bryophytes to low light are similar to those of tracheophytes, with increased chlorophylls and antenna pigments, depressed light saturation and compensation points, and deeper green color. However, some bryophytes at least do not have a lower chlorophyll *a:b* ratio in low light compared to high light, as would the typical tracheophyte. Rather, bryophytes in general have a lower chlorophyll *a:b* ratio in all light conditions than do tracheophytes. This suggests that the bryophyte, with its chlorophyll *a* concentrations maintaining proportionality to chlorophyll *b* concentrations, would be ready for brief opportunities when bright light becomes available. Liverworts seem to be better adapted to shade than mosses, with a lower chlorophyll *a:b* ratio, higher concentration of total chlorophyll, and lower **PPFD**.

Such a strategy would adapt these plants well to the forest habitat where so many reside, permitting them to take advantage of changing positions of the sun as it filters through trees and brief bursts of light as **sunflecks** when the wind changes the arrangement of the overarching canopy.

There is a broad range of **light compensation points** among bryophytes, ranging from 0.03% of full sunlight in deep water species to 7.5% in sun species. **Light saturation points** are likewise low, although some bryophytes seem able to use bursts of high light intensity and can increase their saturation points when higher levels of CO₂ are available.

Acknowledgments

I thank Jiri Kubásek for many email discussions about bryophytes and sunflecks.

CHAPTER 9-2

LIGHT: ADAPTATIONS FOR SHADE

Figure 1. Hemlock hardwood forest in West Virginia, showing the absence of bryophytes among the leaf litter on the forest floor but growing on exposed rocks. Photo by Janice Glime.

Structural Adaptations for Light Capture

Among my favorite posters at the meetings of the Ecological Society of America, 1993, were the several posters on light focussing by seed plants (DeLucia *et al.* 1996). These illustrated principles I have considered for bryophytes but been unable to test. They found that epidermal cells (**lens cells**) that are rounded at the surface can focus the light in the leaf. In shade leaves, these lens cells are spherical; in the sun they are elliptical. In bryophytes, some leaves have **mammillose** (swollen) cells that are similar to the lens cells they describe (Figure 5). The ability of these cell surfaces to focus light on the chloroplasts has not been explored, except in the case of the protonemata of *Schistostega pennata* (Figure 2-Figure 4), as will be discussed in Chapter 9-5 of this volume.

Tracheophytes can move their leaves instead of their chloroplasts. In their study, DeLucia *et al.* (1996) found that further adjustments to the light reaching the chloroplasts of tracheophyte leaves were facilitated by leaf angles. In mesic woods, fewer than 10% of the leaves were angled more than 60°, whereas in xeric sites with high light intensity more than 75% of the leaves were angled. Leaf thickness also related to moisture, with 75% of taxa at the three most open sites having leaves more than 0.4 mm thick, while at more mesic sites less than 12% of the taxa reached such a thickness. High sunlight resulted in palisade tissue on both sides of the leaf.

In a different poster, DeLucia *et al.* (1996) noted attenuation of green light by 2.7 times and red light by 8 times in the air space at the palisade/mesophyll interface. By applying oil to fill the air spaces, they reduced reflectance and caused a decrease in fluorescence by 50%. They interpreted this to mean that reflectance in the air space caused more light to be available for absorbance by the chloroplasts. A thick palisade reduces the reflectance and therefore reduces the light reaching the spongy mesophyll. At light intensities of less than 30 $\mu\text{M m}^{-2} \text{s}^{-1}$, the air space reflectance increased the photosynthetic rate by 30-50%, with lesser increases at higher light intensities.

If we consider the bryophyte branch to act like a leaf, these principles could be tested in bryophytes. Lens-shaped leaf cells (Figure 5) could focus light on cells of overlapped leaves that are more moist because of their internal position. Such a focussing would be facilitated by the tendency for moss chloroplasts to arrange themselves around the periphery of the cell, thus leaving the center of

the cell available for focussing without increasing absorption. Can we find any correlation between the leaf or branch position of bryophytes and the light regimes under which they grow?

Lamellae

Mosses like *Polytrichum* (Figure 6-Figure 7) and *Atrichum* (Figure 8-Figure 9) have a leaf structure with lamellae (Figure 7, Figure 9) similar to the structure of palisade tissue in seed plants, while the internal structure of a branch in most other bryophytes in many ways resembles the air spaces and spongy mesophyll of seed plants.

Surface Reflectance

Lovelock and Robinson (2002) have found that various mosses differ in their surface reflectance properties and that the differences do not correlate with pigment concentrations, suggesting that surface shape and water content may play a role in surface reflectance. In studying the Antarctic mosses *Bryum pseudotriquetrum* (Figure 10), *Ceratodon purpureus* (Figure 11), and *Schistidium antarcticum* (Figure 11), Lovelock and Robinson (2002) found that the reflectance spectra were similar to those of angiosperm leaves with chlorophyll having the major influence. The mosses likewise did not differ from angiosperms in their UV reflectance, but they did differ significantly at 526, 550, and 850 nm light wavelength and seemed to have a different **cold hard band** – that portion of the absorbance that correlates with the formation of the chlorophyll-protein complex that protects against freezing damage. It is no surprise that *Ceratodon purpureus* had higher concentrations of **anthocyanins** (Figure 12), since it is frequently red-tinged, whereas it had lower chlorophyll concentrations than the other two species. *Bryum pseudotriquetrum* (Figure 10) had higher levels of UV-absorbing pigments but lower carotenoid levels than the other two taxa, but the other two taxa had higher levels of pigments associated with photoprotection from visible light. The correlation between surface reflectance and

plant pigment concentration was low, suggesting that surface structure may have played a major role in reflectance. Rehydration of dry *Schistidium antarcticum* resulted in a significant increase in the photosynthetic reflectance (Figure 11), but it is unclear as to the mechanism. The surface reflectance is highly influenced by the environmental conditions under which the mosses are growing and seems to be linked to water content and morphology of the individual plants and their clone.

Altering Wavelengths

Light is modified as it travels through the atmosphere, losing energy and lengthening the wave lengths, thus

changing the quality of the light. This of course doesn't mean good or bad, but rather means the color composition of the light changes.

The mosses themselves also alter the light quality. They reflect the colors we see, absorb others, and transmit still others. They typically absorb blue and red light, as do tracheophytes, but they differ from tracheophytes in having a green peak that responds to the red, brown, or green coloration of various species (Bubier *et al.* 1997). In their study, Bubier and coworkers examined boreal forest and peatland mosses, including feather mosses (forests; Figure 13), brown mosses (rich fens; Figure 20), and *Sphagnum* (bogs and poor fens; Figure 14-Figure 19). They found that the mosses are typically less reflective than are tracheophytes, resulting from strong water absorption features in the range of 1.00-1.20 μm . This absorption results in reflectance peaks at ~ 0.85 , 1.10, and 1.3 μm (NIR 1, 2, & 3). *Sphagnum* species have a minor absorption at 0.85 μm that is absent in all brown and feather mosses and in all tracheophytes. Furthermore, the red absorption is narrow in *Sphagnum*. Bubier and coworkers concluded that the overall moss reflectance in the 1.50-2.50 region is lower than that for tracheophytes because of the higher water content of moss tissue. This is further supported by the high reflectance of lichens, which typically have dry tissues.

Papillae

I wonder how papillae (Figure 21-Figure 28) might fit the reflectance model. I have long thought that papillae might serve to scatter the light on a dry moss while permitting transmission on a wet one. It would seem like a relatively easy thing to test with a microscope and

photometer. And does the shape of the papillae make a difference (Figure 21-Figure 28)?

Figure 21. *Tortula muralis*, a papillose moss of open habitats. Photo from Botany Website, UBC, with permission.

Figure 28. *Pilotrichidium* leaf papillae (SEM). Photo from Duarte-Silva *et al.* 2013, through Creative Commons.

The role of papillae has been controversial at best. Crandall-Stotler and Bozzola (1991) have shown that at least *Andreaeobryum macrosporum* (Figure 29) leaf papillae have narrow channels through which water can enter upon rehydration. It has occurred to me that these channels might also behave as fiber optics – a notion that remains to be tested.

Figure 29. *Andreaeobryum macrosporum*, a moss with channelled papillae. Photo from Botany Website, UBC, with permission.

Proctor (1982) explains that in concave leaves, water is held in the concavity while the convex surface remains dry.

It is this convex surface that often is exposed to light. In papillose mosses such as *Thuidium* (Figure 30-Figure 31) and *Hedwigia* (Figure 32-Figure 35), the tops of papillae tend to remain dry, even when the leaf surface is wet, giving them that waxy or dull appearance. The tiny channels, when present, could function as fiber optics, much as the fur of a polar bear, but on a much smaller scale. Hence, the light could be focussed through the papillae onto the chloroplasts while water is obstructing and altering the light entering other parts of the cell. As can be seen in Table 1, there are lots of potential light adaptations in bryophytes that remain to be tested.

Leaf Area Index

The **leaf area index (LAI)** has been used to show structural responses of tracheophyte leaves to high vs low light conditions. This value represents the percentage of ground area covered by leaves, hence (**total leaf area**) / (**area of ground**). Likewise, bryophytes can exhibit a leaf area index that is directly proportional to the light intensity (Sluka 1983). Unfortunately, few measurements have been taken on bryophytes. Simon (1987) compared two desiccation-tolerant mosses with one more mesic species and found what she considered to be high LAI values. For *Syntrichia ruralis* (Figure 36), the LAI was 44, for *Ceratodon purpureus* (Figure 37) 129, and for the more mesic *Hypnum cupressiforme* (Figure 38) 103. These indeed seem to be enormous. By contrast, forest floor tracheophyte species in a montane forest had an LAI of only 3.8 (Schleppi *et al.* 1999); in a tropical cloud forest the LAI was only 1.6 in a gap less than 8 months old, increasing to the pre-gap level of 5.1 in three years (Lawton & Putz 1988). Larcher (1995) considered 4-6 to be optimal for herbaceous plants with horizontal leaves and 8-10 optimal for grasses. Asner *et al.* (2003) reviewed more than 1000 LAI studies from around the world and found that the maximum for an ecosystem was 18 with a mean of 5.2±4.1. The macroalga *Fucus serratus* (Figure 39) achieved its maximum productivity for an individual at LAI 8-10, while the community did best at 6-8 (Binzer & Sand-Jensen 2002). At the biome level, the LAI seems to range from 0.5 to 16, hardly making a showing against the high values measured by Simon (1987) for bryophytes.

Figure 36. *Syntrichia ruralis*, a species with a high leaf area index (LAI) compared to most tracheophytes, but not as high as forest bryophytes like *Hypnum cupressiforme*. Photo by Michael Lüth, with permission.

Figure 39. *Fucus serratus*, a brown alga with a leaf area index (LAI) closer to that of tracheophytes than to bryophytes. Photo by Stemonitis, through Creative Commons.

Just why should bryophytes have such enormous LAI values? As we know from tracheophytes, leaves arranged with minimal overlap vertically will have maximal exposure to sunlight, whereas crowded leaves that overlap (having a high LAI) will cause the plant to exhibit self-shading. Furthermore, leaves that have a strong vertical orientation will have minimal direct exposure to light, thus requiring more leaves. This latter condition would seem to describe some mosses, but not the thallose or two-ranked leafy liverworts. Simon (1987) suggested that the high leaf area found in bryophytes might facilitate uptake of the high levels of CO₂ found near the soil surface. Other advantages might result from the vertical growth and close packing with neighbors, with clustered apical leaves taking maximal advantage of the light. On the other hand, the entire moss branch might behave much like a single leaf of a tracheophyte, with overlapping leaves protecting the chlorophyll from UV damage and maintaining moist internal spaces. New techniques for tracheophytes using models that incorporate both LAI and a foliage clumping index indicate that both measures are needed to separate sun from shade leaves (Chen *et al.* 2003), and it seems that this technique might permit us to explain the high leaf area index of bryophytes, where many leaves are shaded by the upper leaves of the same plant or by overlying branches of prostrate plants.

Self-shading

Because of their three-dimensional nature, plants typically shade themselves. As a result of the high leaf area index, a moss cushion is a source of rapid light extinction due to self-shading. Using Antarctic mosses, Davey and Ellis-Evans (1996) demonstrated that irradiance decreases with increasing depth within the moss – no surprise there. Furthermore, the greatest loss of light was at wavelengths around 675 nm and less than 450 nm, in the neighborhood of those portions of the spectrum causing the greatest chlorophyll activity. Of course species differed in light attenuation, with stem orientation being the most important factor, along with stem density, leaf size, orientation, and pigment content. Light penetration increased upon drying – seemingly a maladaptive trait that would permit light to damage chlorophyll, but an expected

result for mosses that curl or fold their leaves upon drying. On the other hand, Davey and Ellis-Evans suggested that this deeper light penetration of dry mosses might permit photosynthesis to occur in the deeper layers (these most likely also being more moist) and thus make up for some of the photosynthetic loss in the drier apical parts.

Bryophyte Canopy

As we have just seen, not only do trees and other tracheophytes provide a canopy over the bryophytes, but the bryophytes themselves provide a canopy that alters the light reaching the lower parts of the plants. This canopy is structured differently and functions differently, relating to issues of scale and external transport of water and nutrients (Rice & Cornelissen 2014). Hence bryophytes demand different methodologies to truly understand their use of light and ultimate photosynthetic product.

Habitats vary in their light quality and intensity and the bryophytes further alter this light in the bryophyte canopy (Figure 40) (Tobias & Niinemets 2010). These authors set out to document bryophyte differences in chlorophyll, carotenoids, nitrogen concentrations, and photosynthetic electron transport capacity as they varied with the light profiles above and within populations of the moss *Pleurozium schreberi* (Figure 41). Light differences between habitats resulted in increases in chlorophyll, chlorophyll:N, and chlorophyll:carotenoids as light decreased, thus increasing the light harvesting in low light and increasing light protection in higher light. N levels in the plants were independent of light intensity. In the upper moss canopy (Figure 41) where light was at least 50-60% of the above-canopy light, changes in moss chemistry and photosynthetic output were similar to those observed in the between-habitat light gradient. However, deeper canopy layers mimicked the effects of senescence (Figure 40), with pigment and nitrogen concentrations and photosynthetic capacity decreasing with light availability. They considered the chemical and physiological variation in the moss canopy to be a balance between acclimation and senescence.

Figure 40. *Pleurozium schreberi* showing a canopy with an active green layer and a senescent lower layer. Photo by Janice Glime.

Figure 41. *Pleurozium schreberi* as seen at the top of the moss canopy, a typical species in boreal forests. Photo by Janice Glime.

In low light, the foliage is less densely aggregated and plant density is lower, permitting greater light penetration and greater light interception per unit of leaf area (Niinemets & Tobias 2014). In healthy tissues, chlorophyll increases as light levels diminish. But one of the consequences of aging in mosses is that the tissues senesce. This senescent zone is likewise deeper in the moss mat and consequently gets less light. This senescent moss zone has reduced chlorophyll content.

Canopy architecture differs among species. Species, especially of pleurocarpous mosses, that are able to branch and from new leaves from lateral buds are able to extend into areas with greater light as well as providing more opportunities for catching sunflecks (Niinemets & Tobias 2014). One advantage is that plants in high light intensity tend to have cushion growth forms that protect them from the accompanying desiccation. Those in shaded habitats often also experience the greater moisture that permits them to spread horizontally and capture more light.

Rice *et al.* (2014) examined the effects of drying on light relations in ten species of *Sphagnum* (Figure 15-Figure 19). They found that spatial variation in the rate of photosynthetic electron transport increased during drying and in high light intensities. There was a positive relationship between that rate and light intensity, but the relationship with drying was negative, and the light and moisture interacted to create the spatial variation. Within the canopy of the moss *Pleurozium schreberi* (Figure 41-Figure 41), the mat temperature reached a 9°C span. In the leafy liverwort *Bazzania trilobata* (Figure 42), the Lambert-Beer Law predicted the attenuation of light within the liverwort canopy.

Figure 42. *Bazzania trilobata*, illustrating overlapping branches. Photo by Jan-Peter Frahm, with permission.

Growth and Branching

Low light in plants often results in **etiolation**, elongated growth that often lacks accompanying weight gain, creating thin and often chlorotic plants with long internodes and small, rudimentary leaves. Such growth is seen in grass when a board or rug rests on it for a period of weeks. Bryophytes are no exception to this phenomenon, and increased elongation in incubators should not be mistaken for healthy plants if the plants become long and thin. For example, in one study *Dicranum majus* (Figure 43) had its greatest elongation at the lowest irradiance ($20 \mu\text{m m}^{-2} \text{s}^{-1}$) (Bakken 1995).

Figure 43. *Dicranum majus* with capsules, a species that has the greatest elongation in low light. Photo by Michael Lüth, with permission.

Bates (1988) examined the effect of shoot spacing on growth and branch development in *Rhytidiadelphus triquetrus* (Figure 44). Using intermittent moisture supply and spacings of 5, 10, 20, and 50 mm between shoots, he found that main axis growth was promoted by decreased spacings. Although etiolation occurred when shoots were close together, there was no self-thinning and overall growth seemed to be optimal at or near the closest spacing tested. As a result, productivity was greatest in the most dense colonies ($1000 \text{ shoots dm}^{-2}$). Since growth occurs at the tip, there probably is very little effective light loss at these 5 mm spacings between plants, and water is conserved.

Figure 44. *Rhytidiadelphus triquetrus*. Photo by Janice Glime.

In fact, van der Hoeven and During (1997) found that when plots of three pleurocarpous mosses (*Calliergonella cuspidata* (Figure 45), *Ctenidium molluscum* (Figure 46), and *Rhytidiadelphus squarrosus* (Figure 47) were thinned by 50%, the original density returned rapidly, suggesting that density might be regulated by an intrinsic mechanism. Bates (1988) concluded that this dense packing is an indication of the advantage of reduced water loss in the more densely packed shoots and that this advantage outweighs the reduction in light. However, for *Ctenidium molluscum*, thinning to 50% caused increased growth, presumably due to increased photosynthesis, while its neighbors, *Rhytidiadelphus squarrosus* and *Calliergonella cuspidata* gained no advantage from the same thinning (van der Hoeven 1999). The differences in morphology may account for the success of *C. molluscum* following thinning, for it has dense, overlapping leaves, compared to the spreading leaves of *R. squarrosus* and large, slightly overlapping leaves of *C. cuspidata*. These mosses, after thinning, returned rather quickly to their original density. Like Bates (1988), Van der Hoeven and During (1997) suggested that they have an intrinsic control over their density.

Figure 46. *Ctenidium molluscum*, demonstrating strongly overlapping leaves and branches. Photo by Michael Lüth, with permission.

Figure 47. *Rhytidiadelphus squarrosus*, demonstrating spreading leaves on ascending shoots. Photos by Michael Lüth, with permission.

Pedersen and coworkers (2001) tested this moisture/light trade-off using one acrocarpous (*Dicranum majus*, Figure 43) and two pleurocarpous (*Ptilium crista-castrensis* (Figure 48), *Rhytidiadelphus loreus*, Figure 49) mosses and a leafy liverwort (*Plagiochila asplenoides*, Figure 50). Using several controlled moisture and light levels, they determined that *Dicranum majus* and *Rhytidiadelphus loreus* had peak growth rates at intermediate densities where light and moisture were balanced, a relationship noted by Bergamini *et al.* (2001) as well. On the other hand, when the environment was either dark or humid, the effect of increased density was negative. *Ptilium crista-castrensis* exhibited decreased growth rates under most experimental combinations and *Plagiochila asplenoides* seemed to be unaffected. In all cases, it required light levels that were higher than in their natural spruce forest (Figure 53) habitat before the advantages of greater density were manifest, indicating that it is competition for light that limits optimal density, not low water availability. In a similar experiment, Scandrett and Gimingham (1989) found that *Pleurozium schreberi* (Figure 40-Figure 41), *Hylocomium splendens* (Figure 51), and *Hypnum jutlandicum* (Figure 52) likewise exhibited more intraspecific inhibition from crowding in low light than in high light, but yields were higher among sown fragments in low light.

Figure 48. *Ptilium crista-castrensis*, a species that seems to exhibit no growth rate change with changes in light and moisture levels. Photo by Janice Glime.

Figure 50. *Plagiochila asplenoides*, a species for which growth seems unaffected by light and moisture levels. Photo by Michael Lüth, with permission.

Figure 51. *Hylocomium splendens*, a species in which thinning increases branching. Photo by Michael Lüth, with permission.

One consequence of thinning seems to be increased branching (Rydgren *et al.* 1998; Pedersen *et al.* 2001). And it seems that in *H. splendens* (Figure 51), the increased light increases production of gametangia and subsequent sporophytes (Rydgren *et al.* 1998). This species had ten times as many sporophytes two years after half the bryophyte cover had been removed, compared to non-thinned plots.

Figure 52. *Hypnum jutlandicum*, a common gap species. Photo by Michael Lüth, with permission.

Figure 53. *Picea mariana* forest showing reduced light on the forest floor. Photo through Creative Commons.

We know that light is necessary to make new chlorophyll, and thus we might predict that there is a depth within a moss cushion at which the light attenuates beyond that needed for chlorophyll manufacture. Van der Hoeven, *et al.* (1993) found that chlorophyll concentration decreased down the shoot as light intensity decreased, but they considered that where only 50% of the shoot was green, the light intensity was too high to attribute the mortality of leaves to low light values. Skré and coworkers (1983), however, found that self-shading coincided with the transition from green to brown parts in *Hylocomium splendens* (Figure 51) and felt that light attenuation helped to explain the death of the green moss tissue.

Skré *et al.* (1983) showed (Figure 54) that in *Hylocomium splendens*, PAR (photosynthetically active radiation) at a depth of 3 cm in natural moss canopies is reduced to ~17%; to ~8% in *Pleurozium schreberi* (Figure 40-Figure 41); to ~12% in a mixed canopy of *Pleurozium schreberi* and *Polytrichum commune* (Figure 55); and to only 1% in *Sphagnum subsecundum* (Figure 56). Visnadi and Vital (1989) found that there were more species entangled among themselves in the indirect sunlight of the riverbank than in the river bed, where direct light was available, indicating that self-shading, and neighbor-shading, might not always be a bad thing.

Figure 54. Diminishing PAR in the moss clump. PcPs = *Polytrichum commune* and *Pleurozium schreberi*. Hs = *Hylocomium splendens*. Ps = *Pleurozium schreberi*. Ss = *Sphagnum subsecundum*. Figure redrawn from Skré *et al.* 1983.

Chlorophyll Fluorescence

Chlorophyll fluorescence (light re-emitted by chlorophyll molecules during return from excited to non-excited states; Figure 57) is one measure of stress in leaves. This is expressed as the ratio of variable fluorescence (F_v = difference between the maximum and minimum fluorescence) to maximum fluorescence (F_m = fluorescence resulting from flashing a leaf in the dark with bright light), known as F_v/F_m . The ratio is usually about 80% efficiency; lower measures indicate stress.

Figure 57. *Fontinalis antipyretica* leaf showing red chlorophyll fluorescence. Photo by Janice Glime.

Rice *et al.* (2005) demonstrated that the F_v/F_m ratio decreased when three bryophytes [*Bazzania trilobata* (Figure 42), *Sphagnum girgensohnii* (Figure 60), *Pleurozium schreberi* (Figure 40-Figure 41)] were exposed to high light intensity, indicating stress. But in many bryophytes, while some leaves may be at stress levels, others may be at ideal levels. Using laser technology, Rice *et al.* developed a method to measure surface roughness and depth to first vertical canopy contact, thus permitting a more accurate measurement of light penetration and turbulence and providing a tool that may permit a better understanding of CO₂ exchange.

Morphological Responses

It appears that, like tree leaves, bryophytes might respond structurally to differences in light levels. Dalby (1966b) compared the leaves of the tufa-forming moss *Eucladium verticillatum* (Figure 58-Figure 59) from deep shade with those from the open and found that those grown in deep shade had much broader leaves, not unlike the response seen in some tree species (Figure 61).

At least some species exhibit a seasonal change in their light extinction curves that can be due to a change in leaf weight similar to that seen when tree leaves respond to high light. *Calliergonella cuspidata* (Figure 45), *Ctenidium molluscum* (Figure 46), and *Rhytidiadelphus squarrosus* (Figure 47) all exhibit a higher extinction coefficient in September than in December. In fact, the shoots are 1.5–2.1 times as heavy in September as in December, being so dense that the light intensity at the bottom of the plant approaches zero (van der Hoeven *et al.* 1993; Figure 62).

In culture, the thallose liverwort *Marchantia paleacea* var. *diptera* (Figure 63) exhibited an increase in growth rate with increasing light intensity over the range of 5.4 to 60 W m⁻², whereas a significant decrease occurred at light intensities >60 W m⁻². Many *Sphagnum* (Figure 15–Figure 19) species are high-light plants. In a growth study, weight increase of the species was greatest in unshaded conditions when the water table was low, but in shaded conditions, there was little difference with water table (Clymo 1973). However, when length was considered, plants of all *Sphagnum* species grew less in low water conditions, especially if they were also shaded – hardly an etiolation response.

Physiological Adaptations to Low Light

Although bryophytes in general seem to be shade adapted, at least in their chlorophyll ratios, there are still differences among the species that adapt them to different habitats or give them a competitive edge. For example, *Plagiomnium acutum* (Figure 64) has greater capacity to absorb and use low light, giving it a greater photosynthetic assimilation efficiency than its associate *Herpetineuron toccoeae* (Figure 65) in shady and wet habitats (Li *et al* 1999).

Figure 64. *Plagiomnium acutum*. Photo by Yingdi Liu, with permission.

Buryová and Shaw (2005) affirmed that light treatments had a greater effect of growth and other characters of *Philonotis fontana* (Figure 66) than did water. Different populations, representing different genetic variants, exhibited different patterns of plasticity of form. Variation of leaf dimensions had a strong genetic component (20-30% of total variation), but cell dimensions (Figure 67) seemed to have little genetic variation.

But what are the characteristics that enhance photosynthesis in bryophytes? Waite and Sack (2010) examined ten Hawaiian bryophyte species and quantified 35 physiological and morphological traits. The moss species, typical of shade species, exhibited low leaf mass per area and low gas exchange rate. But their light-saturated photosynthetic rate per mass did not correlate with habitat light intensity. Instead, using canopy mass, not leaf mass, other photosynthetic parameters and morphological traits did correlate with microhabitat light characters. This relationship resulted in an inter-correlation of leaf area, cell size, cell wall thickness, and canopy density. Furthermore, structural allocations such as costa size, canopy height, and mass were linked with these modifications.

Chlorophyll

Bryophytes are C_3 plants. As such, they are adapted to light capture at low light intensities. In tracheophytes, the primary adaptation to low light is to increase the antenna pigment chlorophyll *b*. This provides more opportunities to trap light energy reaching the leaf and to transmit it to the action site of chlorophyll *a*. Sluka (1983) supported the concept of increased chlorophyll concentrations at low light intensities in bryophytes by showing that total chlorophyll content of mosses is inversely proportional to light intensity. As in tracheophytes, it is chlorophyll *b* that increases in response to low light. Szarek (1994), working in the High Tatra Mountains of southern Poland, found that higher light intensities in the middle reaches of the stream did not have any effect on chlorophyll *a* concentrations of mosses compared to areas with less light.

In tracheophytes, this increase in chlorophyll *b* results in a lower *a:b* ratio. Thus, it is not surprising that bryophytes, as predominantly shade plants, typically have a low *a:b* ratio compared to tracheophytes. Mishler and Oliver (1991) reported *a:b* ratios of 1.00-2.5 for the xerophytic moss *Syntrichia ruralis* (Figure 36), a desiccation-tolerant moss that likewise has a higher chlorophyll concentration at low light intensities (Hamerlynck *et al.* 2002). Nevertheless, these *a:b* ratios, even for sun-grown plants, were typical of shade-adapted tracheophytes, whereas the carotenoid:chlorophyll ratio of sun plants was typical of sun-adapted tracheophytes. These acclimation responses reversed in a reciprocal transplant experiment, indicating that this species is capable of making short-term adjustments. Nevertheless, transplanted sun plants of *S. ruralis* did not perform as well in shade as did previously shade-grown plants. Hamerlynck *et al.* (2002) considered this to indicate that the sun-acclimated plants were able to maintain their photoprotective mechanisms, losing them only slowly, whereas the shaded plants were able to maintain activity longer, due to greater moisture, allowing them to adjust to changes rapidly following disturbance that exposed them to greater sunlight. This ability to adjust permits them to persist in their semi-arid grassland home.

Tuba (1987), as already discussed, has a different explanation. He suggests that these low *a:b* ratios are important because poikilohydric plants must depend on atmospheric moisture to regulate their internal water content and that such moisture is most typically available during periods of low light – during a storm or early morning. Since these plants are often desiccated during periods of high light levels, Tuba suggests that it is logical that their chlorophyll is adjusted to low light levels, but that having light compensation points slightly higher than those of shade-adapted tracheophytes permits bryophytes to benefit from occasional sunflecks.

It therefore comes as a surprise to find that the chlorophyll *a:b* ratio in many bryophytes does not decrease in response to low light, while the total chlorophyll increases. For example, in experiments on three species of the thallose liverwort *Riccia*, the highest chlorophyll concentrations occurred in the shade-grown *Riccia discolor*, and the lowest occurred in the floating aquatic species, *Riccia fluitans* (Figure 68), as one would expect. But surprisingly, the chlorophyll *a:b* ratios did not differ among the species (Patidar *et al.* 1986). In *Sphagnum*

fimbriatum (Figure 69), both chlorophyll *a* and chlorophyll *b* increased in dim light; in dim light at 25°C, the *a:b* ratio increased only slightly, while at 15°C, no such increase was observed (Koskimies-Soininen & Nyberg 1991). Similarly, Rincón (1993) compared six species of bryophytes under seven different light conditions and found, as expected, that the total chlorophyll was highest at the lowest level of light, but that the chlorophyll *a:b* ratio did not differ significantly among the treatments.

Figure 68. Terrestrial form of *Riccia fluitans*. Photo by Michael Lüth, with permission.

Figure 69. *Sphagnum fimbriatum*, a species that increases both chlorophylls *a* and *b* in low light. Photo by J. K. Lindsey, with permission.

Yang and coworkers (1994) found that seventeen species of bryophytes at Yuan-Yang Lake in China had lower chlorophyll *a:b* ratios (mean 2.41) than the two aquatic tracheophytes sampled (mean 3.08), but that these bryophyte ratios were considerably higher than values for bryophytes reported in the literature. They considered this to be a demonstration of the ability of bryophytes to adjust their chlorophyll *a:b* ratio within a limited range to a higher light intensity ($250 \mu\text{mol m}^{-2} \text{s}^{-1}$).

As discussed earlier in the study by Marschall and Proctor (2004), chlorophyll content seems to account for liverworts being more common in shade, with more mosses able to survive in bright, open areas. Pande and Singh (1987) found higher concentrations of both carotenoids and chlorophyll in liverworts, with the exception of *Stephensoniella brevipedunculata*, compared to mosses, but in this study liverworts all came from shade and mosses from open areas. Doera and Chaudhary (1991) examined

chlorophyll content of several bryophytes and found that chlorophyll *a* ranged 0.402 ± 0.052 to 2.002 ± 0.700 mg g⁻¹ dry mass, with chlorophyll *b* ranging 0.265 ± 0.067 to 1.634 ± 0.070 mg g⁻¹. Lowest chlorophyll concentrations were found in the moss *Entodon prorepens* (Figure 70) (0.667 mg g⁻¹ dry mass) and highest in the liverwort *Cyathodium tuberosum* (Figure 71) (3.636 mg g⁻¹ dry mass), consistent with the observations of Marschall and Proctor (2004). In these bryophytes, low light intensity resulted in increase in total chlorophyll content and lower chlorophyll *a:b* ratio. On the other hand, Antarctic populations of *Ceratodon purpureus* (Figure 12) can decrease chlorophyll *a:b* ratios in high light (Post 1990). Is it any surprise that these responses are not always the same, that they differ with species, temperature, moisture content, and light level?

Figure 70. *Entodon prorepens*, a species with low chlorophyll concentrations. Photo by Li Zhang, with permission.

Mártínez Abaigar *et al.* (1993) have compared the chlorophyll concentrations on a per unit area basis. Their results, compared to light and water availability, appear in Table 2. Examination of the table does not reveal any relationship among these species with either light availability or water availability and chlorophyll concentration. However, there seems to be a good correlation between chlorophyll concentration and submersion. Only *Schistidium rivulare* (Figure 72-Figure 73) among the emergent taxa has a high chlorophyll concentration. This might be explained by the dark coloration of the cell walls that would filter the high light intensity before it reaches the chlorophyll.

Other Pigments

Other pigments also change in response to light intensity, as shown for *Rhytidiadelphus triquetrus* (Figure 44), *R. squarrosus* (Figure 47), and *Mnium hornum* (Figure 75-Figure 76) (Brinkmeier *et al.* 1999). In these mosses biflavonoid concentration was correlated with periods of active growth and varied with light intensity. The shade-adapted liverworts in Nainital, Kumaun Himalaya, exhibited higher carotenoid concentrations than did the mosses growing in the open (Pande & Singh 1987). However, the chlorophyll:carotenoid ratio seemed not to differ, at least during the rainy season, which is the period of maximum growth. It is reasonable that carotenoid content would be adaptive to shade plants because it can serve as an antenna pigment, much like chlorophyll *b*, providing additional light capture capability and transferring that energy to the chlorophyll *a* reaction center. Such an adaptation is known not only in bryophytes, but also in tracheophytes, where total carotenoid content and β -carotene increase simultaneously with chlorophyll in the shade (Czeczuga 1987). On the other hand, **lutein** (deep yellow pigment) increases in the sunlight.

Figure 75. *Mnium hornum*, a species in which pigments change in response to light. Photo by Bob Klips, with permission.

Figure 76. *Mnium hornum*, illustrating a lighter color that could be a response to different light conditions. Photo by Michael Lüth, with permission.

It is interesting that many of the pigments seem to vary together in concentration, at least in the Antarctic mosses tested (Lovelock & Robinson 2002). Total chlorophyll was correlated highly with total carotenoids (0.91), which in turn were highly correlated with each other (lutein and xanthophyll cycle pigments). **Anthocyanins** also correlated but somewhat less highly with chlorophyll. However, the photoprotective **zeaxanthin** and **antheraxanthin** were negatively correlated with total chlorophyll, as one would expect if chlorophyll *b* increases in response to low light.

Several researchers have found that hydrated mosses, unlike tracheophytes, require only a few molecules of zeaxanthin per reaction center to dissipate light energy (Bukhov *et al.* 2001; Heber *et al.* 2005). Desiccation-dependent fluorescence quenching, however, is independent of zeaxanthin and appears to be a property of the reaction center complex of photosystem II rather than the antenna system.

Chloroplast Movement

In at least some mosses, the chloroplasts move in response to light direction. This ability of chloroplasts to orient themselves in response to direction of light, thus maximizing absorption of light energy, is known elsewhere in the plant kingdom. The green alga *Mougeotia* (Figure 77) has an axial chloroplast that can rotate on its axis to face the sun. Often the two ends seem to rotate independently so the chloroplast becomes twisted in the middle. The ferns *Adiantum capillus-veneris* (Figure 78), *A. caudatum* (Figure 79), *A. diaphanum* (Figure 80), and *Pteris cretica* (Figure 81) all exhibit chloroplast movement in their leaves, responding to blue light; *A. capillus-veneris* chloroplasts also responded to red light (Augustynowicz & Gabrys 1999). The prothallus of the fern *Dennstaedtia punctiloba* (Figure 82-Figure 83), growing in lava caves, exhibits a luminescence similar to that seen in the moss *Schistostega pennata* (Figure 2-Figure 4) (Glime & Iwatsuki, pers. obs.). In *Schistostega pennata*, chloroplasts of the protonemata orient themselves to attain maximum light, as discussed in the light subchapter on cave mosses.

In protonemata of the moss *Physcomitrella patens* (Figure 84), the direction of light, intensity, and wavelength are all important to chloroplast arrangement. When the light is perpendicular to the protonema axis the chloroplasts accumulate next to the crosswalls, but when it is parallel to the protonema axis, *i.e.* perpendicular to the crosswalls, there is no accumulation of chloroplasts there (Kadota *et al.* 2000). The response depends on the intensity, with lower intensities (red light 0.118 W m^{-2} or blue light $0.01\text{--}85.5 \text{ W m}^{-2}$) inducing accumulation, whereas higher ones (red light $\geq 60 \text{ W m}^{-2}$ or blue light 285 W m^{-2}) do not. These responses are mediated by phytochrome. But the protonemata of *Physcomitrella patens* respond not only to the direction of light (Kadota *et al.* 2000), but also to mechanical stimuli (Sato *et al.* 2003). This causes the chloroplasts to accumulate on the side of the cell where contact is made – in as little as 30 minutes! Could this be an adaptation to high light by placing the chloroplasts on the side next to the substrate and therefore on the side farthest from the light source? Such a position would provide more cytoplasm to serve as a filter from UV light and high light intensity. On the other hand, it would also permit the side toward the sun to act as a focussing lens. There is so much we don't know!

Figure 84. *Physcomitrella patens* plants with their protonemata on the left. Photo by Michael Lüth, with permission.

Movement of chloroplasts is a response to blue light intensity (Königer 2014). In low light, they spread out, maximizing light interception. In high light, they move to the sides of the cells in an avoidance reaction, minimizing light interception. But most mosses may be slower to react or not react at all. *Physcomitrella patens* (Figure 84) had no net change in light transmission under increasing blue light intensities up to one hour at $100 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$. The fern *Adiantum capillus-veneris* (Figure 78) likewise showed no accumulation response and only a slow avoidance response. The tracheophyte *Arabidopsis thaliana* (Figure 85), on the other hand, exhibited both strong accumulation and avoidance responses.

Figure 85. *Arabidopsis thaliana*, a species that exhibits both strong accumulation and avoidance responses to increasing levels of blue light. Photo by Nicole Hanley, through Creative Commons.

Light and Storage

The ultimate consequence of changing chlorophyll concentrations and chloroplast position is an altered ability to store photosynthate. Kobe and Silander (1993) have shown that in four trees adapted to low light intensities, survivorship of juveniles in low light conditions is positively related to carbohydrate reserves and inversely related to high-light growth. This demonstrates the importance of storing carbohydrates as opposed to using all of them for growth during periods of high light. Such correlations have not been tested for bryophytes, but may relate to storage of carbohydrates in the spring before the canopy foliage appears for use of the developing sporophyte during the summer and autumn. Kobe and Silander contend that the trade-off between storage and growth relates to survivorship in low-light habitats. Rincón and Grime (1989) have shown that production of biomass is not correlated with shoot extension in five grassland bryophytes, and that it in fact can be an inverse relationship, with shoot extension occurring later, again indicating the importance of storage. Could this be related to the ability to store carbohydrates for use later in low light when IAA may facilitate more elongation? (IAA is inhibited by light in tracheophytes.)

In *Sphagnum fimbriatum* (Figure 87) low light caused increased storage of total lipids (Koskimies-Soininen & Nyberg 1991). However, in darkness, as one might expect, lipid content decreased. When low light was accompanied by a decrease in temperature, the moss stored more palmitic, stearic, linoleic, and arachidonic acids in the galactolipids monogalactosyl diglyceride (MGDG), *i.e.* the chloroplast lipids. At the same time, oleic and α -linolenic acids decreased. The MGDG lipids are important in cold hardening and adjustment of plant metabolism to low temperatures. For example, arachidonic acid has a freezing point of -49.5°C (Gellerman *et al.* 1972), thus maintaining membrane fluidity at any temperature these mosses are likely to experience in nature. Karunen (1982) suggested that the presence both of high quantities of angiospermous type galactolipid fatty acids and the lowest quantities of algal type in the aquatic moss *Fontinalis* (Figure 86) had evolutionary significance in placing this as an advanced genus, at least biochemically.

Figure 86. *Fontinalis duriaei*, a species with high quantities of flowering plant type galactolipid fatty acids and very low quantities of the algal type. Photo by Janice Glime.

Figure 87. *Sphagnum fimbriatum*. Photo by Michael Lüth, with permission.

One cannot generalize from these results, however. When Koskimies-Soininen and Nyberg (1991) compared their results for the shade plant *Sphagnum fimbriatum* (Figure 87) with similar experiments on the high light species *Sphagnum magellanicum* (Figure 19), the responses to light and temperature were different. At low temperatures, *S. fimbriatum* does not increase its unsaturated glycolipids, reaching its lowest level at 10°C , whereas *S. magellanicum* reaches its lowest level at 0°C . In fact, we should expect differences among species, as these are the very things that make many species become species. For example, Li and coworkers (1999) compared photosynthesis of *Plagiomnium acutum* (Figure 64) and of *Herpetineuron toccoeae* (Figure 65) under different weather conditions. Photosynthesis of *P. acutum* was lower on sunny days than that of *H. toccoeae*, but on cloudy and rainy days it was higher. They determined that *P. acutum* has a higher CO_2 assimilation efficiency in shady and wet habitats. Working with mosses on semi-arid granitic boulders, Alpert and Oechel (1987) also found that species occurring in microhabitats with lower light availability had a higher rate of net photosynthesis at low photon flux densities than did other mosses from that site, suggesting a higher chlorophyll concentration.

Based on the literature, it appears that photosynthetic rates of mosses are considerably less than those of tracheophytes. This is consistent with their slow growth rates. For example, in comparing the shade liverwort *Marchantia polymorpha* (Figure 88) with the sun moss *Ceratodon purpureus* (Figure 37), Aro and coworkers (1981) found that the plastid ultrastructures of these two bryophytes were characteristic of shade and sun plants respectively, but both exhibited the photosynthetic rates typical of shade plants. But Martin and Adamson (2001) disagree with the method of representing these determinations of photosynthetic rates in bryophytes. They found that indeed the CO_2 uptake rate (*i.e.* photosynthetic rate) is much lower than that of tracheophytes when expressed per unit of biomass, but when they used the rate per chlorophyll concentration to compare maximum photosynthetic rates of bryophytes vs tracheophytes under the same conditions of light saturation and ambient CO_2 , the photosynthetic rates between bryophytes and tracheophytes did not differ (Shouldn't we expect that?)

The chlorophyll seems to behave the same way in both; it is the concentrations of chlorophyll that differ.

Figure 88. *Marchantia polymorpha* with archegoniophores, a shade plant with plastids characteristic of shade plants. Photo by Rudolf Macek, with permission.

Forest Gaps

Forest gaps are well known to foresters as sites where trees experience release growth, expressed in larger tree rings and greater annual production. Wayne and Bazzaz (1993) explored the relative effects of forest gaps compared to shadehouses on two species of birch [*Betula populifolia* (Figure 89) and *B. alleghaniensis* (Figure 90)] and found that leaf structure (specific leaf mass, leaf mass ratio) in shadehouses more closely resembled that of sun plants than did that of the gap-grown plants, but that gap-grown plants behaved more like sun plants in chlorophyll *a:b* ratios and maximum net photosynthesis.

Figure 89. *Betula populifolia* leaves, a forest gap species that exhibits chlorophyll *a:b* ratios and max net photosynthesis of sun plants when living in gaps. Photo by Richtid, through Creative Commons.

Figure 90. *Betula alleghaniensis*, a forest gap species that exhibits chlorophyll *a:b* ratios and max net photosynthesis of sun plants when living in gaps. Photo by Keith Kanoti, through Creative Commons.

Despite their adaptations to low light, many bryophytes also benefit from the brighter spots in the forest. Even in the relatively open forest types like spruce (Figure 53), light attenuation between canopy and forest floor can be considerable (Figure 93) (Tuba & Nyilas 1980). In stands of *Pseudotsuga menziesii* (Figure 91) and *Tsuga heterophylla* (Figure 92) in Oregon, USA, bryophyte abundance increases in canopy gaps and other places with a higher irradiance within the forest (Rambo & Muir 1998).

T4 and T9 are two sites in a mature black spruce forest in central Alaska. In transect 4 — represents 68% canopy closure; - - - represents 36% canopy closure. In transect 9 — represents 49% canopy closure; - - - represents 33% canopy closure. Figure redrawn from Skré *et al.* 1983.

For bryophytes, forest gaps provide periods of high intensity light that for some species can enhance growth, while for others the additional desiccation and high temperatures can mean cessation of growth. However, in the margins of the gaps, where sunlight is intermittent during the day, bursts of sun, or sunflecks, can be significant contributors to the productivity. Studies on vascular plants suggest that responses to light gaps having intermittent light can be significantly different from continuous low or high light (Wayne & Bazzaz 1993). There are few studies on bryophytes to explore the importance of sunflecks within the forest or the effect of intermittent light in gaps. Yet, in many temperate forests, such intermittent light may be more the rule than the exception. Wayne and Bazzaz (1993) suggest that the plasticity of response by some species to intermittent light may have potential for niche differences and coexistence. Such studies should not be difficult to do on bryophytes using either laboratory conditions or strobe lighting in the field, and with modern electronic recording equipment, even natural sunflecks can be recorded and productivity monitored.

But not all gaps are beneficial to bryophytes. Brunkman (1936) puzzled over the presence of *Hylocomium splendens* (Figure 51) in some of the *Myrtillus* associations but not others. After careful quadrat study, he learned that the *Hylocomium splendens* all but disappeared within four years of cutting the forest. He attributed this disappearance to light, since the soil was "decidedly wet," allowing for the indirect effect of sunlight on the available moisture. Since he found the uncut forest to be just as wet as the cut forest, he concluded that light was the factor resulting in the loss of *H. splendens* in the open. He likewise cited differences in moss cover between north and south slopes (71% and 3%, respectively) as evidence that light was the critical factor. He reasoned that the south slope would have a much longer light day and light season than the north slope. On the other hand, *Hylocomium splendens*, *Pleurozium schreberi* (Figure 41), and *Hypnum jutlandicum* (Figure 52) commonly occur in the gaps formed by degenerate *Calluna vulgaris* (Figure 94) bushes in the dry heathland (Scandrett & Gimingham 1989), so it appears that they can benefit from more light under the right conditions.

Figure 94. *Calluna vulgaris* showing reduced cover in areas with shorter or dying plants. Photo by Willow, through Creative Commons.

In one North American forest, where a storm had uprooted nearly half the trees, moss cover disappeared rapidly, whereas in the part where trees remained upright, the moss cover was nearly normal (Brunkman 1936). Brunkman (1936) further cited evidence from two adjacent plots, one of spruce (Figure 53) with 85% mean cover of moss on 16 quadrats and another of poplar (*Populus*, Figure 95) with 6% mean cover on 16 quadrats. Then he compared the densities of the trees on these and other plots in an attempt to correlate the light availability with decrease in moss cover. To his surprise, no correlation existed. To explain this anomaly, he considered the fact that poplar is lacking leaves for eight months of the year, whereas spruce is never without leaves. While Brunkman seemed uncomfortable with the lack of correlation, he still considered that tree density was important above 0.5, and he concluded that densities above 0.8 have high moss cover, the lowest being 59%. He noted that in light gaps, the moss cover would be moderate to high, and the flora of flowering plants would include a "decidedly larger number of individuals."

Larsen (1980) contends that if a gap occurs in a boreal spruce forest (Figure 53), the spaces are occupied to a greater extent by herbaceous species and moss cover will diminish. It appears that the relationship of moss cover to light availability may be complicated by the availability of suitable species and the length of time since the light became available. In any event, the species occupying the lighted gap will be different from those occupying the forest before the opening was created (Larsen 1980).

In an attempt to determine the importance of "reserve trees" to forest management, Shields (2006) examined not only the woody and herbaceous plants in openings with a single central tree (reserve tree) to those of the forest matrix in uneven-aged northern hardwood forests (Figure 96) in the Upper Peninsula of Michigan, but also the bryophytes. He found that bryophyte cover in the opening was only one-third that of the forest matrix, with four species [*Marchantia polymorpha* (Figure 88), *Pleurozium schreberi* (Figure 13), *Ptilidium pulcherrimum* (Figure 97), *Sphagnum* sp. (Figure 98)] disappearing completely. *Brachythecium* spp. (Figure 99) and *Atrichum undulatum* (Figure 100) both decreased in importance as the opening

size increased. These disappearances most likely involved several factors. Not only did the light increase in the opening, but temperature increased and moisture decreased. Furthermore, substrate availability changed, with coarse woody debris being less available in the cutover openings than in the forest matrix.

Sunflecks

Sunflecks (Figure 95; Figure 101), those tiny patches of bright light that dance about on the forest floor, have reached a new level of importance in our understanding of forest floor dynamics. Skré *et al.* (1983) found that up to 35% of the forest floor in a black spruce (*Picea mariana*, Figure 53) forest in central Alaska could experience sunflecks at the midday soil surface. These flecks usually had an intensity ~76% that of the light reaching the forest canopy and were the major source of light for bryophytes there. Such sunflecks are known to provide for photosynthesis in exposed parts of clones with the resultant photosynthate translocated to shaded parts of the connected clone internally.

For bryophytes, sunflecks have an advantage over full sunlight because of that intermittence (remember how we measure V_{max} ? The least disturbance of the canopy changes their position, thus striking different branches or patches of bryophytes. For a photosynthetic bryophyte leaf, this means relief from the constant bombardment of light energy on the chlorophyll molecules and prevents these low-light adapted plants from suffering from excitation damage. The light dances about from ramet to ramet as it does from leaf to leaf on the trees. Rincón and

Grime (1989) found sunflecks to be very important for six bryophytes from a variety of habitats and referred to the ability of bryophytes to be plastic in rate and direction of shoot proliferation as a "foraging" mechanism that permitted them to exploit resources where they became available, in this case, sunflecks. Bergamini and Peintinger (2002) found a similar foraging behavior in *Calliergonella cuspidata* (Figure 102) and contended that pleurocarpous mosses have a morphological strategy comparable to the "spacer and branching" strategy of some stoloniferous tracheophytes. Even such upright mosses as *Polytrichum* are known to have interconnected ramets that translocate photosynthate to one another.

In the heavily shaded sites of New Zealand, the hornwort *Megaceros pellucidus* (Figure 103) experiences a maximum photon flux density of less than $10 \mu\text{mol m}^{-2} \text{s}^{-1}$ (Watkins *et al.* 2011). Daylight sees only weak variation in intensity. The dense canopy provides little opportunity for sunflecks. Interestingly, hornworts from low light conditions ($0.2 \mu\text{mol m}^{-2} \text{s}^{-1}$) had the same carotenoid concentrations as those from higher light conditions ($6.9 \mu\text{mol m}^{-2} \text{s}^{-1}$), but the chlorophyll content of high light plants was approximately 2X that of low light plants, whereas the chlorophyll *a/b* ratio was the same in both low and higher light conditions. A significant difference is that in low light the hornworts exhibited an absorbance band at 340 nm that was not present in the higher light conditions.

Litter Burial

Of course the most drastic effect of the forest canopy on the bryophytes of the forest floor is the virtually total loss of light caused by leaf litter (Figure 1). Although there may be allelopathic effects from the decomposition of leaves that leads to the release of tannins, loss of light is ultimate death to nearly every plant. Johnsen (1959) demonstrated the severity of litter on bryophytes by showing that raking away litter can greatly increase both number of species and cover of bryophytes on the forest floor. It is the leaf litter that relegates the bryophytes to the steep slopes, tip-up mounds, and other places where leaf litter cannot easily accumulate.

The Partnership Choice

While many bryophytes suffer from self-shading that prevents the lower leaves from photosynthesizing, one species actually lives in that shaded habitat, receiving little or no light due to the surrounding moss vegetation. This species is the thallose liverwort *Cryptothallus mirabilis* (Figure 104). Its name tells much of its story, for it is indeed a hidden thallus, growing beneath the surface in peat, raw humus, or moss carpets (Schofield 1985), yet miraculously surviving in the darkness there. It is totally lacking in chlorophyll (Potemkin 1992); even its spores lack chlorophyll (Hill 1969). It obtains its carbon through a fungal partnership (Malmborg 1933; Airy Shaw 1949; Ligrone *et al.* 1993; Bidartondo *et al.* 2003), although it may not contribute anything to the relationship. It appears that it subsists much like the flowering Indian pipe (*Monotropa uniflora*, Figure 105), actually being a third member in a parasitic relationship with trees, including *Betula* (Figure 89-Figure 90), that reach the canopy to convert light energy into stored energy in the photosynthate (Bidartondo *et al.* 2003). The photosynthate is transferred from the tree to the fungus to the liverwort.

Summary

In general, bryophytes are adapted to low light, relative to other land plants. Bryophyte cells may act as lens cells, at least in some cases, focussing light on the chloroplasts or even on leaves beneath them. Branches may behave like leaves in scattering, focussing, and reflecting light while providing air spaces that give access to CO₂. Papillae may serve to scatter light when the leaves are dry or to channel it like a fiber optic when wet. But these are all speculations.

The **leaf area index (LAI)** of bryophytes appears to be enormous compared to that of tracheophytes (44-129 compared to 3.8 for the forest floor taxa). Perhaps

the branch should be considered instead of the leaves of bryophytes. This same density of leaves results in considerable self-shading, with rapid light extinction within a moss cushion. Light often penetrates deeper in dry mosses, in some cases reaching a level where sufficient hydration exists for photosynthetic activity. Chlorophyll likewise diminishes with depth in a cushion, but this may be a function of age rather than light intensity, at least in some species. Dense packing of stems does not usually seem to deter vertical growth and may actually enhance it through greater conservation of water, despite the attenuation of light. On the other hand, densely overlying mosses seem to benefit from thinning that exposes underlying branches to more light. It appears that light is more important than hydration at determining optimal density.

As in tracheophytes, leaf morphology may respond to shade by such changes as broader leaves. Even leaf weight may decrease as less light becomes available. Other responses to low light are similar to those of tracheophytes, with increased chlorophyll *b* and antenna pigments, depressed light saturation and compensation points, and deeper green color. However, some bryophytes at least do not have a lower chlorophyll *a:b* ratio in low light compared to high light, as would the typical tracheophyte. Rather, bryophytes in general have a lower chlorophyll *a:b* ratio in all light conditions than do tracheophytes. This suggests that the bryophyte, with its chlorophyll *a* concentrations maintaining proportionality to chlorophyll *b* concentrations, would be ready for brief opportunities when bright light becomes available. Such a strategy would adapt these plants well to the forest habitat where so many are residing, permitting them to take advantage of changing positions of the sun as it filters through trees and brief bursts of light as **sunflecks** when angle of the sun changes or the wind changes the arrangement of the overarching canopy. These same adaptations would likewise permit mosses intertwined with grasses to one day be covered by a stem, but a few weeks later have grown past it to receive full light. Accessory antenna pigments such as carotenoids increase with chlorophyll *b*.

Some species have chloroplasts that move in response to direction of light, maximizing light absorption. In *Physcomitrella patens*, chloroplasts accumulate on the side of the protonema where contact is made, presumably giving them maximum protection from light.

Reduction in photosynthesis in low light has its price in reduced storage of photosynthate. In bryophytes, storage can occur without growth, with growth occurring later based on stored reserves. Low light can also increase storage of lipids and temperature can alter the types of lipids being stored. Such adaptations differ among species, especially between sun and shade species.

Sunflecks provide bryophytes with bursts of bright light without the damaging effects of continuous bombardment of UV light and high light intensity on shade-adapted plants. Particularly in pleurocarpous mosses, the many branches provide "**foraging**" opportunities that permit production of photosynthate

that can be translocated to other parts of the clone. Even the upright *Polytrichum* is able to translocate photosynthate from one stem to another in ramets of one connected clone.

Litterfall can completely bury bryophytes and put them in nearly total darkness. However, some bryophytes may benefit from litter in low-light conditions by forming fungal partnerships that acquire photosynthate from the surrounding leaf litter through this the fungus.

CHAPTER 9-3

LIGHT: EFFECTS OF HIGH INTENSITY

Figure 1. *Encalypta rhabdocarpa* in the alpine region where high-intensity UV light can damage chlorophyll and DNA. Photo by Michael Lüth, with permission.

Effects of High Light Intensity

Exposure to UV light has been hypothesized as a major deterrent of evolution to land. Both chlorophyll and DNA are easily damaged by high intensities of direct sunlight (Figure 1). In fact, it has been suggested that a major role of lignin, absent in bryophytes, is to protect cells against UV light. But it appears that the crafty bryophytes have a number of tools at their disposal.

Light and Moisture Relations

One danger of high light intensity in bryophytes is damage it can do to chlorophyll when the moss is dry. In experiments with a number of species, Churchill and Nelson (unpubl. report 1994; pers obs.) have found that the light intensity transmitted through a wet moss leaf is about

twice that transmitted through a dry leaf. Takács *et al.* (2000) found that the non-chlorophyll blue-green fluorescence of *Syntrichia ruralis* (Figure 2) and two lichens increased by an order of magnitude upon drying. They attributed these changes in blue-green fluorescence to altered optical properties, not to any change in pigment or phenolic concentration. Lovelock and Robinson (2002) likewise found that the state of hydration affects the ability of the moss to absorb or reflect light. This increased reflection and decreased absorption by the dry leaf should provide at least some protection from damaging effects of UV radiation that could destroy chlorophyll and damage DNA. It suggests that there may be internal and/or external scattering of light by dry moss, whereas wet moss has a

more homogeneous surface and interior, permitting light to travel with less scattering.

Figure 2. *Syntrichia ruralis* showing hyaline hair points that are drawn close to the stem when the moss is dry and leaves are twisted around the stem. Photo by Michael Lüth, with permission.

Hamerlynck and coworkers (2002) hypothesized that because of its strong desiccation tolerance characters, the moss *Syntrichia ruralis* (Figure 2) would be unable to acclimate to different light intensity regimes. However, they found that in this species sun plants had lower biomass, and lower tissue N, C, and chlorophyll concentrations than shade plants of the species (Figure 3). Interestingly, while the carotenoid:chlorophyll ratios of sun plants were typical of sun plants, they found that as in most bryophytes the chlorophyll *a:b* ratios were typical of shade plants. When transplanted to shade, sun plants were able to adjust to the lower light level by increasing their photosystem II yields; these yields decreased in shade plants transplanted to the sun. Conversely, sun plants transplanted to shade continued to be out-performed there by non-transplanted shade plants. They suggest that in this species, shade plants may be able to adjust relatively quickly to disturbance that exposes them to greater light and desiccation.

Figure 3. Comparison of N and C content of *Syntrichia ruralis* grown in shade and sun in Kiskunság National Park near Budapest, Hungary. Vertical bars indicate 1 SE; letters indicate significant differences ($p < 0.05$). Redrawn from Hamerlynck *et al.* 2002.

Photoinhibition

Because high light intensities can damage chlorophyll, they can cause photoinhibition. Even sun plants like *Sphagnum* (Figure 49) are vulnerable. Shaded *Sphagnum* plants from temperate and Alaskan populations were given more light following removal of tracheophytes, and plants

from full sun were shaded (Murray *et al.* 1993). Previously shaded mosses from both locations in the high-light treatment ($800 \mu\text{M m}^{-2} \text{s}^{-1}$) lost significant photosynthetic capacity in just two days and did not recover in the next 14 days. Increased variation in chlorophyll fluorescence relative to maximum fluorescence suggested this was a result of photoinhibition. By contrast, mosses that were moved from full sun to shade grew at a rate 2-3 times as great as that of those in control plots. Murray and coworkers suggested that the inability to acclimate might relate to low tissue N content of these mosses from low-nutrient habitats.

Bryophytes are limited on both ends of the light scale. At low intensities, they have insufficient energy to replace that lost by dark respiration and photorespiration, but on the other end they suffer chlorophyll damage and photoinhibition. Cleavitt (2002) demonstrated that this photoinhibition in *Mnium spinulosum* (Figure 4) restricted its occurrence to deeply shaded conifer stands, whereas *Bryum pseudotriquetrum* (Figure 5) was limited by its lack of desiccation tolerance. *Mielichhoferia macrocarpa* (Figure 6), on the other hand, occurred in the darkest and wettest sites, yet was tolerant of both high light intensities and desiccation. She showed that what we perceive to be narrow physiological limits that we would expect to limit rare species may not tell the whole story. It appears that our knowledge of light limits and adaptations, coupled with physiological responses of bryophyte tissues, needs additional study.

In Antarctica, the bryophytes experience full exposure to sunlight in summer, but are at least partially protected by ice in winter (Post *et al.* 1990). This high summer exposure causes photoinhibition to be a major factor limiting productivity in these ecosystems. Post and co-workers have documented the damaging effects of low temperatures and high light on the bryophytes in this exposed polar environment. *Schistidium antarctici* (Figure 7) experiences daily changes in photosynthetic capacity, resulting from the changing environmental variables of light and temperature. (See also Chapter 11-2 of this volume.

Adaptations to High Light

When working with *Pohlia wahlenbergii* (Figure 8) from a subalpine area, Coxson and Mackey (1990) were surprised to find that it had a peak of photosynthesis at $8 \text{ mg CO}_2 \text{ g}^{-1} \text{ h}^{-1}$ in the morning, declined to $5 \text{ mg CO}_2 \text{ g}^{-1} \text{ h}^{-1}$ by late afternoon, then fully recovered by late evening. They considered that it might have full recovery from photodestruction of pigment complexes, but such a degree of photosensitivity would be unusual for plants living in high light environments. However, this would seem to be consistent with observations on *Ceratodon purpureus* (Figure 9) (Rintamaki *et al.* 1994). One of its mechanisms to tolerate high light is its rapid turnover of the D1 reaction center protein in photosystem II. In mosses such as *Ceratodon purpureus*, this permits rapid replacement of light-damaged protein, thus serving as protection against photoinhibition. Once again, it seems the bryophytes have outdone the tracheophytes.

Figure 8. *Pohlia wahlenbergii*, a species tolerant of high light. Photo by Michael Lüth, with permission.

Figure 9. *Ceratodon purpureus* leaves, a species tolerant of high light. Photo by Don Loarie, through Creative Commons.

Plants adapt to high light either by structural adaptations or by protective pigments. Tracheophytes have protective epidermal layers, and in most groups there is a palisade layer beneath that epidermis that further serves to absorb light before it reaches the photosynthetic tissue of the spongy mesophyll. Bryophytes lack this structure. Hence, bryophytes must invest more in cellular level

protection to mitigate the damaging effects of high light intensity (Robinson & Waterman 2014). In some cases, the bryophytes use mechanisms already known in algae, such as thermal energy dissipation that is associated with the LHCSR protein, a mechanism no longer present in tracheophytes.

Structural Adaptations

Waite and Sack (2010) found that ten Hawaiian mosses did not demonstrate a correlation between habitat irradiance and light-saturated photosynthetic rate per biomass. However, they found that other photosynthetic parameters and structural traits (leaf area, cell size, cell wall thickness, and canopy density) were aligned with microhabitat irradiance. Furthermore, internally, high light can cause a decrease in thylakoid stacking (Post 1990).

Bryophytes often have filters that help to protect them from high light intensity. For example, several *Polytrichum* (Figure 10) species have **lamellae** (Figure 11) that are enclosed by the inrolled **lamina** (Figure 11) of the leaf, thus rendering the leaf a structure that is not very different from that of a deciduous tree. Others have leaves with **filaments** [*Crossidium* (Figure 12-Figure 13)], **hyaline tips** [*Hedwigia ciliata* (Figure 14-Figure 16)], *Bryum argenteum* (Figure 17-Figure 18)], and **awns** [*Tortula* (Figure 19-Figure 22), *Syntrichia* (Figure 2)] that overlap the next leaf and help to deflect light before it reaches the cell interior. Hyaline hair tips, partially covering adjoining leaves when dry (Figure 14, Figure 20), are spread out of the way of the photosynthetic tissue upon hydration (Figure 15, Figure 21).

Frey and Kürschner (1991) have demonstrated a correlation between "glass hairs" (Figure 13, Figure 18, Figure 16, Figure 22) and increasing aridity, suggesting that they could be useful as UV shields as aridity, and correlated light exposure, increase. Many taxa curl their leaves (Figure 23), wrap their leaves around the stem (Figure 20), or appress leaves (Figure 20) when dry, causing each leaf to help protect at least part of the next leaf. Structures such as papillae become more transparent when wet, typically doubling their ability to transmit light (Glime, unpubl. data). Short turfs likewise help to protect mosses from high light intensity through self-shading (Schofield 1985).

Epiphytes like *Octoblepharum* (Figure 24-Figure 25) and *Leucobryum* (Figure 26-Figure 27) have numerous hyaline cells that might help to filter the light before it reaches the photosynthetic cells. But I have seen no experiments that demonstrate if this really alters the light intensity. They could, instead, focus the light on the interior photosynthetic cells while serving as a water reservoir to maintain photosynthesis in a dry atmosphere.

In boreal wetlands, bryophytes have distinct spectral characteristics compared to those of tracheophytes in the visible, near-infrared (NIR), and short-wave infrared (SWIR, 1.50-2.50 μm) regions (Bubier *et al.* 1997). In the visible portion of the spectrum, these mosses exhibit typical absorption in the blue and red regions but differ from the tracheophytes in having a "green" peak reflective of the color (red, brown, or green) of individual species. The reflectance in the NIR region of mosses is usually less than in the tracheophytes, with strong water absorption features at ~ 1.00 and 1.20 μm , causing distinct reflectance peaks at ~ 0.85 , 1.10 , and 1.30 μm . These are diagnostic of the three groups of mosses – *Sphagnum* (Figure 48-Figure 49), feather mosses (Figure 28), and brown mosses (Figure 29). Bubier and coworkers suggested that these may indicate different cellular characteristics. The high water content causes the overall reflectance of the mosses in the SWIR region to be lower than that found in tracheophytes.

Figure 29. *Scorpidium revolvens*, one of the rich fen brown mosses. Photo by Michael Lüth, with permission.

For aquatic bryophytes, water depth affects light intensity and quality. Martínez Abaigar *et al.* (1993) found that *Scapania undulata* (Figure 30-Figure 31) had a Leaf Specific Area (LSA) of $317 \text{ cm}^2 \text{ g}^{-1} \text{ DW}$ at 5 cm depth, but at 45 cm depth, the LSA increased to $399 \text{ cm}^2 \text{ g}^{-1} \text{ DW}$. Concomitantly, Leaf Specific Weight was reduced from 3.16 mg cm^{-2} to 2.50 mg cm^{-2} . These differences can be interpreted as a response to lower light availability at 45 cm and parallel the kinds of changes that occur in tracheophyte leaves. Canopy leaf fall likewise causes an increase in accessory pigments relative to chlorophyll *a* in this liverwort by increasing the light coming through the canopy.

Some structural timing changes are likely to help in protecting developing tissues from high light damage. In tracheophytes, bud scales and leaf primordia can prevent desiccation and most likely prevent light damage to developing tissues when the canopy is free of leaves in the spring (Budke *et al.* 2012). But mosses have no such mechanism. Nevertheless, in the moss *Funaria hygrometrica* (Figure 32-Figure 35), there are indications that the **calyptra** plays this role for the developing sporophyte. Not only does the calyptra remain on the developing tip of the young sporophyte until the capsule begins to form, but as the calyptra develops, it produces its cuticle before any cuticle develops on the young capsule. In fact, the calyptrae are covered by four layers of cuticle at all stages. Although Budke and co-workers emphasized the importance of the cuticularized calyptra in preventing desiccation, I would consider it likely that this structure also serves as a filter to protect the developing apical cells from UV-B.

Pigmentation

Plant leaves and plant cells are much like a system of filters and lenses. We have already discussed the use of cell structure (lenses) to focus light on a particular location or to alter its intensity. Another way to protect chlorophyll and DNA from high light intensity is through colored pigments (filters) that absorb light.

Increased levels of chlorophyll *b* and xanthophylls, both antenna pigments, are consistent with the suggestion that it is the antenna pigments that dissipate light energy in *Rhytidiadelphus squarrosus* (Figure 36); specifically, **zeaxanthin** strongly enhances **light quenching** (dissipation of light energy) in an atmosphere of 20% CO₂ (Bukhov *et al.* 2001a). This appears to be fundamentally different from mechanisms in tracheophytes, as represented by spinach and *Arabidopsis* (Figure 37), where the reaction center appears to be important in quenching. In *R. squarrosus*, it requires only a few short light pulses, separated by a prolonged dark period, to stimulate the production of additional zeaxanthin (Bukhov *et al.* 2001b). But that was in 20% CO₂! What can it do in the more normal 0.04% CO₂? The interaction of zeaxanthin with thylakoid protonation permits the effective thermal dissipation of light energy in the chlorophyll antenna system of photosystem II in this bryophyte, but not in the two tracheophytes.

It appears that there is a physiological mechanism that facilitates pigment production in response to high light. The gaseous hormone **ethylene** inhibits the synthesis of carotenoids and chlorophyll (Kang & Burg 1972), but stimulates the production of red pigments. Ultimately, its production is inhibited by red light, a convenient feedback mechanism to stop production when the cells have enough red pigment. Ethylene is inhibited by CO₂ and requires O₂ for its formation.

Red pigments become more common in mosses at low temperatures. In our experiments with *Fontinalis squamosa* (Figure 38-Figure 40) (Glime & Rohwer 1983), a water-soluble red pigment (anthocyanin derivative?) was produced as a wall pigment in aborted apical buds (Figure 41) and some of the older leaves under treatment with ACC, an ethylene precursor.

In *Fontinalis antipyretica* (Figure 42), red leaves were present in a population growing in cold mountain water in full sun (Figure 43-Figure 44) (Glime & Rohwer 1983). A similar response occurred when shoots were kept out of the water under fluorescent light (Figure 45). A similar response is present in *Ceratodon purpureus* (Figure 46) in the Antarctic (Post 1990). In high light, the leaves become ginger-colored, a color caused largely by an increase in anthocyanin and decrease in chlorophyll concentrations (Figure 60).

In intense light and cold these C_3 bryophytes would have a high photosynthesis/photorespiration ratio due to the fact that photorespiration is low at low temperatures, whereas photosynthesis, while lowered at these temperatures, will not be lowered as much as photorespiration (Zelitch 1971). This high ratio will result in a high O_2/CO_2 ratio that will favor an increase in ethylene production; ethylene will then inhibit production of carotenoids and chlorophyll while stimulating anthocyanin production. The resulting pigmentation will then reflect, scatter, and transmit red light. Since red light should inhibit ethylene production (Kang & Burg 1972), it appears that this system should be self-limiting, with intense red pigment reducing or turning off ethylene production and protecting chlorophyll from overexcitation in intense light (Figure 47). However, this assumes that the red pigment behaves like anthocyanin.

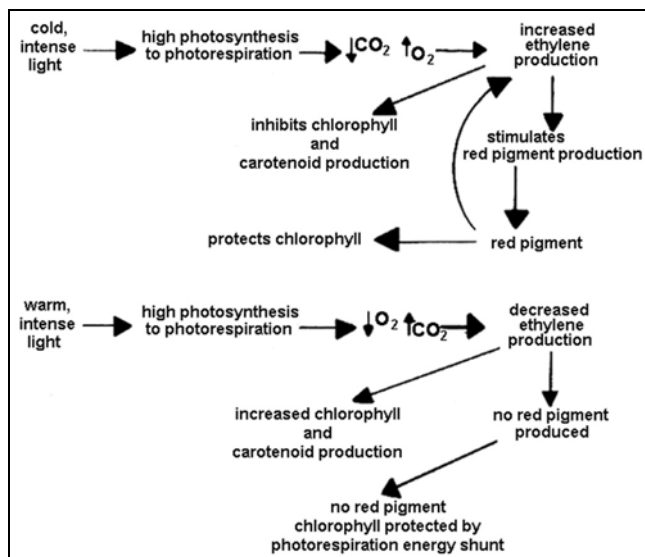

Figure 47. Proposed role of intense light in the production of ethylene and red pigment under cold and warm conditions.

Maseyk *et al.* (1999) compared New Zealand samples of *Sphagnum cristatum* (Figure 48) of different colors to determine the effects of pigmentation on photosynthetic response. Brown mosses required higher light intensities (photon flux densities, PFD) than did green samples, had

lower quantum efficiencies, and had higher light compensation points, all suggesting that the pigments played a role in filtering out light. An interesting correlation to this was that brown moss samples had a wider range of optimum water content (1400-3000%) than did green mosses (1200-2000%).

Figure 48. Multi-colored capitula of *Sphagnum cristatum*. Photo by Janice Glime.

Gerdol (1996) found that *Sphagnum magellanicum* (Figure 49) had its greatest growth rates in the shade in plants with the highest chlorophyll *b* concentrations and that a high ratio of chlorophyll to carotenoids was also beneficial in the shade. In the open, growth rates were negatively correlated with the chlorophyll *a:b* ratio. Gerdol suggested that this negative relationship is due to the greater ease with which chlorophyll *a* is degraded under environmental stress.

Figure 49. Red *Sphagnum magellanicum* resulting from sphagnorubin produced when nights are cold and days are bright in the autumn. Photo by Janice Glime.

Light quality matters. In the thallose liverwort *Marchantia polymorpha* (Figure 50-Figure 51) the red/far-red ratio matters. De Greef and Fredericq (1969) tested this liverwort in a series of R/FR ratios in 10-minute exposures at the end of the day. In a decreased R/FR ratio, there was a decrease in chlorophyll content. The growth of this liverwort was similar to that shown for seedlings of tracheophytes. The researchers concluded that high levels of the Pfr form of phytochrome were necessary to maintain optimal chlorophyll content in these thalli.

Figure 50. *Marchantia polymorpha* demonstrating the pale color of sun plants. Photo by James K. Lindsey, with permission.

Figure 51. *Marchantia polymorpha* demonstrating the dark color of shade plants. Photo by Walter Obermayer, with permission.

Sphagnorubin

As with anthocyanin, concentration of **sphagnorubin**, a red wall pigment in some species of *Sphagnum* (Figure 49), was also highest in the open (Gerdol 1996). However, the sphagnorubin concentration was not correlated with chlorophyll concentration and growth rate.

Sphagnorubin is a flavonoid related to anthocyanin (Rudolph *et al.* 1977). Schmidt-Stohn (1977) found that in *Sphagnum magellanicum* (Figure 49), its synthesis is related to rapid changes in chlorophyll concentration. When Gerdol (1996) did not find the expected negative correlation with chlorophyll concentration, he assumed that the timing of the chlorophyll and sphagnorubin metabolic pathways were different. Sphagnorubin is produced when nights are cold (5°C) and daytime light is intense, but not when both nights and days are warm (18°C) (Rudolph *et al.* 1977; Gerdol *et al.* 1998).

Chlorophyll Ratios in Aquatic Bryophytes

Whereas the brook moss *Fontinalis antipyretica* (Figure 42-Figure 45) likewise can be brilliant red in nature in intense light and cold water (Glime 1984), on the other

end of the scale, aquatic bryophytes alter pigment concentrations as light attenuation occurs with increasing depth. In *Scapania undulata* (Figure 30-Figure 31) populations, plants growing at 5 cm depth gained chlorophyll *a* in summer (from 3.43 to 3.69 mg g⁻¹ dw) while losing chlorophyll *b* (from 1.17 to 0.87 mg g⁻¹ dw), suggesting that they had a much higher light availability in summer (Mártinez Abaigar *et al.* 1993). At 45 cm depth, they lost chlorophyll *a* in summer (from 4.08 to 3.41 mg g⁻¹ dw) and likewise lost chlorophyll *b* (from 1.47 to 1.15 mg g⁻¹ dw). The increase in chlorophyll *b* with depth was significant ($p < 0.01$) in both spring and summer, whereas chlorophyll *a* had a significant increase with depth in spring ($p < 0.01$) but not in summer ($p > 0.05$). The resulting chlorophyll *a*:*b* ratio was significantly less at 45 cm in both seasons. Variance in carotenoid ratios was extremely small, causing differences of less than 5% between the two depths to be significant for spring samples.

Martínez-Abaigar *et al.* (2003) subjected the aquatic moss *Fontinalis antipyretica* (Figure 42) and aquatic leafy liverwort *Jungermannia exsertifolia* subsp. *cordifolia* (Figure 52) to 3 different radiation regimes for 36 days in the laboratory. In *F. antipyretica*, UV-A had little biological effect. UV-B caused decreases in both chlorophyll and carotenoid concentrations, chlorophyll *a*/*b* ratios, chlorophyll/phaeopigment ratios, net photosynthetic rates, light saturation point, maximum quantum yield of photosystem II, and apparent electron transport rate, along with increases in their **sclerophyll index** and dark respiration rates. Most of these changes were indicative of plant stress. In the liverworts, however, UV-B caused only an increase in the concentration of UV-absorbing compounds and a decrease in F_v/F_m . The researchers concluded that these differences would permit the liverwort to tolerate higher levels of UV-B radiation. But in my observations of *Fontinalis antipyretica* growing near the surface in cold water in full sun, the mosses were a deep red-green, protected by red pigments (Figure 42-Figure 44).

Figure 52. *Jungermannia exsertifolia* subsp. *cordifolia*, a species that produces more UV-absorbing compounds in response to high light. Photo by Michael Lüth, with permission.

The **sclerophyll index** has rarely been applied to bryophytes. It was developed to compare features of Australian sclerophyllous plants (literally, hard-leaved plants) and included broad, leathery leaves; reduced leaf size; needle leaves; winged stems; spiny stems; sunken stomata; cutinization and lignification of leaves; development of tannins and resinous substances; strong

development of palisade mesophyll and weak development of spongy mesophyll; and presence of hairs, scales, or waxy bloom on leaf surface (Grieve 1955). Few of these can be applied to bryophytes, but instead **sclerophyll index in bryophytes** is defined as ratio of dry mass to shoot area (Monteforte López 2014), including reduced leaf size, cutinization of leaves, development of tannins (phenolic compounds), thicker leaves, presence of awns or papillae, and waxy bloom might be instructive.

Using 17 species of bryophytes from low light habitats of Yuan-Yang Lake at 1760 m elevation in northern Taiwan, Yang *et al.* (1994) found that the mean chlorophyll *a/b* ratio was 2.41, with all mean ratios equalling or exceeding 2.17. Two hydrophytes used for comparison had a mean of 3.08. Nevertheless, these 17 bryophytes had a higher chlorophyll *a/b* ratio than most mosses reported in the literature, suggesting that they were adapted (or acclimated) to the intense illumination of that elevation ($250 \mu\text{mol m}^{-2} \text{s}^{-1}$).

UV Absorption

Bryophytes are able to produce pigments that absorb UV-A and UV-B while permitting most of the photosynthetically active radiation to penetrate (Jorgensen 1994). These pigments are primarily **phenylpropanoids** and **flavonoids**. Jorgensen suggests that these pigments may have evolved along with the high biosynthetic activity that is needed for UV protection. One of the necessary components of this evolution was to provide a means of sequestering these protective compounds that would otherwise be toxic. Clarke and Robinson (2008) demonstrated that the Antarctic moss *Ceratodon purpureus* (Figure 46) produced cell wall-bound UV protective compounds, an effective place to sequester them to protect their own cells. These UV-B protective compounds not only protect against damaging radiation, but at least some are also important in antiherbivory and antimicrobial activity (Davidson *et al.* 1989; Graham *et al.* 2004).

Unlike the popular perception, some mosses are able to grow in large numbers in full sun. How do these mosses cope with high light and UV-B radiation? *Physcomitrella patens* (Figure 53) is one of these sun-dwelling mosses. This remarkable tiny moss actually has greater ability to survive UV-B stress than the flowering sun plant *Arabidopsis thaliana* (Figure 37) (Wolf *et al.* 2010). This moss has ~400 genes that are expressed in response to UV-B radiation! Its response pathways are also distinct.

Figure 53. *Physcomitrella patens*, a tiny sun-dwelling moss that survives high light better than the weedy tracheophyte *Arabidopsis thaliana* (Figure 37). Photo by Michael Lüth, with permission.

In Norway, Wilson *et al.* (1998) found that the growth of *Hylocomium splendens* (Figure 54-Figure 55) was strongly stimulated by UV-B when provided with extra water, but under its natural water conditions, UV-B displayed no effect on growth or appearance. On the other hand, leaves of the shrub *Vaccinium vitis-idaea* (Figure 56) became thicker, whereas those of deciduous dwarf shrubs became thinner.

Frey and Kürschner (1991) found a correlation between black pigmentation and increasing aridity in mosses. This most likely is an adaptation to protect the moss from UV light during periods of drought. Normally, water helps to protect chlorophyll from UV light, but during periods of drought, this is not possible. The dark color could serve as a filter against the UV, becoming more transparent to light when water returns. Certainly the color should not be needed for warmth by absorbing heat rays since it is during the warmest periods that high light intensity and desiccation provide the greatest problems.

Many members of the leafy liverwort genus *Frullania* (Figure 57) possesses red coloration, grading into nearly black. This genus typically lives on trees and boulders, often at high elevations or high in the canopy. Deeply pigmented species can actually require high light, and account for the presence of this species at high elevations above timberline or high in the canopy of the tropics. On Barro Colorado Island, Panama, epiphyllous liverworts grow more quickly in high light intensities than in the shade, attesting to their adaptations to high light intensity (Coley *et al.* 1993). But these locations also often have higher UV-B light, so the pigmentation may serve as an important filter against UV damage.

Figure 57. Red coloration of *Frullania tamarisci*. Photo by Michael Lüth, with permission.

Searles *et al.* (2002) examined the responses of peatland mosses in southern South America to near-ambient (90%) and reduced (20%) UV-B radiation for three growing seasons. The reduction of UV-B cause an increased height growth in *Sphagnum magellanicum* (Figure 49), but the plant density decreased. Hence, there was no net influence on biomass production. *S. magellanicum* experienced a 10-20% decrease in UV-B-absorbing compounds under the low UV-B regime, but there were no effects on chlorophyll or carotenoid concentrations.

UV radiation is much more intense in terrestrial habitats because in aquatic habitats water quickly absorbs it. It appears that aquatic mosses and liverworts may differ from each other in their UV-absorbing spectra. In ten mosses and four liverworts from a mountain stream at 2,000 m elevation, only the liverworts had high levels of methanol-extractable UV-absorbing compounds, with the exception of *Polytrichum commune* (Figure 58) (Arróniz-Crespo *et al.* 2004). Accumulations of such compounds could protect liverworts against the high UV-B light on stream rocks above and near the surface.

Figure 58. *Polytrichum commune*, a species that produces high levels of methanol-extractable UV-absorbing compounds in high light. Photo by Michael Lüth, with permission.

In their study of aquatic bryophytes, Martínez Abaigar *et al.* (1993) found very little seasonal or species-specific differences in carotenoid ratios, suggesting that the carotenoids responded little to changes in light intensity in these bryophytes. We know that UV-B quickly loses energy in water, converting to longer wavelengths, and perhaps reducing the danger of UV-B damage in aquatic bryophytes.

UV-B penetration changes throughout the day as the Earth turns and the sunlight travels through less atmosphere as time approaches 12:00 hours, then decreases as the rays strike at a greater angle, once again having to penetrate more atmosphere. The aquatic leafy liverwort *Jungmannia exsertifolia* subsp. *cordifolia* (Figure 52) exhibited significant **diel** (within 24 hours) changes, responding within a few hours to changes in radiation levels (Fabón *et al.* 2012). The strongest response was to UV-B. High levels of photosynthetically active radiation (PAR), UV-A, and UV-B radiation elicited significant and rapid diel changes in the components of the **xanthophyll cycle** (process of enzymatic removal of epoxy groups from xanthophylls, *e.g.* violaxanthin, antheraxanthin, diadinoxanthin) to create so-called de-epoxidised xanthophylls). Furthermore, the F_v/F_m , ϕ PSII (absolute quantum yield of CO₂ fixation in photosystem II), and non-photochemical quenching likewise responded quickly to the changes in radiation levels. These changes provided dynamic photoinhibition and protection of PSII, with the xanthophyll cycle providing protection from the excess radiation.

Accessory pigments such as carotenoids can serve to protect chlorophyll from damage by high intensity UV light (Siefermann-Harms 1987) such as that in the Antarctic. The three mosses examined by Siefermann-Harms all had sustained high levels of xanthophyll pigments, especially at exposed sites (Lovelock & Robinson 2002). Among these was an increase in **violaxanthin** (Post 1990). These pigments are photoprotective and indicate that the moss most likely is subjected to continual high levels of photochemical stress (Lovelock & Robinson 2002). *Ceratodon purpureus* (Figure 59-Figure 60) had a higher carotenoid:chlorophyll ratio in high light intensities (0.55) than in low ones (0.35).

Figure 59. *Ceratodon purpureus* green form as it appears when the snow melts. Photo by Janice Glime.

Figure 60. *Ceratodon purpureus* in its golden form that has been subjected to high light intensity. Photos by Janice Glime.

Since the Antarctic has received much publicity due to the ozone hole and resulting increase in UV-B penetration through the atmosphere, many of our studies on bryophyte responses to increased UV-B radiation have involved Antarctic bryophytes. Responses are seasonal, resulting in an increase in photoprotective pigments as the ice melts and the mosses become exposed (Dunn & Robinson 2006). One interesting result of these studies is finding that the two cosmopolitan mosses *Bryum pseudotriquetrum* (Figure 5) and *Ceratodon purpureus* (Figure 46, Figure 59-Figure 60) appear to be better protected against UV-B radiation than is the Antarctic endemic *Schistidium antarctici* (Figure 7). Of these three mosses, *B. pseudotriquetrum* accumulates the highest concentration of UV-B protective pigments, exhibiting a positive correlation between UV-B radiation and both UV-B-absorbing and anthocyanin pigments. Under desiccating conditions, this species has greater concentrations of these protective pigments than in well-hydrated conditions. This combination would mean that at low temperatures and low moisture, the moss would have limited physiological activity and thus be protected from potential UV-B damage.

Ceratodon purpureus (Figure 59-Figure 60) is the most exposed species of the three studied (Dunn & Robinson 2006). It uses a different strategy of protection, with concentrations of UV-B absorbing pigments being stable through varying light and moisture conditions (Dunn & Robinson 2006). Dunn and Robinson suggested that this is evidence that the protective pigments are constitutive in this species. On the other hand, the anthocyanin pigments

were responsive, providing increased antioxidant protection during exposure to high levels of UV-B radiation.

The endemic *Schistidium antarctici* (Figure 7), unlike these two cosmopolitan species, is poorly protected, showing no evidence of pigment production in response to UV-B stimulation (Dunn & Robinson 2006). This raises an interesting question of survival, since this species grows along side *Ceratodon purpureus* (Figure 59-Figure 60). Are there physiological mechanisms that permit its survival, or is it indeed more vulnerable to a diminished ozone layer, as suggested Dunn and Robinson?

A study by Proctor and Smirnov (2011) may explain the survival of *Schistidium antarctici* (Figure 7). Mosses typically saturate at moderate light levels. Light intensities above those levels can therefore be harmful because of more excited electrons than the photosynthetic apparatus can handle. These saturating levels are similar to those of shade species, demonstrated by the moss *Plagiomnium undulatum* (Figure 61) and leafy liverwort *Trichocolea tomentella* (Figure 62). But what about bryophytes that live in exposed sites with no shade to protect them? *Andreaea rothii* (Figure 63-Figure 64), *Schistidium apocarpum* (Figure 65), many *Sphagnum* species (Figure 48-Figure 49), and *Frullania dilatata* (Figure 66) show a non-saturating electron transfer rate at high light levels, accompanied by high non-photochemical quenching (protection from the adverse effects of high light intensity by dissipating excess excitation energy). *Plagiomnium undulatum* and *Schistidium apocarpum* can use oxygen and carbon dioxide interchangeably as **electron sinks** (in this case, binding the electrons so they cannot do damage). These two moss species have a high capacity for oxygen photoreduction when CO₂ assimilation is limited. But when the atmosphere is reduced to 1% O₂ with normal levels of CO₂, non-saturating electron flow is not suppressed. Nitrogen + saturating CO₂ causes a higher relative electron transport rate while depressing the non-photochemical quenching. These high abilities of supporting the electron transport by oxygen photoreduction may be a mechanism to permit such mosses as the Antarctic *Schistidium antarctici* to survive the high UV-B levels in the Antarctic.

The moss *Hennediella heimii* (Figure 67) from Southern Victoria Land, Antarctica, is provided with glacial melt water during the summer. When Pannewitz *et al.* (2003) monitored this moss for 18 days in summer, they found that it had a constant potential photosynthetic activity during that entire period. It grew in the predicament of high light and low temperatures. Nevertheless, it showed no sign of photoinhibition or light saturation, and its electron transport rate response to photosynthetic photon flux densities remained linear at all

temperatures. The researchers speculated that it must have a highly effective non-photochemical quenching system.

Figure 67. *Hennediella heimii*, a species that shows no sign of photoinhibition even in the high UV-B light of the Antarctic continent. Photo by Michael Lüth, with permission.

When the snow melts on the Antarctic Peninsula, bryophytes are suddenly exposed to high UV-B levels while still at near-freezing temperatures. Post and Vesik (1992) studied the only continental Antarctic liverwort,

Cephaloziella varians (Figure 68-Figure 69). It occurs in full sun once its ice cover melts. The researchers compared plants from sun-exposed and shaded sites. Those from full sun exhibited dark purple leaves with an anthocyanin-like pigment in thick cell walls. These purple plants grew in dense turfs, were larger, had more closely spaced leaves, and had a higher carotenoid to chlorophyll ratio than did the shaded green plants. The shaded green plants, on the other hand, contained more chlorophyll per unit weight. Like a number of other bryophyte studies, this one showed no variation in the chlorophyll *a/b* ratio with differences in light intensity. In low light levels the green plants exhibited higher photosynthetic oxygen evolution rates. The two colors of leaves in similar positions on the plants had more appressed thylakoids in green leaves than did the purple leaves. These differences are the same as expected under varying light exposure.

Figure 69. *Cephaloziella varians* showing red coloration typical in high light. Photo by Kristian Peters, with permission.

Snell *et al.* (2007) experimented with the same leafy liverwort species, *Cephaloziella varians* (Figure 68-Figure 69), by covering it with screens containing Mylar polyester

for 44 days. This treatment resulted in changes in thalli, which are normally black, to exhibit a green color. This was the result of reduced concentrations of the anthocyanidin **riccionidin A** in the plant tips. These plants were then exposed to an abrupt increase in their UV-B radiation when the screens were removed. Within only 48 hours the plants were visibly darker. This color change was due to *de novo* synthesis of riccionidin A that reached the same concentrations as that in plants that had not been covered during those 44 days. This synthesis required an equivalent of 1.85% of the carbon fixed during those 48 hours. The F_v/F_m and photochemical quenching were likewise the same in both groups of plants. Nevertheless, the level of chlorophyll fluorescence indicated that non-photochemical quenching was higher in the plants that had just experienced the sudden increase in UV-B.

Otero *et al.* (2008) examined five liverworts and ten mosses from open aquatic habitats of Tierra del Fuego on the southern tip of Argentina, where the atmosphere is thinner than in temperate regions, to determine their responses to UV radiation. They found that the species differed in spectra form and area under the absorbance curve (AUC). The spectra had one, two, or no defined peaks. They suggested that phenolic derivatives might be responsible for the differences in peaks among the species. These phenolic derivatives could serve not only as screening compounds, but also as antioxidants. The AUC values for most of the liverworts were higher than those for most of the mosses. The liverworts *Noteroclada confluens* (Figure 70) and *Triandrophyllum subtrifidum* (Figure 71) had much higher bulk UV-absorption capacity of the methanolic extracts (BUVACME) than did any other bryophyte in the study. The researchers concluded that "accumulation of UV-absorbing compounds might often increase protection against UV radiation in liverworts, but rarely in mosses." Could this difference be related to their location in southern Argentina? But Otero and coworkers did not find the BUVACME of these aquatic bryophytes to differ significantly from that found elsewhere on the planet.

Huttunen *et al.* (2005) compared the UV-absorbing compounds in herbarium specimens of terrestrial and peatland mosses collected from 1926 to 1996 from the sub-Arctic to see if it had changed as fluorines in the atmosphere increased the ozone hole, permitting greater penetration of UV light. They found that the average amount of total compounds (sum of A280-320 nm absorption) per mass from the lowest to the highest was *Polytrichum commune* (Figure 58), *Pleurozium schreberi* (Figure 28), *Hylocomium splendens* (Figure 54-Figure 55), *Sphagnum angustifolium* (Figure 72), *Dicranum scoparium* (Figure 73), *Funaria hygrometrica* (Figure 32-Figure 35), *Sphagnum fuscum* (Figure 74), *Sphagnum warnstorffii* (Figure 75), *Sphagnum capillifolium* (Figure 76), and *Polytrichastrum alpinum* (Figure 77). The amount of UV-B-absorbing compounds per specific surface area correlated with the summertime daily global radiation and latitude, but they found no trend in concentration of UV-B-absorbing compounds from 1920 to 1990 except in *Sphagnum capillifolium*, which showed a significant decreasing trend in concentrations. Huttunen and coworkers suggested that this lack of correlation with the increasing size of the ozone hole could be the result of degradation of the protective compounds or the difficulty in extracting the wall-bound pigments p-coumaric acid and ferulic acid (Davidson *et al.* 1989) and the sphagnorubins (Geiger *et al.* 1997).

Caldwell *et al.* (1998) concluded that some of the most important consequences of elevated UV-B might be indirect effects. In tracheophytes, these include changes in susceptibility of plants to attack by pathogens (fungi & bacteria) and insects, changes in the competitive balance among plants, and altered nutrient cycling. More direct effects seem to occur through altered gene activity rather than direct damage. These changes may be exacerbated or diminished by other changes that are coupled with increased UV-B, such as temperature and CO₂ level changes. Although these indirect effects would seem to be critical, if forest trees and other tracheophyte examples are indicative, we should look for these effects in bryophytes.

Early land plants faced high levels of UV light and at the same time water scarcity from their beginnings on land (Martínez-Abaigar & Núñez-Olivera 2022). Through time, they have developed various physiological and structural adaptations to minimize the effects of UV light on the cell contents. These adaptations vary among the species, with mosses being more UV-tolerant than liverworts.

Desiccation Effects and Light

High light intensities are often coupled with desiccating conditions. Yet, it appears that the mosses that live in such desiccating conditions seldom suffer light damage during their dehydrated periods, and photosynthesis is able to resume immediately upon

rehydration, not requiring synthesis of new chlorophyll to resume (Di Nola *et al.* 1983). For example, the desiccation-tolerant moss *Syntrichia ruralis* (Figure 2) retains all its pigments upon drying, thus rapidly recovering its photosynthetic functions upon rehydration (Hamerlynck *et al.* 2002). This species permits recovery on a daily basis by a thermal dissipation of the excess light energy as the moss dehydrates in the morning, and recovery upon rehydration depends on light conditions and the rapidity of drying.

Tracheophytes do not enjoy this pigment conservation (Heber *et al.* 2001) and rapidly lose their photosystem II capability under desiccation conditions (Hamerlynck *et al.* 2002). In desiccation-tolerant bryophytes, protein protonation, coupled with the presence of high levels of zeaxanthin, seems fully capable of dissipating excess light energy (Heber *et al.* 2001). A similar rise in zeaxanthin with dehydration occurs in the desiccation-tolerant tracheophyte *Selaginella lepidophylla* (Figure 78) (Casper *et al.* 1993). This rise occurs during the dehydration process, and Casper *et al.* hypothesized that zeaxanthin-related protection is engaged in response to the dehydrating conditions, even in low light levels. Nevertheless, chlorophyll fluorescence is lost during drying of predarkened desiccation-tolerant mosses, suggesting that energy dissipation in the dry state is not related to protonation and high levels of zeaxanthin.

Deltoro *et al.* (1998a) found that desiccation-tolerant bryophytes [*Hedwigia ciliata* (Figure 14-Figure 16), *Hypnum cupressiforme* (Figure 80), *Leucodon sciurioides* (Figure 81-Figure 82), *Orthotrichum cupulatum* (Figure 83), *Pleurochaete squarrosa* (Figure 84), *Porella platyphylla* (Figure 85), and *Syntrichia ruralis* (Figure 2)] were able to resume photosynthesis rapidly upon rehydration, whereas desiccation-intolerant bryophytes [*Barbula ehrenbergii* (Figure 86-Figure 87), *Cinclidotus aquaticus* (Figure 88), *Conocephalum conicum* (Figure 89), *Lunularia cruciata* (Figure 90), *Palustriella commutata* (Figure 91-Figure 92), *Philonotis calcarea* (Figure 93), and *Platyhypnidium riparioides* (Figure 94)] from mesic and hydric habitats were unable to resume their photosynthetic activity.

In examining the xanthophyll content of a desiccation-tolerant leafy liverwort, *Frullania dilatata* (Figure 66), they found an increase in de-epoxidized xanthophylls in response to dehydration (Deltoro *et al.* 1998b), whereas this did not occur in the desiccation-intolerant *Pellia endiviifolia* (= *Apopellia endiviifolia*; Figure 95), and the latter species had less ability to dissipate the light while dry. Upon rehydration, *Frullania dilatata* resumed full photosynthetic capability rapidly, whereas *P. endiviifolia*

suffered irreversible damage to photosystem II. They suggested that *F. dilatata* likewise possesses a desiccation-induced production of zeaxanthin, but they were unable to rule out the loss of K^+ from damaged membranes in *P. endiviifolia* as a causal factor for its demise.

Figure 95. *Pellia endiviifolia*, a species with weak ability to dissipate light when dry. Photo by Michael Lüth, with permission.

Bartoskova *et al.* (1999) offer a somewhat different explanation for observed changes in chlorophyll fluorescence during drying. Working with leaves of *Rhizomnium punctatum* (Figure 96), they found a 50% decrease in the F685/F735 ratio in the chlorophyll fluorescence spectrum during drying. No changes occurred in the E475/E436 bands of fluorescence. They could find no functional changes resulting from desiccation at the energy transfer level and suggested that the change in fluorescence ratio is the result of a rearrangement of chloroplasts into groups that enhance the effect of chlorophyll reabsorption. My own experience in extracting chlorophyll from dry mosses is that they extract better if they are rehydrated first. This would be consistent with the grouping of chloroplasts, hence preventing the solvent from reaching the interior of the clump. In a conversation with Zoltan Tuba, I learned that he had experienced a similar response.

Figure 96. *Rhizomnium punctatum*, a species that may rearrange its chloroplasts upon drying. Photo by Michael Lüth, with permission.

At least in alpine areas, where UV light may be more intense, desiccation can affect moss (and lichen) fluorescence differently from its effects on tracheophytes. In its dehydrated state, the moss *Grimmia alpestris* (Figure 97) had very low chlorophyll fluorescence, whereas it was high in the alpine tracheophytes tested (Heber *et al.* 2000). Conversely, upon rehydration, the mosses and lichens experienced increased chlorophyll fluorescence, whereas the tracheophytes experienced a decrease. This is because, unlike their tracheophyte counterparts, the mosses and lichens do not experience photodamage in their dry state. Both groups of plants form potential chlorophyll fluorescence quenchers as a response to desiccation, but only the dehydrated mosses and lichens responded to the energy transfer from light by exhibiting a decrease in fluorescence. It appears that among these alpine taxa, only the poikilohydric *Grimmia alpestris* has a deactivation pathway that enables it to avoid photodamage both in its hydrated and dehydrated states.

Figure 97. *Grimmia alpestris*, a species that has a deactivation pathway that permits it to live in high light conditions. Photo by Jan-Peter Frahm, with permission.

Beckett *et al.* (2005) found that **hardening** (process of increasing resistance) of the moss *Atrichum androgynum* (Figure 98) during drying permitted it to recover fully from dehydration, whereas lack of time for this preparation did not (Figure 99). That is to say, mosses that hardened by slow drying before the silica gel desiccation treatment had a better recovery than mosses that were placed immediately

into the desiccation treatment from full hydration. More importantly, hardening greatly increased the photochemical quenching during the first few hours of rehydration. In these early stages photophosphorylation occurs, but not carbon fixation. Thus, it is in these early stages that photoprotection is most important, and the moss experiences reduced efficiency during drying in order to accomplish photoprotection during rehydration.

Figure 98. *Atrichum androgynum*, a species that recovers fully from dehydration if it is able to undergo hardening during drying. Photo by Clive Shirley, Hidden Forest <www.hiddenforest.co.nz>, with permission.

Figure 99. The effect of hardening on the non-photochemical quenching upon rehydration of 1, 5, and 100 hours compared to quenching prior to desiccation in *Atrichum androgynum*. Redrawn from Beckett *et al.* 2005.

Mosses, as in the tracheophyte resurrection plant *Selaginella lepidophylla* (Figure 78-Figure 79), often have mechanical responses that help to protect them from the damaging effects of light. Lebkuecher and Eickmeier (1991, 1993) have shown that the rolling of the fronds of *S. lepidophylla* serves to protect the plant from light and thermal damage that could be expected in the dry state. In that species, some damage occurs during the drying phase before the curling is complete. It is likely that mosses like *Hedwigia ciliata* (Figure 14-Figure 16) and *Syntrichia ruralis* (Figure 100) might accomplish the same thing. Might the smaller bryophytes curl quickly enough to avoid that early damage? In *Hedwigia ciliata*, an appression of

leaves against the stem is realized, and the tips of the branches tend to curve upward, reducing exposure. In *S. ruralis*, the drying leaves twist (Figure 100) and become more vertically oriented. Hamerlynck *et al.* (2000) suggested that *S. ruralis* has a "coordinated suite of architectural and physiological characteristics maintaining the photosynthetic integrity of these plants." These include not only their ability to change the positions of their leaves, but also to alter the surface reflectance as water leaves the leaf cells. This alteration causes more reflectance from a dry surface than from a wet one.

Figure 100. Dry *Syntrichia ruralis* exhibiting dark color and twisted leaves that protect it from high light intensity. Photo by Janice Glimme.

In the Antarctic, where desiccation is frequent, Lovelock and Robinson (2002) also found significant differences among species and the sites they occupied based on their surface reflectance properties, especially at ~700 nm, whereas pigment concentration did not seem to be important.

Avoidance – Hiding under Rocks

Imagine a light so intense that you must hide under a rock to avoid damaging your pigments. The only light you ever see is that which comes through the rock, or occasionally reflects off the ground around that rock. There are some mosses that take just such a refuge. Using the rock as a filter, *Syntrichia inermis* (Figure 101) survives the intense light (and dryness) of the Californian desert by living beneath a piece of translucent rock (Werger & During 1989).

Figure 101. *Syntrichia inermis*, a moss capable of living under quartz pebbles in the desert. Photo courtesy of Lloyd Stark.

As we have seen, polar deserts are unfriendly habitats due to the damaging effects of UV radiation. For *Cyanobacteria* (Figure 102) and algae, living under translucent rocks is a way to escape that damaging radiation (Thomas 2005). These assemblages can be as productive as their neighbors that are not protected by rocks. It seems likely to me that some members of these microbial communities might enhance the habitat for the few species of bryophytes that live there. For example, *Cyanobacteria* can convert atmospheric nitrogen to a form usable by the bryophytes. Non-photosynthetic bacteria can provide CO₂. This remains another microecosystem begging for ecological study.

Figure 102. *Cyanobacteria* under quartz rock. Photo by Michael Wing, public domain through NSF funds.

Williams (1943) described a "moss peat" under translucent pebbles in the American Great Plains, but there seems to be no publication of the actual species. The rare moss *Aschisma kansanum* is known only from this unique habitat, where it occurs at the base of nearly clear quartz pebbles (Cridland 1959). The thick, leathery protonema, which is persistent, covers the buried part of the pebbles overlying sandy Pleistocene gravels. And in the Antarctic, where mosses must "worry" about the effects of UV light – what better place to hide than behind glass, in the form of quartz. And there one might also find the tiny *Hennediella heimii* (Figure 103) beneath the rock (Fife 2005).

Figure 103. *Hennediella heimii*, a moss that lives under quartz rocks in the Antarctic. Photo by Michael Lüth, with permission.

Marchand (1998) determined that about 1.5% of the full sunlight hitting a milky quartz rock penetrated through about 2.5 cm of rock, comparing this to the light reaching a potted plant in a well-lit office. In some cases, visible light can reach a depth of 5 cm. The rock offers the added advantage of reflecting much of the heat and registering temperatures $\sim 7^{\circ}\text{C}$ less than under a dark-colored volcanic rock.

Terry Hedderson (Bryonet 22 February 2005) tells of quartz-field bryophyte communities beneath stones in the Knersvlakte area of Namaqualand and from the inselbergs of Bosmansland, both in South Africa. He provides this anecdotal account: "The bryophyte assemblages seem to come in two forms: In some areas where there are extensive and relatively deep patches of translucent small quartz pebbles, one can find entire communities comprising *Bryum argenteum* (Figure 17-Figure 18), *Riccia* spp. (Figure 104), *Hennediella longipedunculata*, other small *Pottiaceae*, *Chamaebryum*, *Gigaspermum* (Figure 105) and others, buried to a depth of a few centimetres (3-10 say). These often occur with various *Aizoaceae* seedlings, as mentioned by a previous contributor. Some of the best examples that I've seen of these are on the summits of Ghamsberg and Pellaberg in Bosmansland. In areas where the pebble cover is less continuous (like in the Knersvlakte), I have found communities under flattish single stones that are imbedded in a clay matrix. Here they often occur with lots of blue-greens, with the main bryophyte component comprising *Archidium dinteri*, *Bryum argenteum*, various *Riccias* and small *Fissidens* spp (Figure 106). The vast majority of stones have only blue-greens and it is not at all clear what determines whether bryophytes are present or not. In both cases the plants are often quite vigorous and healthy looking, and not the least bit etiolated, so I imagine that they receive sufficient light."

Figure 104. *Riccia sorocarpa*. Members of this genus are known from under quartz rocks. Photo by Michael Lüth, with permission.

Figure 106. *Fissidens bryoides* with capsules, a tiny species such as those that might occur under flat stones in high light. Photo by Janice Glime.

But records of these sequestered mosses are far more rare than those of algae. This intriguing habitat has led a number of bryologists to overturn numerous rocks in places like the Namib Desert, so far only to find more algae.

In the Antarctic, bryophytes (and algae) occur beneath rocks, stones, and sand (Lewis-Smith 2000). Seppelt (2005) finds buried mosses there occupying ephemeral riverbeds and other places where they have been buried by sand carried by wind or water. *Bryum pseudotriquetrum* (Figure 5) and *B. subrotundifolium* (Figure 107) can be uncovered by sweeping away the sand. In these habitats, as in sand dunes and volcanic tephra, the acrocarpous mosses are able to grow upward and eventually emerge into the light. For those buried by sand, refracted and reflected light may help to sustain them through photosynthesis as they wend their way to the top.

Figure 107. *Bryum subrotundifolium* with Collembola among sand grains on Antarctica. Photo courtesy of Catherine Beard.

Lava fields often provide cracks through which rays of light may penetrate. Yojiro Iwatsuki (the finder), Zen Iwatsuki, and I were surprised in Iceland to uncover a miniature moss garden, predominately *Saelania glaucescens*, hidden under a fissure in the lava rock (Figure 108). Juana María González-Mancebo related an experience in the Canary Islands (Bryonet, 22 February 2005) where the researchers found 69 species of bryophytes living among the second layer of rock, under the rocks of the first layer of lava, in lava tubes, and in volcanic pits. Even the epiphyte *Neckera intermedia* (Figure 109) can grow in the more humid lava flows of Tenerife.

If you are a moss in the Mojave Desert, you can have a rough life. The sunlight is intense and hot. Moisture is all

but non existent most of the time. But *Syntrichia caninervis* has found an unusual way of coping. It lives under white, translucent quartz rocks (ScienceFriday.com 2020). On those rare occasions when it does rain, the moss begins rehydrating immediately and remains moist long enough to replenish its energy supply. Undoubtedly the rock helps to maintain a longer hydration period, but it also filters the intense light.

Summary

Due to their one-cell-thick leaves, bryophytes are especially susceptible to damage by UV light. Dry plants are especially vulnerable to chlorophyll and DNA damage due to the lack of protective water. Some have altered optical properties that reduce the light penetration into cells. Bryophytes can suffer photoinhibition due to overstimulation of chlorophyll in high light, which can result in a decrease in thylakoid stacking.

Some mosses have **lamellae, inrolled leaf lamina, filaments, hyaline tips, and awns** that partially cover the leaf and protect it from light. Others curl the leaves or wrap them around the stem. Aquatic mosses are protected by their water medium.

In response to high light intensities, bryophytes experience a decrease in chlorophyll. By having a relatively high amount of chlorophyll *a* compared to chlorophyll *b* in their shade plants, they are ready for sunflecks and other short periods of light availability, thus making up for the low productivity that is possible in the shade.

Pigments can filter light and reduce its energy, thus protecting the chlorophyll and DNA. Ethylene stimulates the production of red pigments, which are particularly common at low temperatures and in bright light. In *Sphagnum*, this red pigment is a cell wall pigment, **sphagnorubin**. **Violaxanthin** is known to increase in response to high light. **Zeaxanthin** responds by disabling the chlorophyll antenna pigments (**quenching**), thus reducing the energy reaching the chlorophyll *a*.

Bryophytes are superior to tracheophytes in preserving their chlorophyll during desiccation and are thus ready for photosynthesis upon rehydration. This may be due to a rearrangement of the chloroplasts into protective groups. **Hardening** is important in this preparation.

Some bryophytes avoid the intense radiation by growing under translucent rocks. These locations are especially important in deserts where light is intense and desiccation is a major problem. As seen in *Syntrichia caninervis*.

Acknowledgments

Thank you to Rod Seppelt for helping me resolve which liverwort name belonged to species from the Antarctic continent.

CHAPTER 9-4

LIGHT: SEASONAL EFFECTS

Figure 1. Winter condition of *Thuidium tamariscinum*, when the canopy is gone and the temperature is cold. Photo by Michael Lüth, with permission.

Bryophyte View of Light

Light is a constantly changing parameter in the world of the bryophytes. They experience long and short periods (**photoperiod**) as the seasons change. They experience high intensity and low intensity as the leaves grow on the trees. They experience changes from white light to green light as the canopy closes. And each of these changes is coupled with changes in temperature and available moisture. Each of these requires its own set of adaptations to permit the bryophyte to survive. But bryophytes can also take advantage of these changes as signals to them of the upcoming series of climatic events.

High Light and Low Temperatures

When plants are metabolically slowed by low temperatures (ca. 1°C) and light intensity is high (Figure 1), photo-oxidation damage can occur in cells (Kuiper 1978). This can result in such responses as rupture of the chloroplast envelope, formation of vesicles in thylakoids, and rapid degradation of linolenic acid. Adamson and coworkers (1988) suggest that such photoinhibition may be

the major factor in limiting production of Antarctic bryophytes.

Blue light seems to be especially effective in the photo-oxidation of unsaturated fatty acids, indicating that carotenoids (yellow pigments absorb blue light) contribute to the process. One of the causes of the breakdown of chlorophyll can be attributed to the degradation of its complexing lipid, monogalactose diglyceride (Kuiper 1978). Ironically, it is the unsaturated fatty acids that are susceptible to this oxidation, causing a risky condition for plants preparing for the cold of winter while sustaining the bright light of autumn. However, presence of tocopherol, an anti-oxidant, can nullify this photo-oxidation process (Kuiper 1978) and may play a key role in protection of chlorophyll during autumn and spring when such low temperature and bright light conditions prevail.

When days are bright and nights are cold, *Sphagnum magellanicum* (Figure 2) produces **sphagnorubin** and becomes a deep wine red (Gerdol 1996). When the plants occur in the open, where higher light intensities are expected, the concentration of sphagnorubin is greater.

However, in intense light and warm temperatures *Sphagnum magellanicum* does not produce much red pigmentation (Rudolph *et al.* 1977). In this case the photorespiration/ photosynthesis ratio would be high due to the fact that photorespiration has a $Q_{10} = 3$ with very little damping at higher temperatures. Photosynthesis, however, is observed to reach an optimum and then decrease its rate rapidly (Zelitch 1971). This would result in a high CO_2/O_2 ratio that would decrease ethylene production and stimulate chlorophyll and carotenoid synthesis. Anthocyanin (and sphagnorubin?) production would not be enhanced and so no red pigmentation would be found. In the case of warm temperatures, the red pigment would convey no adaptive advantage since the greatly increased photorespiration would serve as an energy shunt to protect the chlorophyll from overexcitation by the intense light (Bidwell 1979).

Figure 2. *Sphagnum magellanicum* colored by sphagnorubin. Photo by Michael Lüth, with permission.

A second function of red pigment at low temperatures could be the heat absorption and warming of the moss, a mechanism already known to warm flowers, such as those enclosed in a red spathe in *Symplocarpus foetidus* (Figure 3), and to increase respiration in cold-adapted copepods (Byron 1982). Zehr (1979) has suggested that the red color of the leafy liverwort *Nowellia curvifolia* (Figure 4), induced by exposure to light when leaves fall, increases the temperature of the liverwort to allow greater photosynthesis and respiration in winter.

Light Effects on Reproduction

Humans don't think in terms of high light intensities for reproduction, but it appears that at least some mosses do. *Hylocomium splendens* (Figure 26) had poor reproduction in all populations except those that had received extra light as the result of removal of stems (Rydgren & Økland 2001). Those that were merely clipped to remove all growing tips and provide extra light did no better than the controls, suggesting that it was not the stimulus of the wounding or the extra energy diverted away from growing buds that caused the greater reproduction. In the second year of the experiment, the removal group had ten times as many sporophytes as the other treatment groups. But is this an indication of good or of bad conditions? Many algae and even flowering plants go into a sexual stage when growing conditions are poor, providing a means for the species to survive through its offspring.

To confound the issue further, Hughes and Wiggin (1969) found that in *Phascum cuspidatum* (Figure 5), light had just the opposite effect. Plants grown in culture in the shade had significantly more antheridia, more antheridial dehiscence, and larger antheridia than plants grown with light from the north sky. They did find more archegonial heads on plants grown in the light, but the success of fertilization was greater for plants grown in the shade (11%) than in the light (6%). However, they suggested that some of these differences could be accounted for by differences in population sizes.

Figure 5. *Phascum cuspidatum* with capsules. Photo by Michael Lüth, with permission.

In the Antarctic, bryophytes are frozen in winter, but in summer they are fully exposed to the polar sun. In fact, Post *et al.* (1990) found that the major limiting factor to

Antarctic bryophyte productivity is photoinhibition. This would not be unusual for C₃ plants such as bryophytes growing at low temperatures in high light. Nevertheless, this topic has rarely been studied in bryophytes.

Seasonal Effects on Pigments

Light intensity changes with the seasons, and at least some plants are adapted to respond to those changes. Tracheophytes change their chlorophyll concentration based on the amount of light reaching the leaf. Plants grown in low light will increase their chlorophyll *b* concentration, and thus their chlorophyll *a*:*b* ratio decreases. Those plants kept indoors in low light will suddenly turn red or become bleached if they are put out in bright sunlight, and the photosynthetic apparatus will become permanently damaged. Leaves growing on the shady side of a tree will be thinner and darker, while those in the sun put on extra layers of palisade tissue. Bryophytes cannot change their leaf thickness in response to light changes, but it is possible for them to change the chlorophyll concentration and the ratio of shoot area to biomass. A bryophyte branch can effectively operate like a leaf of a seed plant and thus some of the same size ratio responses are possible.

Hicklenton and Oechel (1977) found that *Dicranum fuscescens* (Figure 6) from northern Canada exhibited an increase in the light required to saturate photosynthesis from early season until mid summer, with the trend reversing later in the season. They suggest that ability to photosynthesize at low light levels is an advantage to mosses that are still under the snow in early spring. Mosses exposed to high light when they are acclimated to low light actually experience damage, and it appears that the continuous light of summer in the Arctic may likewise be deleterious (Kallio & Valanne 1975). However, the continuous light damage occurred in laboratory experiments and it may be that plants living in the Arctic may acclimate to the seasonal change in photoperiod (Richardson 1981).

Figure 6. *Dicranum fuscescens*, a species that changes its light saturation point as the season changes. Photo by Michael Lüth, with permission.

Van der Hoeven *et al.* (1993) found that shoot area to dry weight ratio increased from September to December in three pleurocarpous bryophytes, but they could offer no explanation for the shift (Table 1). They assumed chlorophyll per gram dry weight would not change seasonally, based on a study of *Pleurozium schreberi* (Figure 7) (Raeymaekers & Glime 1986). But if these

species are more active in summer, a decrease in chlorophyll might be expected in December. On the other hand, if they store photosynthate in the summer and have maximum growth during the cooler autumn and early winter, the loss of weight per shoot length might be expected.

Figure 7. *Pleurozium schreberi*, a species that does not have seasonal changes in chlorophyll content. Photo by Janice Glime.

Table 1. Shoot area to dry weight ratio of mosses in September (n=20) and December (n=25). From van der Hoeven *et al.* (1993).

	September	December
<i>Calliergonella cuspidata</i>	143±12	302±45
<i>Rhytidiadelphus squarrosus</i>	140±10	230±30
<i>Ctenidium molluscum</i>	147±11	226±43

There is sufficient indirect evidence that we might expect chlorophyll differences with seasons. For example, we know that photosynthetic capacity changes between summer and winter in at least some mosses. In *Plagiomnium acutum* (Figure 8) and *P. maximoviczii* (Figure 9), photosynthetic capacity diminishes from 126 and 95 $\mu\text{M CO}_2 \text{ kg}^{-1} \text{ dw s}^{-1}$ in summer to 58 and 62 in winter, respectively (Liu *et al.* 2001). On the other hand, the light compensation point of 40 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ in summer drops to 20 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ in winter while the light saturation point drops similarly from 400 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ in summer to 200 $\mu\text{mol m}^{-2} \text{ s}^{-1}$ in winter. This can most likely be attributed to the lower respiration rate in winter.

Figure 9. *Plagiomnium maximoviczii*, a species that changes chlorophyll concentrations and light compensation points between summer and winter. Photo from Hiroshima University Digital Museum of Natural History, with permission.

Although Raeymaekers and Glime (1986) found similar chlorophyll content in the 2 cm terminal parts of *Pleurozium schreberi* (Figure 7) in August (2.1 mg/g dw), end of September (2.1), and end of October (2.2) in Baraga County, Michigan, I have observed that *Fontinalis* becomes pale by the end of summer (Figure 10) and bright to dark green by February (Figure 11), remaining deep green until June, in New Hampshire and the Upper Peninsula of Michigan. Martínez Abaigar *et al.* (1993) found distinct differences in chlorophyll *a* with season in two species of *Fontinalis* (Figure 15). There is no reason to expect all species to behave the same way, nor to expect the same species to behave the same way in all parts of its distribution.

Figure 10. *Fontinalis antipyretica* exhibiting typical late summer and autumn colors. Photo by Malcolm Storey, through Creative Commons, with online permission.

Figure 11. *Fontinalis antipyretica* exhibiting typical late winter to early spring colors. Photo by Malcolm Storey, through DiscoverLife, with online permission.

In their study of 13 aquatic bryophytes, Martínez Abaigar *et al.* (1993) found considerable differences among species in the chlorophyll concentration changes with seasons (Figure 15). For example, *Fontinalis antipyretica* (Figure 11) had its highest content in summer, whereas *F. squamosa* (Figure 12) had its highest in spring with summer exhibiting the second lowest (Figure 13), the lowest being in autumn. They reported that the greatest chlorophyll content occurred in the immersed species [*Fontinalis antipyretica*, *F. squamosa*, *Fissidens grandifrons* (Figure 14) from San Pedro, *Jungermannia cordifolia* (Figure 16), and *Platyhypnidium riparioides* (Figure 17-Figure 18)]. The emergent *Cratoneuron commutatum* (Figure 19) had the least. This relationship to water is very likely correlated with light availability; the submerged taxa should produce more chlorophyll.

Chlorophyll is not the only pigment to respond to seasons. In *Rhytidiadelphus squarrosus* (Figure 20), *R. triquetrus* (Figure 21), and *Mnium hornum* (Figure 22), the biflavonoid and coumestane concentrations likewise showed seasonal variation, with concentrations increasing with periods of active growth (Brinkmeier *et al.* 1999). These concentrations were also affected by light intensity, independent of season.

Figure 21. *Rhytidiadelphus triquetris*, a species in which biflavonoid and coumestane concentrations increase with periods of active growth. Photo courtesy of Carrie Andrew.

We cannot rule out light intensity as the cause for these observed seasonal differences. In their study on *Brachythecium rutabulum* (Figure 23), Kershaw and Webber (1986) found that total chlorophyll increased from 1.70 mg chl g⁻¹ on 8 May to 11.1 mg chl g⁻¹ on 11 October, corresponding with full canopy conditions that reduced the light intensity reaching the moss. Concomitantly, light saturation declined from 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ to 30 $\mu\text{mol m}^{-2} \text{s}^{-1}$ and the light compensation point declined from 65 $\mu\text{mol m}^{-2} \text{s}^{-1}$ to 4 $\mu\text{mol m}^{-2} \text{s}^{-1}$.

Figure 23. *Brachythecium rutabulum*, a species that increases its chlorophyll content as the tree canopy reduces its available light. Photo by Michael Lüth, with permission.

Mishler and Oliver (1991) found that the amount of green tissue and concentration of chlorophyll per dry weight were higher in summer than in winter or early summer in the xerophytic moss *Syntrichia ruralis* (Figure 24). The chlorophyll *a:b* ratios, however, did not follow any seasonal pattern.

Figure 24. *Syntrichia ruralis*, a species in which chlorophyll content in summer in the Organ Mountains of southern New Mexico, USA. Photo by Barry Stewart, with permission.

But what do bryophytes do in total darkness, as found under deep snow in winter? Only 3-4 mm of older crystalline snow is required for snow to become opaque (Gates 1962), rendering photosynthesis impossible. It appears that at least some of them should have no problem. When grown in total darkness for four months, the leafy liverwort *Plagiochila asplenioides* (Figure 25) rapidly lost starch, but exhibited little loss of chlorophyll (Suleiman & Lewis 1980). Once revived, the tissues were photosynthetically viable immediately. Thus, we should expect that many bryophytes might become photosynthetically active as soon as the snow recedes. Furthermore, low light levels penetrating the snow prior to total melt are sufficient to initiate photosynthesis.

Figure 25. *Plagiochila asplenioides*, a species that loses almost no chlorophyll in the dark, but does lose starch. Photo by Michael Lüth, with permission.

Colors of Light

Those bryophytes living on the forest floor receive quite a different light quality from those in the open. The canopy, with its massive quantity of green leaves, serves as an effective filter against red light, the part of the spectrum creating the greatest photosynthetic activity. Thus, bryophytes on the forest floor must succeed in light that is weighted toward green and diminished in red wavelengths.

But the color of light is a seasonal attribute. When the canopy is gone from a deciduous forest in winter, light quality is nearly that of full sunlight, whereas in summer it is highly displaced toward the green end of the spectrum when red light is filtered out by the canopy. And the quality of light changes at the two ends of the photoperiod as well as light penetrates a greater distance through the atmosphere when it arrives nearly parallel to the Earth's surface.

Lakes present a similar problem, but for different reasons. Water, both liquid and as snow, is an effective filter against both UV light and the low-energy red wavelengths. Hence, the deeper into the water, or snow, the less of these wavelengths available to the moss. Older, crystalline snow is almost completely opaque to infra-red light. While this water medium is good as protection against UV light, it is detrimental in providing appropriate wavelengths for maximal photosynthesis. Nevertheless, bryophytes, with their single layer of cells, are well adapted, compared to tracheophytes, to capture what little light is able to penetrate, and they benefit from the blue and

green wavelengths that have greater penetration through water and ice. One adaptation to this blue and green light environment is that green light can cause major increases in content of chlorophylls and carotenoids in aquatic bryophytes (Czeczuga 1987). The yellow carotenoids are able to capture the blues and greens that penetrate to the greatest depths. Carotenoids, like chlorophyll *b*, serve as antenna pigments, creating additional surfaces for trapping light and transferring it to the active site of chlorophyll *a*. Might a similar change occur in terrestrial bryophytes, adapting them to life beneath the green filter created by the canopy?

Turbidity of water can have other effects on the light quality. Algae will act much like the canopy and absorb red light with their chlorophyll pigments. Detrital and suspended matter also block and filter the light, altering the quality and the intensity. These can have physiological effects on the bryophytes.

Few studies have examined the effects of the wavelength of light, *i.e.* its color, on the growth or physiology of bryophytes. Most of these have been laboratory studies on tropisms, germination, or growth (see chapter on development). However, Jägerbrand and During (2006) experimented with Icelandic *Hylocomium splendens* (Figure 26) and *Racomitrium lanuginosum* (Figure 27) in the greenhouse using shade cloth (black netting; green plastic film) compared to colorless plastic film to alter the light quality and intensity in a manner consistent with forest shade. The reduced light of both shade types caused greater elongation, reduced biomass growth, and a lower biomass:length ratio in new growth for both species, but the number of branches, branch density, and biomass:length ratio were higher for *H. splendens* (Figure 28). Both shade treatments caused similar increases in length (etiolation) and decreases in the biomass:length ratio. Branch density was significantly decreased by the reduction in red:far red ratio in *Racomitrium lanuginosum*, typically a sun species. Such a response to shade would permit greater light penetration and reduce self-shading. Similar behavior is seen in the needles of balsam fir (*Abies balsamea*), in which the arrangement of needles on branches is relatively flat on shade branches but go all the way around the upper half of the branch on sun branches.

Photoperiod Effects

An alternation of day and night has been with plants since their inception. Thus, we should expect that most species have taken advantage of this alternation in various ways. Continuous light over a long period of time can cause mosses to lose their chlorophyll (Kallio & Valanne 1975). The stroma thylakoids are destroyed, much like the destruction seen in continuous dark in the cave experiments of Rajczy (1982). However, many moss taxa flourish in the continuous light of summer in the Arctic, so destruction in this way must not be universal. Or does it depend on the wavelengths?

Continuous darkness will cause bryophytes to use up their reserves. For example, ethanol-soluble sugars and lipids decrease in green portions of *Racomitrium*

barbuloides (Figure 29) maintained in continuous darkness, whereas senescent brown portions of the moss do not lose these substances (Sakai *et al.* 2001). Starch, on the other hand, is maintained within the cells under continuous dark treatments. When this same moss was subjected to continuous light, the ethanol-soluble sugars and lipids initially increased in the green portions, but then decreased, concomitant with a significant decline in photosynthetic capacity. The maximum sugar and lipid concentrations stored under 12 hours light/12 hours dark were similar to those in continuous light, but this day/night treatment did not result in diminished photosynthetic capacity.

Figure 29. *Racomitrium barbuloides*, a species in which continuous darkness results a decrease in ethanol-soluble sugars and lipids. Photo from Digital Museum, Hiroshima University, with permission.

This marked diurnal periodicity under a normal light regime is manifest in peak times for photosynthetic activity. Early morning hours provide the best moisture conditions, so it is not surprising that subalpine populations of *Pohlia wahlenbergii* (Figure 30) exhibited their highest photosynthetic activity in the early hours of morning. This high rate repeated itself in the early evening, suggesting photosensitivity and repair (Coxson & Mackey 1990), or could it be only a moisture relationship? Another possible explanation for the peak twice a day is an endogenous rhythm (Coxson & Mackey 1990). In any case, this would appear to be an adaptive behavior for bryophytes that must contend with drying in the afternoon sun, particularly in their most active photosynthetic tissues near the tips.

Figure 30. *Pohlia wahlenbergii* var. *glaciale*, whose peaks in photosynthetic activity are early morning and evening. Photo by Michael Lüth, with permission.

In *Marchantia polymorpha* (Figure 31-Figure 32), short photoperiod, and not nutrient supply, cause the plants to produce more gemmae cups (Figure 31), whereas on a long photoperiod more gametangiophores (Figure 32) are produced than on plants in a short photoperiod (Voth & Hamner 1940).

Figure 31. *Marchantia polymorpha* gemmae cups, a stage that is promoted by a short photoperiod. Photo by Michael Lüth, with permission.

Figure 32. *Marchantia polymorpha* archegoniophores, a stage that is promoted by long photoperiods. Photo by Janice Glime.

Photoperiod can play a role in development, productivity, acclimation, and other aspects of the bryophyte life (Kallio & Saarnio 1986). These topics will be discussed in other chapters related to these topics.

Summary

Changes in light quality, duration, and intensity can signal changing seasons and cause physiological changes that prepare bryophytes for winter or summer conditions. But high light intensities can damage chlorophyll and DNA, especially at low temperatures.

When photooxidation occurs under high light intensities, bryophytes can experience photoinhibition in the form of rupture of the chloroplast envelope, formation of vesicles in thylakoids, and rapid degradation of linolenic acid. Some bryophytes respond to the damaging effects of high light intensity

and low temperatures by producing **light-quenching pigments** such as **sphagnorubin**. At warm temperatures, photorespiration provides an energy shunt to protect chlorophyll from overexcitation. Red pigments may also warm the bryophytes by absorbing heat.

Increased light intensity may stimulate the production in gametangia, but in others it inhibits them. Chlorophyll concentrations may change with seasons, with some bryophytes having high concentrations in early spring, enabling them to take advantage of low light under diminishing snow. Shoot area to dry weight increases in some bryophytes during autumn, perhaps likewise permitting the plants to take advantage of diminishing light. Some mosses have diminished capacity for photosynthesis in winter, but their compensation point and saturation points are also depressed. The changes vary with species and are part of what makes them different species. Nevertheless, generally the chlorophyll *b* concentration increases as light diminishes. Bryophytes that have been under the snow for months are generally ready to begin photosynthesis immediately upon receiving enough light.

Forest canopy leaves filter out a large portion of red light and transmit green light to the bryophytes below. Water accomplishes a similar filtering function, but the green light can cause chlorophylls and carotenoids to increase in aquatic taxa.

Reduced light can cause greater elongation, reduced biomass growth, and a lower biomass:length ratio in new growth, while the number of branches, branch density, and biomass:length ratio can be higher. However, greatly reduced light can cause etiolation, thus reducing self-shading. A reduced ratio of red:far red can decrease branch density.

Continuous light is detrimental to some taxa, but bryophytes in polar regions thrive on the added summer light. Continuous dark can cause some mosses to use up their energy reserves, but low polar temperatures minimize this effect. Many, perhaps most, bryophytes have their peak photosynthetic activity in early morning and late evening when the most moisture is available. Moss gardeners, take note!

CHAPTER 9-5

LIGHT: REFLECTION AND FLUORESCENCE

Figure 1. *Schistostega pennata*, the luminous moss, growing on the roof of a cave in Rausu, Japan. Photo by Janice Glime.

Cave Mosses - Reflectance

Caves provide a classical example of gradients, with diminishing light and temperatures gradually descending or ascending from the mouth to an interior temperature near 10°C. As light diminishes, so does ability of the plant to meet its light compensation point. Thus, through this gradient, we see that flowering plants are the least tolerant, then ferns, followed by bryophytes, and last algae as the most tolerant (Dalby 1966b).

In non-commercial caves where light diminishes rapidly, or in buried lava caves, finding these bryophytes can be difficult and time consuming. Hanley (1982) used an echo sounder to locate bryophytes in caves and other dark areas such as deep lakes. However, in many caves, artificial lights provide sufficient illumination for algae, bryophytes, and ferns to succeed deep within the cave (Boros 1964). In fact, in many commercial caves, bryophytes have been considered to be a nuisance and measures have been taken to remove them, often using sodium hypochlorite. However, to avoid release of

chlorine and other dangerous gases into caves, researchers tested hydrogen peroxide. But even the dilute 15% hydrogen peroxide necessary to remove bryophytes is destructive to fragile limestone formations, and the solution must be buffered with bits of limestone rock for at least 10 hours before its application (Faimon *et al.* 2003). I fail to understand why the bryophytes are considered offensive!

Schistostega pennata – Luminous Moss

No moss seems to be revered more than the clandestine cave moss *Schistostega pennata* (Figure 1-Figure 3), also known as dragon's gold (Berqvist 1991). Always a delight to find, its protonemata shine like emerald jewels from the darkness of a rock crevice or cave. So intriguing is this moss that the Japanese have a monument to it in Hokkaido (Iwatsuki 1977, Kanda 1988; Figure 2), where it grows in profusion in a cave barely large enough for a child to stand. At just the right position, you can see its marvelous reflections, but move the wrong way and they

are lost. The frond-like gametophyte and terminal sporophyte have none of that ethereal luminescent quality (Figure 3). Ignatov *et al.* (2012) examined the developmental pattern of this species and determined that it has sexual reproduction in September.

Figure 2. Monument to *Schistostega* in Hokkaido, Japan. Photo by Janice Glime.

Figure 3. *Schistostega pennata* plants showing their frond-like appearance and capsules at the end of the stem. Photo by Martin Hutten, with permission.

This unusual jewel-like property (Figure 4) is the result of the protonema (Gistel 1926). The cells are lens-shaped (Figure 7) and their upper surface is curved in such a way as to focus the light on the interior of the cell (Figure 6; Figure 5). This "normal" form is reached only when they grow in light that comes at all times from the same oblique direction. The chloroplasts orient themselves so that they are always at the most intensely lighted spot on the inner wall of the cell (Figure 7). If a change in the light direction occurs, as may happen seasonally, the chloroplasts can reposition themselves within one to three hours.

Like Crum (1973), we find appeal in retelling the account by Kerner von Marilaun in *Pflanzenleben*, as translated by F. W. Oliver in *The Natural History of Plants*:

"On looking into the interior of the cave, the background appears quite dark, and an ill-defined twilight only appears to fall from the center on to the side walls; but on the level floor of the cave innumerable golden-green points of light sparkle and gleam, so that it might be imagined that small emeralds had been scattered over the ground. If we reach curiously into the depth of the grotto to snatch a specimen of the shining objects, and examine the prize in our hand under a bright light, we can scarcely believe our eyes, for there is nothing else but dull lusterless earth and damp, mouldering bits of stone of yellowish-grey color! Only on looking closer will it be noticed that the soil and stones are studded and spun over with dull green dots and delicate threads, and that, moreover, there appears a delicate filigree of tiny moss-plants, resembling a small arched feather stuck in the ground [Figure 10]. This phenomenon, that an object should only shine in dark rocky clefts, and immediately lose its brilliance when it is brought into the bright daylight, is so surprising that one can easily understand how the legends have arisen of fantastic gnomes and cave-inhabiting goblins who allow the covetous sons of earth to gaze on the gold and precious stones, but prepare a bitter disappointment for the seeker of the enchanted treasure; that, when he empties out the treasure which he hastily raked together in the cave, he sees roll out of the sacks, not glittering jewels, but only common earth. . . . On the floor of rocky caves one may discern by careful examination two kinds of insignificant-looking plant-structures, one a web of threads studded with small crumbling bodies, and the other bluish-green moss-plants resembling tiny feathers. The threads form the so-called protonema, and the green moss-plants grow up as a second generation from this protonema ... the gleams do not issue from the green moss-plants, but only from their protonema."

"From the much branched threads ... numerous twigs rise up vertically, bearing groups of spherical cells arranged like bunches of grapes. All the cells of a group lie in one plane, and each of these plants is at right angles to the rays of light entering through the aperture of the rocky cleft. Each of the spherical cells contains chlorophyll-granules, but in small number ... and they are always collected together on those sides of the cells which are turned towards the dark background of the cave.... Taken together, these chlorophyll-granules form a layer which under low power of the microscope appears as a round green spot ... the light which falls on such cells through the opening of a rocky cleft behaves like the light which reaches a glass globe at the further end of a dark room. The parallel incident rays which arrive at the globe are so refracted that they form a cone of light, and since the hinder surface of the globe is within this cone, a bright disc appears on it. If this disc, in which the refracted rays of light fall, is furnished with a lining, this also will be comparatively strongly

illuminated by the light concentrated on it and will stand out from the darker surroundings as a bright, circular patch.... It is well worthy of notice that the patch of green chlorophyll-granules on the hinder side of the spherical cell extends exactly so far as it is illumined by the refractive rays, while beyond this region, where there is no illumination, no chlorophyll granules are to be seen. The refracted rays which fan on the round green spot are, moreover, only partially absorbed; in part they are reflected back as from a concave mirror, and these reflected rays give a luminous appearance. This phenomenon, therefore, has the greatest resemblance to the appearance of light which the eyes of cats and other animals display in half-dark places, only illumined from one side, and so does not depend upon a chemical process, an oxidation, as perhaps does the light from a glow-worm or of the mycelium of fungi which grow on decaying wood. Since the reflected light-rays take the same path as the incident rays had taken, it is clear that the gleams of the *Schistostega* can only be seen when the eye is in the line of the incident rays of light. In consequence of the small extent of the aperture through which the light penetrates into the rock cleft, it is not always easy to get a good view.... If we hold the head close to the opening, we thereby prevent the entrance of the light, and obviously in that case no light can be reflected. It is, therefore, better when looking into the cave to place one's self so that some light at any rate may reach its depth. Then the spectacle has indeed an indescribable charm."

The result of these very reflective chloroplasts in *Schistostega pennata* is that the protonema takes on the appearance of "goblin gold" and can create quite eerie effects (Figure 4-Figure 5; Figure 8-Figure 9).

In Japan, there is an opera written about this moss! The opera, written by Ikuma Dan, is based on a book of the same title, "Luminous Moss," by Taijun Takeda (Glime & Iwatsuki 1987). The story relates the tragedy of several sailors who were stranded by a blizzard on the northern island of Hokkaido. With no hope of escaping that remote northern tip of the island before spring to find food and shelter elsewhere, they hid in a cave. As their rations ran out and their fellow sailors died of starvation, they did the only thing they could to survive – they became cannibals. Finally, the captain alone remains. When he is brought to trial for his unthinkable acts, he reflects on the halo of green (the luminous moss) about the heads of each who has been a cannibal, but he tells the courtroom that the halo is visible only to those who have not been cannibals. He alludes to the cannibal in each of us as we struggle to survive among the millions of the world. Today a cave in Hokkaido is set aside as a memorial to protect this unusual moss (Kanda 1971, 1988; Figure 2).

Schistostega pennata (Figure 8-Figure 10) is widespread in the North Temperate Zone. Bowers (1968) and Conard (1938) have reported it from the Upper Peninsula of Michigan, where I have seen it growing on the roof of a cave behind a waterfall. Outside that same cave, I have observed the leafy gametophore, which resembles a tiny fern frond (Figure 11), growing on a small ledge of the rock wall, but protonemata there, if present, did not exhibit their highly reflective property. Bowley (1973) found the moss in several localities in Vermont, Champlin (1969) reported it from Rhode Island, Christy and Meyer (1991) from Wisconsin, Case (1975) found it in Alberta, Canada. Matsuda (1963) reported it in artificial caves in Japan. Perhaps the most unusual report is that of Koike (1989) who reported its culture in empty bottles in urban areas of Japan. Reinoso Franco *et al.* (1994) considered it to be an acidophile, at least on the Iberian Peninsula.

When I went to Germany, I was delighted to find *Schistostega pennata* (Figure 8-Figure 11) growing at the base of a boulder where it probably did not get direct sunlight except at sunset and most likely did not get direct rainfall very often either. Perhaps one reason for its success in such habitats is the presence of protonemal gemmae (Edwards 1978). In the Europe, *Schistostega pennata* also grows in rabbit holes (Glenny 2020).

Cyathodium

In the thallose liverwort genus *Cyathodium* (Figure 12), some species that grow in caves and similar low-light environments also emit a yellowish luminescence from their thalli (Crum 1973). These liverworts are tropical and subtropical and in China grow in karst caves (Zhang *et al.* 2004).

Figure 12. View through pore of *Cyathodium cavernarum*, a thallose cave liverwort that emits a yellowish luminescence in caves. Photo by Noris Salazar Allen.

Mittenia plumula

In Australia, a similar moss, *Mittenia plumula* (Figure 13), lives on dimly lit, clay-covered rock ledges, at the entrances to wombat holes (Figure 14-Figure 15), and on tip-up mounds of fallen trees (Figure 16-Figure 17). The latter habitat makes the moss rather common after cyclone damage that causes trees to topple. In these locations, the moss lives on soil. Stone (1961, 1986) concluded that *Mittenia* belongs in the order *Schistostegales* with *Schistostega* (Figure 1-Figure 11). Both have a pinnate leaf arrangement, protonemata with similar luminescent properties, similar pale color of the leafy plant, and similar habitats.

Figure 17. *Mittenia plumula* protonemata on tip-up mound. Photo courtesy of David Glenn.

Mittenia plumula differs from *Schistostega pennata* by having protonemata with cylindrical filaments instead of spherical cells that act as a lens. Unlike *Schistostega pennata* (Figure 1-Figure 11), where the protonemal cells are spherical and are obviously acting as a lens, the

protonema of *Mittenia plumula* (Figure 18-Figure 20) is composed of cylindrical filaments and the chloroplasts are not on one side of each cell to take advantage of focused light. Nevertheless, under the compound microscope there is a faintly visible blue luminescence from the filament walls. This luminescence resembles the iridescence seen in some tropical plants of dark forest floors, for instance in *Selaginella willdenowii* (Figure 21).

Cave Communities

Growth of other bryophytes in caves far from a natural light source has been a source of fascination for both bryologists and non-bryologists all over the world, and these bryophytes often form zones around electric lights (Haring 1930). So fascinating are these plants of low light that their descriptions have appeared in non-botanical journals. Boros (1964) was able to publish a paper in the first volume of the *International Journal of Speleology* (**speleology** is the study of caves), reporting on mosses growing around electric light sources deep within a cave. Dalby (1966b) later published a similar article on their growth under reduced light in caves, this time in the first volume of *Studies in Speleology*. Numerous communities have been described from caves around the world: Shiomi (1973) in Japan; Maheu and Guerin (1935) in France; Rajczy (1979) in Greece; Ziober (1981), Komáromy *et al.* (1985), Rajczy *et al.* (1986), and Buczkó and Rajczy (1989) in Hungary; Lo Giudice & Privitera (1984) in Italian grottos; Stefureac (1985) in Romanian grottos; Weber (1989) for both animals and flora, including bryophytes, in two German caves and artificial caverns; Kubešová (2009) in the Czech Republic. Even *Science* has accepted articles on mosses in Virginia (USA) caverns, including the famous Luray Cavern (Lang 1941, 1943), and Prior (1961) again studied Luray Cavern mosses, publishing in *The Bryologist*.

Most cave bryophytes are not specific to these habitats. Reinoso Franco *et al.* (1994) have found *Schistostega pennata* with *Isopterygium elegans* (Figure 22; low-light species of canyons and crevices), *Diplophyllum albicans* (Figure 23; forest epiphyte), *Calypogeia arguta* (Figure 24), *C. azurea* (Figure 25; also an epiphyte), *Pogonatum nanum* (Figure 26), and *Fissidens curnovii* at a pH of 5.7 in caves.

The widespread *Fissidens taxifolius* (Figure 27) grew in Crystal Caverns in Virginia, USA, and aroused the curiosity of a visitor who delivered it to Conard (1932). This moss grew on the damp ceiling, forming circles about 8" from several electric light bulbs, having appeared only a few years earlier. The moss looked normal, but the leaves were further apart than in typical specimens, not an unusual trait for a moss of low light.

Figure 27. *Fissidens taxifolius*, a common moss that can grow on the ceiling of caves. Photo by Jan-Peter Frahm, with permission.

A variety of species seem to be capable of growing in caves. Buczkó & Rajczy (1989) reported nineteen bryophyte taxa from three caves in Hungary. Dalby (1966a) reported the occurrence of the **tufa**-former (rock former resulting in carbonates built upon bryophytes and other plants due to addition of photosynthetic oxygen to dissolved minerals), *Eucladium verticillatum* (Figure 39), in a poorly lit cave, also occurring in caves in Hungary (Buczkó & Rajczy 1989). In Crystal Cave, Wisconsin, Thatcher (1949) found *Barbula unguiculata* (Figure 28), *Brachythecium populeum* (Figure 29), *Brachythecium salebrosum* (Figure 30), *Bryoerythrophyllum recurvirostrum* (Figure 31), *Bryum caespiticium* (Figure 32), *Bryum capillare* (Figure 33), *Ceratodon purpureus* (Figure 34), *Fissidens taxifolius* (Figure 27), *Leptodictyum riparium* (Figure 35), *Marchantia polymorpha* (Figure 36), *Plagiomnium cuspidatum* (Figure 37), and *Warnstorfia fluitans* (Figure 38). Like Conard, Thatcher observed the leaves to be more distant than is typical.

Komáromy *et al.* (1985) likewise found *Eucladium verticillatum* (Figure 39), a *Brachythecium* (*B. velutinum*), and two species of *Fissidens* [*F. dubius* (Figure 40), *F. pusillus* (Figure 41)] in a cave. Within only one year from its first illumination, Howe Cavern in New York, USA, already was adorned with *Amblystegium serpens* (var. *juratzkanum*; Figure 42), *Amphidium mougeotii* (Figure 43), *Brachythecium rutabulum* (Figure 44), *Bryum caespitium* (Figure 32), *Bryum capillare*

(Figure 33), *Leptobryum pyriforme* (Figure 45), and *Marchantia polymorpha* (Figure 36) encircling its new lights (Haring 1930). Buczkó and Rajczy (1989) found that *Amblystegium serpens* (= *A. juratzkanum* var. *juratzkanum*; Figure 42) was the most characteristic moss in several Hungarian caves, extending furthest from the cave entrance that provided the only light, surviving at only 232 lux. Niklas Lönnell reported to Bryonet (3 March 2010) that *Eucladium verticillatum* (Figure 39) introduced at an underground station in Stockholm, Sweden, thrives decades later on moist areas of the walls where artificial light is available.

Tufa formers such as *Eucladium* (Figure 39) (von der Dunk & von der Dunk 1980), *Barbula* (Figure 28), and *Didymodon* (Figure 46) are found in many of these caves, since the caves are usually limestone, and tufa formers must be adapted to relatively dim light to survive the calcium carbonate covering they must endure.

Figure 46. Tufa-forming *Didymodon tophaceus*, a former of didymodontoliths. Note carbonates at base encrusted on older stems. Photo by Michael Lüth, with permission.

With all these reports, it is not unexpected then that Koponen (1977) reported mosses at a depth of 176 m in a mine at Vihanti, Finland. The surprising fact is that the mosses he found are the very light-tolerant *Ceratodon purpureus* (Figure 34) and *Pohlia nutans* (Figure 47). But then, these two mosses seem to do well in extremes, as long as it is not too hot.

Jedrzejko and Ziober (1992) illustrated the effects of light on the species composition of moss communities and the ability of mosses to survive at low light intensities with their study of bryophytes in seven Polish caves. More than 50% of the bryophyte flora occurred where they had full access to daylight. As the investigators went deeper into the caves, the number of species decreased, but with 1.3% of the species occurring only in the darkest zone.

Rockhouses

Rockhouses are really just small caves created by deep recesses in bedrock cliffs. But despite their smaller size, they can create conditions much different from those of their surroundings outside the cavity. They tend to be buffered from extremes in both temperature and moisture, with cold blasts emanating in the summer and protection from severely cold winds in the winter. Nevertheless, despite their moderate climate, their low light levels greatly restrict the potential flora. It is therefore interesting that the greatest affinities of these floras are with the tropics (Farrar 1998). While the species in the rockhouses tend to be endemic to the eastern United States, the conditions created for them mimic the low light intensities of the dense rainforests. It is possible that the climatic moderation of the rockhouses might have permitted adapted plant groups to persist here since the time when a tropical/subtropical climate existed in the eastern US during the Pre-Pleistocene. It is in these secluded habitats that a number of endemic ferns reside, but the most numerous plants are the bryophytes. Farrar considered both groups to be preadapted to this habitat by their vegetative reproduction and their ability to have net photosynthetic gain in very low light.

Responses to Low Light in Caves

If you have ever picked up a board from your lawn, you know how thin and long the grass stems can be. This elongation response by plants in low light is termed **etiolation**. Dunham and Lowe (1927) described etiolation of bryophytes in caves and among boulders in New England, USA. But at least some light should be present, right? Nevertheless, Fries (1945) succeeded in growing the mosses *Funaria hygrometrica* (Figure 48) and *Leptobryum pyriforme* (Figure 45) from protonemata on inorganic media in total darkness. Thus, it would appear that some growth can occur, using the plant's reserves, even in the absence of light.

Rajczy (1978-1979) chose to experiment with growing mosses in total darkness of a cave. He used two common Hungarian species, *Atrichum undulatum* (Figure 50) and *Plagiomnium ellipticum* (Figure 51), which he planted in flowerpots along with their original soil. These were placed in a cave where the climate is very constant, having a temperature of 9.5 ±1°C and 95-100% relative humidity.

Plagiomnium ellipticum rapidly became brown and within three months had produced long, fine, vertical, leafless stems of 4-6 cm length. *Atrichum undulatum*, on the other hand, remained green for two years. Its chloroplasts increased from a mean of 8.8 to 10.3 per cell from May to October. In the cave both species had a much higher ratio of dark CO₂ fixation that did the control samples from normal light (Table 1). One interesting event in Rajczy's experiment was that isopods (*Mesoniscus graniger*; Figure 49) consumed all the dead material of the plants. The mosses soon grew pale, then partly brown.

Figure 48. *Funaria hygrometrica*, a species that is able to grow without a media carbon source in the dark. Photo by Michael Lüth, with permission.

Table 1. Incorporation of CO₂ into moss biomass in caves compared to controls. From Rajczy 1978-1979.

¹⁴ CO ₂ Incorporation				
	Net Activity (cmp/leaf)			Contrib dk fix to total fix
	total fix	dark fix	light fix	
<i>Atrichum undulatum</i>				
control	898	85	813	9%
cave sample	174	81	93	47%
<i>Plagiomnium ellipticum</i>				
control	3790	340	3450	9%
cave sample	550	220	330	40%

Figure 49. *Mesoniscus graniger*, an isopod consumer of dead mosses. Photo by Richard Kovács, through Creative Commons.

When *Atrichum undulatum* (Figure 50) cells were examined with the electron microscope after four months of experiment (September), the chloroplasts differed considerably from those of the control plants. The size of the grana had increased but their number decreased and they were arranged mostly at the periphery of the chloroplast. There were no starch grains. Then, in March, there was a most unexpected change. The chloroplasts contained starch once more and the grains appeared to be identical to those of the control plants. Thylakoids (Figure 52) were even thinner than in September, and only 1-2 stroma thylakoids were present. From 3 to 10 broad, low grana were present.

Figure 50. *Atrichum undulatum*, a species that acclimates to living in caves. Photo by Janice Glime.

Figure 51. *Plagiomnium ellipticum*, a species that seems unable to live in the low light of caves. Photo by Michael Lüth, with permission.

Figure 52. Chloroplast with cutaway view to show inner and outer membrane, stacks of thylakoids that form grana, and connecting stroma. Drawing by Janice Glime

Surprisingly, *Plagiomnium ellipticum* (Figure 51) also had starch grains in March. However, these were not like those of their control plants. Some were far larger, and most chloroplasts lacked them. Most of the chloroplast envelopes were torn up.

In April, samples taken from the cave to the lab had measurable photosynthesis, although they had no exposure to light prior to the time of measurement. For *Atrichum undulatum* (Figure 50), photosynthesis reached 15-20% of that in the controls. Both species retained some photosynthetic activity for the two years of the experiment, but that of *Atrichum undulatum* was greater.

Rajczy (1978-1979) interpreted these results to mean that the mosses were subsisting on heterotrophic energy sources. He could find no other explanation for the sudden appearance of starch after 10 months in the cave. Furthermore, he cited the dark-culturing experiments of Servettaz (1913), Pringsheim and Pringsheim (1935), and Fries (1945) to support his position. Could the mosses be using electromagnetic rays? symbiosis? chemosynthesis? Cave algae are known to subsist using these unusual methods of obtaining energy (Kol 1966; Hadju 1979). And why did both species [*Atrichum undulatum* (Figure 50) and *Plagiomnium ellipticum* (Figure 51)] have starch grains in March when the grains had disappeared earlier? Did some endogenous rhythm, lacking stimulus by photoperiod or temperature, trigger a change in metabolic activity?

Reflectance in the Desert

In desiccation-tolerant species, surface properties often change. This can result in a change in surface reflectance, as exemplified in the xerophytic moss *Syntrichia ruralis* (Figure 53) (Hamerlynck *et al.* 2000). In this species, distinct differences occur in the ability to establish thermal dissipation of excess light energy throughout a range of light levels, helping to protect the sensitive chlorophyll and DNA.

Figure 53. *Syntrichia ruralis*, a species that changes its optical properties when dry vs wet. Photo by Jan-Peter Frahm, with permission.

In the Antarctic, surface reflectance properties differed over a range of water content, but did not correlate with pigment content (Lovelock and Robinson 2002). Nevertheless, the photochemical reflectance was correlated with the concentrations of active xanthophyll-cycle pigments and the photosynthetic light use efficiency as

measured by chlorophyll fluorescence. The water content had a strong influence on both the amplitude and position of the red-edge and may itself cause the differences in reflectance. Continuous high levels of xanthophyll pigments indicate the continual high light levels.

Fluorescence and Other Light Emissions

(coauthored with Magdalena Turzańska)

Definitions

Wikipedia defines **fluorescence** as "emission of light by a substance that has absorbed light or other electromagnetic radiation of a different wavelength." One little-known property of at least some bryophytes is their ability to fluoresce various colors in UV light. Lichenologists are familiar with this property in lichens (Figure 54-Figure 55), using it as an identification tool (Hale 1956). Bees know it in flowers (we call them nectar guides), being attracted to fine lines of marsh marigold (*Caltha palustris* – Figure 56-Figure 57) and black patches of oriental poppy (*Papaver orientale* – Figure 58) petals and by their emission of fluorescence in the UV light of the sun. In fact, Talamond *et al.* (2015) consider **autofluorescence** to be abundant in plant cells. But bryologists seem rarely to use it

Figure 54. The lichen *Xanthoria polycarpa* in natural light. Photo through Creative Commons.

Figure 58. The oriental poppy (*Papaver orientale*) has patches that appear black to us, but that reflect UV light that is visible to bees, guiding them to the center of the flower where the pollen and stigma reside. Photo by Janice Glime.

Fluorescence should not be confused with **bioluminescence**. Fireflies have bioluminescence. Some dinoflagellates (think red tides) have bioluminescence. This is a form of chemiluminescence produced by living organisms. It requires a light-emitting molecule (**luciferin**)

and an enzyme (**luciferase**), wherein the enzyme catalyzes the oxidation of the luciferin. The luciferin and its associated enzyme differ among species. The reaction may also require **ATP** (energy-carrying molecule, adenosine triphosphate). In **luminescence**, something adds energy, causing an electron to get bounced from one orbital to another, emitting light, then decaying back down (Jerry Jenkins, Bryonet 23 April 2022). Bioluminescence is not known in land plants, but since it is present in some bacteria, it is possible that we have not discovered it in some bacteria-bryophyte associations. **Triboluminescence** results from mechanical energy such as crushing sugar cubes or rubbing quartz crystals. Heat produces **incandescence** (emitted from hot body as result of high temperature, *e.g.* incandescent light bulb).

Phosphorescence (microsecond decay that changes spin state, causing prolonged emission of light even in darkness) is a form of luminescence that results from the absorption of radiation (such as light or electrons) and continues for a noticeable time after these radiations have stopped. We have seen these in various items that glow in the dark after being exposed to light. I have seen them on cards with a cross or on ceilings to look like stars.

Fluorescence is not seen by the human eye during the day because our eyes are less sensitive to those short wave lengths and the longer "visible" light waves keep us from seeing it. However, with the right equipment, *i.e.* a UV light source, we can detect it. The discovery of a liverwort that was fluorescing precipitated one of the longest running threads on Bryonet.

Jerry Jenkins (Bryonet 23 April 2022) provided us with a detailed description of the light emissions from organisms. For example, he noted that the light emitted by *Zygodon rupestris* (= *Zygodon viridissimus* var. *rupestris*; Figure 59), shared by Ken Kellman (Bryonet 21 April 2022), could be **fluorescence** or **phosphorescence**. These cannot be distinguished just by using a UV flashlight.

Figure 59. *Zygodon rupestris*, a species known for blue fluorescence. Photo by Jonathan Sleath, with permission.

It is intriguing that the *Zygodon rupestris* (Figure 59) does not emit this light when dry (Ken Kellman, Bryonet 21 April 2022). Kellman suggested that perhaps in the dry state the UV light is blocked from entering the cells and thus there is no stimulation. This could be possible due to structural changes that make the dry cells less transparent. A second possibility is that UV light is able to enter the

cell, but that the change in structure due to drying makes it impossible for the emitted visible light to get out for us to see. Jenkins (Bryonet 23 April 2022) suggested that it is also possible that it is fluorescence that is quenched or red-shifted out of the visible range in the dry moss. This could be caused by neighboring molecules or by binding to membranes [or cell walls?]. Those neighbors can affect the energy levels and frequency of light emission of the excited electrons. (See Wilson & Hastings 2013 for more detail on the mechanism of fluorescence.)

Jerry Jenkins (Bryonet 23 April 2022) ultimately concluded that it was **photoluminescence** (which includes fluorescence) that emitted light from *Zygodon rupestris* (Figure 59) when irradiated with UV. The incoming UV photon interacts with an orbiting electron, causing it to achieve an excited state. Some of the photon energy is transferred to the electron. The remainder is used in vibrations and rotation. As the electron decays, it emits a photon, but with less energy than that of the incoming photon. Thus, the light has a longer wavelength and is shifted toward the red end of the spectrum into the visible spectrum.

Compounds That Fluoresce

The specific compounds in bryophytes that fluoresce have not been studied extensively. However, we know more about those in tracheophytes. Wolfbeis (1985) listed the following compounds from leaves that emit blue-green fluorescence: alkaloids (berberine, quinine, lysergic acid), aurones, chalcones, chromones, coumarins (umbelliferone, esculetin, scopoletin), flavones (except 5-hydroxyflavones), flavins (FMN, FAD, riboflavin), flavonols, furocoumarins (psoralen), hydroxycinnamic acids (caffeic, ferulic, sinapic), isoflavones, nicotinamides (NADH, NADPH), phenolic acids (salicylic, gentisic, ellagic), polyenes (phytofluen), pterines (folic acid, dihydrofolate), quinones (phyllhydroquinone), stilbenes (resveratrol), other coenzymes (pyridoxal-5'-phosphate), and degradation products (kynurenine, polyadenylic acid).

The internal environment can modify the fluorescent response, including such factors as temperature, viscosity, spatial constraints, pH, polarity, and presence of quenchers, such as heavy metals and oxygen, influencing the spectral characteristics and yield (Cerovic *et al.* 1999).

Parts That Fluoresce

Chlorophyll fluorescence is well known in algae and plants, including bryophytes (Shi *et al.* 1992; Proctor & Smirnoff 2011), giving an indication of the health of the plant by its ability to emit light from its active chloroplasts (*e.g.* Csintalan *et al.* 1999; Deltoro *et al.* 1999; Arróniz-Crespo 2008). As in tracheophytes and algae, the chlorophyll of bryophytes fluoresces red in UV light. In the hornwort *Anthoceros* sp., the chlorophyll fluoresces a brilliant red whereas the cell walls fluoresce blue (Figure 60-Figure 64). In *Fontinalis antipyretica*, the cell wall fluoresces yellow, contrasting with the red chloroplasts (Figure 65). A similar contrast is present in *Sphagnum*, with photosynthetic cells showing red chlorophyll fluorescence and cell walls showing a blue-green fluorescence in UV light (Figure 66-Figure 68). In *Funaria hygrometrica*, there is a strong chlorophyll fluorescence, but the cell walls seem to lack any

fluorescence visible in the UV light of a microscope (Figure 69).

Figure 69. *Funaria hygrometrica* leaf chlorophyll fluorescence, showing the typical red fluorescence of that molecule. Note that the cell walls lack fluorescence under the UV light of a microscope. Photo by Janice Glime.

The use of fluorescence to detect the damage to chlorophyll has been established for some time (Proctor 2003). These uses include indication of effects of various intensities of desiccation (Proctor 2003) and of metal contaminant locations within the cell, as shown in *Fontinalis antipyretica* (Figure 70-Figure 71) (Chorvatova *et al.* 2021).

Figure 70. *Fontinalis antipyretica*, an aquatic moss with cell wall fluorescence under UV light and a species where one can trace metals using fluorescence. Photo by Hermann Schachner, through Creative Commons.

Figure 71. Fluorescence of various metals in *Fontinalis antipyretica* located by UV light. From Chorvatova *et al.* 2021.

Various parts of bryophytes are known to fluoresce. Ridgway and Larson (1966) reported on the usefulness of the fluorescence technique to follow sporogenesis in the hornwort *Anthoceros* sp. (Figure 72-Figure 76). Similar changes in color seem to occur in *Riccia* sp. (Figure 77-Figure 80). Using a UV microscope enables us to examine the development and greening of spores (Figure 78-Figure 79), protonemal bud initiation, callose distribution to find phloem-like elements, callose in cross walls of leptoids, events leading to egg formation, events following fertilization (Sarafis 1971; Brandes 1967), and locating elusive propagules (Nordhorn-Richter 1984 a,b,c, 1985 a,b, 1988).

Figure 76. *Anthoceros* sp. sporophyte showing pale fluorescence. Photo by Magdalena Turzańska.

Figure 77. *Riccia cavernosa* young sporangium with green fluorescence of young spores. Photo by Magdalena Turzańska.

Figure 80. *Riccia* sporangia with red chlorophyll fluorescence and blue-green thallus cell wall fluorescence. Spore walls are fluorescing gold. Photo by Magdalena Turzańska.

Figure 78. *Riccia sorocarpa* sporangium with spore tetrads showing green fluorescence and decoration on the spores and nuclei no longer visible through the spore wall. Photo by Magdalena Turzańska, with permission.

Figure 79. *Riccia* sp. mature spores fluorescing differently from younger spores in Figure 78. Photo by Magdalena Turzańska, with permission.

The change in color of the cell walls in spore tetrads to those of the mature spores in *Riccia* sp. suggests that the compounds present change with maturity. The sporangia stand out from the coloring of the thallus internal cell walls in *Riccia* (Figure 80).

My first encounter with the phenomenon of **fluorescence** in bryophytes was on a field trip in Europe where I entered in conversation with Gisela Nordhorn-Richter. She had stopped at a display of microscopes at her university just because the poor guys didn't have many visitors. She took her research organisms, members of the genus *Pohlia* (Figure 81-Figure 82), to test the quality of the microscopes, one of which had UV light capabilities. To her amazement, gemmae lit up all over the place, displaying far more than she had been able to see without the UV aid. She then looked at other species and found that this was a good tool to help in determining number and shape, enabling her to delineate species more easily (Nordhorn-Richter 1984 a,b,c, 1985 a,b, 1988).

Figure 82. *Pohlia bulbifera* bulbils that fluoresce, making them easier to locate. Photo by Des Callaghan, with permission.

An image of a gemma of *Lunularia cruciata* (Figure 83-Figure 84) from Robin Young indicates that this structure fluoresces blue in UV light. Furthermore, the gemmae of *Zygodon rupestris* fluoresce blue (Figure 147). Gemmae can provide multiple colors, including a golden shade in liverworts *Calypogeia* sp. (Figure 85), *Metzgeria* sp. (Figure 86), and *Radula complanata* (Figure 87), and mosses *Aulacomnium androgynum* (Figure 88) and *Tetraphis pellucida* (Figure 89-Figure 90). The gemmae of *Tetraphis pellucida* suggest that the fluorescence color changes with age.

Even branch buds can become more obvious because of a deep chlorophyll fluorescence. This is illustrated in *Physcomitrella patens* (Figure 91).

Figure 91. *Physcomitrella patens* normal light and fluorescence showing greenish leaf cell walls and bright red of bud due to dense chlorophyll. Photo modified from Beata Zagórska-Marek, with permission; published in American Journal of Botany with Creative Commons attribution <<https://creativecommons.org/licenses/by/4.0/#>>.

Merced and Renzaglia (2017) used fluorescence as a tool in viewing the stomata of a variety of bryophytes. In a species of *Bartramia* (Figure 92-Figure 93) the guard cells fluoresce red due to chloroplasts, but the rest of the capsule has a blue-green color in UV light. They also showed the coloration in UV light for *Orthotrichum* sp. (Figure 94-Figure 95), *Physcomitrium* sp. (Figure 96-Figure 97), and *Polytrichum* sp. (Figure 98).

In addition to the fluorescence of stomata in the sporophyte, it appears that the gametophyte thallus and the cells surrounding the pores of *Conocephalum conicum* (Figure 99-Figure 101) and *Marchantia polymorpha* (Figure 102) also exhibit fluorescence.

Figure 99. *Conocephalum conicum* showing raised pores. Photo by Dick Haaksma, with permission.

Figure 101. *Conocephalum conicum* thallus section showing pore and fluorescence. Note the bright red chlorophyll in photosynthetic cells under the epidermis. Photo by Magdalena Turzańska.

Little has been published about fluorescence of sexual structures. Nevertheless, in her photographic images Magdalena Turzańska illustrates that the antheridia (Figure

103-Figure 108) and archegonia (Figure 109-Figure 110) and associated paraphyses can exhibit a colorful display.

The fluorescence of sporophytes seems to be largely unknown. The only images I have seen are those of Magdalena Turzańska for *Phascum* sp. (Figure 111) and *Sphagnum* sp. (Figure 112). The latter appears to lack capsule fluorescence, but exhibits it in the pseudopodium. It would be interesting to see if the fluorescence of spores and capsule are more common in species lacking a peristome, perhaps serving to attract arthropod dispersal vectors.

Figure 111. *Phascum* sp. fluorescence of capsule and spores in capsule with no peristome. Photo by Magdalena Turzańska.

Figure 112. *Sphagnum* sp. fluorescence with capsule apparently not fluorescing, but the developing pseudopodium has some pink, green, and greenish fluorescence. Photo by Magdalena Turzańska.

In liverworts, the spores are nestled among elaters that may help to loosen and expel the spores from the capsules. These, too, can fluoresce (Figure 113-Figure 114). Since I have few records, it is too early to determine if this is a common character in liverwort elaters. I have even fewer examples of fluorescence in peristomes (Figure 115).

Figure 113. *Marchantia* elater dark red fluorescence in UV light. Photo by Magdalena Turzańska.

Figure 114. *Pellia* elater dark red fluorescence in UV light. Photo by Magdalena Turzańska.

Figure 115. Moss peristome golden fluorescence in UV light. Photo by Magdalena Turzańska.

In addition to the fluorescence of the plant parts, it is often possible to distinguish the presence of epiphytes more easily using UV light. This can be seen in Figure 66-Figure 67 for algae on *Sphagnum*, in Figure 116-Figure 117 for *Cyanobacteria* on *Hylocomium splendens*, and *Blasia pusilla* (Figure 118-Figure 121). Can it be used as well to detect and help identify bacteria on the bryophytes?

Which Species Fluoresce?

For some reason, the method of viewing bryophytes with UV light has been neglected. It was not until Dale Kruse inquired about bryophyte fluorescence on Bryonet (25 March 2011) that the subject again surfaced: "I just returned from a trip to Puerto Rico where I visited the rainforests of the Caribbean (El Yunque) National Forest. A 'non-bryological' employee there suggested there were fluorescent mosses in the forests of El Yunque. I did a quick search on the web and found very little information. I have seen fluorescent lichens but not mosses." Bryologists responded with skepticism, suggesting it was a fungus or bacterium (or possibly a lichen). Then Michael Lüth responded (Bryonet 26 March 2011): "We saw a fluorescent *Frullania dilatata* (Figure 122-Figure 124) on an excursion, when someone held a fluorescent lamp to a tree searching for some lichens." And Michael was able to show us proof (Figure 123).

Figure 124. *Frullania dilatata* green cell wall fluorescence. Photo by Magdalena Turzańska.

In 2022, the topic of fluorescence erupted on Bryonet again. Emmet Judziewicz and Virginia (Bryonet 13 March 2022) reported that on a casual one-hour walk in the Hawaiian rainforest, their UV flashlight revealed a "striking bright red fluorescence" in several leafy liverworts. These included **Cephaloziaceae**: *Fuscocephaloziopsis connivens* (Figure 125-Figure 126) subsp. *sandvicensis*, *Odontoschisma denudatum* (Figure 127), and **Lepidoziaceae**: *Lepidozia australis* (Figure 128), *Telaranea nematodes* (Figure 129), but the common *Bazzania praerupta* (= *Bazzania cordistipula*; Figure 130-Figure 131) did not exhibit red fluorescence, nor did the other common leafy liverworts they examined.

Andi Cairns (pers. comm. 27 March 2022) reported *Bazzania vittata* (Figure 132-Figure 134, Figure 174) fluorescing blue beside a *Bazzania corbieri* (Figure 132-Figure 134, Figure 135) that was not fluorescing. The adjacent mosses *Leucobryum aduncum* var. *aduncum* (Figure 132-Figure 133, Figure 136) and *Pyrrhobryum paramattense* (Figure 132-Figure 133, Figure 137) were likewise not fluorescing. Herbarium specimens of *Bazzania vittata* from Thornton Peak in North Queensland, Australia, also fluoresced blue even when dry (Andi Cairns, pers. comm. 29 March 2022). She explored an additional ~20 specimens of dried leafy liverworts from the Australian Wet Tropics and the only one that fluoresced blue under UV light was *Bazzania vittata* (Andi Cairns, pers. comm. 30 March 2022).

Figure 132. *Bazzania vittata* fluorescing blue in UV light with non-fluorescing *Bazzania corbieri*, *Leucobryum aduncum* var. *aduncum*, and *Pyrrhobryum paramattense*. Photo by Will Cairns, courtesy of Andi Cairns.

Figure 133. *Bazzania vittata* fluorescing blue in UV light with non-fluorescing *Leucobryum aduncum* var. *aduncum*, and *Pyrrhobryum paramattense*. *Bazzania corbieri* appears to be fluorescing purple in some branches – perhaps dead ones with cells or structures no longer hiding the fluorescence? David Glenney found fluorescence of *Bazzania tayloriana* (Figure 138) in New Zealand, reported again by John Braggins (Bryonet 18 April 2022) (Figure 139). This is true for specimens from both North and South Islands of New Zealand.

Figure 138. *Bazzania tayloriana*, a species that exhibits blue fluorescence in UV light. Photo courtesy of John Braggins.

Figure 139. *Bazzania tayloriana* showing blue fluorescence. Photo courtesy of John Braggins.

In California, USA, when Ken Kellman (Bryonet 21 April 2022) discovered that the bark of the valley oak (*Quercus lobata*; Figure 140) was fluorescing dark red under the light of a uvBeast V3 MINI, he found that the fluorescence was coming from a tiny moss that proved to be *Zygodon rupestris* (Figure 59, Figure 141-Figure 142). But when he used UV light on the dry specimens, there was no fluorescence. Fluorescence appeared again when the moss was rewet. Both the leaves and the gemmae (Figure 143-Figure 144) were glowing red. The nearby mosses *Antitrichia californica* (Figure 145) and *Homalothecium nuttallii* (Figure 146) did not fluoresce, wet or dry.

Figure 146. *Homalothecium nuttallii*, a pleurocarpous species that seems to lack fluorescence capability. Photo by Michael Lüth, with permission.

Tom Ottley (Bryonet 23 April 2022) followed up on these observations with different collections of *Zygodon rupestris* (Figure 141-Figure 144). Although it seemed to be that the gemmae were fluorescing, after some difficulty he was able to determine with high power of the microscope that it was an alga that was fluorescing dark red. With the help of a UV microscope, Ottley (Bryonet 5 May 2022) was able to see two sorts of fluorescence in *Z. rupestris* (Figure 147). One was the bright whitish-blue from the contents of the gemmae (Figure 147) and the other was red from the chloroplasts of the associated algae (Figure 147). He found no detectable fluorescence in the laminal cells of the moss leaves.

Figure 147. *Zygodon rupestris* fluorescence. **Left:** gemma and alga in LED white light. **Right:** gemma and alga fluorescing in UV light. Photo courtesy of Tom Ottley.

Eric Whiting (Bryonet 26 March 2022) was inspired by the Bryonet discussion to re-examine some of his *Fossombronia* (Figure 148) samples from semi-arid regions of Australia. Using a hand-held battery unit, he was able to see what appeared to be fluorescence in these, but not in other soil-crust bryophytes from New South Wales, Australia. However, with a stronger UV light he discovered that it was **reflectance** and not fluorescence (Eric Shiting, Bryonet 6 May 2022). He raised the question of whether reflectance could reduce the incoming light energy sufficiently to lower it to a tolerable level. He questioned whether UV light might be equally well reflected.

Figure 148. *Fossombronia cf. wondraczekii* in Australia, in a genus that seems to lack macroscopic fluorescence. Photo by Bernd Haynold, through Creative Commons.

Magdalena Turzańska has documented the fluorescence of additional species with her photography. These include the liverworts *Blasia pusilla* (Figure 149-Figure 150), *Barbilophozia* (Figure 151), *Cephalozia bicuspidata* (Figure 152), *Calypogeia* sp. (Figure 153), *Gymnocolea inflata* (Figure 154), *Lepidozia reptans* (Figure 155), *Lophocolea heterophylla* (Figure 156-Figure 157), *Marsupella* sp. (Figure 158), *Metzgeria* sp. (Figure 160), *Plagiochila asplenoides* (Figure 161), *Radula complanata* (Figure 162-Figure 163), and *Trichocolea tomentella* (Figure 164), and mosses *Brachythecium* sp. (Figure 165), *Mnium hornum* (Figure 166), *Polytrichum piliferum* (Figure 167-Figure 168), *Tetraphis pellucida* (), and *Thuidium tamariscinum* (Figure 169-Figure 171).

Figure 171. *Thuidium tamariscinum* showing a blue fluorescence in the costa and yellow fluorescence in the leaf cell walls, indicating that they have different compounds. These colors have been created by adding berberine to cause the fluorescence. Note the striking difference between the natural fluorescence in Figure 170 and that with berberine stain in this image. Photo by Magdalena Turzańska.

A search of internet images turned up some additional species. One such discovery was a beautiful image of two *Sphagnum* species growing together with one (possibly *Sphagnum divinum*) fluorescing a deep blue-purple and the other lacking fluorescence (Figure 172).

Figure 172. *Sphagnum* spp. in white (upper) and UV (lower) light. The fluorescing moss (lower) appears to be *Sphagnum divinum*, based on its reddish tint (upper) and larger, fleshy appearance. Photo ©Damon Noe, with permission.

Sources of Fluorescence

These examples raise the question of the compound(s) causing the fluorescence in bryophytes and why do some have it and others do not. For example, Tamás Pócs (Bryonet 24 March 2022) recalled that *Bazzania vittata* (Figure 173-Figure 174) was the only liverwort with fluorescence among those present on the summit of Bellenden Ker in Queensland, Australia.

The two best-known molecules exhibiting fluorescence are chlorophyll and lignin (Donaldson 2020). However, numerous others also exist. These elicit a variety of colors and some (ferulates – one of phenolic compounds) change color with a change in pH or chemicals such as Naturstoff reagent (flavonoids). Use of glutaraldehyde as a fixing agent can also induce autofluorescence and permit the imaging of proteins in organelles in the cell protoplast.

It is unclear which structures in bryophytes are responsible for the fluorescence. Andi Cairns (pers. comm. 30 March 2022) suggested that the fluorescence might be due to surface quality. To support this idea, she cited the glaucous surface with minute papillae on both *Bazzania vittata* (Figure 173-Figure 174) and *B. tayloriana* (Figure 175-Figure 176) (Meagher 2019). *Zygodon rupestris* (Figure 59) also has multiple papillae per cell (Figure 177).

It is interesting that McClure and Miller (1967) explored the flavonoids causing fluorescence at such an early date without precipitating more studies on this property in a wider range of bryophytes. They found that most of the fluorescence came from flavonoids and some phenolics, as reported by Dave Kofranek (Bryonet 23 April 2022). It is further interesting that none of the

pleurocarpous mosses tested exhibited fluorescence, an observation consistent with that of Ken Kellman (Bryonet 21 April 2022) for *Antitrichia* (Figure 145) and *Homalothecium* (Figure 146). The study only listed blue and purple reactions, so perhaps there was no testing for those that fluoresce red, yellow, or other colors. There is so much remaining for us to understand.

Magdalena Turzańska has found only weak fluorescence in pleurocarpous mosses, as seen here in *Hypnum* sp. (Figure 178).

Figure 178. *Hypnum* sp., a pleurocarpous moss showing a golden cell wall fluorescence. Photo by Magdalena Turzańska.

Role

Fluorescence can help to attract pollinators in flowering plants and thus aid in dispersal, but its role in bryophytes is unknown and unexplored. Andi Cairns speculated on the function of fluorescence in bryophytes as agents of antiherbivory (Andi Cairns, pers. comm. 2 June 2022), and J. K. Oliver suggested that they might just be **spandrels** (phenotypic trait that is byproduct of evolution of some other characteristic, rather than direct product of adaptive selection) – a term introduced by Gould and Lewontin (1979) (Andi Cairns, pers. comm., 24 March 2022).

In tracheophytes, Body *et al.* (2019) found that the yellow fluorescent protein that causes yellow fluorescence was produced in response to **jasmonic acid**, a compound produced in response to herbivory. But we thus far have no evidence that this, or any other fluorescence in bryophytes, is a response to herbivory.

But it is always fun to speculate. It is the start of hypotheses that can be tested. Tom Ottley (pers. comm. 5 May 2022) speculated about the potential role in dispersal of gemmae. Musing that the bryophytes could just make blue pigments instead, he realized that bryophytes are not known to make blue pigments. He suggested that perhaps the compound responsible is able to convert UV light to blue. On the other hand, insects are able to see reflected UV light itself (Turpin 2012). This might be a way of making gemmae and other propagules visible amid the maze of non-emitting leaves, just as it helped Gisela Nordhorn-Richter to locate them for her taxonomic studies. For leafy liverworts, the gemmae are more easily

discernable because of their locations at leaf margins. So far, I have found no information to indicate widespread presence of fluorescence in leafy liverwort gemmae. Perhaps the leaf fluorescence helps the insects to find the plants themselves, with contact with gemmae being almost inevitable.

Lloyd (1924) suggested that the taxonomist could use fluorescent color differences to identify **Cyanobacteria**, especially between closely related species. This seems to be possible with some bryophytes, often being a presence-absence difference. But we need many more UV views of bryophytes to really understand the color variation and its potential use in identification.

Perhaps a more important question needs to be answered. Which of these fluorescent colors can other organisms see? Are the colors we see with UV light under the microscope visible to organisms in nature?

For example, in cross section, a species of **Leucobryum** (Figure 179) demonstrated cell wall fluorescence. On the other hand, when viewed in the field with a UV light source, **Leucobryum aduncum** var. **aduncum** (Figure 132-Figure 133, Figure 136) exhibited no fluorescence.

Figure 179. **Leucobryum glaucum** leaf cs showing fluorescence of the cell walls. Photo by Magdalena Turzańska.

As I saw the color of fluorescence in more and more species of bryophytes, I was inclined to think that these are indeed spandrels. The compounds that produce them are often secondary compounds that serve in functions of structure, antiherbivory, and antibiotics. The fact that they fluoresce is likely just a product of the class of compounds that have these functions. At the same time, there is no evolutionary rule that a compound cannot have more than one adaptive quality. It would be interesting to see if the various colors have any correlation with habitat conditions and if they are inducible or always present.

Methodology

For most of our purposes, the field equipment can be simple and relatively inexpensive. Andi Cairns and colleagues used an LED white light head torch (ASD \$3.00) and a small UV torch (ASD \$14.99, no name, made

in China). For their photography they used a combination of the two lights to obtain both fluorescence of one species while showing lack of fluorescence in the other species present. The photos were taken with an iPhone.

For microscopic work, Magdalena Turzańska uses UV light and an Olympus BX50 fluorescence microscope with an Olympus DP 71 camera.

Staining bryophytes can help to make fluorescence visible in some weakly fluorescing structures. Magdalena Turzańska uses berberine (extracted from *Chelidonium majus* roots) for cell wall staining. These are shown below in **Diplophyllum albicans** (Figure 180) and **Nowellia curvifolia** (Figure 181). Other stains can be used for special purposes.

Bryophytes have been used to develop methods for detecting fluorescent compounds present in small quantities (Delépée & Pouliquen 2002; Zhao *et al.* 2007). Delépée and Pouliquen (2002) used **Fontinalis antipyretica** (Figure 65, Figure 70-Figure 71) to develop a method for detecting oxolinic acid. Cerovic *et al.* (1999) reviewed the potential of using fluorescence signals for remote sensing of vegetation. Can this application be used for bryophytes?

Figure 180. **Diplophyllum albicans** female shoot showing fluorescence of the dye berberine in the leaf and perianth cell walls. This is not natural fluorescence. The fluorescence is too weak to be visible without the dye. Photo by Magdalena Turzańska.

Prospects

It appears that fluorescence in bryophytes is a field wide open for study. So many evolutionary questions remain unanswered. How widespread is it among bryophytes? Are the compounds involved the same as those in tracheophytes? Which structures fluoresce? Does this location differ among species or habitats? Which compounds predominate in the bryophytes, and are there phylogenetic patterns to their presence? Can the colors of fluorescence be used to help in identification? Can it help us find some of the tiny species growing among larger species? Does the fluorescence attract arthropods, especially would-be dispersal agents? If so, to what degree does it improve dispersal chances? Does the phenomenon have any adaptive value in particular habitats? Does the fluorescence change with seasons? with temperature? [we know that chlorophyll fluorescence can change with temperature (Deltoro *et al.* 1999)], with drying? Is fluorescence lost over time in herbarium specimens?

Pigments

As in the algae, one can use the chlorophyll-to-phaeophytin ratio to assess physiological stress in bryophytes (Lopez *et al.* 1997). This ratio proved to be a better indicator of environmental stress than presence-absence data for species in 188 stretches of river in northwest Spain. Organic pollution was indicated most strongly, with pH also strongly correlated.

As discussed in other chapters, pigments can respond to changes in light intensity. Dark-colored wall or cytoplasmic pigments are present in genera like *Frullania* (Figure 123) that are able live high in the canopy or at high elevations (Li *et al.* 1989; Glime *et al.* 1990). Aquatic bryophytes that grow in cold water and full sunlight likewise may produce red cytoplasmic pigments, as seen in *Fontinalis* (Figure 182).

Figure 182. *Fontinalis antipyretica* producing red cytoplasmic pigments under water stress in high light. Photo by Janice Glime.

One can only speculate about the advantages of color. Red pigments can be a bit of an enigma. They can respond

to both high light and low light. In bright light they are protectors, being positioned between the light source and chlorophyll, often in cell walls where they can protect the entire cell. In low light they seem to work best on the lower surface, or the side away from the light source.

In tropical forests some of the flowering plants have purplish-red coloration on the undersides of leaves. Botanists have considered this to be an adaptation to the low light there. Red algae live in the ocean depths and absorb green light using red pigments (Ritz *et al.* 2000), with most of the red light absorbed by the water itself. These deep water algae are able to activate the red pigments and transfer the energy to the chlorophyll antenna system (photosynthetic light-harvesting antennae) where it activates the chlorophyll electrons (Bag 2021). The chlorophyll antenna system works in bryophytes as well. In bryophytes, the most frequent of the antenna pigments are α - and β -carotene, lutein, zeaxanthin, violaxanthin, and neoxanthin (Taylor *et al.* 1972). See Chapter 11-1 of this volume for a more thorough discussion of the role of antenna pigments in bryophytes.

Deep forest plants such as bryophytes are able to absorb the green light that filters through the canopy (Neill & Gould 2000; Ruberti *et al.* 2012) and reflect it, presumably to the chlorophyll. In the red alga *Rhodella violacea*, the genes for the production of the red and blue-green pigments phycoerythrin and phycocyanin, respectively, are down-regulated in bright light (Ritz *et al.* 2000). Since chlorophyll is most active in the red end of the spectrum (Wang & Folta 2013), such red reflectance could offer a light enhancement under a green canopy. In *Arabidopsis thaliana*, when both green and blue light are present, the anthocyanin (red) level is lower than when only blue light is present (Bouly *et al.* 2007; Zhang & Folta 2012) and the degree of reduction of the anthocyanin depends on the rate at which the green light is delivered with the blue light (Zhang & Folta 2012). Melati *et al.* (2019) demonstrated that shaded plants of the Luja plant (*Peristrophe bivalvis*) has a higher red pigment concentration in shade plants than in full light intensity.

More relevant to the purplish liverwort scales is the red coloration on the undersides of rainforest extreme shade plants. Increased anthocyanin coloration on tracheophyte leaf undersides correlates with the increased absorption of light at the upper (violet) end of the photosynthetic action spectrum (Lee & Graham 1986). Whereas increased red pigments can be a stress response to shade plants exposed to high light intensity, it appears that red pigments on the lower surfaces of photosynthetic organs might have a different function in light capture.

Since anthocyanin is often the pigment responsible for a purplish color, it is possible this mechanism is at work in the liverworts as well, reflecting the limited light that manages to penetrate that far and thus increase that which activates the chlorophyll. It is not an antenna pigment because it is not near the chlorophyll. Such a potential advantage has not, to my knowledge, been explored in the liverworts.

Coloration can also be used as a diagnostic tool. In tracheophytes, pigment variations are indicators for several nutrient deficiencies, toxicities, or antagonisms (Martínez-Abaigar & Núñez-Olivera 1998). Little has been done with color as a nutrient status indicator in bryophytes.

We know that the flavonoid pathway is a specialized metabolic pathway in plants (Davies *et al.* 2020). In flowering plants, flavonoids signal pollinators and dispersal organisms, but they also assist in tolerance to abiotic stresses. We have presumed that this pathway arose during the colonization of land, suggesting that it may have arisen in bryophytes as a defense against UV and drought. It is, nevertheless, absent in hornworts. The bryophyte pathway and its regulation are similar in some ways and differ in others when compared to that seen in flowering plants. One proposal is that flavonoids helped early land plants cope with increased exposure to UVB. But they also helped overcome the dangers imposed by desiccation and extreme temperatures (Markham 1988; Jorgensen 1994; Kenrick & Crane 1997; Cockell & Knowland 1999; Rozema *et al.* 2002; Ligrone *et al.* 2012; Mouradov & Spangenberg 2014; Demarsy *et al.* 2017; Davies *et al.* 2018; de Vries & Archibald 2018; Rensing 2018). Alternatively, Stafford (1991) proposed that these compounds regulated auxin action as well as signalling to mycorrhizal and symbiotic fungi, *i.e.*, serving in communication between complementary organisms. Stafford argued against the UVB-screening role because early concentrations would probably have been low, thus limiting their efficiency at a time when UV-B was particularly high.

I have long been confounded by the one-purpose approach of so many biologists, especially ecologists. It seems to me that these compounds could very well have been as Stafford proposed, serving to signal both auxins and fungi, but at the same time contributing to protection from UV-B. As time proceeded, those individuals that produced more flavonoids would have greater survival rates in the face of extreme temperatures, drought, and UV-B, permitting them to occupy habitats not available to those individuals that produced lesser concentrations of flavonoids. Most likely starting as primitive anthocyanins in the liverworts, the flavonoids have kept adding roles and become more effective at them (Berland *et al.* 2019).

Jumping to the 21st Century, researchers have discovered **auronidins** in *Marchantia polymorpha* (Berland *et al.* 2019). But Berland and coworkers discovered that the red pigments in the liverwort *Marchantia* (Figure 102, Figure 110, Figure 183-Figure 184) are not anthocyanins, but rather are phenylpropanoids that they have named **auronidins**, a previously unknown and distinct flavonoid class. Liverworts produce red cell-wall-bound pigments called **riccionidins** (now known to be auronidins) as a response to stresses, including UV-B, drought, and nutrient deficiency. Berland and coworkers suggest that these may have been the first anthocyanidins formed in the early land plants and distinct from the anthocyanins. They provide red coloration similar to that of anthocyanins, but they also have a strong fluorescence. Their antioxidant properties could be important in several pathways, but they seem to be restricted to cell walls.

This suggests that we should look at fluorescence in our consideration of early evolutionary relationships among bryophytes. Martínez-Abadigar and Núñez-Olivera (2022) have reviewed UV effects on bryophytes, noting that these effects depend on species and evolutionary lineage.

Mosses are more UV-tolerant than are liverworts. It should be enlightening to discover where fluorescence exists and how it relates to current habitats and that of the ancestors.

The discovery of auronidins raises so many questions for me. What organs have them? What are the adaptive values, if any, in these organs? Can they tell us an evolutionary story? How do they relate to habitats? Does their fluorescence give the plants any advantage, or is it simply a consequence of having the compound be useful for other characteristics? Are the colors seasonal?

Figure 183. *Marchantia polymorpha* with gemmae, showing distribution of red pigmentation, presumably auronidins. Photo by Dick Haaksma, with permission.

Figure 184. *Marchantia polymorpha* with red archegoniophores, but green thalli, Laxarbakki, Myvatn, Iceland, 26 July 1987. These red pigments are most likely auronidins. Photo by Janice Glime.

Yet another advantage of the auronidins is their ability to enhance resistance to the fungus *Phytophthora palmivora* (Carella *et al.* 2019). Hyphae are unable to penetrate in highly pigmented regions of these plants.

Leaf Canopy

It is well known that chlorophyll concentration increases in response to reduced light availability (Niinemets & Tobias 2014). But within the bryophyte canopy, older tissues are lower on the plant and thus receive less light. In this case, the chlorophyll

concentration decreases with not only age, but also with decreasing light availability (Davey & Ellis-Evans 1996; Niinemets & Tobias 2014). Furthermore, in lower light, the plants are less dense and the leaves are usually farther apart, decreasing the density (Niinemets & Tobias 2014). This reduction in density increases the light interception per leaf area. Pleurocarpous mosses are able to acclimate structurally to light levels by adjusting the density of leaves and branches, whereas non-branching acrocarpous mosses lack the ability to change branching density. In addition, mosses under low water conditions have a greater degree of aggregation, thus further reducing light penetration. But as mosses desiccate they have greater light penetration further down the stem than the same mosses when hydrated, increasing productivity in older parts (Davey & Ellis-Evans 1996).

Absorption is not equal throughout the spectrum. Davey and Ellis-Evans (1996) observed that the greatest attenuation occurred at wavelengths corresponding to the peaks of chlorophyll absorption (675 nm and below 450 nm). Other factors that affect absorption include stem orientation, stem density, leaf size and orientation, and pigment content.

Leaf Angle

Angle of incidence (Figure 185) is the angle formed between the direction of light and the vertical (difference from straight on), so a low sun has a higher angle of incidence. **Leaf angle** (Figure 186) is the angle made by the axil of the leaf and the axis. It affects the reflectance of light in plants. Therefore, a small leaf angle (approaching vertical) creates the effect of a large angle of incidence.

Figure 185. Angle of incidence and reflection pathway. Drawing modified from Clive Dexter at <http://ezbackgrounds.com/blog/ezlighting-guide-angle-incidence.php>.

Howard (1967) demonstrated that leaf angles in four tracheophyte species of 0-30° (=90-60° angle of incidence) made little difference in reflectance, but when the angle of incidence was smaller, the reflectance increased rapidly, consequently rapidly reducing photosynthesis. In the tree leaves of *Eucalyptus regnans*, photosynthesis begins to decrease at ~72° leaf angle, and at 45°, photosynthesis drops to 70% of values of horizontal leaves. At 5° leaf angles it approaches 0% (Kriedmann *et al.* 1964).

In bryophytes, many moss species raise their leaves and wrap them around the stem as they dry, effectively providing greater protection to the chlorophyll by greater

overlapping of leaves. In the desert moss *Syntrichia caninervis* (Figure 187), leaf angle changes (Figure 188) are an important means of protecting against the effects of high light intensity during long periods of desiccation (Wu *et al.* 2014). First, the leaf movement helps to slow drying, permitting the plant to adjust physiologically in preparation for desiccation (see Chapters 7-5 and 7-6 in Water Relations). Second, the acute leaf angle of only 30° of a dry plant protect the photosynthetic cells. And third, when the leaf rehydrates, it returns in 7 seconds to an angle of 69-84°, with the first leaves reaching normal position in only 1 second. The hyaline cells at the leaf base are thin-walled and facilitate rapid uptake of water, swell, and push the leaf away from the stem. The leaf hair also play a role in reflecting light and reducing its impact on the chlorophyll. But the leaf hairs (**awns**) play another role that thus far has not been explained. They somehow are important in adjusting the leaf angle. When these awns are removed, the angle adjustment is retarded.

Figure 186. Incidence light and reflectance on a leaf at an acute angle. In this case, the incident light strikes the leaf at an angle of 60° from the straight up light that would strike the leaf from a perpendicular direction. Redrawn from Howard 1967.

Figure 187. *Syntrichia caninervis*, a species that changes leaf angles in response to drying. Photo by Michael Lüth, with permission.

Figure 188. *Syntrichia caninervis* dry exhibiting twisted leaves with a small leaf angle. Photo by Sheri Hagwood, through public domain.

Xerophytic mosses like *Syntrichia ruralis* (Figure 53) can look much darker and expose less surface area to the atmosphere, whereas the wet cells change the optical properties, making the cell walls more translucent (Glime & Church, unpubl.).

Summary

Protonemata of some mosses, such as *Schistostega pennata*, are able to position their chloroplasts to receive maximum available light and the lens-shaped cells help to focus the light. Their high reflectance provides a luminescence in caves. Similar reflective abilities are present in *Mittenia plumula* that lives in wombat holes. *Cyathodium* species that live in caves have a similar reflective ability in their thalli.

Some bryophytes are able to live in the dim light surrounding light bulbs in visitor caves, exceeded in their low-light survival only by the algae. Many of the cave bryophytes are also typical of other habitats of greater light intensity, including high-light tolerators like *Ceratodon purpureus* and *Pohlia nutans*. Some are the **tufa formers** that often are so encrusted with limestone that only their tips are able to get sufficient light for photosynthesis. *Amblystegium serpens* seems able to live in the lowest light at only 232 lux.

One response to bryophytes in deep caves is **etiolation**, which spaces leaves further apart, thus exposing more surface area to the little light available. In some species, the number of chloroplasts and size of grana can increase and growth can occur even in the dark. Long, thin "exploratory" branches may form. In *Atrichum undulatum* the starch disappeared in winter but reappeared in spring, in the dark! When placed in the light, photosynthesis began without delay.

Various plant parts may exhibit fluorescence. So far this ability is known from leaf cell walls, stems, spores, antheridia, archegonia, paraphyses, capsules, peristomes, elaters, gemmae, and bulbils, in addition to the chlorophyll fluorescence known from all photosynthetic organisms. Fluorescence under the microscope has been exhibited in many bryophyte species, but few seem to have been documented in the field. Fluorescence may be caused by a number of

compounds, including flavonoids, fatty acids, and lignin-like compounds. Its colors vary widely, but are not visible to the human eye when bright sunlight is present. Nevertheless, many kinds of insects are able to see these colors even in daylight. Its role remains unknown, and it may simply be a property of the cell wall components and antibiotic compounds, but its value in attracting dispersal agents should be explored.

Some mosses develop pigments in response to increased light intensity, although chlorophyll concentrations usually decrease. Others change the leaf angles, decreasing the damage to chlorophyll. Antenna pigments help to transfer light energy to the chlorophyll in low light and pigments on the lower surface may help by reflecting red light back to the chlorophyll.

The light intensity diminishes as it penetrates the bryophyte canopy, but when the leaves dry, more light may reach older portions.

Acknowledgments

Thank you to Misha Ignatov for providing me with a prepublication copy of Ignatov *et al.* (2012) and providing me with numerous images of *Schistostega*. And thank you to Martin Hutten for offering his *Schistostega* images. Noris Salazar Allen introduced me to *Cyathodium cavernarum* and provided me with images. Michael Lüth has been especially generous in granting permission for me to use any of his images. I appreciate David Kofranek for his effort to take a picture of *Caltha palustris* with UV light. And I certainly thank all the photographers who posted their images on the web, and later granted me permission to use them in this chapter. I especially appreciate help from Magdalena Turzańska for her wonderful images of structures not illustrated elsewhere and for telling me her staining method. Thank you to Scott Zona for helping me to get in contact with Tony Markham to get his permission to use images from his wombat hole video, and to Tony for giving me permission to use his images. Thank you to Andi Cairns for reviewing an earlier draft of the fluorescence section, for several email discussions on the topic, and for several references. Bryonettors provided me with several enlightening discussions, images, and observations on fluorescence in bryophytes, as noted herein.

CHAPTER 10-1

TEMPERATURE: EFFECTS

Figure 1. Snow on the peak of Mount Edith Cavell, Canadian Rockies, in Jasper National Park, Alberta, Canada. Few plants can grow in this harsh, rocky habitat, but lichens and bryophytes may be found in microsites. Photo by Janice Glime.

Temperature

The temperatures experienced by various microhabitats on the Earth vary widely, from volcanic lava to exposed rock in the Antarctic. Temperatures at which bryophytes exist also vary widely, from those of geothermal fields to glacial polsters (Figure 1). But the daily temperature of a bryophyte may vary more than we had imagined. Gabriel (2000) points out the importance of microclimate temperatures to the growth rate for Azorean forest bryophytes. And on a single sunny afternoon in the Keweenaw Peninsula of Michigan, with an air temperature of $\sim 28^{\circ}\text{C}$, we measured moss leaf temperatures up to 41°C , whereas a nearby black rock, also in the sun, registered only 31°C ! (Hribljan & Glime, unpublished data).

Proctor (2014) includes cooling as one of basic needs of plants on land. Emphasizing the importance of scale, he contends that for large plants (tracheophytes) convective cooling is most important. For low-growing plants such as bryophytes, evaporative cooling is sufficient.

As C_3 plants, bryophytes are adapted to have a net photosynthetic gain at a relatively low temperature, some (e.g. *Racomitrium lanuginosum*; Figure 2-Figure 3) as low as -10°C (Kallio & Heinonen 1973), but would seldom be expected to do as well at temperatures above 25°C . Even tropical bryophytes seem to do poorly above 25°C (Frahm 1990), where their net assimilation rate decreases drastically, respiration rates are high, and they fail to reach their compensation point (Frahm 1987). Those bryophytes that typically experience cool weather during the growing season, as for example *Hylocomium splendens* (Figure 4) from Swedish Lapland, fail to benefit by enhanced growth from a mean increase of $1.5\text{--}3^{\circ}\text{C}$ during the growing season (Jägerbrand *et al.* 2003). It seems that at high temperatures, most bryophytes may become dormant, suffer reversible depression of photosynthesis (Weis *et al.* 1986), or die; irreversible damage to photosynthesis can result from damage to photosystem II (Weis *et al.* 1986).

Figure 2. *Racomitrium lanuginosum* forming large mounds in Iceland. Photo by Janice Glime.

Figure 3. *Racomitrium lanuginosum* showing the awns that help reflect light and reduce the temperature while reducing water loss. Photo by Michael Luth, with permission.

Temperature and seasonal changes can play a significant role in determining the distribution of bryophytes. For example, when comparing bryophyte floras of the French Alps and Britain, Pentecost and Zhang (2002) found that the distribution of *Palustriella commutata* (= *Cratoneuron commutatum*; Figure 5) is influenced more by temperature than by water chemistry, despite the need for free CO₂. Dilks and Proctor (1975) have shown that most bryophytes have a relatively narrow range of temperatures for net photosynthetic gain, experiencing a sharp decline just past the optimum. Indeed, for most bryophytes, the optimum is near 20°C, and for many it is much lower.

Figure 5. *Palustriella commutata* in one of its common habitats (Upper) and closeup (Lower). Photos by Michael Luth, with permission.

Bryophyte Alteration of Temperature

The temperature of a bryophyte is not necessarily the temperature we would feel as we walk by. Often it is quite different in the nearby niches, cooled by air from a rockhouse or warmed by a spot of sun on the absorbing bryophyte tissues. It is the temperature of the microclimate that often determines the growth rate and distribution of the bryophytes (Gabriel 2000).

Not only do cushions retain water, but they moderate the temperature (Rod Seppelt, Bryonet 27 June 2022). In the Antarctic, when the temperature drops below 0°C, the moss cushions likewise drop in temperature. However, when the cushion begins to freeze, latent heat begins to elevate the temperature to as much as 2°C. This delays the denaturation of the cellular proteins.

Imagine a moss sitting in the forest, still hydrated because of the protection of the forest. Yet as the Earth moves and the position of the sun changes, sunflecks dance about the forest floor like butterflies. One minute the hydrated moss is in the cool shade of the forest, but the next it is beset by the heat of the sun. Proctor (1982) reported sunfleck temperatures up to 39°C when the air temperature was a mere 20°C.

In his treatment on the upper temperature limit of life, Kempner stated that there could be "no defense against high temperatures unless the laws of thermodynamics were violated." But the literal meaning of that is simply not true. Animals sweat, taking advantage of evaporative cooling. Tracheophytes transpire, pumping water from below ground to their leaves, then to the atmosphere, cooling by

the heat absorbed as liquid water changes to gas. And bryophytes, too, can take advantage of transferring water from lower parts to their upper parts where it evaporates and cools the growing tips. And plants, like animals, can reflect the sun by presenting white, reflective surfaces to prevent absorption of the sun's rays. In bryophytes, this reflection may be achieved by **hyalocysts** (hyaline cells), as in *Sphagnum* (Figure 6-Figure 8) and *Leucobryum* (Figure 9-Figure 11), white hair tips on the leaves, as in *Racomitrium* (Figure 3), *Tortula/Syntrichia* (Figure 12-Figure 13), and *Polytrichum piliferum* (Figure 16), or possibly even by the refractive nature of papillae (Figure 14-Figure 15) that give the moss a dull appearance to our eyes.

Even as ectothermic animals can modify their temperature by such activities as basking, changing cell shapes, and rearranging scales, bryophytes can survive at sub-zero air temperatures by their own ability to alter the temperature. Lewis Smith (1988) found that in Antarctica the temperature at the surface of a *Schistidium* cushion (Figure 17) could vary from -9.2°C to 42.8°C on a single day in January, whereas only 1 m away the temperature 10 cm down into a *Ceratodon* turf (Figure 17) had almost no variation (Figure 19). He attributed the lack of change in the *Ceratodon* turf to reduction of heat transfer by the moist turf. However, the nearby but typically near-black *Schistidium* could operate as a black body that would absorb daytime heat, then re-radiate it at night.

Figure 17. *Ceratodon purpureus* (left) in depression that maintains a near constant temperature. *Schistidium antarctici* (right) on ledge where dark color absorbs heat in its dry state. Photo courtesy of Rod Seppelt.

A good example of temperature differences is that of temperatures in the Snowy Mountains of southeastern Australia (Körner & Cochrane 1983). On midsummer days, the maximum leaf-air temperature difference in the trees was a mere 7°C, rising to 13°C in the shrubs, 21°C in the dwarf shrubs, and 24°C in the grass tussocks and rosette plants. But in an isolated moss cushion, the temperature was 30°C higher than the air temperature! The differences were less severe at high elevations except for the low plants, where the moss cushion set the record. Temperatures change quickly within the moss cushion, with deeper portions exhibiting less extreme conditions, as seen in the Antarctic (Figure 18-Figure 19). The bare soil, however, reached 81.9°C! Obviously the mosses must germinate and get established well enough to control their own temperatures before that kind of heat is reached.

Figure 18. Isotherms for two days in December through a *Ceratodon* turf down to 10 cm and a *Ceratodon* turf covered by dense *Usnea antarctica*. Redrawn from Lewis Smith 1988.

Figure 19. Differences in summer temperatures of surface and subsurface parts of Antarctic moss communities during 13-day period, expressed as mean percentages per day. Absolute maxima and minima for 13-day period appear in bars. From Lewis Smith 1988.

On Mount Fuji, Japan, *Racomitrium lanuginosum* (Figure 2-Figure 3) experiences as much as a 42°C daily temperature range while *Grimmia elongata* (Figure 20) nearby has only a 26°C range. Maruta (1986) suggests that the difference lies in the less dense mat of *R. lanuginosum*.

Figure 20. *Grimmia elongata*, illustrating the dense mat that insulates and maintains less temperature variation than loose mats. Photo by Michael Luth, with permission.

The state of hydration, as we might expect, plays a major role in temperature. Water is slow to change its temperature, compared to air, so it is not surprising that Rydin (1984) found the highest temperatures among

Sphagnum (Figure 6) species when they were completely dry. Even shade had little effect on the temperature except when the moss was dry, and under any given set of conditions, there was no difference among *Sphagnum* species.

Soil Temperatures

Bryophytes are likewise important in altering the soil temperature. This same ability to act as a black body can add warmth to the soil, but in other cases, the moss could absorb or reflect the heat (or light) and prevent it from reaching the soil beneath.

In the tundra, the bryophytes can prevent warming of the soil. In permafrost areas, mosses contribute to maintaining the permafrost in shallower soils (Van Der Wal & Brooker 2004) compared to bare areas. Van Der Wal and Brooker found that herbivore grazing and trampling by barnacle geese and reindeer reduce the growth of the mosses and hence their depth. This, in turn, increases the soil temperatures. Enclosures that prevented this animal activity and permitted the moss mat to become thicker caused a 0.9°C decrease in the soil temperature in just seven years (Van der Wal *et al.* 2001). This cooling caused a 50% reduction in biomass of the grass *Poa arctica* and the polar cress *Cardamine nymmanii*.

Thick moss cover acts as insulation, preventing the warmth of the sun from reaching the soil. Under cryptobiotic crusts in the alpine tundra basin of the Olympic Mountains, Washington, USA, the soil surface and immediate subsurface was 5-8°C cooler at midday under moss-dominated crusts (Gold *et al.* 2001) than where crusts were absent. Lichens were even more effective, lowering the temperature by 10-11°C compared to bare soil. In alpine areas, this lower temperature could deprive roots of needed heat, but in prairies and deserts where cryptogamic crusts occur, it could prove to be essential for root survival. Konis (1949) found the upper thermal limit for normal plant cell activity to range from 45 to 55°C, although some cells could survive up to 59°C. Therefore, in the hot climates of prairies and deserts, the bryophyte and lichen crusts could be essential to root survival by ameliorating the soil temperature.

In southern Africa, the crusts are important in providing a habitat where nitrogen fixation occurs, and Aranibar *et al.* (2003) suggest that these crusts permit the survival of these N-fixing systems at high temperatures and through long droughts, providing resilience to the ecosystem.

In the Antarctic, the bryophytes perform the opposite function for the Cyanobacteria. Huntley (1971) reported that they maintained a temperature that was typically more than 10°C higher than the ambient temperature, often reaching 20°C during the middle of the day, and providing a suitable temperature for nitrogen fixation activity of the Cyanobacteria. In a Russian study, nitrogen fixation by bacteria in peat did best in the lower layers (20-30 cm) than in the green portion, but could proceed in a range of 5 to 35°C (Kravchenko & Doroshenko 2003).

The role of the bryophytes in ameliorating soil temperature varies with the ecosystem. For example, in geothermal areas, the bryophytes confine the heat, making soil surface temperatures up to 10°C higher than it is with them removed (Glime & Iwatsuki unpublished data). In a

"moss-lichen pine forest" in Russia, Ipatov and Tarkhova (1983) found that the mosses "soften" the temperature fluctuations more than do lichens and also maintain a higher moisture content, contrasting with the alpine tundra study of Gold *et al.* (2001) where the lichens seemed to do more.

It is no wonder the BOREAS temperature model predicted somewhat poorly until the mosses were added to the model (Pauwels & Wood 1999; Litzgus & Brooks 2000). Moss thickness and moisture content turned out to be important parameters in the sensitivity analysis. But it is complicated. Betts *et al.* (1998) contend that the moss layer makes soil temperature dynamics and water dynamics difficult to track because the moss layer is such a good insulator of the soil. It makes it difficult to predict the temperature of the soil or the thaw date.

Degree Days

Plants often respond to the cumulative effects of temperature, known as **degree days**. That is a measure of the product of the number of days times the mean temperature (°C) on those days. We know for tracheophytes that these degree days are a factor in germination of seeds, breaking dormancy in bulbs, and ability to reach fruit maturity before the first frost terminates the growing season.

Degree days are seldom mentioned for bryophytes, as few studies have approached their temperature needs in that way. Bates (1989) found that *Leucobryum glaucum* (Figure 9) cushions in Great Britain had their highest growth rate in summer, and unlike most bryophytes, growth was more related to temperature than to precipitation. Rather, it seemed to be related to degree days above 5°C.

While degree days are not mentioned specifically, many studies imply their importance. Callaghan *et al.* (1997) found that the growth of circumpolar populations of *Hylocomium splendens* (Figure 21) depends greatly on the early summer temperatures and the length of the growing season (degree days for sure).

Figure 21. The staircase moss, *Hylocomium splendens*, exhibiting its steps. Its growth is dependent on a sufficient growing season. Photo by Janice Glime.

Bryophytes can have a profound effect on the **soil degree days (SDD)**, which are important for root growth and storage organ dormancy, among other things. When moss cover and the canopy were removed from boreal

forests of interior Alaska, the soil warmed, on average, by 345 and 408 soil degree days, respectively (Bonan 1991). These were the two parameters having the highest effect on soil temperature, which normally averaged 851 soil degree days, with elevation and soil drainage patterns being of secondary importance, with deviations of 71 and 66 soil degree days.

Safe Sites

Even turtles can benefit from the ability of the mosses to buffer temperatures. In Georgian Bay, Ontario, Canada, some members of the spotted turtle (*Clemmys guttata*; Figure 22) spend their winter under *Sphagnum* (Figure 6) hummocks (Litzgus *et al.* 1999). They enter in early autumn with body temperatures of 12-16°C and stay there until spring (mid to late April) when the air temperature is 1-5°C. Within the safety of the hummock, the turtle's body temperature stays 0.3-3.9°C while air temperatures drop to as low as -35°C. Such data indicate that *Sphagnum* greatly buffers the temperature and creates a very different environment.

Figure 22. *Clemmys guttata* hatching amid mosses. Photo courtesy of Steve Soldan.

Mosses may provide safe sites for seed germination. On iron mine tailings in New York, USA, the turf moss *Polytrichum piliferum* (Figure 23) became a safe seed bed for a variety of grasses (Delach & Kimmerer 2002). It was especially important for those species that germinate early and become established in cool weather. At that time, the mosses can protect the plants from a late frost and even warm the daytime temperatures due their black-body action. However, they can do little to cool the site sufficiently for continued success on the hot tailings rock during the heat of summer.

Life Cycle Effects

Temperature plays a role in all stages of the life cycle of plants. It potentially affects the physiology of a bryophyte in several ways: photosynthetic rate, respiratory rate, reproductive timing, growth, development, and productivity. These together affect its survivorship. Whereas many animals can maintain a relatively constant internal temperature either through physiological means or by behavioral changes, plants are restricted in their positions and very few have any physiological means by which to change their internal temperatures. Thus, plants, including bryophytes, must adapt structurally,

physiologically, or by life cycle alterations to survive periods of extremes of hot and cold. On the other hand, these temperature changes can also signal and initiate changes in life cycle stages (Grime *et al.* 1990), as discussed in the chapters on development and phenology.

Figure 23. *Polytrichum piliferum*, a moss that becomes a safe site for grass seed germination. Reddish cups are antheridial splash cups. Photo by Janice Glime.

Spore germination is often attuned to temperature. In *Mnium hornum* (Figure 24) and *Plagiomnium undulatum* (Figure 25), spore germination is dependent on temperature, with more germinating at 20°C than at 10°C (Newton 1972). Not surprisingly, it also affects regeneration of fragments, but the surprise is that 77% of the female regenerants survived while all the male regenerants of these two species died.

Figure 25. *Plagiomnium undulatum* with capsules, a species for which spore germination is best at ~20°C. Photo by Michael Lüth, with permission.

McLetchie (2001) also found a temperature sex bias in *Sphaerocarpus texanus* (Figure 26), where the spores (Figure 27) that lost dormancy (germinated; Figure 28) on a 25°C day: 15°C night schedule were female biased (Figure 29). McLetchie (1999) found a degree-day type of response in spore germination (Figure 28) of *Sphaerocarpus texanus*, with loss of dormancy increasing with length of time held at a suitable temperature (16/10°C) and germination conditions. But the interesting thing that he found is that spores held at 35/20°C during dormancy lost their dormancy more quickly at 16/10°C than those held at 30/15°C or at 25/15°C, whereas those given the moist conditions needed for germination failed to germinate at all at 35/20°C or 30/15°C. Low temperatures could induce the spores back into a secondary dormancy, much as occurs in seeds of obligate winter annuals.

The **protonema** may be affected differently by temperature. Dietert (1980) found that the optimum temperature for germination (Figure 30) of both *Funaria hygrometrica* (Figure 31) and *Weissia controversa* (Figure 32) was 30°C, but the optimum for the growth of the protonema was only 25°C. This higher requirement for germination is not unusual among plants because it insures a smaller probability that a killing frost will occur and kill all the young plants. Thus, a few warm days with spores on a dark soil surface can be sufficient for germination, but the green and hydrated protonema will hopefully enjoy a lower temperature.

Growth is more than just adding biomass and length. It involves producing buds, branches, rhizoids, and vegetative propagules. Most of these were discussed in the chapter on development, but a brief additional discussion is in order here.

Gametangia have their own set of temperature requirements as well. In her study on *Funaria hygrometrica* (Figure 31) and *Weissia controversa* (Figure 32), Dietert found that cooler temperatures were needed for gametangia development than those for germination. Monroe (1965) likewise found that a low temperature (10°C) stimulated the production of sex organs in *Funaria* (Figure 33) and showed that day length had no effect on their timing.

Figure 33. *Funaria hygrometrica* young sporophytes, a stage that follows low temperatures needed to stimulate development of archegonia and antheridia. Photo by Michael Lüth, with permission.

The **perennial** moss *Brachythecium rutabulum* (Figure 34) had its maximum relative growth rate, shoot length, and leaf area at ~19°C (Figure 35), but these are related to each other and would be expected to increase concurrently (Furness & Grime 1982a).

Figure 34. *Brachythecium rutabulum*, a common forest floor taxon. Photo by Des Callaghan, with permission.

Figure 35. *Brachythecium rutabulum* growth at various temperatures. Redrawn from Furness & Grime 1982a.

Rhizoids, on the other hand, do not necessarily develop at the same time as stem and leaf biomass. For *Fontinalis hypnoides* (Figure 36), the number of rhizoid clumps (Figure 37) produced increased with temperature in the range of 1-20°C in both flowing water and pool conditions (Figure 39) (Glime 1980). For *Fontinalis novae-angliae* (Figure 38), it increased up to 15°C in flowing water conditions, but dropped sharply at 20°C, whereas in pool conditions it continued to rise. The **growth optimum** for these species from the same localities, however, is lower, at 15°C, for both species (Glime 1987a). **Branching** rose sharply from 1 to 5°C in *F. hypnoides* but exhibited little increase with temperature above that (Figure 39) (Glime 1982).

Figure 36. *Fontinalis hypnoides*, a species that develops rhizoids in the range of 1-20°C. Photo by Ivanov, with permission.

Figure 37. *Fontinalis hypnoides* rhizoids. Photo by Janice Glime.

The general pattern, however, for branches and total branch and stem growth in *Fontinalis* (Figure 36) is that they occur together (Glime 1980). This is reasonable, as in *B. rutabulum* (Figure 34), because new branches create a greater total branch and stem length, and in most of these species new branches need new rhizoids (Glime & Raeymaekers 1987). The rhizoids, however, tend to have a strong peak at 15°C for most of these aquatic species (Figure 39).

Figure 38. *Fontinalis novae-angliae* with capsules. Photo by Janice Glime.

Figure 39. Response of rhizoid clumps, branches, and growth in flowing water (flow) and standing water (pool) conditions to temperatures in the range of 1-20°C for 15 weeks. Populations at 20°C were changed to 13°C after 5 weeks to look for recovery. Numbers represent means of 40 stems. All collections are from the Upper Peninsula of Michigan except the population from New York. Redrawn from Glime & Raeymaekers 1987.

Archegonia of *Fontinalis* seemed to respond more like a threshold existed, with the highest production at 15°C in flowing water, but in pool conditions, that temperature produced the fewest archegonia, with the most at 10° and 15°C, so few conclusions can be drawn. In an experiment on *F. dalecarlica* (Figure 40), production of archegonia (Figure 41) was related to photoperiod (Glime 1984), so temperature may not be an important controlling factor.

Figure 40. *Fontinalis dalecarlica*, a species in which different life stages are triggered by different temperatures. Photo by Jan-Peter Frahm.

Figure 41. *Fontinalis dalecarlica* archegonia produced in greatest numbers at 15°C. Photo by Janice Glime.

Bopp and Bhatla (1990) determined the mean temperatures required for induction of gametangia in several taxa (Table 1). But they also concluded that several of the species were controlled by photoperiod, including *Pogonatum aloides* (Figure 42-Figure 43).

Table 1. Mean temperature (°C) at which gametangia are induced. From Bopp & Bhatla 1990.

<i>Pogonatum aloides</i>	21
<i>Funaria hygrometrica</i>	10
<i>Physcomitrella patens</i>	15
<i>Physcomitrium pyriforme</i>	7
<i>Philonotis turneriana</i>	18

Figure 42. *Pogonatum aloides*, a species in which photoperiod and temperature trigger life cycle stages. Photo by Michael Luth, with permission.

Figure 43. *Pogonatum aloides* with capsules. Photo by Michael Lüth, with permission.

The success of the **sporophyte** first depends on the success of the gametangia, then on the actual fertilization, and finally the requirements for its own development. Hohe *et al.* (2002) found that the highest number of sporophytes in *Physcomitrella patens* (Figure 44) were produced at 15°C, with numbers dropping greatly at 25°C. Bopp and Bhatla (1990) had similar results, finding the optimal temperature for capsule production to be at 15-19°C, with production dropping by 80% at 19-21°C. Vegetative growth, on the other hand, was best at 25°C. Thus we can understand that temperature is one of the factors that can keep the various energy-requiring activities of the moss, like reproduction and growth, from occurring at the same time.

Bryum argenteum (Figure 45) required 25°C for capsule development. Bopp and Bhatla (1990) were surprised to find that in *Funaria hygrometrica* (Figure 31), capsules were produced at 10-15°C in 12-16 hours light, but a shorter photoperiod permitted development at higher temperatures.

Figure 44. *Physcomitrella patens* with capsules that are produced in greatest numbers at 15°C. Photo by Michael Luth.

Figure 45. *Bryum argenteum* with capsules. Production of capsules can occur in a range of 10-15°C in 12-16 hours light per day. Photo by Bob Klips, with permission.

One of the more subtle life cycle effects of temperature is the initiation of **dormancy**. For example, the thallose liverwort *Lunularia cruciata* (Figure 46) can be induced into dormancy by temperatures of 24°C in continuous light, or other high temperature combinations with long days. Since this set of conditions is likely to be a harbinger of forthcoming drought, or already coupled with it, it provides a good signal to go dormant.

Figure 46. *Lunularia cruciata*, a species than can be induced into dormancy by high temperatures and long days. Photo from <www.aphotofauna.com>, with permission.

Several species of *Sphagnum* [*S. magellanicum* (Figure 47), *S. capillifolium* (Figure 48), and *S. fallax* (Figure 49) have a quite different dormancy trigger (Gerdol 1995). They are able to grow in summer temperatures if there is sufficient moisture, but they are triggered into dormancy by low night temperatures.

Figure 47. *Sphagnum magellanicum*, a species that grows in summer temperatures but goes dormant if night temperatures are low. Photo by Michael Luth, with permission.

Figure 48. *Sphagnum capillifolium*, a species that grows in summer temperatures but goes dormant if night temperatures are low. Photo by J. C. Schou, with permission.

Figure 49. *Sphagnum fallax*, a species that grows in summer temperatures but goes dormant if night temperatures are low. Photo by David T. Holyoak, with permission.

Even fragments may have their optimum for **regeneration**. Although *Sphagnum* (Figure 47-Figure 49) species typically occur in the sun, go dormant in the fall, and grow when enough moisture is available in summer, their fragments do not seem to survive well in heat. Sagot and Rochefort (1996) tested *S. angustifolium* (Figure 50), *S. fallax* (Figure 49), *S. fuscum* (Figure 51), *S. magellanicum* (Figure 47), *S. capillifolium* (= *S. nemoreum*; Figure 48), and *S. papillosum* (Figure 6) and found that only *S. fallax* survived temperatures as high as 30°C for 48 hours of oven drying. The conditions of oven drying may have dried them too quickly, preventing them from entering dormancy. However, the implications are that harvesting peat in the summer may prevent regeneration from fragments that could dry and heat up too quickly once disconnected from the capillary stream of the plants.

Figure 50. *Sphagnum angustifolium*, a species that does not survive above 30°C of oven drying – perhaps preventing them from the physiological changes normally made during drying. Photo by Michael Luth, with permission.

Figure 51. *Sphagnum fuscum*, a species that does not survive above 30°C of oven drying – perhaps preventing them from the physiological changes normally made during drying. Photo by Michael Luth, with permission.

Growth of any organism is a competition for energy and nutrients. This is especially true for plants that continue to grow throughout their lifetimes or over a long expanse of years. Bryophytes include both **annual** (regrowing from spores every year) and **perennial**

(continuing growth of the same plant for a number of years) growth strategies. This means that some must start the growing season from spores and others simply continue growth from existing plants. Hence we should expect different signals for these two growth processes.

Normal and Extremes for Growth

Aside from these life cycle changes, bryophytes respond physiologically to temperature differences that affect their growth and productivity (Furness & Grime 1982a, b). Most bryophytes have their optimum temperature for growth in the range of 15-25°C (Furness & Grime 1982b). Yet some bryophytes can have an optimum of less than 10°C (Furness & Grime 1982b), as in some species of *Fontinalis* (Glime 1987a). It is likely that this low temperature optimum, at least in *Fontinalis*, results from a cumulative effect of increased respiration at higher temperatures. In experiments where the mosses were acclimated to the test conditions for three weeks, the aquatic species *Fontinalis duriaei* (Figure 52) exhibited optimum net photosynthesis at 10°C (Glime & Acton 1979).

Figure 52. *Fontinalis duriaei*, a species that has optimum photosynthesis at 10°C in the Keweenaw Peninsula of Michigan. Photo by Michael Luth, with permission.

Furness and Grime (1982a) suggested that bryophytes may be able to compete with tracheophytes because the bryophytes are able to grow over a wider temperature range and to exploit the cool months of spring and autumn for growth. They supported this suggestion by showing that while the optimum temperature for growth, shoot length, and leaf area was 19°C in *Brachythecium rutabulum* (Figure 34), the reduction in relative growth was less than 40% at 5°C. In southern Finland, *Sphagnum fuscum* (Figure 51) had a net productivity gain at any temperature above 0°C, provided there was sufficient water (Lindholm 1990). This water limit at higher temperatures seems to be a principle for many bryophytes, although *Sphagnum* generally has a higher temperature optimum than other bryophytes (Koskimies-Soininen & Nyberg 1987; Li & Glime 1990; Li *et al.* 1992).

A number of factors can affect the optimum temperature for growth, and it is likely that a number of physiological races exist. In *Fontinalis novae-angliae* (Figure 38) collected from New Hampshire, USA, the optimum temperature for growth when placed in a common garden was 10°C, whereas the population from the Upper Peninsula of Michigan had its greatest growth at 15°C (Glime 1987b; Figure 53). Furthermore, the New

Hampshire populations had considerably more growth at all temperatures below 20°C than did the Michigan populations. Optima also differed between pool and flowing water conditions, with the New Hampshire population exhibiting its best growth at 5°C in pool conditions. On the other hand, *F. hypnoides* (Figure 36) had almost no difference in growth between pool and flowing water conditions except at 20°C, where the flowing water conditions produced the best growth (Figure 54). In Japan, Saitoh *et al.* (1970) found the optimum for photosynthesis in *F. hypnoides* at 20°C.

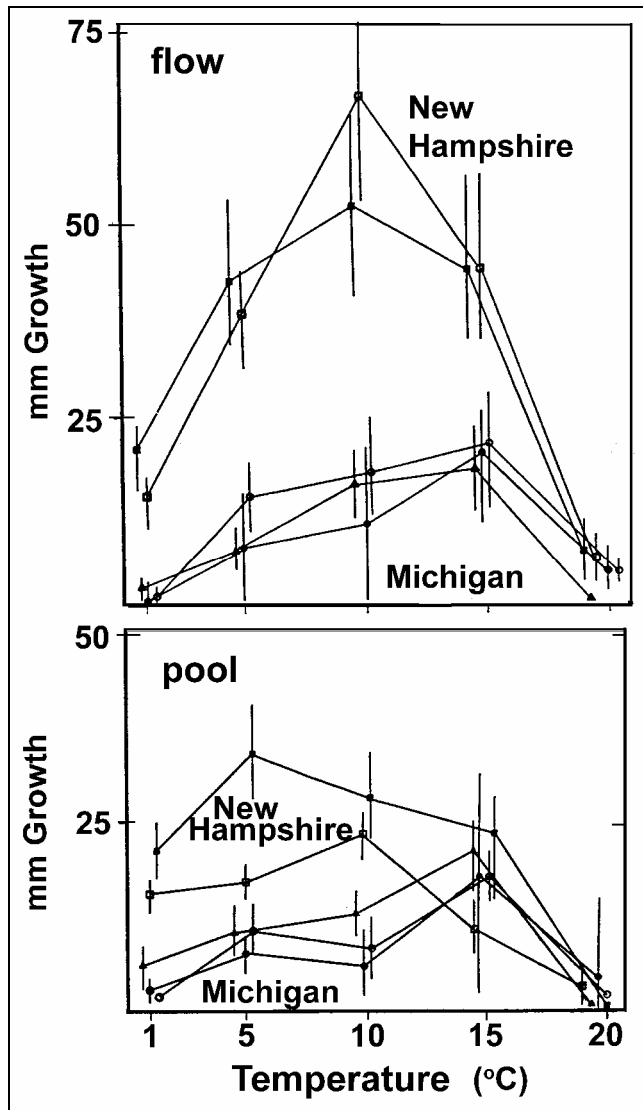

Figure 53. Comparison of growth in flowing water (flow) and standing water (pool) conditions after 15 weeks for *Fontinalis novae-angliae* from two geographic areas. Redrawn from Glime 1987b.

Fontinalis novae-angliae (Figure 38) most likely holds the record for high temperature survival of wet mosses. Glime and Carr (1974) boiled it for 14 or more hours a day for two weeks. A year after it was returned to its native stream, a new green leaf appeared on one of the marked stems that had been in the boiling treatment. All the former leaves were gone or brown.

Short-term studies can be misleading, and past history of the bryophyte can influence the temperature for optimum growth. In *Fontinalis hypnoides* (Figure 36), spring-collected (June) mosses grew best at 15-20°C, whereas plants of the same population collected in September ceased growth after 2-3 weeks at 20°C (Glime 1982). It appears that degree days are at work here.

Figure 54. Growth after 15 weeks for *Fontinalis hypnoides* from Isle Royale, Michigan, USA, in flowing water (flow) and standing water (pool) conditions. Redrawn from Glime 1982.

Mosses seem to have the ability to withstand and even take advantage of high temperatures for short periods of time. Liu (2000) showed that *Plagiommium acutum* (Figure 72), *P. maximoviczii* (Figure 55), *Thuidium cymbifolium* (Figure 56), and *Chrysocladium retrorsum* were able to maintain optimum photosynthetic output at 20-35°C. They actually had a positive net photosynthesis at -15°C and maintained a net photosynthetic gain for 10-30 minutes at 40-45°C. However, the 50% injury temperature (IT₅₀) occurred at 44.8°C for *Thuidium cymbifolium* and at 45.3°C for *Plagiommium acutum*. But even at temperatures less than 45°C, damage to cells and death of the shoot increased with exposure time. None of them survived above 50°C.

Figure 56. *Thuidium cymbifolium* with capsules, a species that exhibits optimum photosynthetic output at 20-35°C. Photo by Li Zhang, with permission.

A measurement of air temperature does not present an accurate picture of actual moss temperatures, so both field measurements, which seemingly represent long-term exposure, and lab measurements, which represent only a short-term duration, present problems in realizing the actual tolerances of bryophytes. For example, Kappen and Smith (1980) found that the geothermal moss *Campylopus praemorsus* tolerated temperatures up to 29.8°C in its active parts, while soil temperatures were much higher. We have seen how bryophytes alter the temperature of both the environment and of themselves relative to ambient air temperature. It is important that field measurements reflect the temperature of the leaves in question through the use of microprobes. And laboratory photosynthetic measurements need to mimic temperatures at which the moss has been maintained if they are to tell us the optimum sustained temperature. Nevertheless, these short-term measurements are useful to tell us short-term tolerances that bryophytes may need to sustain in the field. With a soil temperature reaching 81.9°C in the desert (Körner & Cochrane 1983), they could certainly be subjected to a wide range.

Some more tropical elements of the bryophyte flora seem to find refuge in **rockhouses** (Farrar 1998). These are deep recesses in cliffs and maintain a much buffered temperature regime, but under very low illumination. Although they typically do not get very warm, they seem to be refugia for tropical species that persist there in the absence of extreme winter cold. Perhaps, too, these species are adapted to the low light levels in the lower strata of tropical forests. Although the ferns are more conspicuous in these special habitats, the bryophytes are the most numerous.

Compensation Point

The **temperature compensation point** is that temperature at which photosynthetic gain equals respiratory loss, *i.e.*, net photosynthesis is zero. It is this compensation point, whether for light, temperature, CO₂, or other factor that determines whether a plant is capable of surviving over the long term. While some plants may have a negative gain for a short period of time, they must have a net gain over the annual cycle. In the tropics, low light intensity and high temperatures are major factors in preventing lowland forest bryophytes from reaching their compensation point (Frahm 1987). For most bryophytes, this temperature compensation point is reached somewhere above 20-25°C,

with lowland tropical forest bryophytes having drastic drops in net assimilation above 25°C, soon reaching and surpassing their temperature compensation point (Frahm 1990). We can assume that if 25°C is the upper temperature limit for tropical bryophytes in lowlands, this is most likely the upper limit for bryophytes in general, with the exception of those taxa adapted to special habitats like deserts and geothermal areas.

The lower temperature compensation point most likely varies considerably. For two snowbed bryophytes, this limit is not much below freezing, with *Anthelia* (Figure 57) reaching it at -4°C and *Polytrichum* (Figure 58-Figure 59) at -5°C (Loesch *et al.* 1983). Their high temperature compensation point is 30°C and 32°C, respectively. It is not surprising that they have a relatively high compensation point at the low end because they are protected by snow during the periods when other bryophytes would most likely be in danger of a late or early season cold spell. Such snowbed habitats seem to be refugia for more northern taxa most likely left behind by the glacier (see Belland 1983).

Rütten and Santarius (1993) found productivity temperatures in *Plagiommium affine* (Figure 60) and *P. undulatum* (Figure 25) with lower limits in the summer at -10 to -15°C . For Antarctic bryophytes, even lower temperatures are likely for positive photosynthesis. One must wonder what they could achieve if they could be tested in the Antarctic winter.

Figure 60. *Plagiommium affine*, a species that can survive temperatures of -10 to -15°C in the summer. Photo by Janice Glime.

As the temperature rises, so do the CO_2 and light compensation points and saturation points (Joliffe & Tregunna 1968). *Bryum argenteum* (Figure 45) has a compensation point of 58 ppm at 20.5°C (Rastorfer 1970). In the moss *Sanionia uncinata* (Figure 61), temperatures of 5°C , 15°C , and 25°C have corresponding CO_2 compensation points of 32, 50, and 82 ppm (mg L^{-1}), respectively (Rastorfer 1971). In other words, as the temperature rises, the moss uses more CO_2 to achieve a net gain. This rise in CO_2 requirement is predicted, because these C_3 plants have photorespiration, which increases more rapidly than photosynthesis as the temperature rises. Hence, more fixation would be required to overcome the photorespiratory losses.

Figure 61. *Sanionia uncinata* with capsules, a species that is able to use more CO_2 as the temperature rises. Photo by Michael Lüth, with permission.

Compensation points among tracheophytes are generally considered low at approximately 5 ppm or less (Jackson & Volk 1970) and high at 32-122 ppm in moderately bright light and temperatures of 20 - 30°C (Heath 1962; Goldsworthy & Day 1970).

Antarctic and Arctic

Even Antarctic mosses seem to survive well at higher temperatures. Rastorfer and Higginbotham (1968) reported that the ratio of photosynthesis to respiration in *Roellia roellii* (Figure 62) ranged 11-27:1 in the temperature range of 4 - 24°C , dropping to lower values at 34°C . Nevertheless, 34°C is a relatively high temperature. Ino (1990) found that the maximum rate of net photosynthesis at saturating light levels occurred at approximately 10°C in East Antarctic populations of *Ceratodon purpureus* (Figure 63) and *Bryum pseudotriquetrum* (Figure 64-Figure 65). These were one- or three-day measurements.

Racomitrium lanuginosum (Figure 67), on the other hand, had its photosynthetic optimum in high light intensities at 5°C, with a minimum net gain at -8 to -10°C (Kallio & Heinonen 1973). In short-term experiments the maximum temperature was generally 25-30°C. Furthermore, even though the moss was not productive at -30°C, it quickly became active, reaching 60% activation within three hours of warming.

Acclimation

Acclimation is the gradual and reversible adjustment of an organism to environmental fluctuations, not to be confused with **adaptation**, which is a persistent genetic change that provides the organism with a better ability to survive its environmental conditions. The adjustment to winter cold or summer heat is a result of acclimation.

Many bryophytes seem to be pre-adapted to low temperatures, but have some degree of ability to adjust to high temperatures. Antropova (1974) suggested this for species in seven genera of bryophytes [*Atrichum* (Figure 68), *Calliergon* (Figure 69), *Chiloscyphus* (Figure 70), *Funaria* (Figure 31), *Marchantia* (Figure 66), *Mnium* (Figure 24), *Riccia* (Figure 71), based on ability to **plasmolyze**. Loss of plasmolysis is an indication of membrane damage. As might be expected, incubation at

their tolerant temperatures (10 and 20°C) does not affect their thermostability or cold resistance. However, incubation for three hours at temperatures above their optimum does result in increased thermostability. Unlike typical cold acclimation, this increased thermostability is not accompanied by increased cold hardiness. This response is similar to that of flowering plants but different from that of algae.

Figure 71. *Riccia gougetiana* var. *armatissima*, in a genus that seems to be pre-adapted to low temperatures. Photo by Michael Lüth, with permission.

Rütten and Santarius (1993) defined **frost tolerance** as the lowest temperature at which no more than 50% irreversible damage occurred in net photosynthetic activity relative to unfrozen plants. They found that optimum productivity temperatures in *Plagiomnium affine* (Figure 60) and *P. undulatum* (Figure 25) ranged 10-20°C with lower limits in the summer at -10 to -15°C. Their hardiness to cold increased progressively during autumn, reaching temperatures below -35°C by winter. And, as already known from seed plants, the increase in cold hardiness was coupled with an increase in thermostability at high temperatures. But there was no correlation with an increase in total sugar content (sucrose, glucose, and fructose) of the shoots, despite the considerably higher sucrose content than that of less frost-hardy plants. Rütten and Santarius suggest that the accumulation of sucrose may contribute to frost hardiness of these two species, but felt that the seasonal differences could not be accounted for solely by the alterations in sugar concentrations.

Using *Plagiomnium acutum* (Figure 72) and *P. maximoviczii* (Figure 55) from China, Liu *et al.* (2001) showed that the optimum temperature for photosynthesis rose from winter to summer, ranging 20-35°C; the mosses could maintain positive net photosynthesis for 20-30 minutes at -10 to -15°C and from 40-45°C. Their Q_{10} (change in rate of reaction per 10°C change in temperature) in the range of 0-20°C was only 1.15-1.23. The "average" for non-biological chemical reactions is 2.0. Uchida *et al.* (2002) found that the photosynthetic Q_{10} for the moss *Sanionia uncinata* (Figure 61) was nearly 1 in the range of 7 to 23°C, whereas the respiratory Q_{10} was 3.0, causing net photosynthetic loss as the temperature rose.

Figure 72. *Plagiomnium acutum* from China. Photo by Yingdi Liu, with permission.

But bryophytes apparently do have at least limited ability for short-term heat acclimation. Using chlorophyll *a* fluorescence and electrolyte leakage (evidence of membrane damage) to indicate thermal stability, Meyer and Santarius (1998) showed short-term acclimation of hydrated shoots of *Atrichum undulatum* (Figure 68) and *Polytrichastrum formosum* (Figure 73) to elevated, sublethal temperatures within a few hours. This acclimation lasted several days. Declining water content, on the other hand, caused a dramatic rise in heat resistance.

Figure 73. *Polytrichastrum formosum* 1 Des Callaghan, with permission.

Hicklenton and Oechel (1976) found that the moss *Dicranum fuscescens* (Figure 72) in subarctic Canada raised its temperature optimum for photosynthesis from 0-10°C in the beginning of June to 10-20°C by 7 July, with net productivity dropping drastically by 29 July (Figure 75), but its dark respiration rates showed no evidence of acclimation. The tissue temperatures fluctuated between a low of 3°C and a high of 26°C during that period. The remarkable drop in productivity by the end of July suggests that the moss could not sustain the high temperature respiratory cost and eventually lost net productivity. At the other end, net productivity was negative at temperatures above 15°C on 5 June.

Figure 74. *Dicranum fuscescens*, a species that raises its temperature optimum as summer progresses from June to July in the subarctic. Photo by Michael Lüth, with permission.

In a field study, Oechel (1976) found a close correlation between the minimum temperature at which 85% of maximum photosynthesis was achieved and the mean maximum tissue temperature for the five days preceding the measurement, further supporting an acclimation to the temperature.

Fornwall and Glime (1982) found evidence of acclimation to cold vs warm in *Fontinalis duriae* (Figure 52). Using mosses that were collected in the same section of stream every eight weeks from 27 November until 3 December of the following year, they demonstrated that those individuals that were collected in January at 0-1°C had their peak assimilation rate at 10°C. Those mosses collected in June, before the heat of summer, had a peak at 35°C, the highest optimum found in the 1-40°C temperature range of the experiments. These mosses had already reached an optimum of 30°C by 3 April, even though the stream temperature was only 1°C. This suggests that something other than temperature is triggering the change in photosynthetic response to temperature. For aquatic bryophytes, this could be a nutrient pulse during spring runoff, increasing photoperiod, or both.

Figure 75. Mean optimum temperatures and upper temperature compensation points for *Dicranum fuscescens* photosynthetic activity at Mary Jo lowland near Quebec, Canada, as an effect of acclimation due to increasing and decreasing spring to autumn temperatures. Based on Table 1 in Hicklenton & Oechel 1976.

In the Antarctic populations of *Sanionia uncinata* (Figure 61) and *Polytrichum strictum* (Figure 76), Collins (1976) demonstrated a shift in the photosynthetic curve depending on the acclimation temperature. Those previously growing at a lower temperature had positive productivity at a lower temperature, had a higher optimum, and had lower productivity at higher temperatures in *Polytrichum strictum* (Figure 77). *Sanionia uncinata* had a similar low temperature response to that of *Polytrichum strictum*, with the same optimum in both treatments, but the ones acclimated at higher temperatures exhibited a more rapid photosynthetic decline above the optimum (Figure 77).

Figure 76. *Polytrichum strictum*, a species whose temperature optimum depends on the previous optimum temperature. Michael Luth, with permission.

Cold vs Heat

As seen for the polar regions, those factors that help plants adapt to the cold often incur heat resistance as well. Just as antifreeze in a car keeps it from freezing in winter, it keeps it from boiling in the summer. Such "antifreeze" effects work as well in plants.

In their study of temperature resistance in *Sphagnum* (Figure 47-Figure 51), Balagurova *et al.* (1996) found that differences between species were greater for heat resistance than for cold resistance, but there was, nevertheless, a correlation between the two kinds of resistance.

Acclimation Triggers

One factor that could play a role in acclimation is light intensity, although I don't know what physiological mechanisms might be involved. We know that at 140 lux light intensity *Fontinalis* sp. (see Figure 40) reaches its compensation point at 20°C, but when only 40 lux is present, it reaches compensation at 5°C (Burr 1941). While this should not have been a factor during the lab experiments of Fornwall and Glime (1982), who kept the light intensity constant at 4500 lux, the previous field history of light and photoperiod might have played a role in the temperature performances.

It is often difficult to recognize whether differences are the result of physiological races or of acclimation. For example, Asakawa *et al.* (1991) found that most of the high elevation/high latitude members of several *Frullania* taxa synthesized **tamariscol** (*F. tamarisci* subspecies – Figure 78) and *F. nepalensis*, whereas those in lower altitudes and latitudes did not. (**Tamariscol** imparts intense "mossy" or pleasant odor.) But we have no evidence that this provides any advantage in cooler climates and may be a geographic variant that travels with a gene that is adaptive. On the other hand, particular conditions of the climate at higher elevations and latitudes (in the north) might cause the gene to be expressed, whereas these triggers may be absent at the time of collection from lower latitudes and altitudes.

Figure 78. *Frullania tamarisci*, a high elevation species that produces tamariscol. Photo by Michael Luth, with permission.

Kallio and Saarnio (1986) actually transplanted mosses [*Hylocomium splendens* (Figure 21), *Pleurozium schreberi* (Figure 79), and *Racomitrium lanuginosum* (Figure 2-Figure 3)] from 60°55'N to 69°45'N and from 69°45'N to 78°13'N to determine their adaptations to cold. The physiological stress of these mosses increased as they were moved northward. Kallio and Saarnio concluded that their adaptations were largely due to their ability to acclimate. Day length and temperature served as important environmental cues to acclimation, and these signals changed as mosses were moved to more extreme latitudes.

Summary

Bryophytes may experience temperatures far greater than the ambient temperature due to their dark color and ability to act as a black body. Generally bryophytes are only able to tolerate temperatures up to about 40°C before the temperature becomes lethal. Their optimum, however, is usually much lower than that. They often are able to have photosynthetic gain at temperatures as low as -10°C, but seldom have a net gain at temperatures above 25°C. Rather, they typically become dormant in summer heat and drought. For many species, the optimum is 15-25°C, although it seems to be much lower for stream bryophytes. Even tropical bryophytes have an upper limit of 25°C.

Bryophytes can alter not only their own temperature, but also the temperature of the soil. Evaporative cooling may lower it, but dark color may raise it. They can protect the root zone of the soil from high temperatures on hot prairies and deserts by shading and insulating. In geothermal areas they can raise the soil temperature by trapping the geothermal heat beneath them. With an atmospheric temperature of 20°C, a sunfleck may warm a moss to 39°C. In some locations they may have a temperature 30°C or more higher than ambient. Their insulating role in the Arctic has a major role in the Arctic temperatures, delaying the thaw cycle by absorbing the heat that would have gone to the soil and decreasing the number of **soil degree days**, and making them essential to the BOREAS temperature model.

Bryophytes can transfer water from lower parts to growing tips and use evaporative cooling much as in tracheophytes. **Awns**, **hyalocysts**, and **papillae** can reflect light to maintain cooler temperatures (See Chapter 7-4). Mosses such as *Sphagnum* retain considerable water, and experience little temperature change. They provide safe sites for small animals such as overwintering turtles and for germinating seeds.

Temperature affects photosynthetic rate, respiratory rate, reproductive timing, growth, development, and productivity. Spore germination temperature is often set higher than that of protonema growth to prevent germination when freeze damage is still likely. Branches, rhizoids, and stem growth may have similar requirements to keep them in consort or may have different temperature requirements to spread out the energy needs or take advantage of suitable conditions for attachment. Gametangia typically have different temperature (or photoperiod) requirements that avoid the competition for energy and to place gametangial maturity at a time when water is available. Sporophyte development may be cued by temperature to delay until after dangers of winter cold. Dormancy is typically triggered by temperature, protecting plants in summer from drought or from being hydrated at a lethal temperature. Even successful development of fragments is dependent on temperature.

Bryophytes seem able to grow over a wider temperature range than tracheophytes, particularly at the low end of the scale. Changes in temperature below their optimum have only modest effects on their productivity, demonstrated by their relatively low **Q₁₀**

in that range, but net productivity drops off rapidly above their optimum. Physiological races exist within species that can give them quite different temperature responses and optima. However, recent past history of temperatures may be responsible for their **acclimation** rather than their **adaptation**. Optimum temperatures for photosynthesis are typically lower in winter than in summer and may actually rise before the ambient temperature rises, suggesting that temperature is not necessarily the signal.

Some tissues are more resilient than others and may even survive extensive boiling for several weeks, giving rise to new tissues at a later time. Short-term studies may be misleading for testing lethality and optima because of the importance of acclimation and internal tissue protection. Nevertheless, they can tell us the **compensation point** under a specific set of conditions if the recent history is known.

Low temperature acclimation seems to prepare mosses for high temperatures as well, giving Antarctic bryophytes the ability to survive high temperatures. Lack of proper signals for acclimation can prevent bryophytes from extending their ranges into new latitudes.

CHAPTER 10-2

TEMPERATURE: COLD

Figure 1. *Racomitrium heterostichum* mostly imbedded in ice while some branches are free and available for photosynthesis. Photo by Michael Lüth, with permission.

Low Temperature Limits

In general, bryophytes seem able to withstand cold in their leafy state much better than their tracheophyte counterparts. Ochi (1952) found that most mosses (18 species tested) were resistant to cold to -20°C . Seven of these species were resistant to -27°C . He was unable to find any trend in relationships to osmotic value, permeability, or seasonal fluctuations. Ochi's results support the later statement of Kallio and Heinonen (1973), that *Racomitrium lanuginosum* (Figure 2), a cosmopolitan moss, is pre-adapted to its abode in the Arctic and Antarctic (see Table 1) and suggest that such pre-adaptation may be a common feature of bryophytes. This contention is supported by the low temperatures that become lethal for bryophytes in the tropics (Table 2).

Figure 2. *Racomitrium lanuginosum*, a species pre-adapted to living in the polar regions with long, white hair tips. Photo by Janice Glime.

Surprisingly, Arctic liverworts do not seem to be so cold resistant. Among the nine species tested by Biebl (1968), seven were mostly dead at -16°C , with only the leafy liverworts *Barbilophozia hatcheri* (Figure 3) and *Chandonanthus setiformis* (Figure 4) surviving well. The moss *Aulacomnium turgidum* (Figure 5-Figure 6) also survived at -16°C . All species survived -6°C . But these were July responses in Greenland; a quite different picture might emerge in winter. On the other hand, all of them survived up to 42°C for half an hour, but twelve-hour exposures killed parts of most of them, the same seven, at 38°C . *Aulacomnium turgidum* survived up to 48°C for half an hour and up to 40°C for twelve hours. This supports the hypothesis that low temperature survival is coupled with high temperature survival.

Figure 4. *Chandonanthus setiformis*, a leafy liverwort that survives to -16°C . Photo by Michael Lüth, with permission.

Tropical mosses seemed rather similar. After 24 hours of exposure, *Homaliodendron flabellatum* (Figure 7) and *Leucoloma amoene-virens* survived -14°C and *Schistochila commutata* (Figure 8) survived -11°C (Biebl 1967). Tropical *Plagiochila* (Figure 9), *Metzgeria* (Figure 10), and *Bryum* (Figure 11) species each survived to at least -4°C . Try doing that to a tropical *Maranta* (Figure 12).

Table 2. Comparison of temperature resistance of leaves of plants from different climatic regions. Limiting temperatures are for 50% injury (TL₅₀) after exposure to cold for 2 or more hours, or after exposure to heat for 0.5 h. Bryophytes appear in **bold**. Tracheophyte data from Larcher 1983, based on data from many authors; cold tracheophytes had been cold-hardened. Data marked by * from Biebl 1967; Data marked by + from Liu *et al.* 2003.

Plants	°C for cold injury	°C for heat injury in growing season
Tropics		
Trees	+5 to -2	45-55
Forest undergrowth	+5 to -2	45-48
Mountain plants	-5 to -10	~45
<i>Schistochila commutata</i> *	-14	44
<i>Plagiochila</i> sp.*	-7	44
<i>Homaliodendron flabellatum</i> *	<-14	52
<i>Leucoloma amoenervis</i> *	<-14	
<i>Bryum</i> sp.*	-11	52
Subtropics		
Sclerophyllous woody plants	-8 to -12	50-60
Subtropical palms	-5 to -14	55-60
Succulents	-5 to -10	58-65
C ₄ grasses	-1 to -3(-8)	60-64
Temperate zone		
Evergreen woody plants of coastal regions with mild winters	-6 to -15 (-25)	50-55
<i>Plagiomnium acutum</i> ⁺		45 (50 dry)
Arcto-tertiary relict trees	-10 to -25 (-15 to -30)	
Dwarf shrubs of Atlantic heaths	-20 to -30	45-50
Winter-deciduous trees and widely distributed shrubs	(-25 to -40)	~50
Herbs		
Sunny habitats	10 to -20 (-30)	48-52
Shady habitats	40-45	
Water plants	~10	38-42
Cold-winter areas		
Evergreen conifers	-40 to -90	44-50
Boreal broad-leaved trees	(-196)	42-45
Arctic and alpine dwarf shrubs	-30 to -70	48-54
Herbs of the high mountains and arctic	(-30 to -196)	44-54

Stress Protection

Bryophytes are well known for their secondary compounds. These defend against competition, microbes, and herbivory, while often protecting against UV radiation, providing drought tolerance, and freezing survival (Xie & Lou 2009). These latter protections can all be associated with cold temperatures. Specifically, bibenzyls and bis(bibenzyls) have provide desiccation tolerance; fatty acid derivatives and phenylpropanoids provide freeze tolerance.

But bryophytes seem to have a large arsenal of protectors against cold stress. They are able to accumulate soluble sugars and abscisic acid (ABA) (Bhyan *et al.* 2012). The latter increases freezing tolerance in plant cells and also is important in desiccation tolerance – a likely consequence of ice crystal formation. During acclimation in *Physcomitrella patens* (Figure 13) that was developed to be insensitive to ABA, the cells accumulated sucrose to levels similar to those found in ABA-normal plants. But the trisaccharide theandrose did not accumulate in the ABA-deficient plants. Furthermore, these deficient plants had very limited accumulation of LEA-like boiling-soluble proteins. On the other hand, Minami *et al.* (2005) found an accumulation of several transcripts for LEA proteins and boiling-soluble proteins during freeze-tolerance acclimation. Bhyan *et al.* (2012) concluded that cold acclimation requires an ABA-dependent signalling system. Cold-induced sugar acclimation, however, may or may not be dependent on the ABA system. This ABA dependence is in contrast to the study by Minami *et al.* (2005), which concluded that ABA had no role in cold hardening in *P. patens*.

Figure 13. *Physcomitrella patens* with young sporophytes. Photo by Michael Lüth, with permission.

Freezing

As the external temperature is depressed, the bryophyte cell cools rapidly, presenting a rather different pattern from that of tracheophytes. In tracheophytes, leaf hairs, thick cuticle, and epidermis all serve to insulate the internal leaf cells from rapidly changing temperatures. Bryophyte leaves have none of these.

Freezing presents a number of problems for cells. Formation of crystals can cause physical damage by poking holes in the cell membrane or distorting the cell so that solutes can leak out more easily. Crystals are hygroscopic, attracting the water molecules from the cells to the cell

surface or intercellular spaces where the crystals may reside. This loss of water from the cells causes them to dehydrate. And cell membranes may be damaged or not function properly as fatty acids with higher solidification points become nonpliable.

Despite being perennial above ground, many, perhaps most, bryophytes survive freezing. Fletcher (1982) provided representative species from New Zealand [*Papillaria crocea* (Figure 14), *Hypopterygium* spp. (Figure 15), *Hymenodontopsis bifaria*, *Cyathophorum bulbosum* (Figure 16), *Calyptrochaeta brownii* (Figure 17)], South Africa [*Hypopterygium* sp. (Figure 15)], Australia [*Gigaspermum repens* (Figure 18), *Goniomitrium acuminatum* subsp. *enerve* (Figure 19)], and from Florida, USA [*Rhizogonium spiniforme* (Figure 20)] that survive freezing. In addition, Fletcher demonstrated that *Takakia lepidozoides* (Figure 21-Figure 22) remained healthy, as did *Sphagnum* spp. (Figure 24) and *Mnium* spp. (Figure 23). That number only provides us proof that some species survive, but gives us no idea of the world picture.

Figure 21. *Takakia lepidozoides* habitat, Japan. Photo from Digital Museum, University of Hiroshima, with permission.

Figure 24. *Sphagnum capillifolium*, a species that does not show frost damage above -16°C. Photo by Michael Lüth, with permission.

Sphagnum capillifolium (Figure 24) exhibits a critical freezing temperature threshold for photosystem II that is identical to its ice nucleation temperature (-1.1°C) (Buchner & Neuner 2010). But frost damage (LT_{50}) is not visible until the temperature reaches -16.1°C. The LT_{50} is the condition/level at which the condition is lethal to 50% of the population.

Something is going on in nature that does not seem to be mimicked in the lab. *Haplomitrium hookeri* (Figure 25) from New Zealand and *H. mnioides* (Figure 26) from Japan are able to grow in winter in their native habitats, but in cultivation all plants were unhealthy after being subjected to frost (Fletcher 1982). *Moerckia blyttii* (Figure 27), *Symphogyna* sp. (Figure 28), *Corsinia coriandrina* (Figure 29), and *Asterella* sp. (Figure 30-Figure 31) became severely bleached by frost in cultivation, but

Corsinia coriandrina remained healthy on an exposed wall top and in an unheated greenhouse down to a temperature of -5.5°C . Blackening occurred in *Dumortiera hirsuta* (Figure 32), but the plants survived. *Asterella* and *Monoclea forsteri* (Figure 33) likewise were blackened by frost in the greenhouse. *Fossombronia* (Figure 34) and *Anthocerotophyta* (Figure 35-Figure 36) experienced thallus decay, a phenomenon that they exhibited commonly in winter in nature. Plants of the hornworts *Anthoceros punctatus* (Figure 35) and *Phaeoceros laevis* (Figure 36) remained healthy in the greenhouse. Likewise, *Lunularia* (Figure 37), *Pellia* (Figure 38), *Preissia* (Figure 39), *Riccardia* (Figure 40), *Riccia* (Figure 41), and *Marchantia polymorpha* (Figure 42) showed no frost damage in the lab.

This raises the question of how do these exposed bryophytes survive. Why don't they suffer structural damage from internal ice crystals? How are they protected from severe desiccation as crystals on the outsides of leaves draw water from the cells?

Melick and Seppelt (1992) investigated these questions in *Schistidium antarctici* (Figure 43), *Ceratodon purpureus* (Figure 43, Figure 50), *Bryum pseudotriquetrum* (Figure 44-Figure 45), and *Cephaloziella exiliflora* (Figure 46) that were collected in late summer in the Antarctic Wilkes Land. Following 16 days of immersion, the plant loss of the carbohydrates glucose and fructose was relatively low (ca. 10-29% of the sugar content) in healthy mosses. However, in the senescing tissues of *S. antarctici* 69% of these sugars were lost. Following 16 freeze-thaw cycles the bryophytes experienced a sugar loss 2-3 times as great as in non-frozen controls in all but the dead brown tissue. *Bryum pseudotriquetrum* lost 65% of its total sugar content after a freeze-thaw cycle, whereas the other species lost less than 28%. Freezing points varied from -8.3° to -3.5°C , with dead material having the highest freezing temperatures. Freezing temperatures and sugar loss did not correlate and there was no change in the freezing point temperature of tissues after the sugar loss.

Figure 46. *Cephaloziella exiliflora*, a species that loses little sugar following 16 days of immersion. Photo by Tom Thekathyl, with permission.

On Windmill Islands of continental Antarctica, there was almost no seasonal change in the soluble carbohydrate content of the bryophytes and lichens (Melick & Seppelt 1994). The researchers considered that this lack of change

may be the result of the extreme climate and rapid temperature fluctuations.

Desiccation Tolerance

One of the consequences of freezing is dehydration. Consider the loss of moisture from your meat in the freezer when ice crystals form on the meat surface. Ice crystals are hygroscopic, pulling moisture from adjacent tissues. Furthermore, ice within the cell deprives the cell of the use of that water. The desiccation tolerance of bryophytes, therefore, helps them to survive freezing (Segreto *et al.* 2010). In their study of cryopreservation of bryophytes, Segreto and coworkers found that this natural desiccation tolerance negated the need for pretreatment or use of cryoprotectants before preserving live bryophyte tissues through freezing. They also found that longer or larger shoots of the leafy liverwort *Herbertus* (Figure 47) were able to regenerate more easily than smaller fragments, a phenomenon that suggests they are either able to transport from healthy cells to those that have been harmed, or that the greater amount of tissue helps to protect some of the cells.

Figure 47. *Herbertus hutchinsiae*; longer and larger shoots regenerate more easily in this genus. Photo by Michael Lüth, with permission.

Much like their resistance to hot temperatures, at least some bryophytes (*Syntrichia ruralis* – Figure 48-Figure 49) are more likely to survive freezing if they are dehydrated first (Bewley & Thorpe 1974). Those that were frozen in the hydrated state had lower rates of respiration and showed signs of freeze damage when rehydrated. Nevertheless, the respiration of desiccated mosses and of those desiccated and immersed in liquid nitrogen (frozen) was much higher on recovery than that of the controls that had remained hydrated at room temperature.

Desert species should be particularly adapted to freezing. They are endowed with various adaptations to survive desiccation, and they have a high probability of being desiccated when they experience freezing temperatures. But winter is the active season for the semi-desert grassland mosses in Hungary, with overwintering green shoots that are frequently exposed to temperatures below zero at night (Tuba *et al.* 2008). Daytime temperatures reach 0-5°C, and the dark-colored mosses (*Tortula/Syntrichia* – Figure 48-Figure 49) are even warmer (-2.1° to 6.9°C). The bryophytes were among the

18 out of 20 species that exhibited positive net photosynthesis. The abrupt increase in temperature in March did not affect the productivity rate of the mosses.

Figure 49. *Syntrichia ruralis* dry, showing twisting leaves and awns that help to slow drying and protect at least some leaf cells from UV damage. Photo by Misha Ignatov, with permission.

Lenne *et al.* (2010) found that the ubiquitous moss *Ceratodon purpureus* (Figure 50) did not accumulate ice within the moss tissues during freezing. However, external ice induced desiccation. The water-filled hydroid cells cavitiated at -4°C. Parenchyma cells of the stem's inner cortex lost 20% of their original volume and exhibited **cytorrhysis** (permanent and irreparable damage to cell wall after complete collapse of plant cell due to water loss and consequent loss of internal positive pressure) at the lowest temperature of -20°C. Nevertheless, following freezing at -20°C, chlorophyll fluorescence showed no damage to the chlorophyll. Once again, desiccation played a major role. In hydrated mosses, internal ice nucleation occurred at -12°C, but desiccated mosses showed no evidence of freezing at the lowest temperature of -20°C. There was nothing left to freeze.

Figure 50. *Ceratodon purpureus*, a species that experiences **cytorrhysis** due to desiccation that results from freezing, but chlorophyll remains undamaged. Photo by Janice Glime.

Tolerance to desiccation is one feature that helps bryophytes to survive freezing. Since leaves are generally only one cell thick, and most other parts only a few cells thick, water is easily drawn from the tissues during the slow cooling that occurs in nature. This increases the solute concentration and lowers the freezing point. Hence, intracellular freezing does not occur (Mazur 1969, in Smith 1982). In fact, some mosses are able to photosynthesize at temperatures below 0°C. In **nunataks** (area escaping glaciation) of Queen Maud Land, Antarctica, the air temperature rarely exceeds 0°C, yet moss photosynthesis occurs during the summer as long as there is sufficient water availability (Gjessing & Ovstedal 1989). Narrow clefts and stone blocks shield the mosses from desiccation and maintain less heat loss, but they are also shielded from direct solar radiation most of the time. Nevertheless, short-term periods of warming, even to -2°C, can greatly increase the moss temperature. These microsites permit mosses growing in such severe habitats to have the highest photosynthetic rates.

In the Arctic, *Racomitrium lanuginosum* (Figure 2) has an optimum temperature of 5°C at high light intensities (12,000-15,000 lux), but can sustain photosynthesis down to -10°C (Kallio & Heinonen 1973). Even after exposure to -30°C this moss is able to activate quickly (60% within 3 hours) when warmed. Thus, the bryophytes that exist in such harsh environments as the Antarctic and Arctic must have high freezing resistance, a high resistance to light stress, and a low photosynthetic temperature optimum (Alberdi *et al.* 2002).

In *Marchantia berteroana* (Figure 51), an Antarctic liverwort, freezing greatly reduces photosynthesis, but the author suggested that photosynthesis was also possible at temperatures below freezing (Davey 1997). Rather than temperature, this species is greatly limited by desiccation stress.

Protection of Photosynthetic System from Light

High light intensities at low temperature levels can be extremely damaging to bryophytes that have leaves only one cell thick. Nevertheless, it appears that many, and perhaps most, bryophytes have mechanisms that protect them. In the Antarctic, where such conditions are common, the reversible inhibition present during freezing suggests that mosses such as *Schistidium antarctici* (Figure 43)

have processes that protect them from such photoinhibitory damage (Lovelock *et al.* 1995a) and thus do not require the repair processes that would require temperatures favorable for such repair enzyme activity. Rather, these mosses, when subjected to snow removal, suffered photoinhibition that was reversed when the temperature became warmer (Lovelock *et al.* 1995b). Nevertheless, the greatest recovery occurred in low light. Lovelock and coworkers (1995b) suggest that the photoinhibition during freezing is a protective process that down-regulates photosystem II when photosynthesis cannot keep up with the light-stimulated excitation of electrons.

Figure 51. *Marchantia berteroana*, a species limited by desiccation stress, but freezing only reduces photosynthesis. Photo by Andrew Hodgson, with permission.

Pannewitz *et al.* (2003b) showed similar protection for *Hennediella heimii* (Figure 52) at Canada Flush in Antarctica. Constant meltwater in the summer kept this moss continuously hydrated at near-freezing temperatures while light levels were frequently high. Yet there were no signs of either light saturation or photoinhibition. Rather, the electron transport rate response to light was linear at all temperatures. Pannewitz and coworkers suggested that the moss might be acclimated by building up non-photochemical quenching systems.

Figure 52. *Hennediella heimii*, a very cold-tolerant moss while continuously hydrated. Photo by Barry Stewart, with permission.

For those bryophytes that are epiphytes, it is unlikely that enough mechanisms exist to avoid freezing entirely. But living on a dark tree trunk is likely to mean frequent freeze-thaw cycles. This not only presents problems of desiccation, but also presents potential light damage to the photosynthetic system. Working with the Mediterranean epiphytic moss *Leucodon sciurioides* (Figure 53), Deltoro *et al.* (1999) found that one aspect of bryophyte freeze-thaw survival could be their ability to enhance their non-radiative dissipation of absorbed light energy by freeze-induced decrease in CO₂ fixation, hence protecting their photosynthetic system from excess excitation. This temporary reduction in CO₂ fixation is quickly returned to normal after freezing.

Figure 53. *Leucodon sciurioides* on a tree trunk where it is exposed to atmospheric temperatures all year. Photo by Michael Lüth, with permission.

Rütten and Santarius (1992a) found that photosynthetic apparatus in mature tissues of *Plagiomnium* (Figure 55) species was more frost tolerant than that of either young or old leaves. As freezing stress increased, fluorescence decreased and the photosystem II-mediated electron transport system became inactivated. This resulted in inhibition of electron donations to the photochemical reaction of photosynthesis, differing little from the pattern in tracheophytes. Nevertheless, there was little decrease in transfer of excitation energy through antenna pigments to reaction centers of photosystem II as a result of lethal freezing stress.

Role of Calcium

Calcium seems to play a role in cold tolerance through its role in regulation of membrane transport. In *Physcomitrella patens* (Figure 13), wild type plants respond to cold shock (0-10°C) by increasing cellular content of calcium (Russell *et al.* 1996). It is most likely not calcium itself, but its effect on membrane permeability and other processes in the cell that provide actual protection. In the thallose liverwort *Conocephalum conicum* (Figure 54), Krol *et al.* (2003) likewise found that calcium played a role in climate response. A sudden drop in temperature causes it to generate all-or-none action potentials that appear to be the result of membrane potential changes due to influx of Ca⁺⁺ derived from both internal and external sources.

Figure 54. *Conocephalum conicum*, a species in which membrane potentials change in response to freezing. Photo by Janice Glime.

The activity and thermosensitivity of superoxide dismutase (SOD) is highly sensitive to ions of Ca⁺⁺ and Zn⁺⁺ (Christov & Bakardjieva 1999). In *Plagiomnium affine* (Figure 55), calcium was most important for the one cytosolic and mitochondrial SOD's, whereas zinc was more important for the chloroplastic and two cytosolic SOD's.

Figure 55. *Plagiomnium affine*, a species that increases its cold tolerance from summer to winter. Photo by Michael Lüth, with permission.

Abscisic Acid

Physcomitrella patens (Figure 13), as in many studies, has contributed to our understanding of freezing protection in bryophytes. When this species was grown on ABA agar, it accumulated up to 22% of its dry weight as sucrose, compared to 3.7% in control (non-ABA) tissues (Davey 1997). Sucrose serves as a protectant during both freezing and drying, but is insufficient as the only agent for freezing protection. When subjected to temperatures down to -80°C, it survived a freeze-cycle only when provided with the cryoprotectant DMSO, a compound that makes membranes more permeable. This species can only survive slow drying, which it does down to 0.02 g H₂O per g DW. Sugar composition and glass transition temperatures differed little between slow and fast drying. Nevertheless, the strength of the hydrogen bonding in the cell's glassy matrix was greater in the slow-drying conditions.

ABA (abscisic acid) is produced in tracheophytes in preparation for cold temperatures and permits plants to survive to lower temperatures, somewhat like antifreeze.

Nagao *et al.* (2005) have shown that media containing ABA does indeed lower the LT₅₀ (temperature at which 50% of cells die) for *Physcomitrella patens* (Figure 13) from -2°C to -10°C and even lower. They observed that there was a "dramatic" alteration in the appearance of the organelles, manifest in slender chloroplasts with reduced starch grains. The vacuoles became segmented rather than the typical single large vacuole. ABA also protected the cells from membrane lesions that occurred in controls at -4°C. One of the mechanisms of protection stimulated by the ABA treatment was an increase in the osmotic concentration of cells of the protonema, most likely due to the increased sugar concentration that accompanied the ABA treatment. But that only tells us what ABA can do. Next we need to determine that mosses do indeed produce it or increase its production at the right time, what stimuli cause this production, and can lunularic acid (ABA analog in liverworts) do the same for liverworts.

But the story does not appear to be straight-forward. Although they reported ABA-induced freezing tolerance in *Physcomitrella patens* (Figure 13) in 2003, Minami *et al.* (2003, 2005) reported that freezing tolerance was not associated with an increase in the level of endogenous abscisic acid in *P. patens*, but that it was associated with increases in the expression of stress-related genes. It seems that the role of ABA is to induce the genes, not to offer protection itself (Nagao *et al.* 2001; Minami *et al.* 2003, 2005). When they subjected protonemata of *P. patens* to -4°C, following normal growth conditions, more than 90% of the cells died, indicating that protonema cells are freezing-sensitive (Minami *et al.* 2003, 2004). ABA treatment resulted in a significant increase in the expression of all PPAR genes within 24 h. These genes are known to participate in the increase of freezing tolerance, and indeed, the death rate decreased significantly.

Minami *et al.* (2005) likewise studied freeze tolerance in *Physcomitrella patens* (Figure 13). They found that in the temperature range of 10°C and 0°C, and especially at 0°C, freeze tolerance increased significantly. But they found that internal tissue levels of ABA did not increase during that acclimation period. Furthermore, removal of ABA by activated charcoal did not affect the developing freeze tolerance. Hence, they concluded that ABA is unimportant in freeze tolerance. I would guess that it is, however, important in surviving the accompanying desiccation.

Transporter Proteins, ABA, and Ca

Further studies on *Physcomitrella patens* (Figure 13) support this conclusion. Two novel transporter-like proteins increase dramatically with low temperature treatment, among other stresses, and increase the cellular tolerance to freezing stress (Takezawa & Minami 2004). It is likely that calmodulin is used by the cell to regulate these novel proteins, and that ABA serves to induce the expression of the necessary genes. However, in *P. patens*, slow freezing to -4°C caused death of more than 90% of the protonema cells (Minami *et al.* 2003). ABA treatment for 24 hours caused a dramatic increase in the freezing

tolerance of this plant, but cold treatment had little effect. This seems to contradict the earlier findings of Nagao *et al.* (2001). They found that both ABA and low temperatures caused an increase in gene expression with concomitant enhancement of freezing tolerance in *Physcomitrella patens*. The LT₅₀ dropped from -2°C to -10°C when the protonemata were grown in a medium with enhanced ABA (Nagao *et al.* 2005). It appears that ABA might be the agent needed to effect expression of the freeze-tolerance genes, but how much advance notice does it require?

Sugars and Plasmolysis

But it appears that ABA also is associated with the increase of soluble sugars in the protonemata of *Physcomitrella patens* (Figure 13) (Nagao *et al.* 2003). Such sugars increase freezing tolerance, most likely by depressing the freezing point.

Rütten and Santarius (1992b) found an increase in cold tolerance from summer to winter in the mosses *Polytrichastrum formosum* (Figure 56), *Atrichum undulatum* (Figure 57), *Plagiomnium undulatum* (Figure 61), *P. affine* (Figure 55), and *Mnium hornum* (Figure 58), and the thallose liverwort *Pellia epiphylla* (Figure 38). The frost resistance between summer and winter differed by more than 25°C in some species, but *Pellia epiphylla* showed little hardening. Concomitant with this increase in frost tolerance, they found a rise in sucrose concentration (except in *Mnium hornum*), and those mosses that were highly frost resistant had a total sugar concentration of 90-140 mM, 80% of which was sucrose. The mosses *Brachythecium rutabulum* (Figure 59) and *Hypnum cupressiforme* (Figure 60) were highly frost tolerant in summer and at that time had high sucrose levels. Furthermore, as sucrose levels declined during artificial exposure to higher temperatures, cold hardiness declined.

Figure 61. *Plagiomnium undulatum*, a species that increases its cold tolerance from summer to winter. Photo by Michael Lüth, with permission.

However, Rütten and Santarius (1993a) found that different levels of sucrose, glucose, and fructose at the cellular level had no bearing on the frost tolerance of leaves of *Plagiomnium affine* (Figure 55) and *P. undulatum* (Figure 61). Sucrose seemed to contribute in some way to the tolerance, increasing from summer to winter, while temperature limits increased from -10°C in summer to less than -35°C in winter, but there was no correlation between increased sugar content of shoots and frost resistance. They concluded that other factors were also necessary to the increased frost tolerance.

Studies on membrane permeability suggest that sugar uptake and release may be altered as mosses prepare for winter (Rütten & Santarius 1993b). Liu (2000) showed that as the temperature increased above 40°C in these and other species, the membrane permeability increased. At the cold end of the scale, it appears that protection against an increase in membrane permeability may be a necessary step in cold hardiness. Greater retention of sugars could account for the higher concentrations in cold temperatures.

On the other hand, reversible plasmolysis can protect cells by permitting water loss and preventing crystal damage.

This relationship to membrane permeability is supported by studies on *Physcomitrella patens* (Figure 13) (Minami *et al.* 2003). Minami and coworkers subjected protonema cells to hyperosmotic concentrations of NaCl and mannitol, causing an increase in freezing tolerance. They interpreted this increase to indicate that ABA and cold stress trigger the expression of cryoprotectant genes. Oldenhof *et al.* (2006) suggested that sucrose might act as an osmotic spacer in membranes, while at the same time ABA mediates the synthesis of proteins, strengthening the cellular glasses. But we know that ABA can cause membranes to leak. Might there still be a more direct role for ABA than simply a trigger for genes, or is its usual role in membrane leakage one of triggering genes that cause this response?

Aro and Karunen (1988), in studying protonemata of *Ceratodon purpureus* (Figure 50), found that the content and unsaturated level of membrane lipids increased significantly in low growth temperatures, apparently contributing to frost hardiness. Hakala and Sewón (1992) found that both drought and low temperatures (6°C) caused an increased incorporation of ^{14}C into the neutral lipid fraction and decreased its incorporation into the glycolipid fraction in *Dicranum elongatum* (Figure 62), suggesting a preferential accumulation of acetylenic triacylglycerols. Such responses, when adaptive, can permit the moss to prepare for the drought of winter through the signal of low temperature.

Figure 62. *Dicranum elongatum*, a subarctic moss. Photo by Michael Lüth, with permission.

The protonema stage is often ignored in understanding the ecology and physiology of bryophytes. Yet if it is unable to reach a mature state of development and produce gametophores, the species will be greatly limited in its establishment survival. Nagao *et al.* (2006) demonstrated that like the leafy plant, the protonema responds to ABA application, increasing its freezing tolerance. This response includes the accumulation of low-molecular-weight soluble sugars, including theanderose (G6- α -glucosyl sucrose). This accumulation was inhibited by an inhibitor of nuclear-encoded protein synthesis (cycloheximide), resulting in a marked decrease in freezing tolerance. Theanderose is

promoted by cold acclimation and by treatment with hyperosmotic solutes, both of which increase cellular freezing tolerance.

Freezing Longevity

Just how long can a bryophyte remain frozen and survive? In the Antarctic on Signy Island, *Chorisodontium aciphyllum* (Figure 63-Figure 64) and *Polytrichum strictum* (= *P. alpestre*; Figure 65) form a major part of the vegetation. Recently, Roads and Longton (2013) reported *C. aciphyllum* that was extracted from a core at 138 cm depth. This depth remains permanently frozen. There was no great surprise that regrowth occurred from specimens of *C. aciphyllum* retrieved from depths of 0-30 cm, but three new shoots grew from specimens extracted from 110 cm! And in addition the leafy liverwort *Cephaloziella varians* (Figure 66) regenerated new shoots from the muddy base of that core at 123-138 cm. Based on radiocarbon dating, these plants had been there ~1750 years and had been frozen a good portion of that time!

Internal Cushion Temperatures

The internal temperatures in bryophyte cushions follow the ambient temperature until the cushion temperature drops below 0°C and the water there begins to freeze (Rod Seppelt, Bryonet 27 June 2022). When the cushion begins to freeze, latent heat is released, elevating the cushion temperature ~2°C. This slows freezing and provides more time for physiological processes to acclimate, including that of protein partial denaturing. These physiological modifications reduce tissue damage.

Freezing Effects

Freezing can have many consequences on cells of plants. In bryophytes, it can cause disorganization of the chloroplast lamellae, thus damaging the photosynthetic system (Pihakaski & Pihakaski 1979), damage the cell membranes, and cause desiccation and loss of solutes. In the thallose liverwort *Pellia epiphylla* (Figure 38) that had been chilled and hardened at -22°C, ultrastructural changes occurred. Vacuoles contained a fine granular substance in hardened tissues. Those that had only been chilled had large electron-dense particles embedded in a finer granular substance. The oil bodies changed, with abundant lipid-

like bodies in the cytoplasm. These resembled the oil globules of oil bodies, with oily-looking flecks in the vacuoles. Large starch grains were present in the chloroplasts and the lamellar system lost some of its organization. Interestingly, the net photosynthesis was highest in material that had spent the longest time at -22°C.

Supercooling Intracellular Water

But what is it that permits plants to survive the sub-zero temperatures of winter? One of the first requirements for survival at below freezing temperatures is supercooling of intracellular water (George & Burke 1977). If the water in the cells were to freeze, ice crystals and expansion of water in its frozen state could cause mechanical damage to the cell. We can observe that many trees have as their northern limit the line where -40°C is rarely reached. This is significant since the lower limit for supercooling of water is -41°C (Kuiper 1978), and George and Burke (1977) have observed ice formation in xylem at -30 to -40°C.

Ice Crystals Increase Solutes

Although ice crystals outside the cells can kill plants by desiccation, as in the case of the Florida orange trees, they can also be a means of "winterizing" cells by increasing internal solute concentrations. Molecules have vibrational energy. When an ice crystal forms, the vibrational energy is much reduced, creating an energy gradient between the liquid water molecules in the cell and the crystallized ones outside it (Marchand 1991). The result is that the more active liquid molecules migrate toward the area of less energy on the outside of the cell, adding to the mass of the crystals. Of course the result inside the cell is an increase in concentration of cytoplasmic solutes, thus lowering its freezing point, just as antifreeze does in a car battery. The process of protein denaturation, discussed below, causes the membranes to be leaky, facilitating this emigration of water. In many cells, there seems to be a second change as the temperature continues to decrease, and that change seems to correspond with cell death. One theory suggests that this may be accompanied by failure of water to leave the cell, resulting in internal crystallization and membrane destruction. Even in the absence of internal crystallization, cells still face another problem as the temperature decreases. As additional water is lost, irreversible dehydration may occur and toxic concentrations of solutes may accumulate (Weiser 1970).

Crystal Damage

It is the formation of crystals, not the low temperature itself, that damages cells irreparably, whether it is external crystals that cause dehydration and toxicity, or internal crystals that physically disrupt cell membranes (Schmitt *et al.* 1985). Therefore, another possibility exists for at least some plants to survive the cold, a process called **glass formation** (Marchand 1991). Glass formation results from **vitrification**, in which water solidifies without reorienting into a crystal (Figure 1). This process occurs when we immerse tissue in liquid nitrogen and thus permits us to preserve tissues without ice crystal damage. Balsam poplar trees are known to "form glass" at temperatures below -28°C (Hirsh *et al.* 1985). This means that the contents of

the cell are solid, thus preventing crystal damage, desiccation, and concentration of solutes to toxic levels.

Preventing Ice Crystals

Growers protect oranges by spraying non-nucleating bacteria on them, thus out-competing the bacteria that form the centers for ice crystals on the oranges. Some frogs make tiny proteins that become the centers of small crystals rather than large ones. And it appears that bryophytes and algae may also form special proteins that diminish crystal damage to cells.

One of the means by which plant cells are able to protect themselves from freeze damage is to modify or prevent ice crystals. Crystals form around tiny "nuclei" such as dust particles and bacteria. Being hygroscopic, these crystals grow by taking moisture from their surroundings, including cells. On the outside of the cell, they can desiccate a cell by extracting the water and binding it to the crystal. Inside the cell, they can not only desiccate the cell, but can also cause physical harm by protruding through a cell membrane.

In the Antarctic, Cyanobacteria, algae, and mosses form macromolecular substances that modify growing ice crystals, causing pitting of the crystals, and that cause them to go through an ice phase during freezing (Raymond & Fritsen 2000) – **glass formation** (Figure 67). One Antarctic species of *Bryum* (Figure 68) can modify these crystals by using this macromolecular substance to modify the shape of the growing crystals, and it may be that the mechanism of these macromolecules is to prevent recrystallization of ice (Raymond & Fritsen 2001). These substances are absent in temperate Cyanobacteria and mosses, but do occur in mosses from cold North American habitats. Their actual role is unknown, but their ability to be destroyed by temperatures of 45-65°C suggests that they are protein. It is possible that they may be non-nucleating proteins that reduce crystal formation.

Figure 68. *Bryum cryophilum*, showing the red pigments common in polar regions. One species of *Bryum* can modify ice crystals, somehow reducing damage to the plant cells. Photo by Michael Lüth, with permission.

Rate of Freezing

The effectiveness with which these mechanisms can protect the cell are dependent upon the rate of freezing. White and Weiser (1964) found that leaves on the southwest side of a tree could drop in temperature by 9.5°C per minute across the freezing point of cell water at sunset! The result of this rapid freezing was cell death due to crystallization of water trapped inside the cell. Yet the same species was able to tolerate temperatures as low as -87°C when the temperature decreased slowly. Marchand (1991) contends that slow cooling of 10°C per hour is common in nature and permits time for the removal of water from cells by exterior crystal formation.

But what do all these tracheophyte scenarios mean for bryophytes? In 1912 Irmischer reported that at least some mosses were tolerant to desiccation and cold. Antropova (1974) found that temperatures above optimum for 3 hours did not affect cold resistance of moss cells, nor did temperatures within the optimum range influence either thermal stability or cold resistance. From these experiments he deduced that bryophytes respond similarly to tracheophytes but differently from algae to changes in temperature.

But the cooling process in bryophytes is different from that of tracheophytes (Dilks & Proctor 1975). If a tracheophyte cell is cooled rapidly, the cell contents freeze, and this usually causes fatal damage to the cell. However, the normal condition in nature is slow cooling. Because mosses and liverworts lack protective cells or thick, waxy cuticles, and are mostly one cell thick, this process is much more rapid. As the ambient temperature cools to below freezing, bryophyte cell contents will supercool and lose water to the surroundings, depending on the water-potential gradient. Levitt (1972) found that the injurious freezing rate for cell sections of tracheophytes is 60 times as rapid as for whole plants. Since bryophytes are much like a section of tracheophytes, they could experience a similar rapid freeze, one that could occur during a sudden drop in temperature, making bryophytes more vulnerable than tracheophytes. However, as water freezes outside bryophyte cells, the internal freezing point decreases due to loss of water and increasing concentration of cell sap (Dilks & Proctor 1975). And here tracheophytes have a disadvantage compared to bryophytes. Rather, they are

inhibited from water loss by a hydrophobic cuticle, and even if they accomplished this loss, their cells are more likely than those of bryophytes to be damaged by desiccation. Hence, cells high in water content and having little waxy cuticle for protection, like those of lettuce, turn to mush when frozen.

Among the bryophytes compared in Figure 69, the mosses *Hookeria lucens* (Figure 70) and *Plagiothecium undulatum* (Figure 71) are the most like wet filter paper, with a plateau in cellular cooling as the cell reaches the freezing temperature of water and water leaves the cell. The thallose liverwort (*Conocephalum conicum*, Figure 54), on the other hand, is more similar to the tracheophyte *Arbutus unedo* (Figure 72), with a slow decline in temperature below the freezing point of water.

Hydration State

The state of hydration is an important consideration in the tolerance of bryophytes to temperature. It is well-known that they tolerate much higher temperatures in the dry state, but they also often tolerate lower temperatures in the dry state as well. This is predictable because of the danger of water forming crystals that can harm membranes.

Dilks and Proctor (1975) subjected nine moss species and one thallose liverwort species to sub-zero temperatures in a desiccator at 32% relative humidity. All survived to -30°C in this dry state except the cushion moss *Leucobryum glaucum* (Figure 73) and leafy liverwort *Plagiochila asplenoides* (Figure 74) var. *major*, both of which died in the desiccator with and without the cold treatment. In the wet state, however, of the 27 mosses tested, 20 had 50% or more death at -10°C and lower. For three of the taxa (*Andreaea* spp., Figure 75), the status could not be determined. *Hylocomium splendens* (Figure 76), *Racomitrium aquaticum* (Figure 77), *R. lanuginosum* (Figure 2), and *Scorpiurium circinatum* (Figure 78) survived to -10°C. *Hookeria lucens* (Figure 71), *Leucobryum glaucum* (Figure 73), *Mnium hornum* (Figure 58), and *Plagiopus oederianus* (Figure 79) were dead or mostly dead at -5°C. Among the liverworts, none of the thallose liverworts survived at -5°C. Among the leafy liverworts, four species survived as well as the mosses, but two had more than 50% mortality at -5°C. Only *Plagiochila spinulosa* (Figure 80) survived to -10°, with 50% survival. It is interesting that such epiphytes as *Porella platyphylla* (Figure 81) had poor survival when moist at -5°C, because that leafy liverwort lives in northern habitats where it is likely to experience such conditions in the winter, but perhaps acclimation and physiological races differ.

Lipids in Membranes and Protein Denaturation

We know that bryophytes are able to exist farther north (and south) than woody plants and yet lack the insulating effects of a thick layer of bark. Furthermore, the plasma membrane must remain intact if cellular nutrients and other solutes are to be contained upon thawing. As the temperature drops, the lipid matrix of a plasma membrane can crystallize, and the degree of crystallization depends upon the types of lipids. Saturated lipids crystallize first, with less saturated ones crystallizing at lower temperatures. The crystallization causes membrane proteins to aggregate, setting off a chain reaction. These aggregated proteins make possible the oxidation of sulfhydryl groups of the protein molecules because the close contact permits the formation of disulfide bridges (Levitt 1969). This denaturation of the membrane protein is irreversible and results in membrane destruction, often leading to cell death. It seems then that bryophytes must have some means to prevent this series of events from occurring.

Tracheophytes typically increase their lipid content in response to decreasing temperatures, resulting in winter hardiness. The lipids phosphatidyl choline and phosphatidyl ethanolamine in particular seem to contribute to increased resistance to cold (Kuiper 1970; Yoshida 1974; Siminovitch *et al.* 1975; De La Roche *et al.* 1972, 1975; Willemot 1975). The unsaturated fatty acid linolenic acid likewise seems to play a major role in reducing frost damage (Kuiper 1978).

Unsaturated Lipids

Gellerman and coworkers (1972) reported highly unsaturated lipids in several genera of bryophytes. When Al-Hasan and coworkers (1989) examined *Bryum bicolor* (Figure 82) to determine the effects of temperature on cold hardening, they found that the lipids of this species contained higher proportions of digalactosyldiacyl glycerols and sulfoquinovosyldiacyl glycerols when incubated at 5°C than when plants were incubated at 25°C. An interesting and seemingly non-adaptive aside is the greater production of linolenic acid under continuous illumination at 5°C, since low temperatures generally coincide with short days.

Fatty Acid Alterations

One of the means by which organisms prepare for changes in temperature is to alter fatty acid components to those with lower solidification points. Lemmings change the fatty acids in their foot pads by eating bryophytes that contain lots of arachidonic acids, thus providing these tissues with cell membranes that are more pliable at low temperatures (Prins 1981). Meanwhile, the bryophytes are also preparing for winter in a different way.

The protonema of the common moss *Ceratodon purpureus* (Figure 50) prepares for winter by increasing its content and unsaturated level of membrane lipids (Aro & Karunen 1988). The galactolipids typically found in chloroplast membranes increased; phospholipids nearly doubled when plants were acclimated at 4°C vs 20°C. But this seems to have little effect on the frost hardness. Rather, it permits these acclimated protonemata to retain a high phospholipid content. If, as is typical of unhardened protonemata, the phospholipids had been lost, that would have caused irreversible damage to CO₂ fixation following freezing and thawing. Aro and Karunen concluded that while the changes in membrane lipids were themselves not an important component of hardening, they were somehow involved in other factors that contributed to frost hardness.

In *Sphagnum fimbriatum* (Figure 83-Figure 84), when the temperature decreases in the range of 5-15°C, the amounts of linoleic, α linolenic, and arachidonic acids in their glycolipids [both monogalactosyldiacyl glycerols (MGDG) and digalactosyldiacyl glycerols (DGDG)] also decrease (Koskimies-Soininen & Nyberg 1991). These are replaced with increased proportions of palmitic, stearic, and oleic acids, especially in MGDG. However, if light intensity also decreases, as it would as winter approaches, this species exhibits an increase not only of palmitic and stearic acids, but also of linolenic and arachidonic acids, in MGDG, while oleic and α -linolenic acids decrease. But this pattern is certainly not universal. Even the related *S. magellanicum* (Figure 85) responds differently (Koskimies-Soininen & Nyberg 1987). It had its largest changes in fatty acid composition at lower temperatures (0-5°C) and short photoperiods (3-6 hrs daylight). But, unlike *S. fimbriatum*, in decreasing light and temperatures, *S. magellanicum* exhibited a decrease in linolenic acid.

Figure 85. *Sphagnum magellanicum*, a species that has its largest changes in fatty acids at 0-5°C. Photo by Michael Lüth, with permission.

There are indications that the fatty acid composition of bryophyte cells change as the temperatures do (Saruwatari *et al.* 1999). *Marchantia polymorpha* (Figure 42) exhibited changes in the percentages in linolenic acid, arachidonic acid, and eicosapentaenoic acid when the temperature was changed from 25°C to 15°C. Both linolenic acid and eicosapentaenoic acid increased greatly. However, the changes were not equal throughout the cell. Arachidonic acid and eicosapentaenoic acid increased in the chloroplast fraction but not in the rest of the cell, while the level of linolenic acid was increased in both fractions. We need to understand this in the context of the high levels of arachidonic acids known in bryophytes and the suggestion that some animals eat bryophytes to prepare for winter because of these high levels. Prins (1982) has proposed that they provide more fluid fat pads for animals that run around on frozen ground in winter.

One study on lichens might help us predict the way in which bryophytes could respond (Dertien *et al.* 1977). In forested areas, both bryophytes and lichens can be found on tree trunks as well as on the forest floor and in open soil areas. In their study of lichens, Dertien and coworkers (1977) found that lichens of tree trunks contained high levels of the unsaturated linoleic and linolenic acids; however, nearby sand dune species had large quantities of cyclic acids rather than unsaturated acids. This may relate

to the greater likelihood of low temperatures on the tree trunks.

Fatty Acids and N

Using *Ctenidium molluscum* (Figure 86), *Pogonatum urnigerum* (Figure 87), *Dichodontium pellucidum* (Figure 88), and *Tortella tortuosa* (Figure 89), Al-Hasan *et al.* (1991) demonstrated that increasing the nitrogen concentration of the medium causes a decrease in the dominant unsaturated fatty acids arachidonic acid (in *C. molluscum*), eicosatrienic acid (in *P. urnigerum*), and linoleic acid (*D. pellucidum*, *T. tortuosa*). Nitrogen availability generally decreases as the growing season progresses in forests, so it is possible that such a decrease could serve as a signal for mosses to store more unsaturated fatty acids. Arachidonic acid and eicosapentaenoic acid are widespread in mosses (Hansen & Rossi 1990), but arachidonic acid never occurs in angiosperms (Karunen 1990).

Triglycerides

The role of triglycerides in low temperature survival seems yet to be explored. Karunen (1981) found that in the subarctic moss *Dicranum elongatum* (Figure 62) triglycerides commonly increased only at low temperatures of 1-6°C. But what might they do for frost hardiness?

Polyribosomes

In the desiccation-tolerant moss *Syntrichia ruralis* (Figure 48-Figure 49), temperatures down to 2°C cause a proliferation of polyribosomes, accompanied by a decrease in single ribosomes (Malek & Bewley 1978). The number of ribosomal subunits does not change. Mosses that have not been desiccated exhibit leucine uptake and were able to synthesize protein at 2° and -2.5°C. However, slowly dried mosses do not contain polyribosomes and instead reform them upon rehydration. There seems to be no change in the

rate of protein synthesis in mosses kept at cold temperatures (2°C) or winter collected. Rather, the moss appears to be pre-acclimated or pre-adapted to freezing year-round. Malek and Bewley concluded that this moss does not have any seasonal cold hardening.

Age Difference to Freezing

Hudson and Brustkern (1965) found that old and young leaves of mosses may differ in their responses to sub-zero temperatures. They found that *Plagiomnium undulatum* (Figure 61) mature leaves experienced extracellular freezing when cooled slowly, thus preventing intracellular freezing. Young shoots, on the other hand, could not tolerate temperatures below 12°C. When subjected to freezing temperatures, young leaves of *P. undulatum* do not experience extracellular ice formation, thus making intracellular freezing more likely. Rütten and Santarius (1992a) found that not only young leaves, but also old leaves of *Plagiomnium*, had much less frost tolerance than mature leaves.

Freezing Effect on Distribution and Niche

Green *et al.* (2007) reported that freeze-thaw cycles are extremely common in parts of Antarctica, with up to 110 occurring in a single year in the northern maritime. Some lichens adapt to this by growing in the pores of rocks, so we should look for bryophytes that have similar safety mechanisms.

The ability to survive freezing will influence both geographic and habitat distribution of bryophytes. Shirasaki (1984) found that *Bryoxiphium norvegicum* (Figure 90) subsp. *japonicum* is distributed in southern Japan at altitudes of 80 m to 2350 m, whereas further north the upper limit declines. Although this species occurs in areas where there is deep snow for a long period of time, it lives mostly on the vertical faces of overhanging rocks in ravines where it is not likely to be covered directly by snow. However, it is positioned where the overhanging soil and snow protect it from the cold wind.

Figure 90. *Bryoxiphium norvegicum* growing on a rock face. Some varieties of this species are able to grow at high elevations. Photo by Janice Glime.

Shirasaki (1987) also found that the distributions of the leafy liverworts *Bazzania trilobata* (Figure 91) and *B. yoshinagana* (Figure 92) in Japan seem to relate to differences in cold and related desiccation tolerance. *Bazzania trilobata* grows on soil that receives sunshine and

good drainage. It is able to survive in areas with little snow where early spring subjects it to severe cold and desiccation. By contrast, *B. yoshinagana* lives primarily on the floor of dense conifer forests where deep snow covers it all winter, thus maintaining moisture and insulating it from the sub-freezing air.

As was seen for *Fontinalis* (Figure 123-Figure 124) species in the previous subchapter on temperature, adaptation to cold can be a contributing difference between species, permitting them to live where they do. It seemed that for centuries we concentrated on morphological differences between species and attempted to see their geographic separations in that perspective. However, physiological differences are much more likely to determine where plants live than are their morphological differences. In some cases, morphology can cause

physiological differences, such as growth forms that alter temperature, but we should not stop there in our quest for niche delineation.

A good demonstration of these physiological differences is seen in the genus *Sphagnum*. In their study of five species, Balagurova *et al.* (1996) found that the photosynthetic leaf cells of *Sphagnum balticum* (Figure 93), *S. subsecundum* (Figure 94), and *S. teres* (Figure 95) were more frost-resistant than were those of *S. magellanicum* (Figure 85) and *S. fuscum* (Figure 96).

For the sunny species of *Sphagnum magellanicum* (Figure 85) and *S. papillosum* (Figure 97), short days induce dormancy and long days induce growth (Li & Glime 1990; Gerdol 1995). This corresponds well to their optimum growth temperature of 30-35°C, a high optimum for bryophytes. Nevertheless, *Sphagnum magellanicum* can grow actively whenever it has sufficient moisture and the nighttime temperature exceeds 0°C (Gerdol 1996). It appears that nighttime temperature can be critical to the growth of *Sphagnum* species. *Sphagnum capillifolium* (Figure 24) suffered a five-fold reduction in growth at low nighttime temperatures (Gerdol *et al.* 1998). There seemed to be no alteration in photosynthetic pigments or pigment ratios, but rather enzymatic reactions were limited at low temperatures.

Regulation of Mammal Reproduction?

There is interesting evidence that some plants stimulate reproductive activity in small mammals that eat them by providing to them their own growth substances. Gibberellic acid, common in germinating seeds, and 6-methoxybenzoxazolinone (6-MBOA, a glycoside derivative) have such an effect. Is it possible that bryophytes, developing under the snow, provide a source of

green food to small mammals, such as voles and lemmings, under the snow pack and help to regulate their reproductive cycle?

Overwintering under Snow

Snow affords great protection from the ravages of winter, and we might have a very different polar and boreal flora without it. Flock (1978) found that it was the areas with deep, late-season snow where bryophytes reached their highest species indices on the Niwot Ridge of Colorado, USA, an alpine area. An interesting separation of acrocarpous and pleurocarpous mosses occurred, with acrocarpous mosses being the most abundant ones in the dry areas that had only a light snow cover. Pleurocarpous mosses were nearly restricted to the wet sites with deep snow, where they outnumbered the acrocarpous taxa. Only *Hypnum vaucheri* (Figure 98-Figure 99), *H. revolutum* (Figure 100), and *Abietinella abietinum* (Figure 101) among the pleurocarpous mosses ventured into the dry areas with little snow. Liverworts were rare. This distribution may be more one of moisture needs than of temperature, but at least the possibility exists for some mosses to enjoy the greater protection from extreme cold when most of the area may be free of snow.

Figure 99. *Hypnum vaucheri* in Norway. Photo by Michael Lüth, with permission.

Figure 100. *Hypnum revolutum*, a species that is able to survive in cold but dry areas with little snow. Photo by Michael Lüth, with permission.

On the other hand, snow cover can be a detriment when the growing season is short, preventing sufficient productivity to complete a life cycle. In the Antarctic, Pannowitz *et al.* (2003a) found that indeed the snow cover was a good insulator, but late-lying snow retained the winter cold that kept the bryophytes inactive long after the ambient air temperature was warm enough for activity. Unlike some north temperate areas where the sub-surface soil may be 10°C in the winter (Jiquan Chen, University of Toledo, unpublished data), temperatures under the Antarctic snow were typically less than -10°C while snowmelt was complete in surrounding areas.

Figure 101. *Abietinella abietina*. Photo by Michael Lüth, with permission.

Snow Temperatures

In the temperate and boreal zones, winter cold and snow can play a major role in ecosystem behavior. Snow cover can be an essential factor in protecting plants from severe cold and wind, while in many cases providing a steady stream of water and nutrients to the soil. Soil temperatures at 5 cm beneath the surface under deep snow in Houghton, Michigan, USA, can remain above freezing for an entire winter while air temperatures plummet to -10°C or lower (Jiquan Chen, University of Toledo, unpublished data). Longton (1979) reported temperatures at the moss level (*Polytrichum strictum*; Figure 65) at Pinawa, Manitoba, Canada, to remain between 0° and -10°C under the winter snow, but in summer sun the diurnal temperatures fluctuated widely. The mosses clearly ameliorate the temperature in spring and autumn, with

fewer freeze-thaw cycles and higher minimum temperatures at moss levels than at 200 cm above the ground.

We have mostly ignored winter ecology in bryophytes. Do they photosynthesize under the snow? How will they respond to shorter winters as the climate warms? Are any or all of them dormant in cold winters? What is the effect of snow depth on their physiological behavior?

Pannewitz *et al.* (2003a) found that it was possible to measure photosynthetic activity of lichens under undisturbed snow. The snow cover provides a good insulator for both lichens and mosses. But this insulation works at both warming and cooling temperatures. These lichens were inactive at subzero temperatures, even when the air temperatures had warmed enough to allow metabolic activity. For lichens, the maximum activity occurred during the 10-14 days following the final disappearance of the snow. But some species were activated at temperatures below -10°C when water became available from the high air humidity. Similar accounts of bryophyte responses are largely lacking in most winter ecosystems.

Nutrients from Snow

Inputs and losses of soil nutrients change as temperatures slow processes and snow melt leaches nutrients from collected dust. During January to March, nitrate export can increase from 0 to 1 kg ha⁻¹ as the temperature increases from -10 to -3°C (Park *et al.* 2004 in Campbell *et al.* 2005).

These processes will certainly affect the mosses, positioned at the interface between snow and soil. In her studies on *Sphagnum russowii* (Figure 102) in a Jack pine forest (*Pinus banksiana*), Scafione (unpubl) found that the mosses were frozen in a block of ice under the snow as the melt season began in April. But is this the case all winter? Do the mosses receive nutrients that trickle through the snow, trapping them and sequestering them for an early spring surge of growth? Or do they remain frozen until after the snow is gone, facilitating the movement of nutrients past them to breaks in the ice-covered moss carpet? Figure 103 suggests that they don't. How little we know of their winter ecology!

Epiphytes

Mosses in the North Temperate Zone seem to appear in the spring in a much fresher condition than they were in the previous fall, and some of them seem to be further developed. Our data on epiphytes in Keweenaw County, Michigan, USA, suggest that perhaps winter affords them an opportunity to grow in a moist, light environment, protected from winter winds (Trynoski & Glime 1982). We suggested this possibility because, contrary to the popular misconception, the mosses were more abundant on the south side of the trees at 1 m above the ground. In Keweenaw County, the winds come predominately from the north and northwest, bringing desiccation to mosses on that side of the tree. Of course, the south side of the tree is subject to the drying heat of the sun in the summer, but only if the canopy allows it to pass. Our conjecture is that in winter the deep snow (1 m or more) provides a haven. Snow cover does not hug a tree all the way to the surface of the snow. Instead, it forms **tree wells**, where snow is separated from the tree trunk by a small funnel of air, caused at least in part by the reradiation of heat from the dark trunk of the tree (Figure 104). Within this funnel, there is little air movement, and if our theory about the reradiation is correct, the temperature must be near melting, *i.e.* 0°C. Under such conditions, we would assume that the funnel must be moist in winter, at least on sunny days. On the south side of the tree, the temperature would be higher, causing more hours of moist air and above freezing temperatures. Furthermore, sun penetration through the snow should provide ample light at this low temperature. Under such circumstances, we conjecture that mosses could achieve a slow but steady growth during 4-5 months of winter.

Figure 104. Tree well at the base of *Acer platanoides*. Although the snow has melted considerably, this shows the funnel that can form. Photo by Janice Glime.

As we pondered the tree funnels, we also considered that mosses on rocks and soil under the snow probably receive a relatively steady moisture supply, ample light, and a 0°C temperature, permitting the cold-adapted ones to achieve photosynthesis, little respiratory loss, and some level of growth during at least part of the winter. This raises the interesting question as to what role the snow on the side of a tree trunk might play in the distribution of mosses, providing moisture and light for growth in winter and probably occurring on the side that receives the most direct rain in summer, assuming the prevailing wind direction does not change seasonally. But how much, if any, light penetrates several feet of snow?

Light through Snow

Fortunately, Marchand (1993) has provided proof that many of our theories about snow are possible. He was trying to explain how voles managed to be reproductively active just 10 weeks before the snow melted, and when the snow pack was deeper, they delayed their reproductive activity, again being active just 10 weeks before the snow melt, which occurred a full month later. Assuming they had no more ability to see into the future than do we, he began taking measurements under the snow. Some startling facts were discovered (although, I suspect some physicists would not be surprised).

As expected, the more dense the snow at a given depth, the less light penetrated. However, what Marchand did not predict was that as the snow melted and filled in the spaces between the snow crystals, the light penetration increased. (See transparency in Figure 1). Hence, the voles could use light intensity as an indicator of the coming of clear ground, and our bryophytes could carry out photosynthesis and grow or develop well before the snow was gone in the spring.

He found that any combination of depth:density that was greater than 200 gave maximum thermal protection, resulting in a near 0°C temperature under the snow. Thus, 20 cm of snow with a density of 0.1 g cm⁻³ (very fresh snowfall) would completely buffer most temperature fluctuations. When the density increases to 0.2 g cm⁻³, twice as much snow is required for the same thermal

protection. This means that additional snowfall can ameliorate the lowered temperature effects of increasing density of compacted older snow.

But what of light? Marchand knew that only a small amount of light, principally in the blue and blue-green range (Figure 105), could penetrate the deep snow pack. Under only 3-4 mm of older, crystalline snow, no infra-red radiation penetrates (Gates 1962).

Photosynthesis is greatest in the red range, with a smaller second peak in the blue range. When the snow density reaches 0.3 - 0.4 g cm⁻³, typical of the upper part of the snow pack in late winter, only 2 - 3% of the surface light reaches a depth of 15 cm. When Marchand's group compacted the snow as much as they could, attaining a density of 0.5 g cm⁻³, the light penetration was nearly zero. That seemed to be the critical density – the density possible by compaction alone. It was following that experiment when they discovered that melting snow actually increased in transmission of light. Instead of refracted, scattered light passing through tiny ice grains, the light was now passing through larger, fused grains that caused much less scattering and absorption. Although less than 0.1% of incident light seems to reach the ground from late December to early April when the snow depth is greater than 40 cm and density > 0.25 g cm⁻³, the late season snow provides an insulating source of water as it melts, increasing the transmission of light.

Late Snowbeds

Unique communities of bryophytes occur adjacent to summer snowfields, taking advantage of the cooler temperatures and most likely greater moisture. In such cool habitats, one might find red mosses that increase their leaf temperatures by absorbing the light rays and reradiating them as heat. These mosses might have their lower parts in meltwater at 0°C while their growing tips are much warmer in the rays of the sun with this "red body" heating. Such mosses include *Andreaea nivalis* (Figure 106), *Bryum muehlenbeckii* (Figure 107), and *Racomitrium sudeticum* (Figure 108) (Bailey 1933; Belland 1983). Others are white, perhaps being protected from the bright light reflecting from the nearby snow, while

being subjected to temperatures that do not allow rapid use of excited electrons among the chlorophyll antenna pigments (see Figure 2 of *Racomitrium lanuginosum* for an example). The genus that once was *Webera*, and now most likely is *Pohlia* (Figure 109-Figure 110), seems to have several species that thrive in this unique habitat (Bailey 1933; Woolgrove & Woodin 1994). Bailey comments that in the Cascade Range, Washington, USA, all of these taxa are acrocarpous. Only *Isopterygiopsis pulchella* (Figure 111) among these is a pleurocarpous moss.

Figure 110. *Pohlia ludwigii*, a late snowbed bryophyte. Photo by Michael Lüth, with permission.

Löscher *et al.* (1983) reported that only the top 4 mm of the late snowbed liverwort *Anthelia juratzkana* (Figure 112-Figure 113) has enough chlorophyll to be capable of net gain in photosynthesis. This species reaches its low temperature compensation point at -4°C . It easily sustains life in 9 months of darkness, cold, and wetness. However, its respiration rate increases, causing the net photosynthetic rate to decrease following snow melt. In *Polytrichum sexangulare* (Figure 114-Figure 115), also a snowbed moss, the low temperature compensation point is -5°C . However, this species did not tolerate being wet and cold in

the dark for so long. Both species survive in these snowbed communities because of their ability to use low light intensities at low temperatures (optimum of 6-11°C). *Anthelia juratzkana* is able to grow at the edge of snowbanks at very cold temperatures. *Polytrichum sexangulare* succeeds because of its more rapid growth rate, permitting it to outcompete the seed plants. But this evades the question, how do these bryophytes survive the alternating warm and freezing temperatures at the edge of the snowbeds, or do they?

Acclimation and Adaptation

Could the Antarctic climate be so severe that the bryophytes are always ready? Melick and Seppelt (1994) found little or no change in soluble carbohydrate levels. However, as already noted, both chlorophyll and carotenoids did respond to seasons. But are bryophytes elsewhere ready both to remain dormant when conditions are too cold and to grow during periods that are warm enough?

Winter Growth

I have long suspected that a number of bryophyte species are able to grow in cold winter months, perhaps even under the snow. For example, mosses like *Brachythecium rutabulum* (Figure 59) have better growth at temperatures below 18°C in winter collections than those from summer collections (Furness & Grime 1982).

In a study of 40 bryophyte species in Europe, Furness and Grime (1982) found that most species had an optimum growth temperature of 15°-25°C. Nevertheless, many species continued to grow at temperatures less than 10°C.

Winter Warming Events

What happens to a frozen moss when those sunny days take its temperature above freezing? We know that tracheophytes can be severely damaged when "spring

comes early" and then winter returns. Buds may begin to open, then the tender young leaves killed when frost returns. This expensive energy loss uses stored resources and cannot be tolerated frequently. But what happens to bryophytes under these same circumstances?

Bjerke *et al.* (2011) simulated such events in a sub-Arctic heath using infrared heat lamps and soil warming cables. Among the dominant cryptogamic flora, they subjected the boreal moss *Hylocomium splendens* (Figure 76) to such warming events for three consecutive winters. Unlike the lichen *Peltigera aphthosa* (Figure 116), *H. splendens* exhibited a significant decrease in summertime net photosynthesis (up to 48%) and growth rate (up to 52%). The lichen does not have seasonal life cycle stages, but *H. splendens* has seasonal stages when it produces new branches and leaves. The most critical of these responding to winter warm periods is the initiation of growth. These young shoots are vulnerable if the cold period returns shortly thereafter. Such winter warm periods have been experienced in areas such as my home in the Keweenaw Peninsula of Michigan and are likely to increase in frequency as the global climate changes.

Snowbed bryophytes are not likely to experience winter melt, but in the spring the bryophytes at the edge of the snowbed may experience alternating warming and freezing periods. We have seen above that late snowbed bryophytes like *Anthelia juratzkana* (Figure 112-Figure 113) and *Polytrichum sexangulare* (Figure 114-Figure 115) survive the short growing season and long period of snow cover because of their ability to have a net photosynthetic gain in low light at low temperatures (Lösch *et al.* 1983). But how do these bryophytes, especially *A. juratzkana*, fare at the edge of the snowbed if it melts, then freezes again? Our knowledge of bryophytes in winter, and especially when experiencing intermittent warming, is extremely meager.

Pigments and Color Changes

One protection against high light intensity is development of red pigments (Quinn 2008). Just as high elevation mosses may be red, like those discussed as living in late snowbeds, and snow algae such as *Chlamydomonas nivalis* (Figure 117), are red, some bryophytes produce red pigments to provide protection against UV radiation and

may even receive an added bonus of warmer daytime temperatures due to color. Anthocyanins, known in both bryophytes and tracheophytes, convert light to heat; this is especially important in the cooler days at the beginning and end of the growing season (Quinn 2008).

Several species of *Sphagnum* (Figure 102) have this color response, wherein cold temperatures induce production of the red cell wall pigment **sphagnorubin**, a flavonoid (Tutschek 1982).

Figure 117. Pink snow caused by the alga *Chlamydomonas nivalis* in the Arctic. Photo through Creative Commons.

Bendz *et al.* (1962) pointed out that the color of a bryophyte can vary widely, depending on solar radiation and nutrient availability. These red pigments appear to be anthocyanins. *Bryum cryophilum* (Figure 68) exhibits deep red color in the Arctic along stream borders. These proved to be anthocyanins in the cytoplasm. Red cell wall pigments occur in *Sphagnum magellanicum* (Figure 85) and *S. capillifolium* (*S. nemoreum*; Figure 24). Likewise, *Warnstorfia pseudosarmentosa* has red anthocyanin cell wall pigments. One of its pigments chemically resembles those of *B. cryophilum* and the other resembles those of the two aforementioned *Sphagnum* species.

In the Antarctic, Post and Vesik (1992) found that the leafy liverwort *Cephaloziella exiliflora* (Figure 46) was green in shaded sites and dark purple in sunny locations. This red color was due to an anthocyanin-like pigment bound in the thick cell walls of the sun plants. These plants grew in dense turfs and their leaves were larger and more closely spaced, most likely increasing moisture-holding capacity and reducing sun damage. It is interesting that the chlorophyll *a/b* ratio did not vary, but the green shade plants had more chlorophyll per unit weight.

Charlie Campbell (Bryonet 12 December 2013) found that the red *Sphagnum magellanicum* (Figure 85) was more photosynthetically active after freezing than the yellow-brown *S. papillosum* (Figure 97). Others (Quinn 2008) have reported that more highly colored species live in colder mountainous regions, compared to those close to the sea. Other color changes are noted in response to sun. *Hypnum imponens* (Figure 118-Figure 120) and *Thuidium delicatulum* (Figure 121-Figure 122) definitely change from medium green (Figure 119, Figure 121) to yellow-green or vivid yellow tones (Figure 120, Figure 122) when exposed to more sunlight (Annie Martin, Bryonet 12 December 2013).

In *Sphagnum capillifolium* (Figure 24), Gerdol *et al.* (1998) found no trigger for the formation of red wall pigments when nighttime temperatures were 5°C and above

One principle to keep in mind in this discussion is that being cold and in bright light at the same time is a problem for plants, especially bryophytes. The light excites the chlorophyll electrons, but the cold temperature slows down the physiological processes. Hence, pigments that absorb some of that light energy can help to protect the chlorophyll from damage. These should not be part of the chlorophyll antenna system because that would transfer even more energy to the chlorophyll. Rather, they can be cytoplasmic or cell wall pigments. In the chapter on light, I have already discussed the reaction of *Fontinalis antipyretica* (Figure 123-Figure 124) in cold water exiting an underground stream into full sunlight. The moss was crimson!

Exposure to UV-B radiation is often the trigger for higher levels of pigmentation (Robinson *et al.* 2005). However, the Antarctic species *Schistidium antarctici* (Figure 43) did not increase UV-B absorbing pigmentation under higher UV-B radiation, unlike many other species in the Antarctic.

Figure 123. *Fontinalis antipyretica* exhibiting red color from the stress of high light levels and cold temperatures. Photo by Janice Glime.

Figure 124. *Fontinalis antipyretica* red cells that result from stress. Photo by Janice Glime.

Dunn and Robinson (2006) suggest that *Bryum pseudotriquetrum* (Figure 44-Figure 45) will have an advantage over other species under conditions of high UV-B radiation that occurs with low temperatures. This will be mediated in *B. pseudotriquetrum* by the presence of UV-B absorbing and anthocyanin pigments that limit physiological activity during periods of low temperatures and desiccation, but also limiting photoprotective and repair mechanisms.

In the same study (Dunn & Robinson 2006), *Ceratodon purpureus* (Figure 50) is intermediate among the three species studied. Rather than responding to high levels of UV-B, it has a stable, constitutive concentration of UV-B- absorbing pigments. However, the anthocyanin pigments in this species were more responsive than those of *Bryum pseudotriquetrum* (Figure 44-Figure 45), most likely providing antioxidant protection during periods of high UV-B radiation (Turnbull & Robinson 2009). *Bryum pseudotriquetrum* did decrease the accumulation of photosynthetic product as the temperature rose. Of the three species, *Schistidium antarctici* (Figure 43) presents the least protection and seems to have no UV-B protective response (Dunn & Robinson 2006).

In a different Antarctic study, Melick and Seppelt (1994) found that pigment levels varied seasonally. Total chlorophyll and the chlorophyll *a/b* ratio dropped during winter. Carotenoids increased in the summer, presumably responding to the higher light intensity.

Summary

The optimum growth temperature for most bryophytes lies between 15 and 25°C, but it can go much lower in habitats that remain cold for most of the year. The lowest extreme for photosynthesis appears to be about -15°C and the uppermost around 40-45°C. However, it is unlikely that there would be a sustained photosynthetic gain at these higher temperatures.

Snow provides insulation and may serve as a source of nutrients and moisture during the winter. Acrocarpous mosses seem more able to tolerate dry areas with only light snow cover, whereas pleurocarpous mosses are more common on wet sites with deep, long-lasting snow. Some epiphytes may benefit from the moist, protected funnels of air between the snow and tree trunk. Light quality is altered through the snow to principally blue and blue-green and diminishes rapidly from the surface.

Bryophytes near late snowbeds remain cold from melt water while experiencing high light intensities and, like bryophytes from regions of extreme cold, are often red, deriving protection from UV and possibly benefitting from warming. White tips also seem to help in reflecting the bright light. Like the exposed bryophytes, these typically are acrocarpous, with *Isoeterygiopsis pulchella* being a notable exception.

Freezing of cells can result in damage from crystals that poke holes in membranes, loss of solutes, and desiccation. Hence, desiccated cells are more likely to survive freezing than hydrated cells. Some bryophytes have net photosynthetic gain on nunataks and other areas where the temperature rarely exceeds 0°C. Net gain at -10°C is not uncommon.

But low temperature and high light intensity can cause photoinhibition. Bryophytes gain protection through colored pigments and down-regulation of photosystem II to prevent over-excitation of electrons. Mature tissues seem to exceed both young and senescing tissues in their frost tolerance.

Calcium and ABA seem to have a role in cold tolerance, although the mechanism is incompletely understood. ABA stimulates the activity of genes that code for stress proteins. These, in turn, increase freezing tolerance and decrease the death rate. Presence of ABA protects cells from membrane lesions and causes an increase in the sugar concentration of cells, but this may be an indirect effect through activation of genes that code for the production of stress proteins. Calcium alters membrane permeability, thus affecting membrane transport. Cold temperatures seem to increase the cellular content of Ca^{++} , which comes from both internal and external sources. An increase in soluble sugars could lower the freezing point or provide energy for rapid repair. Depressed temperatures stimulate the

bryophytes to prepare for winter by activating these mechanisms.

Membrane integrity may be maintained by alteration of fatty acids and lipids, with those having high freezing points being replaced with ones having lower freezing points. There seems to be a change to more unsaturated fatty acids as weather cools. Decreasing N levels may signal this change to occur. Some experiments suggest that arachidonic acids diminish as the temperature cools, but if light intensity decreases, as it would as winter approaches, at least some mosses exhibit an increase not only of palmitic and stearic acids, but also of linolenic and arachidonic acids. Such fatty acids as arachidonic acid may even be important in protecting the footpads of lemmings that eat the mosses prior to the onset of winter.

Bryophytes respond differently from tracheophytes to freezing. Because they are only one cell thick and lack internal air spaces, their external surfaces are able to form ice rather than crystals. This helps to insulate the cell. Furthermore, cellular loss of water in preparation for winter deprives the external surfaces from drawing water from the cells to grow crystals. Presence of macromolecular substances, most likely proteins, help polar and cold region bryophytes to form ice rather than crystals. The rapid cooling achieved by the one-cell-thick leaves also causes water loss from the cell, increasing solute concentration and lowering the freezing point inside the cells. This also contributes to the prevention of internal crystal formation. Thallose liverworts with multiple cell layers are more likely to suffer freezing damage.

The ability to accomplish the various means of surviving freezing plays an important role in the niche width and distribution of closely related species.

CHAPTER 10-3

TEMPERATURE: HEAT

Figure 1. Condensation of moisture in heated air emerging from geothermal vents at Namakolla, Myvatn, Iceland. Note the green covering of bryophytes that endure this warm, moist environment. Photo by Janice Glime.

Heat Stress and Heat Resistance

Since air temperatures rarely exceed 40°C, it might seem unlikely that bryophytes ever experience the high temperatures often used in experiments. But such levels are not as uncommon as supposed (Larcher 1995). Black mosses on rocks of cliffs and exposed boulders can attain considerable internal heat, and even forest mosses can get hot in sunflecks. When the air temperature is only 20°C, mats of *Mnium hornum* (Figure 2) can reach 39°C. *Sphagnum* can reach a temperature 10°C higher than air temperature (Longton 1979) and habitats such as freshly burned soil can reach 65°C (Larsen 1980). Yet mosses are known to suffer injury when the temperature exceeds 40°C (Larcher 1995), and temperatures in the range of 42-51°C are typically lethal (Nörr 1974; Richardson 1981; Meyer & Santarius 1998; Proctor & Pence 2002). *Grimmia* (probably *Schistidium*; Figure 3-Figure 4) grown at 38°C produced fewer protonemata and shoots, and more plants turned brown than when grown at 27°C (Keever 1957). Hence, it is of ecological interest to understand the effects of high temperatures on bryophytes.

Figure 4. *Schistidium apocarpum* with capsules, showing white awns that help to keep the plants cool and add protection from UV rays. Photo by Michael Lüth, with permission.

Most bryophytes seem to have a heat tolerance of 39–45°C (Scheibmair 1938; Dirckson 1964; Nörr 1974). When they are constantly wet, they have an even lower tolerance for continuous warm temperatures, as for example species of *Fontinalis* (Figure 5) that lose their vitality and chlorophyll at sustained temperatures of 20°C (Dilks & Proctor 1975; Glime 1987b, c). On the other hand, the warm soil of geothermal areas permits a haven for some species such as *Hypnum plumaeforme* (Figure 6), which reaches its northernmost limits in Japan in a geothermal area (Iwatsuki & Glime 1983). In such areas, bryophytes dominate on warmer soils due to high root zone temperatures that are lethal to roots of tracheophytes. By living on the surface, bryophytes are subject to cooling effects of the atmosphere while insulating the soil and causing it to retain more geothermal heat (Glime & Iwatsuki 1997). This heated ground is particularly important to the Antarctic bryophyte flora.

We can consider two major types of heat-related environmental parameters. In one case, the environment is characterized by permanently high temperatures, and in the other, the plants are subjected to thermal extremes (Kappen 1981). For those plants surviving constant heat, the mode of survival must be physiological. However, for those that must survive heat stress only occasionally when extremes arrive, the plant adaptations may require some degree of physiological tolerance, coupled with mechanisms for avoiding the heat. For many plants, this latter avoidance

mechanism often involves a dormant life cycle stage that is metabolically inactive, permitting it to survive physiologically. For bryophytes, this could be accomplished by spores or vegetative diaspores that survive underground or on the surface as inactive tissue. This does in fact aid some flood plain species and other ephemerals that disappear for long periods of time and appear only when conditions are suitable. But for the vast majority of bryophytes, their slow growth makes this annual strategy impractical and they more typically survive in a state of desiccation (in dormancy) in which their temperature tolerance is typically much higher (Hearnshaw & Proctor 1982).

Figure 5. *Fontinalis antipyretica*, a cool temperature species that loses its vitality and chlorophyll at sustained temperatures of 20°C. Photo by Andrew Spink, with permission.

Figure 6. *Hypnum plumaeforme* from a geothermal site near Lake Wakoto, Japan. Photo by Janice Glime.

If neither of these strategies is possible, as in wetland bryophytes, their adaptations must include a physiological tolerance to heat, whether it be for short daily periods in summer or for longer duration, or a cooling mechanism. For example, many species of *Sphagnum* (Figure 19–Figure 23) have their optimum temperature for growth at 30–35°C (Li & Glime 1990), whereas most bryophytes have an optimum near 20°C (Dilks & Proctor 1975). The cosmopolitan *Bryum argenteum* (Figure 7) populations, living from the continent of Antarctica through the hot lowland tropics, exhibits heat stress at 30°C, exhibiting its optimum at 22°C day/15°C night (Hedderston & Longton 1999). But air temperature is not indicative of bryophyte temperature, and emergent bryophytes may in fact lower their temperature through evaporative cooling. When that

water is no longer available, the bryophyte is approaching a state of desiccation in which it can become dormant.

Figure 7. *Bryum argenteum* with capsules, a cosmopolitan species that exhibits heat stress at 30°C. Photo by Keith Bowman, with permission.

Responses to heat are not immediate in bryophytes. In their study of *Pohlia wahlenbergii* (Figure 8), Sandvik and Heegaard (2003) found that the response to nutrient addition was immediate, but that to temperature was delayed. Likewise, *Fontinalis* (Figure 5) species can continue to look healthy for several weeks at temperatures above 15 and even 20°C in the field, but after prolonged additional exposure in the lab, they lose their green color and cease growing (Glime 1987b). Such behavior permits them to weather the daily fluctuations as well as the day-night differences in their environments and to sustain short periods of hot weather in summer.

Figure 8. *Pohlia wahlenbergii*, a species that responds immediately to nutrient addition, but has a delayed response to temperature. Photo by Michael Lüth, with permission.

Heated Habitats

Tropical areas and geothermal habitats present special constraints on bryophytes due to their persistent high temperatures (see Makinde 1993). One would therefore expect that such bryophytes would possess unique adaptations to permit their survival. However, even tropical bryophytes seem to do poorly above 25°C (Frahm

1990). Such high (but not uncommon) temperatures cause their net assimilation rate to decrease drastically, their respiration rates to rise to high levels, and they fail to reach their compensation point (Frahm 1987).

Bryophytes growing in geothermal areas must be capable of tolerating prolonged high temperatures (Given 1980; Hearnshaw & Proctor 1982). For some, this can be done in a dry state, when heat tolerance is much greater. During periods of rain or dew, evaporative cooling can help to maintain a tolerable temperature and permit photosynthetic activity. *Bryum japonense* has been found growing at 40°C, *Philonotis falcata* (Figure 9) and *Bryum cyclophyllum* (Figure 10) at 38°C (Watanabe 1957), and *Campylopus* (Figure 11) at 53°C (Glime & Iwatsuki 1994), although the temperature of the actively growing apical region may be much less (e.g. 30°C in *Campylopus praemorsus*; Kappen & Smith 1980). Although liverworts are often considered intolerant, Volk (1984) demonstrated tolerance up to 80°C dry and 50°C wet in *Riccia* (Figure 12). Other geothermal taxa, for example *Bryum argenteum* (Figure 7) (Hedderson & Longton 1999) and *Polytrichum* (Figure 33) species (Loesch *et al.* 1983), exhibit a wide latitudinal range, yet exhibit thermal stress at a mere 30°C and 32°C, respectively. One must exercise caution in interpreting temperature data, however, because they may represent only the soil or air temperatures, which can differ significantly from that of the growing tip of the bryophyte.

Sporophyte Stress

Little attention has been paid to temperature relationships of the sporophyte. But in desert mosses, this can be a limiting part of the life cycle. And it appears that post-embryonic sporophytes in at least some desert mosses can only develop in the cooler, wetter months (McLetchie & Stark 2006). It is the perennial gametophytes that permit these plants to survive from year to year. In the desert species *Microbryum starckeanum* (Figure 13), all gametophytes survived temperatures of 35-75°C for 1-3 hours, subsequently producing protonemata and shoot buds in a 35-day recovery period. Some leaves exhibited symptoms of stress at 55°C, including leaf burning and discoloration of shoots. However, sporophyte recovery was poor, with reduction in growth and maturation. No sporophytes reached meiosis after exposure for one hour at 75°C. Furthermore, maternal shoots suffered more than did those that aborted their sporophytes in the 35° and 55°C treatments. These shoots took longer to regenerate through protonemata. The reason for this susceptibility of the sporophyte remains unknown. It might be simply less thermotolerance in the sporophyte, or it might be that the gametophyte in some way affects the thermotolerance of the sporophyte.

Figure 13. *Microbryum starckeanum*, a xerophyte for which the sporophyte is more likely to be damaged by heat than is the gametophyte. Photo by Richard Zander, with permission.

Plant and Cellular Responses

Effects of heat stress can include loss of membrane integrity (Liu *et al.* 2003), color change to brown (Keever 1957), shoot damage (Liu *et al.* 2004), and enzyme and pigment destruction (Larcher 1995; Meyer & Santarius 1998; Liu *et al.* 2004). Liu *et al.* (2004) found that *Plagiommium acutum* (Figure 14) survived well at 35-40°C, exhibiting no cellular damage, but at 45°C both wet and dry moss cells were damaged (Figure 15). They could find no differences with leaf age, as assessed by position on stem.

Figure 14. *Plagiommium acutum*, a species that tolerates temperatures up to 40°C, but suffers damage at 45°C. Photo by Show Ryu, through Creative Commons.

Figure 15. Cells of *Plagiommium acutum* following wet heat treatment. **Left:** 35°C for 8 hours. **Right:** 45°C for 1 hour. Photos by Yingdi Liu, with permission.

It appears that membrane permeability varies with temperature even within a normal range of daily temperature fluctuations. Liu *et al.* (2003) demonstrated a temporal fluctuation in cell membrane permeability for *Thuidium cymbifolium* (Figure 16) and *Plagiomnium acutum* (Figure 14) submersed in water through a 94-hour period. The permeability tracked the temperature almost perfectly (Figure 17).

Figure 16. *Thuidium cymbifolium* with capsules, a species in which cell membrane permeability tracks the temperature. Photo by Li Zhang, with permission.

Figure 17. Effect of surrounding temperature on the membrane permeability of two mosses. Redrawn from Liu *et al.* 2003.

In a series of studies, Glime (1980, 1982, 1984, 1987a, b, c) and coworkers (Glime & Knoop 1986; Glime & Raeymaekers 1987) have shown that temperature affects rhizoid production, growth, branching, and gametangia formation in several species of the aquatic moss *Fontinalis* (Figure 5; see subchapter on Temperature Effects). And certainly elevational restrictions imply physiological effects that preclude many taxa from growing at higher elevations. These restrictions may even be gender-specific, as in *Macromitrium* (Figure 18), where the dwarf male plants are restricted to lower latitudes and altitudes (below the 6°C January isotherm in Japan), presumably due to low-temperature stress (Une 1985; Une & Yamaguchi 2001).

It appears that even the aquatic moss *Fontinalis antipyretica* (Figure 5) may have physiological races adapted to high temperatures. Long exposures to a high temperature could eliminate all but the hardy, and eventually develop a population that is able to withstand the higher temperatures. Such might seem to be the case for this moss growing in a river with abnormally high temperatures due to heated water from hot springs. But

when Carballeira *et al.* (1998) transplanted the moss from a normal river site (16°C) to the heated river (34°C), there was no notable change in pigment ratio, photosynthetic rate, or respiratory rate after 25 days at the new high temperature. Furthermore, after 2, 4, and 10 days of exposure of mosses from the 16°C river to 30°C, then back to 16°C, these parameters recovered to 50% of their normal values within 10 days. Photosynthesis and respiration both recovered more slowly than did the pigment ratios.

Figure 18. *Macromitrium microstomum*, member of a genus in which at least some species have dwarf males that are more sensitive to cold temperatures than are females. Photo by Janice Glime.

The ability to tolerate heat is important in dispersal and establishment in a new habitat. Whole colonies can regulate their temperature through insulation. But fragments, often the best means of propagation, lack this protection. When fragments (stem pieces) of several species of *Sphagnum* were air dried at 20°C and a relative humidity of ~60%, they survived up to 14 days without water. *Sphagnum fallax* (Figure 19) and *S. magellanicum* (Figure 20) resisted desiccation better than did *S. fuscum* (Figure 21). As one might expect, desiccation delayed the onset of regeneration, most likely due to the need to repair damaged membranes and recover lost nutrients. Oven drying of for 48 hours at 20°C and above was lethal at all temperatures in *S. angustifolium* (Figure 22), *S. fuscum*, *S. magellanicum*, *S. capillifolium* (= *S. nemoreum*; Figure 25), and *S. papillosum* (Figure 23). Only *S. fallax* was able to survive up to 30°C.

Figure 20. *Sphagnum magellanicum*, a species in which fragments can survive up to 14 days at 20°C without water. Photo by Michael Lüth, with permission.

Figure 21. *Sphagnum fuscum*, a species whose fragments can survive up to 14 days at 20°C without water, but that does not resist desiccation as well as *S. fallax* and *S. megellanicum*. Michael Lüth, with permission.

Figure 22. *Sphagnum angustifolium*, a species that dies when dried in an oven at 20°C. Photo by Jan-Peter Frahm, with permission.

Li and Glime (1990), on the other hand, demonstrated an optimum growth temperature of 30-35°C for clumps of *S. magellanicum* (Figure 20) and *S. papillosum* (Figure 23) from the Keweenaw Peninsula of Michigan, USA. Rydin (1984) found no temperature-tolerance differences

among *Sphagnum* species from Europe. It is likely that the rate of drying differed among these studies so that moisture state may have contributed to the contrasting results, but geographic races may also have been involved in these distant populations. *Sphagnum fuscum* (Figure 21) responded to summer warming with enhanced length increment (42-62%) and greater biomass increase, while bulk density decreased (Dorrepall *et al.* 2004). Added snow in winter increased the biomass gain by 33%, but growth in length and bulk density did not change significantly. These changes suggest that not only is the health of the plant affected by temperature, but the structure and moisture-holding capacity are altered, potentially having a major impact on the ecosystem.

Figure 23. *Sphagnum papillosum*, a species that dies when dried in an oven at 20°C. Photo by Janice Glime.

Biochemical Responses

The observed variations in responses among bryophyte species undoubtedly also result from biochemical differences. Al-Hasan & coworkers (1989) demonstrated a greater concentration of glycerols in *Bryum bicolor* (Figure 24) incubated at 5°C than in those at 25°C. It appears, from work with the tracheophyte *Arabidopsis thaliana*, that a reduction in polyunsaturated lipids enhances the thermal stability of the photosynthetic electron transport system (Hugly *et al.* 1989).

Figure 24. *Bryum bicolor* decreases its concentration of glycerols when incubated at 25°C compared to those plants at 5°C. Photo by Michael Lüth, with permission.

Isoprene

More recently, Hanson & coworkers (1999) have suggested that heat tolerance in mosses may be due, at least in part, to the production of isoprene, a mechanism of thermal tolerance that seems to have been lost multiple times among more advanced plants. Although little is known thus far about its universality among bryophytes, we do know that at least some bryophytes produce isoprene in response to high temperatures or high light intensities, at considerable cost in carbon – greatly exceeding 2% at temperatures above 30°C (Harley *et al.* 1999). These responses suggest that isoprene may have a role in ameliorating the stresses associated with high temperatures, a role consistent with the physiological evidence. On the other hand, isoprene may contribute to human stress, because it plays a major role in the formation of ozone in forested regions (Harley *et al.* 1999). Isoprene is widespread within the plant kingdom, but it seems to exercise no phylogenetic affinities, is not stored in the leaves, and has no antiherbivory role. Its production in conditions of high light or temperature suggests its protective role in those conditions.

Although isoprene emission is common among mosses and ferns, it is absent in liverworts and hornworts and less predictable among other tracheophytes (Hanson *et al.* 1999). It may be especially useful in certain habitats. Bryophytes growing in the open, such as many *Sphagnum* species, are more likely to suffer from thermal stress. This stress could be particularly important when these mosses, with their lower parts in water, may still be in a hydrated state. *Sphagnum capillifolium* (Figure 25) from a northern Wisconsin, USA, bog is subject to these large temperature fluctuations and enjoys the benefits of isoprene as a means of increasing its thermotolerance (Hanson *et al.* 1999).

Figure 25. *Sphagnum capillifolium*. Photo by Jan-Peter Frahm, with permission.

Sugars

In some temperate mosses, sucrose declines upon exposure to high temperatures, resulting in a decline of cold hardiness (Rütten & Santarius 1992), but its loss seems to imply no apparent advantage for heat hardening.

Peroxidase

Marchantia polymorpha (Figure 26) contains a peroxidase that has been characterized as a glycoprotein that is different from any known tracheophyte peroxidase

(Hirata *et al.* 2000). Hirata and coworkers demonstrated that it is able to perform oxidative polymerization of lunularin, the liverwort counterpart of ABA. It may play a role in stabilizing the cell membrane during desiccation events. The thallose liverwort *Marchantia polymorpha* contains a peroxidase that has been characterized as a glycoprotein that is different from any known tracheophyte peroxidase. Little seems to be known about peroxidases in mosses. In *Mnium* sp. (Figure 2), peroxidase appeared to be relatively stable up to 70°C, but then dropped rapidly as the temperature rose (Bakardjieva *et al.* 1996). Addition of Ca helped to stabilize the peroxidase at higher temperatures. Zinc ions helped to stabilize its activity at high temperatures but inhibited the activity at lower temperatures. When these responses were compared to those of the fern *Polypodium vulgare* (Figure 27), zinc had little effect on that plant at 70°C. The stability of peroxidase at relatively high temperatures may help the bryophytes to survive the desiccation occurring as the bryophyte approaches high temperatures.

Heat Shock Proteins

Early identification of genes and gene function in *Physcomitrella patens* (Figure 28) revealed the presence of at least two heat shock protein genes (Machuka *et al.* 1999). It appears that heat shock proteins were present early among the bryophytes (Waters & Vierling 1999a). *Funaria hygrometrica* (Figure 29) has at least six such small heat shock proteins (Waters & Vierling 1999a, b). Waters and Vierling considered that genes for these cytosolic proteins must have originated at least 450 million years ago, much earlier than genes for phytochromes. Interestingly, the patterns and rates of evolution in *F. hygrometrica* seem different from those of angiosperms. Some, but not all, of the amino acid sequences are the same in both groups.

Figure 29. *Funaria hygrometrica*, a species in which we know at least six small heat shock proteins. Photo by Brian Eversham, with permission.

It appears that these ancient bryophyte heat shock proteins have been largely ignored, at least if Cambridge Scientific Abstracts is a good test. We know from the fungus *Phycomyces blakesleeanus* (Figure 30) that blue light and high heat will induce them in that organism (Rodriguez-Romero & Corrochano 2004). Perhaps light, as well as temperature, also plays a role in the photosynthetic bryophytes. But what is that role?

Figure 30. *Phycomyces blakesleeanus*, a fungal species in which heat shock proteins are induced in blue light and high temperatures. Photo by Phil Bendle, through Creative Commons.

Heat shock proteins help the cells to survive the stress induced on other proteins in the cells (Feder & Hofmann 1999). These authors concluded that all species have heat shock proteins and that their expression is correlated with the natural levels of stress they encounter in their environment. From this, it follows that they also are correlated with resistance to stress.

Basile *et al.* (2013) found that heat shock proteins induced by atmospheric pollution cause effects similar to those under the stress of heavy metals in the thallose liverwort *Conocephalum conicum* s.l. (Figure 31), including severe alterations to the organelles. The implication is that it is the heat-shock proteins that make this liverwort tolerant of heavy metals. When subjected to stress, newly translated proteins can be unstable. The heat shock proteins serve as chaperones that remain attached to these unstable proteins for an extended period of time (Kültz 2005). This chaperone permits the correct folding of denatured proteins, thus stabilizing them and providing defense against damage or dysfunction. It is this capability that labelled them as stress proteins (Wang *et al.* 2004). Furthermore, Neumann *et al.* (1995) concluded that small heat shock proteins protected cells against heavy metal and other stresses by creating a more resistant membrane or improved repair mechanisms.

Figure 31. *Conocephalum conicum* s.l., a species in which heat shock proteins are produced in response to heavy metal stress. Photo by Robert Klips, with permission.

Saidi *et al.* (2005) have helped us to understand this role. They found that in *Physcomitrella patens* (Figure 28), a temperature of 38°C promoted expression of heat shock genes over three orders of magnitude, whereas at 25°C there was little expression of the promoter genes. This increase in expression permitted the accumulation of GUS (β -glucuronidase) and demonstrated labelled F-actin cytoskeleton in all cell types in all tissues.

In the aquatic moss *Fontinalis antipyretica* (Figure 5), temperatures between 20° and 30°C induced production of heat shock proteins. The mean annual temperature of this moss is ~9.5°C (Rau *et al.* 2007). When subjected to heavy metals, this moss produced heat shock proteins, but these did not correspond to any known proteins.

But how does the cell "sense" that the temperature is increasing? Using *Physcomitrella patens* (Figure 28), Saidi *et al.* (2011) indicated that physiological and biochemical evidence suggest that the primary sensory role may be Ca^{++} ions. The primary sensor seems to relate to the plasma membrane and may result from the fluidity-sensitive Ca^{++} channels in plasma membranes.

Light vs Dark

Light vs dark can affect response to heat, with plants of *Plagiomnium acutum* (Figure 14) in the dark requiring a longer time to exhibit cell damage and death than those in the light, perhaps because of light damage and higher photorespiratory rates at high temperatures (Liu *et al.* 2004).

Acclimation

Evidence on heat acclimation in bryophytes provides conflicting scenarios and clearly more studies are needed. Some studies indicate that bryophytes have little ability to acclimate to near lethal temperatures and that high temperature hardening may be effectively absent. For example, Meyer and Santarius (1998) found only a 1°C increase for membrane thermal stability from short-term acclimation to sublethal temperatures in two genera. *Fontinalis antipyretica* (Figure 5) exposed to a prolonged near-lethal temperature of 30°C exhibited little difference in response between populations previously grown at normal river temperatures and those grown in a river with abnormally high temperatures resulting from hot springs (Carballeira *et al.* 1998).

Both acclimation temperature range and duration influence the acclimation response. Antropova (1974) found that incubation of bryophytes for 72 hours at tolerance temperatures (10 & 20°C) did not influence thermal stability or cold resistance, but that exposure to above optimum temperatures for only 3 hours did increase heat resistance in a behavior similar to that of flowering plants. Glime (1987) found that members of the genus *Fontinalis* (Figure 32) were able to tolerate elevated temperatures (above 15°C) for several weeks, but that after prolonged exposure of months they ceased growth and become yellow.

Based on laboratory studies, there is evidence that at sublethal temperatures acclimation to high temperatures occurs (*e.g.* *Fontinalis duriaei*, Figure 32, Glime & Acton 1979; Fornwall & Glime 1982; *Polytrichum commune*, Figure 33, Sveinbjörnsson & Oechel 1983), but results are conflicting. Weis *et al.* (1986) found that the thallose

liverworts *Preissia quadrata* (Figure 34), *Conocephalum conicum* s.l. (Figure 31), and *Marchantia polymorpha* (Figure 26) survived mild heat treatment with a reversible depression of photosynthesis. However, more severe heat caused irreversible damage to photosystem II, much as in higher plants. Nevertheless, these thalli did not have any significant increase in thermal stability of their photosynthetic apparatus as a result of exposure to high sublethal temperatures.

Figure 34. *Preissia quadrata*, a species that experiences reversible damage at mild heat treatments, but at higher temperatures it is irreversible. Photo by Michael Lüth, with permission.

Contrasting with the delayed response of temperature acclimation in *Pohlia wahlenbergii* (Figure 8) (Sandvik & Heegaard 2003), Antropova (1974) found that exposure of

only 3 hours at temperatures above their optimum increased heat resistance in bryophytes in a manner similar to that of flowering plants, whereas incubation within their optimum range of 10-20°C had no effect. Whereas Carballeira and coworkers (1998) found that when exposed to 30°C *Fontinalis antipyretica* (Figure 5) showed little difference in pigment ratio, photosynthetic rate, or respiration rate between populations previously grown at normal river temperatures and those grown in a river with abnormally high temperatures resulting from hot springs, Glime (1987) found that this species (collected in Houghton, Michigan, USA) became chlorotic after several weeks of exposure to temperatures above 15°C.

Balagurova *et al.* (1996) found that differences in heat resistance among several *Sphagnum* (Figure 19-Figure 23) species was less than that for their cold resistance, but that those differences were correlated. In the case of *Sphagnum*, environmental conditions strongly affected the thermal resistance. Clearly, the causes and mechanisms of response are complex.

Night Temperature

It is interesting that it is nighttime temperature that is the limiting factor for growth of *Sphagnum magellanicum* (Figure 20) in the southern Alps of Italy (Gerdol 1996). It exhibited active growth whenever the night temperature was above 0°C. This is consistent with the concept that IAA is inhibited by light and therefore most growth occurs at night. Long-day photoperiod promoted growth of all *Sphagnum* species [*S. capillifolium* (Figure 25), *S. magellanicum*, and *S. fallax* (Figure 19)] in an earlier study, with induction requiring both short days and low nighttime temperatures (Gerdol 1995).

Gerdol *et al.* (1998) likewise found that low nighttime temperature limited the growth of *Sphagnum capillifolium*, causing a five-fold reduction in growth. A nighttime temperature of 5°C triggers production of red wall pigments, which may contribute to reduced productivity by lowering light intensity reaching the chlorophyll. No degradation of the chlorophyll itself occurred.

Hydration State

The state of hydration is of great importance in the thermal tolerance of bryophytes and their ability to acclimate (Table 1). Dry bryophytes have much greater thermal tolerance than hydrated ones (Figure 35; Figure 42). Alpert (2000) contended that desiccated plants are able to endure temperatures from -272 to 100°C. But hydrated *Fontinalis novae-angliae* (Figure 36) had at least some stem tissue that survived intermittent boiling for more than one week (Glime & Carr 1974). In the moss *Homalothecium lutescens* (Figure 37), a decrease in the water content was responsible for an increase in heat tolerance (Dulai *et al.* 2002). An osmotic treatment of only 30 minutes shifted the lethal temperatures upward. But if the plants were kept in the dark, the curves did not shift upward as the water deficit increased, suggesting that the thermal stability of PS II may occur only in the energized photosynthetic membranes. On the other hand, Li *et al.* (1999) found that dark respiration decreased as temperature increased (and hydration state decreased) in *Herpetineuron toccoeae* (Figure 38) and *Plagiomnium acutum* (Figure 14),

perhaps explaining part of the greater heat tolerance of dry mosses.

Table 1. Wet and dry 50% lethal temperatures (LT₅₀ – °C) for various mosses, based on Nörr 1974 and Kappen 1981.

	wet	dry
<i>Hylocomium splendens</i>	43	91
<i>Rhytidiadelphus loreus</i>	42	92
<i>Mnium hornum</i>	44	99
<i>Pleurozium schreberi</i>	42	92
<i>Hypnum cupressiforme</i>	44	102
<i>Dicranum scoparium</i>	45	103
<i>Racomitrium lanuginosum</i>	48	105
<i>Sphagnum capillifolium</i>	46	
mosses	41-51	85-110
liverworts	39-45	70-110

Figure 35. Lethal temperatures for various dry mosses. Based on Lange (1955), using the highest temperature below which most of the mosses first survived for 30 minutes.

Figure 36. *Fontinalis novae-angliae*, a species in which some stem tissues survived being in intermittent boiling for more than one week. Photo by John Parker, with permission.

Figure 37. *Homalothecium lutescens*, a species that becomes more heat tolerant at lower moisture levels. Photo by Michael Lüth, with permission.

Figure 38. *Herpetineuron toccoae*, a species in which dark respiration decreases at higher temperatures with lower moisture levels. Photo by Michael Lüth, with permission.

In two Polytrichaceae [*Atrichum undulatum* (Figure 39) and *Polytrichastrum formosum* (Figure 40)], short-term acclimation of hydrated shoots occurred within a few hours and provided a small but significant increase in the stability of the cellular membranes and photosynthetic apparatus (Meyer & Santarius 1998). By contrast, it required several days to dehardening the tissues. Contrasting with this minimal resistance of hydrated tissues, the increase of heat tolerance in desiccating tissues was dramatic, with an inverse relationship between hydration and heat tolerance.

As one might expect, water use efficiency (WUE) plays a role in heat tolerance in bryophytes. In the moss *Herpetineuron toccoae* (Figure 38), transpiration usually is lower and water use efficiency higher than that of *Plagiommium acutum* (Figure 14) in the same habitat (Li *et al.* 1999). This seems to endow *H. toccoae* with a greater capacity for heat tolerance and dry habitats.

Clausen (1964) explored the relationship between temperature and humidity in 20 species of liverworts from a wide range of locations throughout the globe (Figure 42).

Figure 39. *Atrichum undulatum*, a species that is able to acclimate to temperature changes within a few hours. Photo by Brian Eversham, with permission.

Figure 40. *Polytrichastrum formosum*, a species that is able to acclimate to temperature changes within a few hours. Photo by Michael Lüth, with permission.

A common method of drying mosses in the laboratory for temperature experiments has been to place the plants in a sugar or salt solution until they plasmolyze (Figure 43). This pretreatment induces heat resistance, most likely by suspending cellular metabolism.

Figure 41. *Plagiochila asplenoides*, a species that exhibits plasmolysis when pretreated with a sugar solution and heated to 55°C, but exhibits loss of membrane integrity when pretreated with salt. Photo by Michael Lüth, with permission.

Figure 42. Effects of temperature and state of hydration on 20 leafy liverworts from Europe. Redrawn from Clausen 1964.

Duration

Not only is the actual temperature important, but the duration is also important. Just as we might walk through a hot boiler room unscathed, but be unable to stay for an hour in there without getting sick, bryophytes likewise are able to tolerate short-term bursts of heat as might come from

dancing sunflecks. For example, the tropical liverwort *Schistochila commutata* dies at 32°C in water with 12 hours exposure, but survives at 42°C (but not 44°C) with only 1/2 hour exposure (Biebl 1967). The tropical mosses *Homaliodendron flabellatum* (Figure 44) and *Bryum* sp. (Figure 7) tolerate temperatures up to 50°C in water for half an hour, contrasting with the 25°C limit for tropical bryophytes reported by Frahm (1990). Figure 45 demonstrates the effect of time in the moss *Plagiomnium acutum* (Figure 14).

Figure 45. Effect of time on the lethality of temperature in *Plagiomnium acutum* (Figure 14). $n=30$. From Liu *et al.* 2004.

Age and Structure

In some cases, age is a factor in temperature tolerance of tissues, as shown for two *Plagiomnium* species in response to low temperatures, with mature tissues being more tolerant than young or senescent ones (Rütten & Santarius 1992, 1993). Yet there seems to be no effect of age on the lethal high temperature of *Plagiomnium acutum* (Figure 14) treated wet at 30–60°C for up to 240 minutes (Liu *et al.* 2004). Known cellular damage of high temperatures on bryophytes mainly includes destruction of the plasma membrane as evidenced by loss of electrolytes (Liu *et al.* 2003), loss of differential permeability, chemical disorganization, and death of cells or tissue (Liu 2004), all factors where one might expect young and old tissues to respond differently. In studying *Plagiochila asplenioides* (Figure 41), Scheibmair (1938) did indeed find that young leaves survived better than older leaves. The older cells died, protoplasm became deformed, and the membrane and cytoplasm became colored. The young leaves survived up to 53°C for 10 hours, whereas the older leaves died after 6 hours at 48°C.

Although a variety of measures have been used to assess damage in bryophytes, the actual physiological responses of bryophytes to temperature are not well understood. One complication is that optimal temperatures for one aspect of a bryophyte life cycle might be detrimental for another, as shown for example in *Fontinalis* rhizoid production, gametangia formation, growth, and branching (Glime 1984, 1987a, b, c; Glime & Knoop 1986; Glime & Raeymaekers 1987). Chlorophyll content (Miyata & Hosokawa 1961; Melick & Seppelt 1994), photosynthesis (Shimizu *et al.* 1983), growth, weight, and number of branches (Bengtson *et al.* 1982; Bakken 1993) are often used as measures of bryophyte health.

It appears that we know almost nothing about the effect of temperature on the development of the sporophyte. Working with desert bryophytes, Stark (personal communication, April 2005) suggested that stress on the gametophyte might trigger the plant to abort its sporophyte, making it difficult to determine independent stress on the sporophyte itself. It appears that once expansion has been initiated, they are very stress tolerant when dry.

HP

Reversible Effects

In thallose liverworts, heat-stress depression of photosynthesis can be reversible (Weis *et al.* 1986). *Preissia quadrata* (Figure 34), *Conocephalum conicum* s.l. (Figure 31), and *Marchantia polymorpha* (Figure 26) all were able to recover from mild heat stress, with the recovery period dependent on the extent of the damage. With severe damage, Photosystem II suffered irreversible damage. Nevertheless, unlike in tracheophytes, treatment with high sublethal temperatures had no significant effect on their heat stability.

Decomposition

Few studies have examined bryophyte decomposition, and many misconceptions occur among ecologists about bryophyte decomposition. It is quite a different thing to be decaying from the bottom up on a live plant than to drop leaves and branches that henceforth decay. By being still connected to living plant tissue, decaying portions of a bryophyte are able to move internal and external constituents upward or outward to living portions. Such movement can be influenced by temperature.

Thormann *et al.* (2004) compared decomposition between the sedge *Carex aquatilis* (Figure 46) and the moss *Sphagnum fuscum* (Figure 21) in the boreal peatlands. They found a 5 to 17-fold decrease in bog *Sphagnum fuscum* litter decomposition with elevated temperature, whereas decomposition of the sedge litter was either enhanced 2- to 30-fold or was unaffected by elevated temperatures. Fungal decay was favored over bacterial decay in elevated temperature conditions. The fungi were able to use polyphenolic polymers as their carbon source, hence favoring their existence over the bacteria in the peat. Nutrient quality seemed to play a major role, favoring the nutrient-rich litter of sedges (8.0–25.7%) over that of bryophytes (0.2%) at higher temperatures. Hence, increases in temperature may not cause the positive feedback to temperature that has been anticipated for all peatlands. Rather, intermediate and rich fens may cause a positive feedback, but poor fens and bogs may actually cause a negative feedback that reduces the input of carbon to the atmosphere.

Figure 46. *Carex aquatilis*, a species with high nutrient content that decomposes much more rapidly at elevated temperatures than does bog litter (which decreases its decomposition rate). Photo by Max Licher, SW Biodiversity, with online permission.

Summary

Although the air temperature seldom exceeds 40°C, bryophyte temperatures can reach 60-70°C in some circumstances. Most bryophytes have a hydrated tolerance limit of 45°C or less.

Bryophytes can survive the heated periods as spores or other dormant propagules, by becoming dormant (if desiccated), or by physiological adaptations to the elevated temperatures, including desiccation that leads to dormancy. Emergent bryophytes can use evaporative cooling to maintain lower tissue temperatures.

Despite potentially high temperatures, tropical bryophytes typically do poorly above 25°C, due to high respiration rates. Geothermal bryophytes often provide their own insulation, with hot bases but cool growing tips. The record for wet heat tolerance seems to be *Riccia* at 50°C, although *Fontinalis* stem tissue survived more than a week of intermittent boiling. Colors, evaporative cooling, and physical properties can alter the temperature of the growing region of a bryophyte, so air and substrate temperature data may not reflect tissue temperatures.

Heat stress can cause loss of membrane integrity, color changes, shoot damage, enzyme denaturation, pigment destruction, and negative photosynthetic gain. Temperature can promote differential development times for spores, gemmae, rhizoids, branching, growth, gametangia, and sporophyte maturation. Some of these effects are gender specific and may restrict the male and female plants or expression of sexual organs to different elevations or microclimates. **Cryptic species, microspecies, or physiological races** may exist that are not mirrored by differences in morphology, permitting a species to occupy a wide range of climatic conditions.

It appears that heat may damage bryophytes in the light more than in the dark, perhaps due to energy loss to photorespiration. Nighttime temperatures may be important for some taxa, with minimal temperatures required for growth.

Known biochemical responses to elevated temperatures include an increase in **glycerols, isoprenes, and heat shock proteins**, whereas **sugars** decrease, but we know little about any of their roles. **Peroxidase** may play a role in stabilizing cell membranes during thermal stress and desiccation, with Ca and Zn contributing to its stabilization at high temperatures.

Many bryophytes seem to lack the ability to acclimate to high temperatures. Nevertheless, heat resistance can increase in as little as three hours of exposure to above-optimum temperatures, but plants may take several days to **deharden**. It appears that some physiological processes such as photosynthesis may acclimate, but that thermal stability does not change as easily. Even *Sphagnum* exhibited more change in its cold resistance than in its heat resistance, but the two acclimations were correlated.

Desiccated bryophytes have far greater thermal tolerance than hydrated ones, with some apparently surviving the entire temperature range from -272 to 100°C. In fact, one mechanism for increased heat tolerance is for the plant to decrease its water content, whether by changing its osmotic relationships or by coincidence with a drying atmosphere. One explanation for this is that dark respiration can decrease in response to increased temperatures and concomitant drying. Duration is important, with short durations being tolerable when longer ones are not. Greater **water use efficiency** seems to endow mosses with a greater heat tolerance, but may not be helpful to thallose liverworts.

Age plays a role in heat tolerance in some species, with mature tissues being the most tolerant, and young and senescent ones being less so. Sporophyte responses are poorly known, but some evidence suggests that heat may cause embryo abortion in some taxa.

Decomposition may be altered differently among bryophytes compared to that of tracheophytes. Elevated temperatures can favor fungal over bacterial decay, promoting the decay of the polyphenolic polymers in bryophyte cell walls. High nutrient litter increases decay more with temperature increases than does bryophyte litter. This results in some habitats losing bryophyte litter more quickly while others lose it more slowly.

CHAPTER 10-4

TEMPERATURE: SPECIES AND ECOSYSTEMS

Figure 1. Mountainous habitats provide a wide range of temperatures. Here *Ditrichum flexicaule* grows in the foreground. Photo by Michael Lüth, with permission.

Species and Distributions

Importance of Climate

In his study of the Gulf of St. Lawrence region of Canada, Belland (2005) found that climatic variables were the most important factors determining moss species distributions, with warmth of the growing season being the most important. Acebey *et al.* (2003) likewise found that climate accounted for the reduced bryophyte species diversity and changes in growth forms from submontane rainforest in Bolivia to the 4-15-year-old fallows at 500-650 m elevation. In central Belgium, species composition could be predicted based on four life-history traits

(minimum spore size, life expectancy, type of gametophyte, and papillose leaf cell walls) and three ecological traits (indicator values of light, temperature, and soil acidity) (Vanderpoorten & Engels 2002). For bryophytes of the eucalypt-dominated forests in Tasmania, minimum temperature in the coldest month and precipitation were the most important variables predicting bryophyte cover, richness, and composition (Pharo *et al.* 2005). These were reduced by the cover of vascular plants. Certainly temperature plays an important role at all stages of the life cycle.

While some species are limited in their extension toward the poles by cold temperatures, others are unable to survive further away from the poles due to the heat. *Grimmia torquata* (Figure 2-Figure 3) is an arctic-montane moss that reaches its southern limit in Newfoundland, where further southward expansion seems to be limited by high summer temperatures (Hedderson & Brassard 1990). On the other hand, *Aulacomnium androgynum* (Figure 4) and *Isoetecium myosuroides* (Figure 5-Figure 6) reach their northern limit there due to low winter temperatures and water availability.

Figure 3. *Grimmia torquata*, a northern species that is limited in distribution by heat. Photo by Michael Lüth, with permission.

In nearly every study, however, the importance of water availability is the major limiting factor for growth of bryophytes within a region. Temperature may define the bounds of their distribution, but water availability determines their growth rate within that suitable temperature range. For example, in their study of nine bryophytes [*Racomitrium lanuginosum* (Figure 7), *Pleurozium schreberi* (Figure 8), *Sphagnum austini* (Figure 9), *S. fuscum* (Figure 10), *S. rubellum* (Figure 11), *S. papillosum* (Figure 12), *S. lindbergii* (Figure 13), *S. tenellum* (Figure 14), and *S. pacificum* (Figure 15)] in a

coastal peatland in British Columbia, Canada, Asada *et al.* (2003) found that growth was most strongly correlated with precipitation and less so with temperature. Surprisingly, temperature thresholds for *Sphagnum* were lower than those for *Pleurozium schreberi* and *Racomitrium lanuginosum*, and winter growth was important for these *Sphagnum* species. But we must keep in mind that temperature often co-varies with precipitation, with cooler summer temperatures in a suitable range occurring when there is precipitation.

Warming Studies

Studies on effects of global warming (to be discussed in detail in a later chapter) are helping us to understand how bryophytes are affected by temperature and how they affect the temperatures of the soil beneath them. In a

species-poor Icelandic moss heath where *Racomitrium lanuginosum* (Figure 7) dominated, mean daily surface temperatures were 1-2°C higher under a simulated warming regime, but the soil temperatures tended to be lower than in the control plots (Jonsdottir *et al.* 2005). In several other habitats that were more species-rich, changes were more moderate. In the Arctic, it appears that warming temperatures are likely to decrease bryophyte relative cover as graminoids increase (Hollister *et al.* 2005). Wahren *et al.* (2005) found a similar increase in sedges (*Eriophorum vaginatum* – Figure 16) and decrease in bryophytes in Alaska after eight years of increased temperatures, but even the control plots had a similar response. Ironically, plots with additional snow cover were actually warmer due to the greater insulating effect. They also benefitted by the additional moisture available.

Figure 16. *Eriophorum vaginatum* (cottongrass), a species that increases in abundance after warming for eight years. Photo by Martin Olsson, through Creative Commons.

In northern habitats, the moss *Hylocomium splendens* (Figure 17) has been studied in many contexts, permitting us to understand its biology well. In a study on circumarctic populations, its growth was strongly correlated with both the early summer temperatures and the length of the growing season (Callaghan *et al.* 1997). The mildest of the subarctic sites fostered the greatest annual segment mass increase, growth rates, and degeneration rates, whereas the lowest were at the high arctic site. Conversely, longevity increased as the climate became more harsh at the more northern sites. Growth between years at two contrasting sites correlated significantly with the temperatures of June and July. This moss is tolerant of a wide range of daily temperature variation, so it is not likely to be seriously affected by global warming. However, not all Arctic systems are likely to respond in the same way. Even *Hylocomium splendens* responded negatively to perturbations of climate at a sub-Arctic site, perhaps due to lower humidity and non-equilibrium responses in the relatively short term of the study (Callaghan *et al.* 1999).

Seasonal Fluctuations

As seen in the previous chapters, temperature can invoke changes in the biochemical constituents of the bryophyte cells. In a study on bryophytes of Windmill Islands, Antarctica, Melick and Seppelt (1994) found that pigment levels varied seasonally, with total chlorophyll and chlorophyll *a/b* ratios decreasing in winter, most likely as a light response. Total carotenoids increased in summer, primarily in response to the greater light intensity. Water content was greatest in summer. Soluble carbohydrate levels, on the other hand, varied little among seasons, contrasting with fluctuations seen in bryophytes from other polar regions. This lack of change in carbohydrates may be due to the rapid temperature fluctuations seen on a daily basis during the Antarctic growing season.

Species Differences

Within a genus, the responses of different species to temperature vary (Koskimies-Soininen & Nyberg 1991). For example, in the predominantly sun-adapted *Sphagnum*, the shade-tolerant species *S. squarrosum* (Figure 18-Figure 19) suffered loss in its photosynthetic capacity and chlorophyll content when exposed to the heat and bright light following canopy removal (Harley *et al.* 1989), although this may have been strictly a light response. *Sphagnum fimbriatum* (Figure 20) responded in very different ways from *S. magellanicum* (Figure 21) to changes of temperature (Koskimies-Soininen & Nyberg 1987, 1991). When *Sphagnum* species [*S. austinii* (Figure 9), *S. fuscum* (Figure 10), *S. rubellum* (Figure 11), *S. papillosum* (Figure 12), *S. lindbergii* (Figure 13), *S. tenellum* (Figure 14), and *S. pacificum* (Figure 15)] were compared to other boreal bryophytes, they exhibited lower temperature thresholds than did *Pleurozium schreberi* (Figure 8) or *Racomitrium lanuginosum* (Figure 7) (Asada *et al.* 2003). These differences often relate to habitat in ways that are obvious, such as hummock vs hollow. Despite the tolerance for heat in some *Sphagnum* taxa, winter growth was important for these species.

Figure 21. *Sphagnum magellanicum* hummock, a species that responds differently to elevated temperature from *S. fimbriatum* to elevated temperature. Photo by Michael Lüth, with permission.

Cryptic Species

Many more species most likely have physiological races (cryptic species, microspecies) that differ in their ability to cope with a variety of environmental differences. It is these physiological races that may some day become different species if they remain isolated from each other long enough to become reproductively isolated. Until then, they confound the ecologist by responding to environmental parameters differently.

Physiological races provide physiological differences among populations that appear to be morphologically identical, permitting them to take advantage of a wider range of ecological conditions. A number of cryptic species permit the cosmopolitan *Grimmia laevigata* (Figure 23) to survive the extremes of temperature, UV light, and desiccation in its rock habitat (Fernandez *et al.* 2006), often fully exposed to the sun where its black color can cause extremely high temperatures.

Figure 22. A green form of *Grimmia laevigata* that may also differ in physiological responses to temperature and desiccation. Photos by Michael Lüth, with permission.

Production of gametangia must be attuned to the growing season, which becomes shorter as one moves toward the poles or to higher elevations. Two species of *Pohlia* [*P. nutans* (Figure 24), *P. cruda* (Figure 25)], widely separated in the sub-Arctic and Britain, exhibited shorter maturation periods for both gametangia and

sporophytes in the Arctic and sub-Arctic than they did in Britain (Clarke & Greene 1970). One cannot rule out, however, the longer days as compensation for the shorter growing season.

Ecosystem Relationships

Even within a small geographic region, **aspect** (compass direction a slope faces) can have significant effects on the microclimate. On the Cushetunk Mountain of New Jersey, USA, the south slope experiences heavy shade with a nearly isothermal air temperature at 2 m (Cantlon 1953). Under light shade, in small openings, and during the leafless season, this same 2 m in height experiences sharp changes in temperature, with the highest daytime temperatures being near the ground. The north slope, on the other hand, has its lowest temperatures near the ground in all seasons. The greatest differences between the two slopes are in the 5 cm zone above the ground, where soil bryophytes would grow. Furthermore, the greatest vegetation differences between the two slopes were seen in the bryophyte layers, with the fewest between tree layers.

Altering Ecosystems

Bryophytes play a significant role in their ecosystems in altering soil temperatures. Serving as insulation, they keep the soil cooler in summer and warmer in winter. Dark-colored soil serves as a heat-absorbing body, but covered by a moss mat, that soil is protected from the direct radiation that could raise its temperature. In other words, bryophytes buffer the soil temperature (Figure 26).

Figure 26. Effects of moss mat on soil temperature. Modified from Richardson 1958.

Especially in northern climates, bryophytes may be instrumental in altering soil temperatures and retarding nutrient turnover, *i.e.*, serving as ecosystem engineers (Eckstein 2000). Not only do they slow the rate of turnover through their insulating effect, but they retard it through their contributions of organic acids and low nutrients that discourage the growth of decomposer microorganisms.

Mosses themselves are very resistant to decomposition, whereas grasses are among the highest (Hobbie 1996). Therefore, any climate change that favors the growth of mosses will reduce the availability of stored nutrients, whereas their decrease will accelerate nutrient turnover and release more carbon to the atmosphere.

Disturbed Habitats

Liverworts are often colonizers of disturbed habitat such as flood plains, where they are subjected to very high temperatures as the soil dries. Genera such as *Riccia* (Figure 27) can withstand temperatures of more than 80°C dry and up to 50°C wet (Bolk 1984).

Figure 27. *Riccia ciliata*, a drought tolerant species of disturbed habitats. Photo by Michael Lüth, with permission.

Grassland

Grasslands generally do not have many bryophyte species, but some taxa may be relatively abundant there. Some grasses can buffer temperatures and hold moisture near the ground by providing a canopy.

In a study of limestone grasslands in the southern Pennine Hills of the United Kingdom, Bates *et al.* (2006) subjected bryophytes to 3°C winter warming. Responses were relatively minor. Drought was the greatest problem, with total bryophyte cover and cover of *Calliergonella cuspidata* (Figure 28) and *Rhytidiadelphus squarrosus* (Figure 29) responding negatively. *Fissidens dubius* (Figure 30) increased in drought-simulated plots. Winter warming caused *R. squarrosus* and *Lophocolea bidentata* (Figure 31) to decrease, along with overall species richness, but *Campyllum chrysophyllum* (Figure 32) increased.

Figure 28. *Calliergonella cuspidata* at Swallow Falls, Wales, a species that experiences reduced cover when experiencing drought. Photo by Janice Glime.

Figure 31. *Lophocolea bidentata*, a species that decreased in the United Kingdom with winter warming. Photo from <www.aphotofauna.com>, with permission.

In a different grassland study, Ingerpuu *et al.* (2005) found rather different results. They planted typical forbs [*Trifolium pratense* (Figure 33), *Festuca elatior* var. *pratensis* (Figure 34), *Prunella vulgaris* (Figure 35)] in pots with either of two bryophyte species [*Brachythecium rutabulum* (Figure 36), *Rhytidiadelphus squarrosus* (Figure 37)]. Using four different densities of tracheophytes, they found that bryophyte cover increased with tracheophyte density, presumably due to creation of more favorable temperatures.

Tropics

Within a given tropical ecosystem, temperature ranges are less extreme than in most other regions of the world. This homogeneity of temperature makes water and light availability of paramount importance to distributions of many species. But loss of energy to respiration at frequent

high temperatures can be severe. In aquatic habitats, where bryophytes may remain hydrated despite high temperatures, few temperate aquatic taxa are able to survive.

Greater temperature variation is seen when one compares the lowlands with the montane areas. In the tropical areas of Pernambuco State, Brazil, the submontane forest is more favorable for bryophyte growth than is the lowland forest (Cavalcanti Porto 1992). This can be attributed to the lower temperatures of the higher elevations, coupled with additional moisture that results from condensation, despite the lower actual precipitation at the higher elevation. These cooler, more moist conditions favor considerably greater bryophyte diversity than can be found in warmer lowlands.

Polar and Alpine

Polar and alpine regions maintain cool temperatures favorable to C_3 plants such as bryophytes throughout the growing season. Even on days that may exceed temperatures favoring net carbon gain, most of the day is generally cool enough to favor fixation over respiration. Such temperature conditions, when coupled with sufficient moisture, are highly favorable to the growth of bryophytes.

The dominant bryophytes [*Bryum argenteum* (Figure 38), *B. pseudotriquetrum* (Figure 39), and *Ceratodon purpureus* (Figure 40)] on the Antarctic continent all are cosmopolitan and are widespread in the habitable terrain of Antarctica (Lewis Smith 1999). Each of these species predominates in its specific hydrologic zone. But the hydrologic conditions strongly influence the thermal regime for its moss dwellers. There are frequent long periods of 24-hour sunshine, during which temperatures within the moss turf remain above freezing. These long warming periods can result in more than 3.5 mm annual growth in each of these species. Despite the fact each of these species has an optimum temperature of 15°C for photosynthesis, they are able to maintain significant photosynthesis at 5°C. At 5°, 10°, and 20°C, photosynthetic rates were *B. argenteum* > *B. pseudotriquetrum* > *C. purpureus*.

Figure 40. *Ceratodon purpureus*, one of the dominant bryophytes on Antarctica. Photo by Jiří Kameníček (BioLib, Obázek), with permission.

Jonasson *et al.* (1999) predict that warming trends in the Arctic will elicit positive responses of tracheophytes under a regime of both increased warming and higher nutrient levels, causing a decline of bryophytes. In the Antarctic, however, experiments in which soils were incubated at temperatures ranging 2 to 25°C caused rapid development of algae, mosses, and lichens (Kennedy 1996). Some of the species that grew from these propagule banks at warmer temperatures were species not currently known from Antarctica. Further evidence of the importance of temperature in the Antarctic is the dense cover of bryophytes from temperate areas (e.g. *Campylopus introflexus* (Figure 41), *Marchantia polymorpha* (Figure 42), *Philonotis acicularis*) in the geothermal areas, while other areas support only sparse cover of any vegetation. Continued dominance and increased cover of bryophytes in the Antarctic will, at least initially, be sustained through bryophytic propagules in the soil bank and the near absence of sources of tracheophyte propagules.

Figure 41. *Campylopus introflexus*, a cosmopolitan moss that survives in geothermal areas in Antarctica. Photo by Jan-Peter Frahm, with permission.

Figure 42. *Marchantia polymorpha* with archegoniophores, a species that survives in geothermal areas in Antarctica. Photo by Janice Glime.

Like the polar regions, alpine areas experience extremes of temperature on a single day. On Mt. Fuji, *Racomitrium lanuginosum* (Figure 43) experiences up to 42°C temperature range in a single day, whereas differences in microhabitat permit *Grimmia elongata* (Figure 44) to experience only 26°C difference at the same time. This microhabitat difference is at least in part orchestrated by the moss itself – *R. lanuginosum* has a less dense mat than *G. elongata*, but the former experiences a small increase in storage heat that results in a large increase in its daily temperature.

Predictions of the effects of warming on the cold tundra have varied from increasing productivity of the bryophyte heath to decreasing productivity, and from increasing CO₂ loss to the atmosphere to increasing it. Johnson *et al.* (1996) found that elevated temperature alone did not change the net CO₂ storage because losses of CO₂ from respiration were offset by gains in photosynthetic uptake. However, methane (CH₄) losses are temperature-dependent and could be a substantial source of transfer from carbon sinks to the atmosphere, further amplifying global warming. Such predictions are further complicated by the availability of water and the type of vegetation.

The presence of permafrost is strongly influenced by the type of vegetation present (Camill 1999a). Changes in temperature would influence these vegetation patterns and impact the locations of permafrost and availability of surface water. Plateau regions characterized by black spruce (*Picea mariana* – Figure 45) with little *Sphagnum* and high cover of feather mosses (*Pleurozium schreberi* (Figure 8), *Hylocomium splendens* (Figure 17), and *Ptilium crista-castrensis* (Figure 46)] may change considerably in character if their underlying permafrost were to diminish. Cores in these habitats suggest that thawed aquatic habitats progress to aquatic lawn areas, then to hummock communities (Camill 1999b). Such hummock communities can form permafrost in less than 80 years, but such permafrost formation in today's landscape is unlikely due to the climate-warming trend.

Figure 46. *Ptilium crista-castrensis*, a species that is likely to diminish if the permafrost melts. Photo by Janice Glime.

Some mosses that are relatively cosmopolitan extend into the Antarctic. On a continent that is only 2% ice free, 24 species of mosses and 1 of liverworts are known (Seppelt & Ochrya 2008). One such moss, *Hennediella heimii* (Figure 47-Figure 48) finds its southern limit for sporophyte production (Figure 48) in Antarctica (Seppelt *et al.* 1992).

Lakes

Although being spared the extremes of the Antarctic terrestrial habitats, the Arctic lakes are a less than favorable habitat. They are both cold and nutrient-poor, with a short growing season (Sand-Jensen *et al.* 1999). These conditions provide the advantage of clear water to great depths, but the attenuation of light, especially red light, makes growth of bryophytes on the bottom of these lakes extremely slow. However, slow growth (~10 mm per shoot per year) is accompanied by slow decomposition, giving these bryophytes an "unprecedented" longevity, compared to other macrophytic vegetation. Because of their ability not only to tolerate these extreme conditions, but to persist for long periods of time, bryophytes are often the exclusive macrophytes in these lakes.

Seppelt (pers. comm. 7 April 2015) reports that *Ricciocarpus natans* (Figure 49) and *Riccia fluitans* (Figure 50), both floating aquatic liverworts, are common in Alaskan lakes. They survive winter under a layer of snow or encased in ice. But he points out that under the snow is actually the warmest place in the area. He supports the concept that hot dry adaptations may be the same as those for cold and dry.

Figure 50. *Riccia fluitans*, a species that can survive winter in ice or under snow. Photo through Creative Commons.

Streams

In riverbeds, strong gradients of temperature and moisture exist, providing excellent testing grounds for hypotheses related to moisture, light, and temperature. Arscott *et al.* (2000) used mosses from Alaska streams to test the hypothesis that *Schistidium agassizii* (Figure 51-Figure 52) would have greater tolerance to desiccation and that *Hygrohypnum* [*H. alpestre* (Figure 53), *H. ochraceum* (Figure 54-Figure 55)] would have greater tolerance to elevated temperatures. *Hygrohypnum* spp. not only had greater tolerance to temperatures above 20°C, but also had significantly higher photosynthetic rates at light saturation at all temperatures measured. *Schistidium agassizii*, on the other hand, had little response to increased light and was inhibited by high temperatures, but recovered rapidly from desiccation. Such studies as these indicate the importance of temperature coupled with other variables, especially light and moisture availability.

Figure 55. *Hygrohypnum ochraceum*, a species that tolerates temperatures above 20°C and higher photosynthetic rates at light saturation. Photo by Michael Lüth, with permission.

Warmer temperatures of aquatic habitats not only challenge the carbon gain of photosynthesis over carbon loss to respiration, but they can alter solubility of some contaminants. In an Arctic stream (Alaska, USA), *Hygrohypnum alpestre* (Figure 53) and *H. ochraceum* (Figure 54-Figure 55) were able to take advantage of added

phosphorus by having greater productivity, but *Schistidium agassizii* (Figure 51-Figure 52) was not (Arscott *et al.* 2000). The *Hygrohypnum* had greater tolerance to temperatures above 20°C, with significantly higher productivity at all temperatures, perhaps accounting for its greater P uptake, whereas *S. agassizii* recovered more easily from desiccation but lacked tolerance for high temperatures.

There are most likely differences among species in their response to heavy metals at different temperatures. If a plant is temperature stressed, one might expect it to be more easily damaged by heavy metals, much as humans are more vulnerable to new infections when they are already sick. Nevertheless, Claveri and Mouvet (1995) found that when *Platyhypnidium riparioides* (Figure 56) was moved from 7°C to 29°C, both control and copper-contaminated (80 g L⁻¹) mosses exhibited chlorophyll denaturation, but copper uptake kinetics did not change.

Figure 56. *Platyhypnidium riparioides*. Photo by Michael Lüth.

Peatlands

Peatlands provide a good test for temperature effects because the mosses are so abundant and they are widespread in the northern part of the northern hemisphere. Furthermore, they provide a gradient of microclimates from hollows to hummocks within the same macroclimate (Figure 57). Nicholson *et al.* (1996) examined the climatic relationship of peatlands along a north-south gradient in the Mackenzie River Basin, Canada. Surprisingly, in this system climate was secondary to surface water chemistry, pH, solute concentration, and height above water table. Among the climatic variables, temperature and length of growing season shared importance with precipitation, a major factor in height of water table. Hummock species such as *Aulacomnium palustre* (Figure 58), *Dicranum undulatum* (Figure 59), *Hylocomium splendens* (Figure 17), *Pleurozium schreberi* (Figure 8), *Polytrichum strictum* (Figure 60), *Sphagnum fuscum* (Figure 10), and *Tomenthypnum nitens* (Figure 61) had the widest ecological amplitude (Nicholson & Gignac 1995). Permafrost in northern habitats has created higher peat surfaces, permitting more hummock species to survive. Lawn and hollow species, on the other hand, have narrower ecological amplitude and are therefore less frequent in more northern peatlands due to continuously frozen hollows.

Diversity seems to depend less on climate and more on habitat heterogeneity (Vitt *et al.* 1995). Nevertheless, habitat heterogeneity (46%) and temperature (15%) explain 61% of the variation in peatland diversity in 96 peatlands of continental western Canada. Vitt *et al.* (1995) found that habitat heterogeneity, coupled with pH or temperature, can predict biodiversity in some peatland types. For example, *Sphagnum fuscum* (Figure 10, Figure 57) is a hummock species. For *Sphagnum fuscum* in southern Finland, growth was limited to the time when the temperature was above 0°C, but was further limited to times with ample moisture (Lindholm 1990) and thus would be affected by its height above the water table.

Although we tend to think of *Sphagnum* microhabitats as being defined by moisture, temperature can play an important role in competition between *Sphagnum* species. In a competition experiment among *S. fuscum* (Figure 10, Figure 57) and *S. balticum* (Figure 62) from a site in northern Sweden and *S. magellanicum* (Figure 21) and *S. cuspidatum* (Figure 62) from southern Sweden, all four species grew more in height and biomass production with an increase in temperature, using 11.2°, 14.7°, 18.0°, and 21.4°C, but bulk density decreased (Breeuwer *et al.* 2008). The hollow species *S. cuspidatum* was the least responsive. The hummock species *S. fuscum*, on the other hand, increased biomass production 13-fold from the lowest to highest temperature when in **monoculture** (only one

species in culture). *Sphagnum balticum* proved to be the better competitor against *S. magellanicum* and *S. fuscum*, but it lost its competitive advantage at the highest temperature.

Summary

Climate, and especially temperature and water availability, is the primary determinant in the distribution of bryophytes. Temperature typically defines the boundaries of distribution, but water availability defines their growth and distribution within those boundaries. The ability of a species to cope with these two parameters determines, to a large degree, the breadth of the niche for a species and is often a determining difference among species and among **physiological races (microspecies, cryptic species)**.

Studies on potential effects of global warming have provided us with much of what we know about bryophyte responses to temperature. In polar regions, specific habitats may respond differently, with bryophytes increasing where sufficient water is available, but decreasing where conditions favor tracheophytes. Bryophytes in non-polar regions will most likely increase, whereas those in warmer regions will most likely decrease.

Bryophytes experience seasonal changes in temperature yearly. These usually are accompanied by temperature and light/photoperiod changes. Responses may include concentration changes in chlorophyll and other pigments, soluble carbohydrate content, and in water content. Where daily fluctuations are extreme in the Antarctic, carbohydrate content changes little on an annual basis.

Bryophytes can play a major role in altering the soil temperature of an ecosystem, hence altering nutrient turnover rates. Their own decomposition is slowed by cold temperatures.

Disturbance often exposes bryophytes to intolerable heat, but other taxa, such as *Riccia* species, are adapted to survive in such areas. Grasslands can buffer temperatures enough to permit survival of some species. Tropical habitats are too warm for most

aquatic bryophytes, but high elevations, where it is cooler and usually moist, there may be considerable diversity. Polar and alpine regions generally favor bryophyte growth relative to tracheophyte growth, causing dominance of bryophytes in many areas. Cold Arctic and alpine lakes may be populated exclusively by bryophytic macrophytes that have very slow growth, but exceptional longevity. Cold streams favor the growth of bryophytes, whereas warm ones favor tracheophytes. Peatlands provide a wide range of moisture and temperature combinations that favor a high diversity of species within the genus *Sphagnum*.

CHAPTER 11-1

PHOTOSYNTHESIS: THE PROCESS

Figure 1. *Antitrichia curtipendula* on a good photosynthetic day in late spring. Photo by Michael Lüth, with permission.

Photosynthesis: The Productivity Engine

In **primary productivity** of plants, solar energy is transformed to biomass. Using photosynthesis, green plants convert solar energy, carbon dioxide, and water to glucose and other carbon-based compounds and eventually to plant tissue. **Gross primary productivity** is the product of that photosynthetic fixation of carbon, whereas **net primary productivity** is the carbon that is actually converted into biomass, *i.e.*, the fixed carbon that remains once one subtracts that lost to respiration. Consider it like your income. The gross value is your salary, but the net is what is left after taxes, social security, and other "maintenance" deductions. Respiration is the maintenance tax the plant must pay from its gross carbon fixation.

Productivity might be considered the measure of success of a plant. As stated by Anderson *et al.* (1996), photosynthesis provides energy, organic matter, and oxygen for nearly all biotic processes, and it is the only renewable energy source on Earth. If productivity is reduced in the presence of another species, we assume a competitive interaction that deprives the species of some needed resource. Thus, we might think of productivity as being the central issue in ecology around which all other issues revolve.

In order to understand bryophyte productivity, it is necessary to understand the differences in the bryophyte photosynthetic apparatus, especially the structure of the leaf or **phyllid**, compared to that of higher plants. I included the term phyllid here because technically, the bryophyte has no true leaves. This is because bryophytes lack lignified vascular tissue. However, few bryologists use the term phyllid, but rather have chosen to retain the term leaf, recognizing that the structure is different.

The CO₂ concentration in the atmosphere of early land plants was much higher than that found today (Raven & Edwards 2014). This would have supported much higher rates of photosynthesis than the current ones. Since those early times, bryophytes have evolved, adjusting to drastic climatic changes, "surviving and thriving through an incredible range of climatic and environmental variation" (Hanson & Rice 2014). Even some of the early growth forms of bryophytes are still present today, whereas many other groups of early land plants lack any presence today.

Early Studies

Much of our basic knowledge about the process of photosynthesis was learned through studies including bryophytes. In 1910, Blackman and Smith published their

work on effects of CO₂ concentration on photosynthesis and respiration, including *Fontinalis antipyretica* (Figure 2) in the study. In fact, *F. antipyretica* was included in a number of early landmark studies (Plaetzer 1917; Harder 1921, 1923). One of the most important but overlooked of these early studies on bryophytes is the one by Bode (1940) in which he described a kind of respiration that occurred in the light and that was different from that occurring in the dark. He further described that the greatest respiration occurred in blue light and the greatest photosynthesis in red light. Dilks (1976) further elaborated on this **photorespiration** in bryophytes in a study of many species, demonstrating a lower rate of ¹⁴CO₂ loss in light compared to dark that he attributed to partial reassimilation of the ¹⁴CO₂ produced, a partial inhibition of dark respiration by light, or a low rate of glycolate synthesis and oxidation. We now know that photorespiration typically is greater than dark respiration in **C₃ plants** (see below), and that dark respiration is suppressed in the light, and during the day it occurs mainly in darkened organs of plants, like roots.

Figure 2. *Fontinalis antipyretica*, the subject of many classical studies on photosynthesis. Photo by Michael Lüth, with permission.

In the higher plants, especially seed plants, photosynthesis occurs inside a complex leaf structure that both limits and protects its activity. Only the internal structures of the leaf are involved in photosynthesis, and these are protected by an epidermis on each surface. For photosynthesis to occur in these tracheophyte plants, CO₂ must enter the leaf, which it does through openings called **stomata**. This imposes a limit based on the capacity for holding gases and the speed with which the stomata can open to admit the gases. Furthermore, when the leaf begins to dry, the stomata close, thus ending the entry of new CO₂.

The tracheophyte method of obtaining water can both limit and enhance tracheophyte photosynthesis. It means that the plant can obtain its water from the soil after the dew has gone and the rain has stopped. On the other hand, replacement of water, and its contained nutrients, is a somewhat slow process that can take minutes to hours following the addition of water by rainfall.

Bryophytes do not have these restrictions. The small size of a bryophyte leaf creates some fundamental differences in the way they achieve photosynthesis. Their

ability to dry to 5-10% of their wet weight (Proctor 1990) and recover is unrivaled by most tracheophytes. Their one-cell-thick leaves have no epidermis, little or no waxy cuticle, and no stomata. Therefore, the photosynthetic cells are directly exposed to light for photosynthesis and have direct access to atmospheric gases. They furthermore have no midrib with lignified vascular conduction, but rather usually absorb their water directly through all their leaf surfaces. This means that they are able to respond to the addition of water from dew or fog and can immediately take advantage of a brief rainfall, but they have limited means of obtaining additional water from the soil to replenish that which is lost to evaporation and use. Nevertheless, many bryophytes do have a **costa**, which is the moss version of a midrib, and which at least in some species can conduct limited amounts of water and most likely other substances as well. The role of the costa and other water-responsive cells has been discussed in the chapter on water.

With these gross morphological structures in mind, we can examine the internal workings of the photosynthetic organ, the leaf. It is here that most of the chlorophyll resides and it is here that most of the photosynthesis occurs.

Structural Adaptations

Based on the foregoing discussion of tracheophyte leaves, one might assume that a plant like *Marchantia polymorpha* (Figure 3) would be well adapted to photosynthesis. It has a thallus with tissue arranged like the spongy mesophyll of a maple leaf, abundant air chambers, pores surrounded by tiers of cells that function somewhat like guard cells, and a cuticularized epidermis (Figure 4) (Green & Snelgar 1982). But when compared to the functioning of a solid thallus in *Monoclea forsteri* (Figure 5), *Marchantia foliacea* (Figure 6) achieves little photosynthetic advantage over the simple *Monoclea forsteri*. Furthermore, although the chambering of *Marchantia* provides an advantage for water relations, *Monoclea* still seems to have the photosynthetic advantage in very moist habitats. Woodward (1998) asked if plants really need stomata, and answered this question by citing evidence that the number per unit area has increased in geologic time as the CO₂ concentration has decreased. It would be interesting to see if the number of pores in thalli of the **Marchantiaceae** is affected by CO₂ concentration.

But our suggestion that internal spaces and an epidermis should benefit photosynthesis is not all wrong. Some bryophytes do benefit from added internal spaces that contribute to surface area for gas exchange. In

Polytrichum commune (Figure 7), leaf lamellae (Figure 8) increase the surface area 2.4-fold (Thomas *et al.* 1996). This seed plant "want-to-be" also has a waxy cuticle to prevent water loss and repels water that could block the movement of CO₂ into the leaf. Proctor (2005) demonstrated that this arrangement of lamellae seemed to protect these mosses from non-photochemical quenching that occurred in other mosses in exposed habitats. He showed that unistratose leaves are limited in their photosynthetic output by their CO₂ diffusion resistance, especially at high light levels. Mosses in the **Polytrichaceae**, on the other hand, enjoy more than a six-fold increase in leaf area, reducing the CO₂ diffusion constraint. The importance of these lamellae can be illustrated by *Atrichum undulatum* (Polytrichaceae; Figure 9-Figure 12) compared to non-polytrichaceous mosses (Krupa 1984). Leaves of this species had a higher photosynthetic rate per cm² than did leaves of *Rhizomnium punctatum* (Figure 13) or *Funaria hygrometrica* (Figure 14) with single-layered leaves. And the tiny *Aloina rigida* (Figure 15-Figure 16) with succulent, lamellose leaves had a photosynthetic rate nearly 4.5 times that of *Funaria hygrometrica*, a moss of similar size.

Some species of *Polytrichum* have an additional adaptation similar to that of *Aloiina rigida* (Figure 15-Figure 16). They have colorless margins that fold over the leaf lamellae (Figure 20). In alpine populations of *Polytrichum juniperinum* (Figure 17-Figure 20), this margin forms a greater part of the leaf than in the woodland populations. Bazzaz *et al.* (1970) suggested that this is an adaptation to the alpine habitat. This interpretation is consistent with the higher light saturation intensity for the alpine population (10,000 lux) compared to that of the woodland population (5000 lux).

Mosses can actually change the structure of their chloroplasts in response to different **wavelengths** of light. In *Funaria hygrometrica* (Figure 14), the chloroplasts responded to red light by an increase in area and a decrease in thickness, shrinking in volume by about 10% (Zurzycki 1974). In low intensity of blue light, the effects were similar, but in high levels of blue light, there was a strong reduction of the surface area and a 35% shrinkage in volume. Both effects were reversible. In *Marchantia polymorpha* (Figure 3-Figure 4), far-red light at the end of the photoperiod caused 20-30% drop after only a 5-minute exposure following 8-hour days for one week (Fredericq & DeGreef 1968). Longer days caused less reduction.

CO₂ concentration can also modify the size and shape of chloroplasts (Bockers *et al.* 1997). In *Marchantia polymorpha* (Figure 3-Figure 4), high CO₂ concentrations caused a modification of the chloroplast shape, and the cell had ~70% more chloroplasts. However, the chlorophyll content differed little, indicating that the greater number of chloroplasts exhibited less chlorophyll per chloroplast. The cells themselves were ~37% smaller in the high (2.0%) CO₂ concentrations compared to the 0.4% concentrations. These changes did not imbue the cells with any greater photosynthetic capacity or efficiency. Furthermore, the CO₂ levels are very high compared to an atmospheric concentration of less than 0.04%, so the responses may be somewhat meaningless. Sonesson *et al.* (1992) reported only 0.04-0.045% CO₂ around *Hylocomium splendens* (Figure 21) plants growing on soil.

Figure 21. *Hylocomium splendens*, a plant that grows in a relatively low CO₂ environment on the forest floor. Photo through Wikimedia Commons.

Despite their small size, bryophytes respond to light much as do tracheophytes. Bryophytes increase their chlorophyll content as the light intensity decreases and increase their mean leaf area as light intensity increases (Sluka 1983).

Water is clearly a factor that limits photosynthesis. *Sphagnum* (Figure 22-Figure 26) has a unique way of avoiding a water problem most of the time, making photosynthesis possible long after other bryophytes are too dry (Rice & Giles 1996). It maintains its own reservoir. Each photosynthetic cell is in contact with a large **hyaline** (transparent) cell (Figure 23, Figure 25-Figure 26) that holds water. When Rice (1995) compared three species pairs, the submerged member of the pair always had greater allocation to photosynthetic tissue and greater relative

growth rates than did the non-aquatic member of the pair. This can be accomplished by allocating more tissue to photosynthetic cells rather than to hyaline cells and by increasing the light-harvesting chlorophyll proteins.

Figure 22. *Sphagnum papillosum*, a sun-dwelling hummock species. Photo by David Holyoak, with permission.

But obtaining CO_2 is especially problematic in the aquatic environment. In *Sphagnum*, reduction in the water-filled hyaline cells (Figure 23-Figure 26) helps. Additional adaptations include larger, thinner branch leaves with fewer per length of branch, reducing the boundary layer resistance to CO_2 diffusion (Rice & Schuepp 1995). Aquatic photosynthetic cells have more surface exposure than those in leaves of above-water plants. A biochemical adaptation complemented this structural adaptation by a shift that favors light-reaction proteins (Rice 1995). Proctor *et al.* (1992) demonstrated that the Δ^{13} for *Sphagnum* photosynthetic cells with hyaline enclosure on both sides (compare Figure 26 to Figure 27) is significantly lower than for other terrestrial species, being consistent with the greater resistance to CO_2 uptake with increasing submersion.

Bryophytes have a variety of ways to trap air within or among the leaves. Interestingly, some of our evidence comes from fossils in amber (Robinson 1985). Fossil *Octoblepharum* (Figure 28-Figure 29) shows trapped air in the leaves. Live *Sphagnum* (Figure 22-Figure 27), on the other hand, does not have air trapped in the hyaline cells – or does it? *Leucobryum* (Figure 30-Figure 33) has large air bubbles in its hyaline cells, with bubbles that actually extend through many cells. Unlike *Octoblepharum*, *Leucobryum* leaves develop air pockets as they enlarge, but non-functional older leaves lose their air-entrapment ability. Furthermore, older leaves at the base of the plant use the hyaline cells to hold water.

One possibility to consider is that as air bubbles from photosynthesis form on the surfaces of the plants, CO₂ may enter the bubble by diffusion, much like the diving bell or the plastron used by some aquatic insects. But it would seem this would provide very small amounts indeed.

Photosynthetic Apparatus – the Chloroplast

Chloroplast Structure

Bryophytes, like tracheophytes and green algae (among others), have **chlorophylls a** and **b** and these chlorophyll molecules are organized within a complex structure called the **chloroplast**. These two photosynthetic pigments are supplemented by the **chlorophyll antenna system** of **xanthophylls** and **carotenes** that serve to trap light energy and transfer it to the chlorophyll *a* action center, all within the **chloroplast**. In all plants and green algae, **starch** is stored within the chloroplast, but it will disappear after as little as 24 hours in darkness (Raven *et al.* 1992).

Chlorophyll in all plants resides in special double-membrane-bound structures called **chloroplasts** (Figure 34). These chloroplasts have within them stacks of membrane-bound structures called **thylakoids**, and it is within these thylakoid membranes and the surrounding fluid, the **stroma**, that the photosynthetic reactions take place (Figure 35).

Figure 34. Cells of *Fontinalis antipyretica* showing chloroplasts in cells. Photo by Janice Glime.

Figure 35. Structure of a single chloroplast. The chlorophyll molecules occur in the thylakoid membranes. Drawn by Janice Glime.

Associated Proteins

Associated with the chlorophyll molecules are proteins, known as **light-harvesting chlorophyll proteins (LHCP)**. There is some evidence that the protein association with chloroplasts in bryophytes might be unique. Aro (1982a) demonstrated differences in the protein complexes associated with photosystems I and II, using *Ceratodon purpureus* (Figure 36), *Pleurozium schreberi* (Figure 37), and *Marchantia polymorpha* (Figure 3-Figure 4). This is suggested by their ability to survive desiccation and freezing much more easily than plastids of tracheophytes (Tuba 1985). Further evidence came from their limited solubility in acetone when dry, but ability to dissolve much more easily if rehydrated for 15 seconds first (personal observation). Genetic evidence also supports the presence of chlorophyll proteins that are unique to bryophytes. *Marchantia polymorpha* has an *frxC* gene that codes for the sequence for an ATP-binding, Fe-protein that is a bacterial type not present in the tobacco chloroplast (Fujita *et al.* 1989). Furthermore, Neuhaus *et al.* (1990) found only 94% sequence conservation of I polypeptide of Photosystem II between *Marchantia* and mustard (*Sinapis alba*, Figure 38).

Figure 36. *Ceratodon purpureus*, a species with protein complexes associated with PS I and PS II. Photo by Michael Lüth, with permission.

Figure 38. *Sinapis alba*, a species with photosystem II polypeptides that differ from those of *Marchantia*. Photo by Ariel Palmon, through Creative Commons.

Aro (1982b) compared bryophyte chlorophyll protein composition to that of the floating aquatic plant duckweed (*Lemna*, Figure 39) and cucumber (*Cucurbita*, Figure 40). Both the moss *Ceratodon purpureus* (Figure 36) and the thallose liverwort *Marchantia polymorpha* (Figure 3- Figure 4) had more chlorophyll associated with the light-harvesting chlorophyll protein (LHCP) complexes and fewer with reaction center complexes than did the two tracheophytes. Harrer (2003) supported that observation with his study on *Marchantia polymorpha*, demonstrating that more than 50% of the PS II particles from *Marchantia polymorpha* carry one or two additional masses in the protein complex. So it is possible that bryophytes may have both differences in their kinds of chlorophyll protein, and have different amounts associated in different ways, giving their chlorophyll unique protection.

Fatty Acids

Valanne (1984) and Gellerman *et al.* (1972) have suggested that the C₂₀ polyunsaturated fatty acids increase the ability of mosses to adapt to extreme conditions. Those taxa living in shaded habitats have larger grana and contain even more polyunsaturated fatty acids than do sun-adapted species (Karunen & Aro 1979). It appears that polyunsaturated lipids play a role in maintaining structure

and thermal stability of chloroplast membranes (Hugly *et al.* 1989), but little has been done to help us understand this relationship in bryophytes. Current studies on the genome and its function in the moss *Physcomitrella patens* (Figure 41) and liverwort *Marchantia polymorpha* (Figure 3- Figure 4) (*e.g.* Ikeuchi & Inoue 1988) are likely to help us understand these roles in the near future.

Figure 41. *Physcomitrella patens*, a species that permits us to test gene function. Photo by Michael Lüth, with permission.

Need for Light

Color Retention in the Dark

Light is required to make chlorophyll. In the dark, chlorophyll can degrade, and dry mosses can lose chlorophyll in the light. Hence, when bryophytes first encounter light after a prolonged period of darkness, one might expect them to be pale and have reduced photosynthetic activity. But Valanne (1977) found that protonemata of *Ceratodon purpureus* (Figure 36) that had been in darkness for 1-2 months were able to produce starch within 30 minutes. Maximum photosynthesis, however, was not reached until the second day, providing enough time for the development of light-type chloroplasts. PS I had much higher activity in the dark-adapted protonemata than in that grown in light, whereas the activity of PS II was greater in light-grown protonemata.

Chloroplast Replication

Chloroplast replication requires light. Hahn and Miller (1966) demonstrated this in *Polytrichum commune* (Figure 7) by showing that in the light chloroplasts replicated, but in the dark, chloroplasts would only replicate when sucrose was present in the medium. Rather, in continuous dark, and when given 15 minutes of far-red light per six hours, chloroplasts became larger. Electron micrographs revealed that the increase in size was due at least in part to the synthesis and degradation of starch.

Photosynthetic Capacity

In general, bryophytes are considered to have lower photosynthetic capacity than that of tracheophytes (Martin & Adamson 2001). In support of this, Rao *et al.* (1979) demonstrated that the Hill reaction (light-driven splitting of water in PS II) rates of three marchantialian liverworts are lower than those of seed plants. But Martin and Adamson (2001) have challenged this view. They too found that, when expressed on the basis of dry weight, net CO₂ uptake

was considerably lower in mosses than in the six tracheophytes they studied. But the differences disappear when expressed on the basis of chlorophyll content. It would appear that the photosynthetic capacity of moss chloroplasts at light saturation and normal CO_2 levels is as great as that of tracheophytes.

One factor to be considered in the photosynthetic rate of bryophytes is their photosynthetic enzyme, ribulose biphosphate carboxylase/oxidase (RUBISCO). In a study by Rintamäki and Aro (1985) on a wide range of plant species, it was the moss *Ceratodon purpureus* (Figure 36), along with the grass *Deschampsia flexuosa* (Figure 42), that had the highest ratios of activity of RuBP carboxylase/oxidase to RuBP oxidase, suggesting yet another adaptation for a high photosynthetic capacity. But *Ceratodon purpureus* is a sun moss and is only one example. It is premature to generalize from this single study.

Figure 42. *Deschampsia flexuosa*, a grass that has one of the highest ratios of activity of RuBP carboxylase to RuBP oxidase, as did *Ceratodon purpureus*. Photo by Kelly O'Donnell, through Creative Commons.

Antenna Pigments

The actual trapping of light energy results in a rapid spin on one of the electrons of a pigment. But this initial pigment need not be chlorophyll. Rather, it can be one of the pigments (chlorophyll *b*, carotene, xanthophyll) in the **chlorophyll antenna system** (Figure 43). These pigments occur in the thylakoid membranes within the chloroplasts and are part of Photosystem I and Photosystem II. This extra spin puts the electron in a higher energy state than before and the electron spins off the pigment molecule and is transferred to another and another of the pigment molecules until it reaches the reaction center, chlorophyll *a*.

The antenna pigments permit the chloroplasts to absorb energy in the regions where chlorophyll *a* has little ability to absorb. The two dimers of chlorophyll *a* absorb best at 680 and 700 nm and very poorly between 450 and 650 nm (Martínez Abaigar & Núñez Olivera 1998). Chlorophyll *b* helps to absorb in this latter range. The carotenoids extend the absorption spectrum farther into the 450–490 nm range. Furthermore, **zeaxanthin**, a xanthophyll pigment, can deactivate singlet chlorophyll, and other carotenoids can deactivate both triplet chlorophylls and singlet oxygen that result from excess light energy. Thus, these serve as protective mechanisms against photo-inhibition and protect the chlorophylls from photooxidation, as discussed below.

Figure 43. Antenna pigments such as carotene, xanthophyll, and chlorophyll *b* in Photosystem I and Photosystem II transfer light energy to chlorophyll *a* within a single thylakoid membrane. Excitation of electrons in chlorophyll *a* occurs in both photosystems. Modified by Janice Glime from Goodwin & Mercer 1983 and Jensen & Salisbury 1984.

The most frequent of the antenna pigments in bryophytes include α - and β -carotene, lutein, zeaxanthin, violaxanthin, and neoxanthin (Taylor *et al.* 1972; Schmidt-Stohn 1977; Czezcuga 1980, 1985; Czezcuga *et al.* 1982; Huneck 1983; Farmer *et al.* 1988; Boston *et al.* 1991). Because these antenna pigments include yellow, orange, and sometimes red, as well as the different green of chlorophyll *b*, they are able to trap energy from different wavelengths of light instead of just the red that excites chlorophyll *a*. This is advantageous for the many species that inhabit locations that are low in red light. Among ~60 species tested, pigment types differ little between aquatic and terrestrial habitats (Martínez Abaigar & Núñez Olivera 1998). Among the exceptions is the unusual pigment **aurioxanthin** found in the obligate aquatic *Fontinalis antipyretica* (Figure 2) (Bendz *et al.* 1968).

Heber *et al.* (2005) demonstrated that **zeaxanthin** was necessary for the dissipation of light energy in hydrated mosses. They suggest that only a few molecules of zeaxanthin are needed to suppress the excess energy at the dissipation centers in the antenna system of Photosystem II. Desiccation-dependent quenching, on the other hand, does not require zeaxanthin and apparently is a property of the reaction center complex of Photosystem II.

Many more antenna pigments actually exist among the bryophytes. In a single study on only ten species of liverworts, Czezcuga (1985) found nineteen carotenoids. In addition to the seven named above, he found lycopene, lycoxanthin, α -cryptoxanthin, β -cryptoxanthin, lutein epoxide, β -carotene epoxide, antheraxanthin, α -doradexanthin, adonixanthin, mutatoxanthin, rhodoxanthin, and apo-12'-violaxanthin. All but three of these pigments were already known from mosses. Of the three new ones, α -cryptoxanthin was known in algae, lichens, and higher plants, α -doradexanthin is common in Crustacea and fish, and rhodoxanthin is known in club mosses, horsetails, ferns, conifers, and some species of the pondweed, *Potamogeton*, a flowering plant (Figure 44).

Figure 44. *Potamogeton gramineus* showing a red pigment, possibly rhodoxanthin. Photo by Pellaea, through Creative Commons.

Type of Photosynthetic Pathway

Among the tracheophytes, the **C₃ photosynthetic pathway** is most common, but some have a **C₄ pathway**, and some have a **CAM pathway**, neither of which seems to be available to bryophytes. These pathway names are based of the initial placement of the CO₂ when it is taken into the plant. The **C₃ pathway** is assumed to be the primitive pathway, known from algae and bryophytes, as well as tracheophytes, in which the carbon of CO₂ is fixed into a 3-carbon compound in its initial fixation within the plant. In tracheophytes, photosynthesis occurs in the mesophyll tissue of the leaf. There are no special adaptations for internal storage of the carbon for later use in photosynthesis – it must be used immediately and thus is placed immediately into the photosynthetic pathway to form **PGA** (phosphoglyceric acid; Figure 45), the 3-C compound. This immediate use is apparently characteristic of all bryophytes. This distinction of immediate use versus later use in photosynthesis is best understood by comparison with the other two pathways.

Figure 45. Melvin Calvin and associates found that the carbon from CO₂ is placed into RuBP to make a 6-carbon compound that immediately splits to form two molecules of 3-phosphoglycerate (PGA). This is the first step of the Calvin cycle and is the carbon fixation step for C₃ plants.

The **C₄ pathway** in tracheophytes permits storage of carbon from CO₂ into a 4-carbon compound such as malic or oxalic acid in the mesophyll, to later be transported to the bundle sheath around the vascular tissue, where CO₂ is released and put into the photosynthetic pathway in the bundle sheath. The advantage is that stomata of a C₄ plant can remain open for a short time, CO₂ can be stored rapidly, and photosynthesis can continue for an extended period of time after the stomata are closed. Since the stomata are the major source of water loss from the plant, this is a tremendous savings in water loss and permits the plant to be more productive in dry regions than C₃ plants.

The **CAM pathway** is similar except that stomata open at night instead of daytime as in other plants. Since photosynthesis cannot occur at night, CAM plants survive because carbon from CO₂ is stored in malic acid or other C₄ compound in the mesophyll for use in the daytime. However, in the CAM plant, the CO₂ is released in the mesophyll and photosynthesis takes place in the mesophyll tissue. Table 1 compares many of the structural and physiological attributes of plants with these three pathways.

Each of these has certain ecological advantages and disadvantages (Table 1). The C₃ pathway requires the least energy as ATP and is thus the most energy-efficient. The others, however, impart ecological advantages in hotter and/or drier climates and are more efficient in use of CO₂.

Table 1. Comparison of tracheophyte plants with different types of CO₂ fixation. From Larcher 1983, compiled from many authors.

Characteristic	C ₃	C ₄	CAM
Leaf structure	Laminar mesophyll, bundle sheaths	Mesophyll radially around chlorenchymatic bundle sheaths (Kranz-type anatomy)	Laminar parenchymatic arranged mesophyll large vacuole
Chlorophyll a/b	~3:1	~4:1	<3:1
CO ₂ -compensation concentration at optimal temperature	30-70 µl l ⁻¹	<10 µl l ⁻¹	in light: 0-200 µl l ⁻¹ in dark: <5 µl l ⁻¹
Primary CO ₂ acceptor	RuBP	PEP	In light: RUBP in dark: PEP
First product of photosynthesis	C ₃ acids (PGA)	C ₄ acids (malate, aspartate)	In light: PGA in dark: malate
Photorespiration	Yes	Not measurable	Yes
Photosynthetic depression by O ₂	Yes	No	Yes
CO ₂ release in light (apparent photorespiration)	Yes	No	No
Net photosynthetic capacity	Slight to high	High to very high	In light: slight in dark: medium
Light-saturation of photosynthesis	At intermediate intensities	No saturation at highest intensities	At intermediate to high intensities
Temperature optimum	10-25°C	25-35°C	20-35°C?
Redistribution of assimilation products	Slow	Rapid	Variable
Dry-matter production	Medium	High	Low

In fact, some bryophytes are capable of photosynthesis at temperatures below freezing, and some species of *Fontinalis* (Figure 2) (and probably others) have a temperature optimum near 5°C (Glime 1987a, b). Their light saturation point is less than full sunlight, and they are capable of net photosynthetic gain at very low light intensities (such as caves and deep water). These characteristics are unknown in C₄ plants. These capabilities greatly extend the growing season for mosses and undoubtedly contribute to their success in ecosystems such as the tundra and boreal forest.

In the aquatic system, CAM photosynthesis seems to be an adaptation of some tracheophytes to the low CO₂ concentration, permitting them to gain CO₂ at night when most of the algae and other aquatic plants are respiring CO₂. The cooler atmosphere may likewise contribute to a reduced loss of the CO₂ from the body of water. It is amazing to me to learn that the C₃ *Fontinalis antipyretica* (Figure 2) has a higher carbon uptake rate than does the CAM plant *Isoetes bolanderi* (Figure 46) (Sandquist & Keeley 1990). Does this relate to its lack of cuticle and epidermis, permitting the immediate availability of CO₂ at any time of the day regardless of the light intensity? Perhaps a storage mechanism is not needed if uptake is always possible.

Figure 46. *Isoetes bolanderi*, a CAM plant that sequesters CO₂. Photo by Steve Matson, through Creative Commons.

C₃ Evidence

Several studies have attempted to locate a pathway other than the C₃ pathway among bryophytes, examining the most likely deviants, the aquatic and xerophytic taxa. Thus far, there is no conclusive evidence for any pathway other than C₃. It appears that bryophytes have all the earmarks of C₃ plants, exhibiting higher CO₂ compensation points than those of tracheophytes (Rudolph 1990). Since C₃ plants are unable to sequester CO₂ and have only RUBISCO to help incorporate it into their photosynthetic pathway, they require higher concentrations of CO₂ than plants with C₄ or CAM pathways.

Raven *et al.* (1998) have reviewed the evidence for the C₃ pathway in bryophytes. Biochemically, bryophytes are C₃ plants, as far as is known. Their first carboxylation reaction accounts for more than 95% of the CO₂

incorporation. The ratio of *in vitro* RUBISCO carboxylase activity to that of *in vitro* PEP carboxylase activity is far higher than that known for C₄ or CAM plants (Rintamäki & Aro 1985; Farmer *et al.* 1986; Keeley *et al.* 1986). There is insufficient PEP carboxylase activity to support the observed photosynthetic carbon flux (Rintamäki *et al.* 1988; Madsen *et al.* 1993).

The CAM pathway can be excluded because there is no evidence of nighttime activity and there is no increase in acidity or accumulation of malic acid in the dark (Keeley & Morton 1982; Keeley *et al.* 1986; Raven *et al.* 1987).

Raven *et al.* (1987) then evaluated the physiological evidence, which is primarily based on the CO₂ compensation point. These data support the relatively high CO₂ compensation point of a C₃ plant (Fock *et al.* 1969; Ruttner 1947; Allen & Spence 1981; Raven *et al.* 1987).

Further evidence to support that bryophytes use a C₃ pathway comes from the ¹³C/¹²C discrimination values. Although there are difficulties with boundary layer resistance, especially in aquatic bryophytes, overall these values are consistent with a C₃ pathway (Raven *et al.* 1987, 1994; Keeley & Sandgren 1992; Rice & Giles 1994, 1996; Smith & Griffiths 1996a, b).

CO₂-concentrating Mechanisms – Exceptions to C₃?

Although bryophytes are considered C₃ plants (Rundel *et al.* 1979, James 1981; Raven *et al.* 1998), certain evidence makes us wonder if there are other variations among them. *Fissidens cf. manateensis* (see Figure 47) and *Fontinalis antipyretica* (Figure 2) seem to have some sort of CO₂-concentrating mechanism (Salvucci & Bowes 1981; Bowes & Salvucci 1989; Raven *et al.* 1998). CO₂-concentrating mechanisms permit the plant to obtain CO₂ at a higher concentration than conditions would normally allow for a C₃ plant. This can be especially important for plants living in aquatic habitats with pH values in the range where the equilibrium shifts from CO₂ to bicarbonate or carbonate.

Figure 47. *Fissidens grandifrons*, a species that might have some sort of CO₂-concentrating mechanism that permits it to live in alkaline water. Photo by Janice Glime.

Raven (1991) summarized the ecological relationships of CO₂-concentrating mechanisms in plants. He found them to be negatively correlated with areas of CO₂ enrichment caused by respiration of organic carbon that had been produced elsewhere, such as the respiration of

bacteria and other organisms in sediments. Less pronounced relationships seem to exist with low temperatures during the growing season, low pH external to the plant, and rapid water movement over the plants that could replace the CO_2 as it is used in photosynthesis.

When growing submerged in Florida, USA, winter conditions ($12^\circ C$, 10 h day length), *Fissidens cf. manateensis* (see Figure 47) had a typical C_3 compensation point (Salvucci & Bowes 1981). However, when grown in Florida summer conditions ($30^\circ C$, 14 h day length), it had the ability to concentrate CO_2 . This concentrating ability can be accomplished either by concentrating CO_2 around the RUBISCO to a greater concentration than that of the medium, using a C_4 -like mechanism, or by using active transport of inorganic carbon across the membrane.

But *Fissidens cf. manateensis* (see Figure 47) is not the only aquatic moss that appears to have some sort of CO_2 -concentrating mechanism. Peñuelas (1985) found two more aquatic mosses [*Fissidens grandifrons* (Figure 47) and *Fontinalis antipyretica* (Figure 2)] that could carry out net photosynthesis in high inorganic carbon concentrations with high pH values that should have shifted the CO_2 – bicarbonate equilibrium toward the bicarbonate or carbonate end, providing less free CO_2 than that required to reach the compensation point. Several possibilities exist. As suggested earlier, there might be a mechanism for moving this inorganic carbon across the membrane by active transport. Or the moss could use its carbonic anhydrase (Steeman Nielsen & Kristiansen 1949; Arancibia & Graham 2003) externally to convert the HCO_3^- to free CO_2 . I suggest a third possibility, that H^+ ions available from cation exchange sites might be sufficient to lower the pH and shift the equilibrium toward CO_2 at the moss surface, despite the pH being too high elsewhere in the water for that shift to occur. The latter explanation would be consistent with the observations that the CO_2 compensation point and the $^{13}C/^{12}C$ discrimination values for central and Northern European populations of *Fontinalis antipyretica*, *Fissidens rufulus* (Figure 48), *Riccia fluitans* (Figure 49), and *Ricciocarpos natans* (Figure 50-Figure 51) are consistent with a C_3 pathway (Ruttner 1947; Osmond *et al.* 1981; Allen & Spence 1981; Raven *et al.* 1987, 1994, 1998).

This concentrating mechanism, whatever its nature, could explain the presence of bryophytes in calcareous water of streams and lakes where the pH would suggest there would be insufficient free CO_2 for mosses to reach their CO_2 compensation point. And, in fact, some bryophytes of calcareous streams seem to be limited to

waterfalls where high turbulence permits gaseous atmospheric CO_2 to come in contact with the moss surface.

One of the most intriguing finds, mentioned above, is that *Fontinalis antipyretica* (Figure 2) has a higher C uptake rate from the water column than does its CAM companion, *Isoetes bolanderi* (Figure 46) (Sandquist & Keeley 1990). It appears that even aquatic bryophytes, contrasting with other aquatic macrophytes, lack or have only poorly developed CO_2 -concentrating mechanisms (Raven 1991). But what about *Fontinalis*? Steeman Nielsen and Kristiansen (1949) have demonstrated the presence of carbonic anhydrase in that genus. Is it able to concentrate CO_2 ? Can it convert bicarbonate to CO_2 , perhaps through a pH-lowering mechanism? And how should we explain the delay in carbon fixation in *Fontinalis antipyretica* (Søndergaard & Sand-Jensen 1979)? Aquatic plants like *Elodea* (Figure 52) have internal air chambers that can delay the emission of respiratory CO_2 and slow the time from uptake to the time it actually enters photosynthesis. But *F. antipyretica* has no air chambers. However, it has the lowest delay (0.2%) of the three plants tested, with *Elodea* having 8% and *Littorella* (Figure 53) having 14%. Some researchers have treated this delay in *Fontinalis* as evidence of a concentrating mechanism, but the low percent seems insignificant.

Figure 52. *Elodea canadensis*, an aquatic flowering plant species with a delay in carbon fixation. Photo by Kristian Peters, through Creative Commons.

Figure 53. *Littorella uniflora*, an aquatic flowering plant species with a delay in carbon fixation. Photo by Christian Fischer, through Creative Commons.

In a separate comparison between the aquatic moss *Leptodictyum riparium* (Figure 54) and the tracheophyte *Elodea canadensis* (Figure 52), the moss had nearly double the RuBPCase activity (11.8 vs $6.0 \mu\text{M mg}^{-1} \text{chl h}^{-1}$) of the tracheophyte, but also had approximately double the PEPcase activity (0.7 vs $0.3 \mu\text{M mg}^{-1} \text{chl h}^{-1}$) (Keeley *et al.* 1986). Keeley *et al.* concluded that it is very unlikely that *Leptodictyum riparium* can utilize bicarbonate, whereas *Elodea* has been reported to use it freely.

Figure 54. *Leptodictyum riparium*, an aquatic moss. Photo by Michael Lüth, with permission.

Bicarbonate Uptake

Aquatic tracheophytes typically are able to take in bicarbonate for use in the photosynthetic pathway (Farmer *et al.* 1986). Some aquatic tracheophytes, in particular species of *Isoetes* (Figure 46), have a CAM photosynthetic pathway that permits them to take in CO_2 at night. But in their study of 15 species of aquatic macrophytes, Farmer *et al.* found that the aquatic moss *Fontinalis antipyretica* (Figure 2) had no PEP carboxylase, took in no CO_2 at night, and used RUBISCO for its photosynthetic CO_2 fixation. Steeman Nielsen (1947) stated outright that *Fontinalis antipyretica* "is unable to utilize HCO_3^- in the surrounding water for photosynthesis." On the other hand, Harder (1921) showed that as bicarbonate concentration increased from 0.01% to 0.64%, the assimilation plus respiration of *Fontinalis antipyretica* increased from 0.66 to 3.14. Burr (1941) likewise found that *Fontinalis* was more productive in water with bicarbonate than that with CO_2 . But what does this genus use as a mechanism to get its CO_2 , especially in water with a high pH where bicarbonates or carbonates predominate? Steeman Nielsen and Kristiansen (1949) suggested that there is evidence that CO_2 enters the photosynthetic reactions in hydrated form (bicarbonate?). But how is that accomplished?

Perhaps Peñuelas (1985) has discovered the differences behind these contrasting conclusions. He demonstrated that *Fontinalis antipyretica* (Figure 2) from the River Muga in N.E. Spain was able to have a positive net photosynthesis up to a pH of 11.8-12.0 in a NaHCO_3 solution, a remarkably high pH and indicative of use of a carbon source other than CO_2 . Further support of this conclusion is that this population of *Fontinalis antipyretica* increased its photosynthetic rate when higher HCO_3^- concentrations at constant CO_2 were used. But in populations from other localities, this same researcher did

not find evidence of its use of bicarbonates, suggesting that physiological races exist. This is consistent with my observations in eastern United States that it is absent in limestone streams and streams with pH high enough to preclude free CO_2 , but in other parts of the world I have observed it growing on concrete and in alkaline streams.

Bain and Proctor (1980) tested twenty bryophytes from a variety of aquatic habitats to look for evidence of bicarbonate uptake. The ability of some bryophytes, such as *Scorpidium* (Figure 55), to live in water with high pH suggests that such a mechanism might exist. However, they found that the pH compensation points were in the range expected for C_3 plants dependent on free CO_2 for their carbon source. Only *Anthoceros husnotii* succeeded in having photosynthetic gain up to pH 9.5 in 2.0 mM $NaHCO_3$. For the others, the equilibrium clustered around pH 9.0 for 2.0 mM and 8.0 for 0.2 mM $NaHCO_3$. The four species of bicarbonate-using tracheophytes had final pH values ranging 10.1 – 10.9. As suggested above, there may be physiological races with different capabilities. The other possibility is that the mechanism for using bicarbonates may be inducible and was not sufficiently activated during the short-term lab experiments to make a difference.

Pyrenoids

The slightly elevated pH compensation point for *Anthoceros husnotii* is consistent with other data on *Anthoceros* that suggest the **pyrenoids** (proteinaceous bodies serving as nucleus for starch storage) have a role in concentrating CO_2 in some hornworts. Members of the **Anthocerotophyta** (hornworts; Figure 59) with pyrenoids [*Anthoceros* (Figure 56), *Phaeoceros* (Figure 57)] exhibit a well-developed ability to concentrate CO_2 (Raven 1997; Smith 2000). However, it appears that among land plants, only *Notothylas* (Figure 58), *Phaeoceros*, and *Anthoceros*, all members of the phylum **Anthocerotophyta**, have such a mechanism (Smith & Griffiths 2000; Hanson *et al.* 2002). When a number of bryophytes were subjected to carbonic anhydrase inhibitors, only *Phaeoceros laevis* (Figure 57), a member of **Anthocerotophyta**, exhibited reduced CO_2 affinity and its CO_2 compensation point rose from 2.5 Pa to 20 Pa. No depression occurred in the other liverworts or mosses in the study. These results suggest the role of carbonic anhydrase as a CO_2 -concentrating mechanism.

Figure 58. *Notothylas orbicularis*, member of a genus that uses pyrenoids to concentrate CO_2 . Photo by Michael Lüth, with permission.

Raven *et al.* (1998) have reviewed the evidence supporting a CO_2 -concentrating mechanism in the pyrenoids of some members of the **Anthocerotophyta**. Such a mechanism was already known in algae with pyrenoids (Vaughn *et al.* 1990, 1992). Pyrenoid-containing hornworts exhibited a $^{13}C/^{12}C$ discrimination of 7.2-11.7% compared to 16.4-35.1% in hornworts lacking pyrenoids

(Smith & Griffiths 1996a, b). The higher values are consistent with a C_3 pathway, whereas the low values of the pyrenoid-containing hornworts are consistent with some sort of CO_2 -concentrating mechanism. The CO_2 compensation point has only been investigated in *Anthoceros crispulus* (Figure 56), with a value of $26 \mu M CO_2 \text{ mole}^{-1}$, a value higher than that typical of C_4 plants, but lower than that for C_3 liverworts and mosses in the Smith and Griffiths studies ($49\text{--}68 \mu M \text{ mole}^{-1}$).

Figure 59. *Phaeoceros carolinianus*. Photo by Michael Lüth, with permission.

Plants with a CO_2 -concentrating mechanism have a higher affinity for external CO_2 than do typical C_3 plants. *Notothylas* (Figure 58) and *Phaeoceros* (Figure 57) exhibit CO_2 compensation points of $11\text{--}13 \text{ ppm } CO_2$ compared to 31 ppm for *Megaceros* (Figure 62) and 64 ppm for *Marchantia polymorpha* (Figure 3-Figure 4) (Hanson *et al.* 2002), where no concentrating mechanism seems to be present.

Those plants with a CO_2 -concentrating mechanism can maintain a pool of CO_2 that is immediately available after dark-light transition. *Anthoceros crispulus* (Figure 56) exhibited a pool size of $17.6 \mu mol CO_2 g^{-1} \text{ chlorophyll}$, whereas four of the five C_3 pathway bryophytes had no pool, and the thallose liverwort (with internal air chambers), *Conocephalum conicum* (Figure 60-Figure 61), had only $5.5 \mu mol CO_2 g^{-1} \text{ chlorophyll}$ (Raven *et al.* 1998). *Notothylas* (Figure 58) and *Phaeoceros* (Figure 57) have an inorganic carbon pool of $19\text{--}108 \mu M g^{-1} \text{ chlorophyll}$; *Megaceros* (Figure 62) does not maintain any dissolved inorganic carbon pool (Hanson *et al.* 2002).

But what is this CO_2 -concentrating mechanism? The concentrating mechanism of the pyrenoid suppresses the oxygenase activity of RUBISCO, hence reducing the loss of CO_2 and energy through photorespiration. We do not know the immediate CO_2 -fixation products in these pyrenoid-bearing hornworts. Nor do we know the PEP carboxylase to RUBISCO ratios. Is this some primitive C_4 plant struggling between relative amounts of PEP carboxylase and RUBISCO?

The Bottom Line

Nevertheless, no one has been able to demonstrate any direct evidence of a C_4 pathway, and consideration of a CAM pathway seems illogical since there are no stomata in the leaves. Therefore, we can only infer certain characteristics of bryophyte photosynthetic physiology. Like the tracheophytes, we should expect bryophytes to have low photosynthetic temperature optima, ranging $10\text{--}20^\circ C$ in most species. This is in part due to the loss of CO_2 beyond that gained in photosynthesis at higher temperatures. This loss is from photorespiration, which occurs only in light and increases with temperature more rapidly than does photosynthesis. C_4 plants either lack photorespiration or immediately grab the lost CO_2 and store it as malate. As C_3 plants, all mosses must have photorespiration and would therefore have more photosynthetic gain at low temperatures relative to C_4

plants. It appears that the first record of photorespiration in any plant was in the aquatic moss *Fontinalis* (Figure 2) (Bode 1940), yet the best evidence we have for the possibility of an alternative pathway of CO₂ uptake in bryophytes is in this genus. The bottom line – we still don't understand how these CO₂-concentrating mechanisms work, especially in bryophytes lacking pyrenoids.

Diurnal Patterns in Photosynthesis?

Strong daily patterns exist in some bryophytes. *Pohlia wahlenbergii* (Figure 63), in a sub-alpine habitat in midsummer, had its highest light-saturated photosynthetic uptake early in the morning (8 mg CO₂ g⁻¹ hr⁻¹) (Coxson & Mackey 1990). By late afternoon, this had declined to ~5 mg CO₂ g⁻¹ hr⁻¹. The plants showed full recovery during late evening and nighttime. The authors considered that these daily oscillations could be recurring photodestruction and repair of the pigment complexes – an unusual response for plants in high light habitats such as this. They suggested that instead these fluctuations may represent a daily, endogenous photosynthetic rhythm as known in some phytoplankton populations. Although this is an intriguing idea that would permit the moss to gain CO₂ at a time when tracheophytes are slowed by the reduced light intensity and cool temperatures, much more evidence is needed to conclude that any endogenous rhythm exists.

Figure 63. *Pohlia wahlenbergii*, a species of wet habitats that strong daily photosynthetic patterns. Photo by Michael Lüth, with permission.

I would be more inclined to attribute these morning and evening increases to the increased moisture in the atmosphere. In some parts of the world, fog and dew are the only sources of water for bryophytes. Bryophytes taken from a desiccator will rapidly gain weight on a balance as they absorb atmospheric moisture. A similar phenomenon may permit these plants to have low levels of photosynthetic gain in the low light but higher moisture levels of early morning and pre-dusk conditions.

Products of CO₂

Generally, textbooks present glucose as the final product of photosynthesis, but in fact, this is misleading. Photosynthesis makes PGA that can then be converted to a variety of products, glucose being one of them. In

bryophytes, other products are likewise possible. Valanne (1984) reported that the principal sugars made by bryophytes are sucrose, glucose, fructose, and mannose. She pointed out that evidence for notable exceptions in carbohydrate metabolism of bryophytes compared to that of tracheophytes is lacking (Allsopp 1951; Eschrich & Steiner 1967; Huneck 1969; Margaris & Kalaitzakis 1974; Valanne 1984). In the leafy liverwort *Plagiochila asplenioides* (Figure 65), volemitol, sucrose, and starch are the principal photosynthetic storage products (Suleiman & Lewis 1980).

Lipids are also an important photosynthetic product (Valanne 1984) in bryophytes. In the Arctic, growing shoots typically contain more lipids than carbohydrates (Rastorfer 1972).

Koskimies-Soininen and Nyberg (1991) found that the types of lipids were dependent on temperature and light. In *Sphagnum fimbriatum* (Figure 64), the amount of total lipid increased in dim light conditions at both 15 and 25°C. Conversely, in darkness at 25°C the lipids decreased. Under normal light levels, a decrease in temperature in the range of 5-15°C causes a decrease in the amounts of linoleic, α-linolenic, and arachidonic acids. Concomitantly, concentrations of palmitic, stearic, and oleic acids increase. When light intensity is also decreased, there is an increase in palmitic, stearic, linoleic, and arachidonic acids and a decrease in oleic and α-linolenic acids. Both temperature and light decreases elicit similar responses in total fatty acid desaturation and concentration of α-linolenic acid.

Figure 64. *Sphagnum fimbriatum*, a species that stores more lipids in low light. Photo by David T. Holyoak, with permission.

Dark CO₂ Fixation

These newly incorporated carbohydrates don't necessarily remain in the same products as are initially stored. In as little as two hours, a number of other products are possible. Within two hours in the leafy liverworts *Plagiochila asplenioides* (Figure 65) and *Scapania undulata* (Figure 66), the amino acids asparagine, glutamine, and glutamic acid were dominant products (Gupta 1976). Citric acid and malic acids, along with an unknown acidic compound, were also common in both. In addition, *Plagiochila* contained fumaric, glycolic, and succinic acids, although the fumaric and glycolic acids took longer than two hours to show ¹⁴CO₂. Soluble carbohydrates included sucrose, glucose, mannitol, fructose, and a series of fructans, differing little from the ones reported by Valanne (1984). But concentrations

differ, with volemitol being the most labelled soluble carbohydrate in *Plagiochila asplenioides* and sucrose in *Scapania undulata*. Interestingly, malic acid, a product associated with CAM photosynthesis, was the most labelled organic acid in both species.

Figure 65. *Plagiochila asplenioides*. Photo by Michael Lüth, with permission.

Figure 66. *Scapania undulata*. Photo by Michael Lüth, with permission.

In the dark, non-photosynthetically fixed carbon is incorporated into amino acids (>60% of total non-photosynthetic carbon fixation), making primarily aspartate, alanine, and glutamate (Dhindsa 1985). Most of the remaining non-photosynthetic fixation incorporates carbon into organic acids (<40%). This dark fixation permits rehydrated mosses in the dark to repair damage due to desiccation.

Transport of Photosynthate

Little is known about the movement of most substances in mosses and liverworts, but we do have evidence that both nutrients and photosynthate are indeed moved about. Alpert (1989) reported that within 26 hours, at least 10% of the photosynthate was translocated out of the leafy shoot of *Grimmia laevigata* (Figure 67).

Transport of photosynthate in the bryophyte is often similar to that in tracheophytes. In *Polytrichastrum alpinum* (Figure 68), photosynthate is translocated from the above ground shoots to the rhizomes (Hobbs & Pritchard 1987). It does not move in the **hydroids** (water-

conducting cells, but rather moves in the phloem-like **leptoids**, as demonstrated in *Polytrichum commune* (Figure 7) (Eschrich & Steiner 1967). Héban (1975) demonstrated that a cut stem will exude a clear liquid from the leptoids and associated parenchyma. The associated parenchyma cells seem to function much like companion cells of phloem. These cells have high enzyme activity and most likely are responsible for the movement of substances into and out of the leptoids (Richardson 1981).

Figure 67. *Grimmia laevigata*. Photo by Michael Lüth, with permission.

Figure 68. *Polytrichastrum alpinum*. Photo by Michael Lüth, with permission.

While tracheophyte botanists are still trying to understand the mechanisms of xylem and phloem transport in the tracheophytes, bryologists are struggling with much smaller systems in bryophytes. One bryophyte stem is little larger than a single vascular bundle in one of these lignified plants. And the aphids that live on the fluids in the tracheophytes are larger than the diameters of bryophyte stems. So how do bryologists measure something so small when mechanisms of movement in its larger counterpart have been such an enigma for plant physiologists?

For measuring phloem transport, the old adage that if there is a niche, there is an insect to fill it, comes to the rescue of the bryologists. There are indeed tiny aphids (for example *Myzodium*, Figure 69) that live on the fluids in the phloem of *Polytrichum* (Figure 7, Figure 70) species. And Bob Thomas, with his coworkers, has used them to help us understand how mosses transport things from place to place internally.

Figure 69. *Myzodium modestum*, an aphid genus with members that feed on substances in leptoids of *Polytrichum* species. Photo by CBG Photography Group, through Creative Commons.

Figure 70. *Polytrichum commune* stem cross section, showing location of the leptoids that carry the sugars. Photo from Botany Website, UBC, with permission.

Thomas and coworkers (1990) found that *Polytrichum commune* (Figure 7, Figure 70) transports things from **source-to-sink**, just as we find in those other plants. Through some of their early experiments, Thomas *et al.* (1988) found glucose, fructose, and sucrose in pulse-labelled stems 30 minutes after treatment in *Polytrichum commune*. The translocated carbon appeared in starch and cell wall polysaccharide pools within 1-6 weeks after treatment and could be used or stored. Perhaps the greater surprise is that 3.3% of the labelled sugar appeared later in neighboring stems, presumably following a source-to-sink gradient. This seems to be attributable to the transport of sugars in the leptome through perennating rhizomes, which often connect multiple stems.

But does it work the same way as in those other plants? Leaf conducting cells of *Polytrichum commune* (Figure 7, Figure 70) have high solute concentrations, as revealed by incipient plasmolysis, and high ATPase activity at membrane surfaces (Thomas *et al.* 1990).

Thomas and coworkers concluded that this permits the moss leaf to use a process analogous to **phloem loading** in minor veins of flowering plants. Furthermore, this sugar loading seems to be coupled with proton transport, suggesting a **proton pump** to get things across cell membranes.

Just how effective is this movement in transporting sugars and other substances from leaves to basal regions? Using petroleum jelly across leaf bases to prevent external capillary movement, Thomas and Lombard (1991) found that 17-38% of the translocated label could be detected in feeding aphids within four hours – not a very rapid rate by tracheophyte standards, where rates are more commonly about 30 cm per hour (Saupe 2005). In fact, the *Myzodium* had to divert nutrients away from the food-conducting tissues of the stem and alter the normal source-to-sink flow in order to get enough. Even then, the aphids had to aggregate in order to compete with the natural source-to-sink travel within the moss. In *Polytrichastrum alpinum* (Figure 68), the photosynthate reached underground rhizomes at a rate of 3 mm h⁻¹ (Collins & Oechel 1974). On the other hand, this moss can move things upward at 32 cm h⁻¹ (Eschrich & Steiner 1967).

All this discussion has been on **Polytrichaceae**! We know almost nothing beyond their successful lives to tell us about the other bryophytes in which the conducting system is less well developed. *Hylocomium splendens* (Figure 21), a predominately ectohydric moss, moved its photosynthate so slowly that 98% remained at the fixation site 48 hours later (Callaghan *et al.* 1978).

Skré *et al.* (1983) have helped to demonstrate some of the differences and consistencies between the endohydric **Polytrichaceae** and the more common ectohydric pattern of other mosses. *Polytrichum commune* (Figure 7) behaved much like the C₄ plants and retained most of its labelled ¹⁴C after two hours. However, after 35 days it had sequestered a large portion (second highest of the four species) in its brown tissues. The ectohydric *Sphagnum subsecundum* (Figure 71) retained the least of its labelled ¹⁴C, but moved the highest portion to its brown tissues after 35 days. *Hylocomium splendens* (Figure 21) and *Pleurozium schreberi* (Figure 37) had inconsistent patterns of translocation, but all four species accumulated ¹⁴C in their growing shoot tips and senescent brown tissues and all four experienced high losses of ¹⁴C through respiration during the peak summer growing season.

Figure 71. *Sphagnum subsecundum*, a species that moves large portions of its carbon to its brown tissues. Photo by Michael Lüth, with permission.

Storage of Photosynthate

Mosses and liverworts differ in their storage of photosynthate. In liverworts, sugar alcohols are important (Suleiman *et al.* 1979). In the mosses, the soluble product is primarily sucrose (Margaris & Kalaitzakis 1974; Suire 1975). Although most of the carbohydrates in aboveground portions of mosses are soluble sugars, the belowground parts are typically richer in starch (Hicklenton & Oechel 1977; Sveinbjörnsson & Oechel 1981). Witt and Teubert (1992) noted the contributions of phosphorylase in starch synthesis in all the sinks for starch in young gemmalings of the thallose liverwort *Riella helicophylla* (Figure 72). This included gemmae, meristems, and regenerating cells.

Figure 72. *Riella helicophylla*, a species that uses phosphorylase in starch synthesis in starch sinks of gemmalings. Photo by NACICCA through Creative Commons.

In *Polytrichum* (Figure 7), which may not be typical, the green, photosynthesizing shoot has the largest amount of nonstructural carbohydrate and the stem the least (Sveinbjörnsson & Oechel 1981). Sugars are highest in the green shoots; starches are highest in the belowground parts. The above ground portion can move more than 30% of its daily carbon gain to the below ground rhizome. In a more ectohydric *Dicranum fuscescens* (Figure 73), the green part of the shoot has ~7.0-10.5% ash-free tissue dry mass as carbohydrate (Hicklenton & Oechel 1977), approximating about 0.7-1.3% of its fresh weight (Rastorfer 1972).

Figure 73. *Dicranum fuscescens*, showing lower, light brown, senescent portion near lower portion of picture on right. Photo by Michael Lüth, with permission.

As already seen, even senescent tissue is able to store carbon products (Skré *et al.* 1983). The senescent portion of *Dicranum elongatum* (Figure 74) incorporates labelled carbon into lipids (Hakala & Sewón 1992). Hakala and Sewón concluded that the ability of the moss to transport such substances both upward and downward permitted this senescent portion of the moss to serve as an energy store. However, in *Dicranum fuscescens* (Figure 75) little change is seen in the starch content of brown, senescing parts of the shoot, while the green, leafy part increases its total carbohydrate content during the growing season. Even so, the starch content of the leafy shoots of this species, as well as *Polytrichum commune* (Figure 7) and *Polytrichastrum alpinum* (Figure 68), is less than 2% (Hicklenton & Oechel 1977), with similar values in *Pleurozium schreberi* (Figure 37) and *Ceratodon purpureus* (Figure 36) (Aro & Valanne 1979).

Figure 74. *Dicranum elongatum*, a species in which senescent portions incorporate carbon into lipids. Photo by Michael Lüth, with permission.

Figure 75. *Dicranum fuscescens*, a species that does not seem to store energy in its senescing parts, but rather in the green leafy part. Photo by Michael Lüth, with permission.

Sphagnum (Figure 71) increases its lipid content in the spring in growing parts but decreases it in the senescent parts (Rastorfer 1972; Karunen & Salin 1981). *Dicranum elongatum* (Figure 74), on the other hand, stores large quantities of lipids in its senescent parts (Karunen & Mikola 1980; Karunen & Liljenberg 1981). In cold weather, mosses, at least in the Arctic, store high quantities of triglycerides (Karunen & Kallio 1976; Swanson *et al.* 1976; Karunen 1981; Karunen & Salin 1981). Both triglycerides and unsaturated fatty acids diminish in elevated temperatures (Karunen 1981).

Illumination affects the ratio of starch to protein, with *Pleurozium schreberi* (Figure 37) and *Ceratodon purpureus* (Figure 36) in continuous illumination showing an increase in starch content and decrease in protein in the leafy shoots (Aro & Valanne 1979).

During periods of darkness, both the older, senescent portions and active photosynthetic portions of the mosses can lose stored products. In *Racomitrium barbuloide*s (Figure 76), the concentrations of ethanol-soluble sugars and lipids in green portions decreased in the dark, indicating their use as storage substances (Sakai *et al.* 2001). However, sugars and lipids in the brown, senescent portions did not decrease and starches remained constant in both portions. Continuous light caused initial increase of sugars and lipids in the green portion, but later these decreased in these conditions. This regime caused a significant decline in photosynthetic capacity.

Figure 76. *Racomitrium barbuloide*s, a species that uses ethanol-soluble sugars and lipids as storage products. Photo by Digital Museum, Hiroshima University, with permission.

The type of carbohydrate stored determines its rate of turnover from storage. In the leafy liverwort *Plagiochila asplenioides* (Figure 65), breakdown of starch in the dark is rapid, but much carbon still remains as sucrose and volemitol due to their very slow turnover (Suleiman & Lewis 1980).

In limiting habitats where light limits photosynthesis, exogenous sugars may help the plants to maintain a positive carbon balance (Graham *et al.* 2010). In peat mosses, a 1% glucose solution increased photoautotrophic growth by a factor of 1.7. Air-grown mosses exhibited a 28X biomass with a 1% emendment and 39X with a 2% emendment of glucose. Similarly, fructose enhanced growth by 21X at 1% and sucrose at 2% enhanced it by 31X. Graham and coworkers suggest that this **mixotrophy** is a trait that evolved early in evolution of photosynthetic organisms. This ability to use external sugars correlates with the development of protective cell wall polyphenolics, suggesting that the sugars may "subsidize" the cost of producing these protective compounds.

Sporophyte Photosynthesis

Although mature sporophytes are seldom green, they are typically green during the earlier stages of their development. This is easy to suppose in mosses, and confirmed in such mosses as *Funaria hygrometrica* (Figure 14) (Krupa 1969), but liverworts do not elongate

their setae until the sporophyte is mature, and the developing capsule is confined within the perianth (Figure 77). Nevertheless, Thomas *et al.* (1979) confirmed photosynthesis in liverwort sporophytes of *Fossombronina foveolata* (Figure 78-Figure 79), *Lophocolea heterophylla* (Figure 80), *Pellia epiphylla* (Figure 81), *Ptilidium pulcherrimum* (Figure 82), and *Riella affinis*. In the leafy liverwort *Lophocolea heterophylla*, 40% of this photosynthetic activity was attributable to spores. They confirmed that the gametophyte tissue surrounding the young sporophyte did inhibit the photosynthesis of the sporophyte by up to 50%.

Krupa (1969) found that at certain stages in development, the sporophyte of *Funaria hygrometrica* (Figure 14) is photosynthetically self-sufficient. Nurit and Chevallier (1978) confirmed this, finding that the *F. hygrometrica* gametophyte has a constant production of oxygen in the light throughout its development, but that the production of oxygen in the sporophyte decreases as the

capsule matures. Although the weight of the seta (Figure 83) decreases as the weight of the capsule increases (Figure 84-Figure 85) in *Polytrichum* (Figure 7), this is not the case in *Funaria* (Paolillo & Bazzaz 1968), suggesting that in *Funaria* the capsule does its own photosynthesizing. Nevertheless, the gametophyte makes a major contribution to sporophyte biomass in bryophytes.

Atanasiu (1975) compared the gametophyte and sporophyte of *Dicranum scoparium* (Figure 86) and *Tortella tortuosa* (Figure 87). The ratios of net photosynthesis to dark respiration were 0.77-0.97 in the sporophyte and 3.50-5.17 in the gametophyte, suggesting little or no net photosynthetic gain by the sporophyte. These differences were supported by the determination that the gametophytes had 3-4 times the chlorophyll content of the sporophytes. Atanasiu concluded that in these two species the sporophyte is not capable of supporting itself photosynthetically.

Respiration

Bryophytes, like C_3 tracheophytes, have two types of respiration. The productivity of photosynthesis creates an environment in which ATP is produced and dark respiration is suppressed. This respiration, however, occurs in the dark to produce ATP and maintain the biological process of the plant. I am aware of no studies to determine if dark respiration occurs in rhizoids in the daytime, but one might suppose that it does, as it does in roots. But whereas photosynthesis suppresses dark respiration, the presence of the RUBISCO enzyme catalyzes not only photosynthesis, but also catalyzes photorespiration, both in the light. It is this photorespiratory process that causes C_3 plants to have

such a low temperature optimum for net photosynthetic gain. As the temperature rises, the rate of photorespiration increases more rapidly than does the rate of photosynthesis, until ultimately the plant loses more CO_2 and energy than it gains. For example, in the High Arctic Svalbard populations of *Sanionia uncinata* (Figure 88), photosynthesis at near light saturation remained nearly constant in the range of 7 to 23°C, suggesting a Q_{10} near 1.0, but the respiratory Q_{10} in that range was 3.0 (Uchida *et al.* 2002). For this reason, most plants, including bryophytes, that have survived the test of time are those that become dormant as the temperature rises, causing both processes to cease. In bryophytes, this is often effected by drying that occurs at higher temperatures.

Figure 88. *Sanionia uncinata*, a species that in the high Arctic does not seem to alter its photosynthetic rate in response to temperature, but that has a respiratory Q_{10} of 3.0. Photo by Michael Lüth, with permission.

Even dark respiration, which is generally only about 1/2 to 1/3 that of photorespiration, can result in a significant carbon loss. In studying tropical bryophytes, Zotz *et al.* (1997) found that more than half the carbon gained by photosynthesis in the daytime was lost during the night as respiratory loss. This left the bryophytes to gain only about 45% of their initial carbon in new carbon per year. As is common, water was the primary limiting factor for carbon gain.

In early experiments on the effects of light on respiration, Egle and Fock (1965) used, among others, the thallose liverwort *Conocephalum conicum* (Figure 60-Figure 61). They found that the results were similar in the liverwort and tracheophyte leaves, but that the curves for the liverwort were more pronounced. They learned that increasing oxygen concentrations (1, 25, & 75%) severely depressed photosynthesis. Following darkening, the CO_2 output increases steadily for about 5 minutes, at which time the stationary dark respiration rate is reached. Initially, high O_2 concentrations caused a strong burst of CO_2 in the dark, but within 15 minutes the thallus reaches the same equilibrium level of dark respiration. The level of oxygen from 1-99% does not influence the dark respiration. Higher light intensities increase the intensity of the CO_2 outburst at the onset of the next dark period. Using experiments that inhibited photosynthesis in the light, Egle and Fock demonstrated that the liberation of CO_2 in the light is greater than that in the dark. High O_2 concentrations cause this photorespiration to greatly exceed

the uptake of CO₂ by photosynthesis. Furthermore, old leaves exhibit more light respiration than do young leaves, contrasting with the reverse effect in dark respiration (Zelitch & Barber 1960; Fock 1965). Egle and Fock were convinced that this process was not the same respiratory process of decomposing assimilates that occurred in the dark. Rather, they discouraged the terminology "light respiration," considering that the light liberation of CO₂ might be only a side reaction of metabolism.

Peñuelas *et al.* (1988) compared the respiration rates of different parts of aquatic plants with that of the shoots of bryophytes. For the aquatic bryophytes studied, shoots had a respiratory rate of 53-66 $\mu\text{mol O}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$. The green alga *Cladophora glomerata* (Figure 89) had 96 $\mu\text{mol O}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$ respiration. The algae and bryophytes had rates higher than those of flowering macrophyte stems (13-71 $\mu\text{mol O}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$), but lower than that of their leaves (30-142 $\mu\text{mol O}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$).

Summary

Net productivity is the photosynthetic gain, measured as CO₂ uptake or O₂ emission, of a plant, whereas gross photosynthesis is the total CO₂ fixation, frequently obtained by adding respiratory loss to measured CO₂ uptake. However, photorespiration occurs in the light and cannot be measured by the dark respiration method. Photorespiration, apparently first discovered in bryophytes, contributes to CO₂ loss, and its rate is generally higher than that of dark respiration.

Bryophyte photosynthesis can respond quickly to moisture from dew and fog as well as from rain. It likewise responds quickly to light. The structural simplicity of bryophyte leaves, with only a single cell layer and no need to bring CO₂ in through stomata that close in dry atmospheres, permits bryophytes to take advantage of photosynthetic opportunities immediately. In some cases, leaf lamellae increase the surface area and chlorophyll available for photosynthesis. Pores in some liverwort thalli may control CO₂ uptake. In some cases the chloroplast structure changes in response to changes in wavelengths of light.

Bryophyte chloroplasts are typical of plants, but their chlorophyll proteins and fatty acids appear to be somewhat different from those of tracheophytes. Furthermore, the chlorophyll is conserved for long periods in the dark, whereas it is not in tracheophytes.

Bryophyte productivity is generally low, but the photosynthetic capacity, when measured on the basis of chlorophyll concentration, is similar to that of tracheophytes.

The chlorophyll antenna system, as in tracheophytes, permits bryophytes to use and transmit energy in a variety of wavelengths, directing it to chlorophyll *a*. The most common of these antenna pigments are α - and β -carotene, lutein, zeaxanthin, violaxanthin, and neoxanthin.

Although some bryophytes seem to be able to enhance CO₂ uptake, for example through pyrenoids in many of the Anthocerotophyta, their photosynthetic pathway seems to be entirely C₃. Some aquatic bryophytes, such as *Fontinalis antipyretica*, seem to be able to take up CO₂ in high pH conditions that should permit only very little free CO₂, suggesting some sort of concentrating mechanism.

Photosynthate is transported in the phloem, as demonstrated by tiny aphids. It can be stored in a variety of forms, particularly sugar alcohols (liverworts) and sucrose (mosses). Lipids may be stored in senescent portions and used later for spring growth.

Sporophytes of mosses are photosynthetically active in their young stages, but liverworts do not elongate their setae until the capsule matures, causing little light to reach the developing sporophyte.

CHAPTER 11-2

PHOTOSYNTHESIS: PHOTOINHIBITION

Figure 1. *Conostomum tetragonum* exposed to the high light intensity of an alpine area. Photo by Michael Lüth, with permission.

Photoinhibition

In high light intensities, chlorophyll can be damaged by the enhanced activity of electrons beyond that which it can process. This results in **photoinhibition** by decreasing the photosynthetic capacity. In tracheophytes, this is particularly pronounced in dehydrated plants, but in bryophytes, it seems the pattern is quite different.

Seel *et al.* (1992) compared the desiccation-tolerant moss *Syntrichia ruralis* var. *arenicola* (= *Tortula ruraliformis*) (Figure 2) with the desiccation-intolerant moss *Dicranella palustris* (Figure 2). It appeared that desiccation in the dark had no effect on total concentrations of chlorophylls or carotenoids in either moss, but in *D. palustris* it resulted in loss of protein and accumulation of TBA, suggesting lipid peroxidation. *Dicranella palustris* was unable to recover its photosynthesis during rehydration, whereas photosynthesis of *Syntrichia ruralis* var. *arenicola* had only marginal depression in photosynthesis upon rehydration, and only at the highest irradiance. In the light, *D. palustris* likewise lost not only protein, but also chlorophyll and carotenoids, while lipid peroxidation increased. Again, *S. ruralis* var. *arenicola* suffered little damage. Greater damage occurred to this species when hydrated and exposed to high irradiance. Thus we can include that desiccation tolerance affords some protection to the chlorophyll in the presence of high light intensities, at least in some bryophyte species.

Figure 2. Upper: *Syntrichia ruralis* var. *arenicola*. Lower: *Dicranella palustris*. Photos by Michael Lüth, with permission.

Temperature plays a major role in photoinhibition and light damage. At low Antarctic temperatures with exposure to high light intensity, *Schistidium antarctici* (Figure 3) experienced reduction in its **photosynthetic capacity** (light-saturated rate), **photosynthetic efficiency** (ratio of energy stored to energy of light absorbed), ratio of **variable to maximum fluorescence**, and rate of **fluorescence quenching** when exposed to moderate light (Adamson *et al.* 1988). Adamson *et al.* suggested that photoinhibition may play a major role in limiting photosynthesis and productivity in the Antarctic region. On the other hand, Alpert (1988) showed that *Grimmia laevigata* (Figure 4-Figure 5) exhibits no chlorophyll damage during 20 months of desiccation if it is shielded from potential photodamage.

Quenching

Two means, known as **quenching**, seem to be available to plants, or at least to bryophytes, to reduce excessive activation energy and avoid damage from high light activity. In higher plants and bryophytes, this can be done by the reaction center itself. But bryophytes seem to behave somewhat differently from tracheophytes. For example, the leafy liverwort *Bazzania trilobata* (Figure 6) exhibits no decrease in quantum yield in its open reaction centers when oversaturated with light, whereas both peas and barley do (Horton *et al.* 1988), suggesting that the behavior of the reaction center is not essential to prevent photoinhibition in at least some bryophytes. Rather, at least some bryophytes seem to be able to accomplish photoquenching by use of accessory pigments (Paulsen 1998).

Figure 6. *Bazzania trilobata*, a species that does not decrease its quantum yield when oversaturated with light. Photo by Dick Haaksma, with permission.

One might expect such quenching activities to be especially important in alpine bryophytes. Fluorescence in bryophytes in alpine areas with high UV light intensity can result in different effects from those on tracheophytes (Heber *et al.* 2000). When dehydrated, alpine populations of *Grimmia alpestris* (Figure 7) had very low chlorophyll

fluorescence while alpine tracheophytes had high levels. On the other hand, mosses and lichens increase their chlorophyll fluorescence upon rehydration, whereas tracheophytes experience a decrease. Heber *et al.* considered this increase in mosses and lichens to relate to their lack of photodamage in a dry state. Nevertheless, tracheophytes, bryophytes, and lichens all can form chlorophyll fluorescence quenchers as a response to desiccation, but only the bryophytes and lichens exhibit a decrease in fluorescence in response to light energy transfer while dehydrated. Thus, among the alpine taxa they examined, only the bryophyte *Grimmia alpestris* used deactivation to avoid photodamage in both its hydrated and dehydrated states.

Figure 7. *Grimmia alpestris*, a species with low chlorophyll fluorescence. Photo by Henk Greven, with permission.

Zeaxanthin

One explanation for photo-protective quenching is that in high intensity light, the carotenoid violaxanthin, which itself inhibits quenching, is de-epoxidized to form **zeaxanthin** (Paulsen 1998). The theory is that this transformation to zeaxanthin lowers the energy level sufficiently to permit it to trap energy from the chlorophyll excited state. However, **auroxanthin**, a diepoxy xanthophyll, has an even higher energy level than that of violaxanthin, but it promotes fluorescence quenching and aggregation in isolated major light-harvesting complex II, similar to the effect of zeaxanthin. Ruban *et al.* (1998) have challenged this interpretation of trapping chlorophyll energy because auroxanthin behaves similarly to zeaxanthin as a stimulator of quenching. Rather, Ruban *et al.* contend that it is the flat shape of zeaxanthin and auroxanthin, compared to the perpendicular shape of violaxanthin, that permits them to perform their quenching function.

Sunflecks can initiate rapidly reversible photoprotection within minutes to elicit non-photochemical chlorophyll fluorescence quenching (Matsubara *et al.* 2005). This is vitally important to bryophytes living in forests where low light is supplemented by these ephemeral bursts of bright light. Detectable conversion of the violaxanthin pigment to the protective antheraxanthin or zeaxanthin takes longer, suggesting that there may be more than one mechanism for photoprotection.

In prolonged strong light, photoprotection is usually stabilized within hours of exposure through this reversible violaxanthin cycle, but there is also a slowly reversible conversion of the pigment lutein epoxide to lutein. Matsubara *et al.* suggested that the lutein "locks in" a primary photoprotective mechanism in some species, causing light-harvesting antenna pigments to serve as centers for dissipating excitation energy in high light. Czeccuga (1985) found that lutein epoxide accumulated in *Marchantia polymorpha* (Figure 8) thalli in late summer, autumn, and after winter. However, thus far we have no evidence of the specific role of lutein or lutein epoxide in bryophytes.

Figure 8. *Marchantia polymorpha*, a species that accumulates lutein epoxide seasonally. Photo by Jan-Peter Frahm, with permission.

Bukhov *et al.* (2001a) found that light quenching of chlorophyll fluorescence in the moss *Rhytidiadelphus squarrosus* (Figure 9) apparently originated in the pigment antenna system, but in the tracheophytes *Arabidopsis thaliana* (Figure 10) and *Spinacia oleracea* (Figure 11) it appeared to originate in the reaction center. The quenching in *R. squarrosus* was strongly enhanced by the pigment **zeaxanthin** (Bukhov *et al.* 2001b). Short bursts of light were sufficient to cause an increase in levels of zeaxanthin in this moss, albeit in a 20% CO₂ atmosphere. In fact, only one molecule of zeaxanthin was needed to quench the efficiency of charge separation in Photosystem II by 50%.

Heber *et al.* (2001) concluded that the absence of ATP consumption in reactions associated with the coupled electron transport of PS II permitted the acidification needed in the thylakoids for binding zeaxanthin to the chlorophyll-containing thylakoid protein. These form energy-dissipating traps in the antennae of PS II. Furthermore, the competition for energy capture decreases the activity of PS II. Both mosses and lichens benefit from the protein protonation and zeaxanthin availability in the

dissipation of energy in PS II, whereas this is not the case in tracheophytes. The energy dissipation in mosses and lichens in the dry state is not related to protonation and zeaxanthin availability, as indicated by the absence of chlorophyll fluorescence. For mosses and lichens, the big advantage is that excitation of PS II by sunlight is not destructive when they are dry, whereas dry leaves of tracheophytes rapidly lose their PS II activity under strong illumination.

Rintamäki *et al.* (1994) found that strong light induced the PS II centers to increase their capacity for repair of photochemical damage in the moss *Ceratodon purpureus* (Figure 12). This increased tolerance was associated with a rapid turnover of the D1 protein, apparently mediated by lincomycin. In the absence of lincomycin, strong light resulted in a net loss of this D1 protein, suggesting that the rapid degradation of the protein was independent of the resynthesis of polypeptide. They interpreted this to mean that synthesis was the limiting factor in the turnover of the D1 protein during photoinhibition. Furthermore, the initial level of fluorescence was correlated with the production of inactive PS II reaction centers that were depleted of the D1 protein. The higher the fluorescence level, the greater the depletion of the D1 protein. Addition of lincomycin facilitated the recovery of the D1 protein, and the rate of D1 protein synthesis after photoinhibition exceeded that of control plants during the first hours under recovery conditions.

Figure 12. *Ceratodon purpureus*, a species in which strong light induces PS II centers to increase their capacity for repair of photochemical damage. Photo by Janice Glime.

Deltoro *et al.* (1998) compared a desiccation-tolerant (*Frullania dilatata*, Figure 13) and desiccation-intolerant (*Pellia endiviifolia*, Figure 14) liverwort to examine the effects of desiccation and light on non-photochemical quenching. In *F. dilatata*, there was a rise in the concentration of de-epoxidized xanthophylls that can protect the cells from chlorophyll damage when photosynthesis cannot occur to trap the excited electrons. Dry *Pellia endiviifolia*, on the other hand, experienced less dissipation of electron activity and did not experience a rise in de-epoxidized xanthophylls. The increase in de-epoxidized xanthophylls appears to be induced by desiccation and mediated by zeaxanthin.

Chloroplast Position

The position of the chloroplasts plays a role not only in maximizing the light capture by the cell in low light, as in protonemata of *Schistostega pennata* (Figure 15), but also in minimizing chlorophyll fluorescence during desiccation. Grouping of the plastids during drying may enhance the effect of chlorophyll reabsorption, causing a notable decrease in the F685/F735 ratio in the chlorophyll fluorescence spectrum, as shown in *Rhizomnium punctatum* (Figure 16) leaves (Bartosková *et al.* 1999).

Sun and Shade Plants

Photosynthetic organs of plants typically adjust their chlorophyll concentrations as light conditions change (Martin & Churchill 1982). Hence, those organs in high light intensity tend to have lower concentrations of chlorophyll *b* and total chlorophyll than those in the shade (Valanne 1977; Martin & Churchill 1982). The chlorophyll *b* serves as one of the antenna pigments to trap light energy and transfer it to the chlorophyll *a* reaction center.

Within the bryophytes, there are both chlorophyll and plastid structural differences between plants typical of shade and those of sun, but these may not necessarily be accompanied by photosynthetic differences (Aro *et al.* 1981). For example, *Marchantia polymorpha* (Figure 8) has a plastid structure characteristic of shade plants, and *Ceratodon purpureus* (Figure 12) of sun plants, but both have the photosynthetic kinetics of shade plants.

Chlorophyll Concentration

Bryophytes in general have chlorophyll concentrations typical of shade plants (Tieszen & Johnson 1968; Table 1). Deora and Chaudhary (1991) examined the chlorophyll content in a number of Indian bryophytes and reported the ranges. Chlorophyll *a* ranged 0.402 ± 0.052 to 2.002 ± 0.700 mg g⁻¹ dry mass. Chlorophyll *b* ranged 0.265 ± 0.067 to 1.634 ± 0.070 mg g⁻¹ dry mass. The highest level of chlorophyll was in the cave moss *Cyathodium tuberosum* (Figure 17) (3.636 mg g⁻¹ dw) and the lowest in *Entodon prorepens* (Figure 18) (0.667 mg g⁻¹ dw). They found that, like the tracheophytes, high solar irradiances corresponded with low chlorophyll content and high *a:b* ratios. Martínez Abaigar and Núñez Olivera (1998) compiled data from a number of studies to show that on either a weight or areas basis, bryophytes have lower chlorophyll concentrations than do tracheophytes (Figure 19). They attributed this higher level in tracheophytes to the more complex structure of these plants.

Figure 19. Comparisons of chlorophyll concentrations on an area (upper) and biomass (lower) basis. Redrawn from Martínez Abaigar and Núñez Olivera (1998), based on data from Martínez Abaigar *et al.* 1994.

Marschall and Proctor (2004) examined 39 moss and 16 liverwort species to compare chlorophylls and carotenoids in relation to light intensity and light saturation. They found a median total chlorophyll concentration of 1.64 mg g⁻¹ for mosses and 3.76 mg g⁻¹ for liverworts. Mean chlorophyll *a:b* ratios were 2.29 and 1.99, respectively. The chlorophyll:carotenoid ratio mean was 4.74 for mosses and 6.75 for liverworts. Light saturation values were low, with almost all less than 1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$; the median for mosses was 583 and for liverworts 214 $\mu\text{mol m}^{-2} \text{s}^{-1}$. These numbers suggest that liverworts, in general, are more shade-adapted than are mosses. Deora and Chaudhary (1991) reached the same conclusion in their study of Indian bryophytes. Pande and Singh (1987) also compared mosses and liverworts during the rainy season in Nainital, Kumaun Himalaya, finding the liverworts to be more prominent in the shade and mosses in the sun, likewise having more chlorophyll and carotenoids in the liverworts. However, they found no chlorophyll:carotenoid differences between liverworts and mosses.

Marschall and Proctor (2004) concluded that bryophytes are **not** "inherently" shade plants and do include sun plants. For example, species of *Polytrichum* have lamellae that provide additional surface area for gas exchange, permitting greater CO₂ uptake; these species had the highest **photosynthetic photon flux density (PPFD)**. Masarovičová and Eliás (1987) supported this conclusion by showing that *Polytrichum commune* (Figure 20-Figure 21), with well-developed lamellae, had a higher saturation photosynthetic rate (3.67-5.62 mg CO₂ g⁻¹ dry mass h⁻¹) and higher photosynthesis per chlorophyll concentration (0.53 mg CO₂ chl h⁻¹) than did *Atrichum undulatum* (Figure 22-Figure 23) (which has less-well-developed lamellae; Figure 23) (3.41 mg CO₂ g⁻¹ dry mass h⁻¹) or *Hypnum cupressiforme* (Figure 24) (which has no lamellae) (2.56 mg CO₂ g⁻¹ dry mass h⁻¹). Marschall and Proctor found that chlorophyll concentration, chlorophyll *a:b* ratios, and chlorophyll:carotenoid ratios all were significantly correlated with PPFD at 95% saturation in the bryophytes tested. Nevertheless, the light saturation levels of all bryophytes were lower than those for tracheophytes of open sun habitats. Marschall and Proctor attributed the lower saturation levels to the difficulty of obtaining CO₂ into the cells of bryophytes.

Chlorophyll degrades into phaeophytin. Chlorophyll *a* degrades more easily than does chlorophyll *b*; hence,

phaeophytin *a* has been used as an indication of chlorophyll damage that can result from pollution or other stress. Bastardo (1980) suggests that a chlorophyll *a* to phaeophytin ratio of less than 1.0 in the aquatic moss *Fontinalis* (Figure 25) indicates irreversible damage to the chlorophyll component. However, in their study of submerged mosses, Martínez Abaigar *et al.* (1994) found that chlorophyll of aquatic mosses did not degrade into phaeopigments.

Deep lakes provide some of the darkest habitats for bryophytes. Fully hydrated, bryophytes are able to take advantage of the CO₂ emitted from the sediments for a slow but steady growth without competition from other macrophytes. These plants are highly shade adapted and have a low light saturation level. The leafy liverwort *Chiloscyphus rivularis* (see Figure 26) in Crystal Lake, Wisconsin, USA, is saturated at ~50 μM photons $\text{m}^{-2} \text{s}^{-1}$ (Farmer *et al.* 1988). This leafy liverwort has high concentrations of chlorophylls *a* and *b* as well as carotenoids. The carotenoids produced consist mostly of **lutein**, a yellow-orange pigment that has most of its absorption at 470-500 nm (blue light). The light energy is transferred through the pigment antenna system to chlorophyll *a*. Table 1 compares chlorophyll levels of a number of bryophyte species.

Figure 26. *Chiloscyphus polyanthos*; *C. rivularis* has high concentrations of chlorophylls *a* and *b* and carotenoids. Photo by Bernd Haynold, through Creative Commons.

In seemingly sharp contrast to this deep-water lutein production, Czeuczuga (1987) grew bryophyte leaves under various light intensities with seemingly conflicting results. As in other studies, in the shade the total carotenoid content and β -carotene increased, along with chlorophyll, but in the

sunlight there was a marked increase in the lutein content of the leaves. Why should these leaves increase their antenna pigments, particularly lutein, in the sunlight? Is it serving as a filter, unconnected to the antenna function?

Age Differences

Masarovičová and Eliás (1987) showed that chlorophyll concentrations differ with age. One need only look at bryophytes in the spring to observe that older parts are typically dark and new growth is a light (Figure 27), almost chartreuse, green. However, storage of other substances in senescing parts contributes to their dark color.

Figure 27. *Polytrichum commune* with new, green growth from splash cups and darker, brownish lower parts. Photo by Štěpán Koval, with permission.

Chlorophyll *a:b* Ratio

Chlorophyll *a:b* ratios can vary considerably, depending on the light available, time of year, and the adaptations of the bryophytes. Martin and Churchill (1982) reported a mean of 2.69 (2.29-2.99) for 20 moss species in an oak-hickory (*Quercus-Carya*, Figure 28) woods in Kansas, USA. But in his study of North Carolina, USA, Martin (1980) reported only 1.14-2.1 for 11 moss species. Masarovičová and Eliás (1987) found a range of 2.14-2.85 for woodland mosses in SW Slovakia in July.

The genus *Riccia* frequents a variety of disturbed habitats as well as living on the water surface of lakes and ponds. Patidar *et al.* (1986) found that within this genus, the highest chlorophyll concentrations occurred in shade-grown *Riccia discolor* (Figure 29). The lowest concentrations occurred in *Riccia fluitans* (Figure 30), a species that floats on the water surface, often in direct sunlight. But surprisingly, the chlorophyll *a:b* ratios did not differ among the species in these different habitats.

An increase in irradiance will cause an increase in productivity up to the point where light saturation is reached. In a 36-day laboratory experiment using seven different light levels, Rincón (1993) demonstrated this concept with six bryophyte species [*Brachythecium rutabulum* (Figure 31), *Eurhynchium praelongum* (Figure 32), *Lophocolea bidentata* (Figure 33), *Plagiommium*

undulatum (Figure 34), *Pseudoscleropodium purum* (Figure 35), *Thuidium tamariscinum* (Figure 36)]; all responded to the higher light intensities with greater biomass increase. But they also demonstrated (except for *Lophocolea bidentata*) that lower light intensities resulted in greater shoot length increase, a response suggesting that IAA was being inhibited by the greater intensity of light. Like Patidar *et al.* (1986), they found that all species had higher chlorophyll levels at low irradiances, but there were no distinct changes in chlorophyll *a:b* ratios with light intensity.

Tieszen and Johnson (1968) pointed out the importance of bryophytes in tundra ecosystems by examining the chlorophyll distribution within several

communities. Those communities with the lowest overall chlorophyll had the greatest amount of it in their moss and ericaceous components. In the Dry Sedge tundra, about one-third of the chlorophyll was in the moss component. However, in the Wet Sedge tundra, only about 2% was in the moss component. Like other studies discussed earlier, they found that the moss layer had the lowest chlorophyll *a:b* ratio, which ranged 1.5-2.5 for all plants. These are relatively low chlorophyll *a:b* ratios overall and correspond with the lower light intensities of Arctic latitudes.

Yang *et al.* (1994) compared bryophyte chlorophyll *a:b* ratios in 17 species from Yuan-Yang Lake. The minimum ratio was 2.17, with a mean of 2.41. This mean was lower than that found for the two aquatic tracheophytes (3.08), but was nevertheless somewhat higher than most bryophyte values reported (Table 1).

Seasonal Differences

As light intensity changes, antenna pigments, cytoplasmic water-soluble pigments, and wall pigments change. This results in seasonal changes in the color of the bryophytes.

Martin and Churchill (1982) found that total chlorophyll content of woodland mosses increased from early spring (1.45 mg g⁻¹ dry mass) before canopy closure to that attained after full canopy closure (4.36 mg g⁻¹ dry mass), demonstrating the wide range of plasticity in the chlorophyll content in these plants. Kershaw and Webber (1986) found a similar relationship in *Brachythecium rutabulum* (Figure 31), with chlorophyll concentrations increasing from 1.70 mg g⁻¹ on 8 May to 11.1 mg g⁻¹ on 11 October. During this time, light saturation declined from 200 μM m⁻² s⁻¹ to 30 μM m⁻² s⁻¹ by 6 July, with the light compensation point likewise falling from 65 μM m⁻² s⁻¹ to 4 μM m⁻² s⁻¹. It is clear that at least some bryophytes have a large capacity to adjust to changing light levels.

Epiphytes are subject to almost constant drying in both summer and winter. Their highest chlorophyll production is in the autumn, October to November, in Japan (Miyata & Hosokawa 1961), when autumn rain and temperatures suitable for C₃ plants make photosynthesis possible. Their lowest concentrations are in summer.

Gerdol *et al.* (1994) took a novel approach to determining seasonal differences in pigment concentrations in *Sphagnum capillifolium* (Figure 37). They compared plant segments and found that both chlorophylls were highest in the midsummer segment. Carotenoids were fairly stable except in spring. Chlorophyll degradation products (phaeophytin, pheophorbide, and chloride) accumulated in the autumn capitulum segment. They interpreted this autumn segment to indicate a rapid degradation of chlorophyll coincident with the night chilling of the end of the growing season.

Czeczuga (1985) quantified the carotenoid pigment concentration in *Marchantia polymorpha* (Figure 8) from March until November. Percentage of total pigments were close to or more than double in June, July, and August (17.8-25.0%) compared to the other sampled months (1.8-9.3%). At the same time, the chlorophyll *a:b* ratio dropped steadily from 1.41 on 1 April to 1.00 by 14 October.

In a study of aquatic bryophytes the chlorophyll *a* and *b* values ranged widely from 1.52 to 6.67 mg chl *a* g⁻¹ dry mass and from 0.61 to 2.70 mg chl *b* (Martínez Abaigar *et al.* 1994; Figure 38). In autumn and winter, chl *a* ranged 2.11-6.27 and chl *b* ranged 0.91 to 2.95. The ranges of *a:b* ratio remained nearly the same in all four seasons (1.95-3.25). But when the bryophytes were separated by habitat, several patterns emerged. Those from habitats subject to summer desiccation had a low summer concentration of chlorophyll and *a:b* ratio with an increase in the carotenoid portion. Those from under a dense tree canopy increased in chlorophyll content from spring to summer, and some continued that increase into autumn, while others dropped down again. Those that were continuously submerged demonstrated the smallest seasonal pigment variations.

Habitat Differences in Chlorophyll

Desert and Dry Areas

In the desiccation-tolerant *Syntrichia ruralis* (Figure 39) from the Organ Mountains of southern New Mexico, Mishler and Oliver (1991) found that the total chlorophyll on a dry weight basis was higher in late summer and winter than in early summer. The chlorophyll *a:b* ratios were relatively low (1.00-2.50), compared to those of tracheophytes, and seemed to have no regular variation pattern.

Figure 38. Seasonal changes in chlorophyll in thirteen species of aquatic bryophytes. Based on Martinez Abaigar *et al.* 1994.

Figure 40. *Cephaloziella exiliflora*, a species that produces a purple anthocyanin-like pigment in response to high light. Photo by Tom Thekathyl, with permission.

Aquatic

Martínez Abaigar *et al.* (1994) compared stream bryophytes to tracheophytes and found that the chlorophyll concentrations were higher (2.2-92. mg g⁻¹ dry mass and 97-351 mg m⁻²) than those of terrestrial bryophytes and comparable to those values for epilithic river algae, but lower than for the tracheophytes. The chlorophyll *a:b* ratio of 2.1-2.8 was significantly lower than they found for tracheophytes. Of note is their find that chlorophyll degradation in underwater bryophytes did not produce phaeopigments. This is an important consideration for those persons who would choose a measure of phaeophytin to indicate damage to the bryophytes in pollution studies.

Antarctic

In a habitat where light is obscured by snow for more than six months of the year, it is not surprising that chlorophyll levels diminish. In the Antarctic, bryophyte chlorophyll levels decrease in winter, as does the chlorophyll *a:b* ratio (Melick & Seppelt 1994). In summer the rise in carotenoid levels corresponds to the period of high light intensity. The only Antarctic liverwort, *Cephaloziella exiliflora* (Figure 40), copes with the high light exposure in the Antarctic summer by producing a purple anthocyanin-like pigment (Post & Vesik 1992). Compared to more protected and shaded plants of the species, these plants had higher carotenoid:chlorophyll ratios, more dispersed thylakoids with fewer grana, fewer appressed thylakoids, more closely spaced leaves, and were larger, growing in a dense turf. Shaded plants had more chlorophyll per unit weight, but their *a:b* ratios did not seem to vary much.

Summary

Photoinhibition results from over excitation of electrons under conditions when the plant is unable to use all of those electrons in photosynthesis. It is a common occurrence under high light intensities, especially at low temperatures. This temperature relationship may account for the limitations of some species that prevent their surviving in polar regions. Desiccation-tolerant species seem to be able to dissipate this energy better than the desiccation-intolerant species. Unlike tracheophytes, bryophytes can suffer greater damage when hydrated than when dehydrated.

Quenching is the ability of the plant to redirect the energy in a way that it does not damage the chlorophyll. Accessory pigments can do this by filtering the light or stabilizing the energy level. In bryophytes, the pigment **zeaxanthin** has been implicated in this role, along with a number of other pigments that depend on the species, reacting in some cases almost instantaneously and in others taking hours.

In some cases, clumping of chloroplasts and changes in shape permit the plastids to protect each other.

Bryophytes are typical shade plants, although some species do have adaptations to sun. Under low light intensity, bryophytes increase their chlorophyll *b* concentrations, providing more locations for trapping the light energy. Chlorophyll *a:b* ratios generally range between 2 and 3, but can be as low as 1 in some habitats and as high as 3.6 in others.

Lutein is commonly produced in aquatic bryophytes, but also in sunlight, causing its function to be uncertain.

Chlorophyll concentrations change seasonally, with highest concentrations generally being during the rainy growing season.

CHAPTER 11-3

PHOTOSYNTHESIS: LIMITING FACTORS

Figure 1. *Schistidium maritimum* growing on rocks where desiccation and salt spray exceed the limits of most bryophytes. Photo by Michael Lüth, with permission.

Limiting Factors

"The actual magnitude of assimilation in a leaf at any moment is determined by one or other of the main controlling conditions, light, temperature, or CO₂-supply, acting as a limiting factor." That was the conclusion of Blackman and Smith (1910-1911) in the ninth of their series of papers on vegetable assimilation and respiration. We know that water is another important parameter, but we are still trying to understand completely just how these parameters limit bryophyte photosynthesis. Perhaps Blackman and Smith again best sum it up in their statement that studies on photosynthesis "are more harmoniously interpreted from the point of view of interacting limiting factors than by the conception of optima."

Gerdol *et al.* (1998) illustrated this principle of interacting factors in their study of *Sphagnum capillifolium* (Figure 2). They found that low nighttime temperatures could lower growth five-fold, that nutrients limited growth when nighttime temperatures were high, that N and P limited growth at optimum temperatures. Different enzymes are turned on at different temperatures and different pH levels, and Gerdol *et al.* suggested that

enzymatic reactions could be limited at unfavorable temperatures.

Figure 2. *Sphagnum capillifolium*, a species in which productivity is affected by nighttime temperatures, nutrients, and N and P at optimum temperatures. Photo by Li Zhang, with permission.

Compensation Point

The **compensation point** is that point at which plant assimilation and respiration are compensated, so that gas exchange is null (Harder 1923). The compensation point can be expressed in terms of temperature, CO₂, or light. When plants are at their compensation point, they have reached a limiting factor for that parameter.

Water Availability

Water as a limiting factor is probably the best understood. Productivity on a worldwide scale seems to be correlated with water availability, at least in *Polytrichum strictum* (Figure 3) (Longton 1994). *Sanionia uncinata* (Figure 4) in Svalbard, Norway, living on the glacial foreland of the high Arctic, has its highest photosynthetic activities only on rainy days or soon after, indicating that it is not light, but water, that limits the productivity (Uchida *et al.* 2002). Collins (1976) related net productivity to water content in these two species, likewise demonstrating its importance (Figure 5).

Figure 3. *Polytrichum strictum* with capsules, a species in which water limits productivity. Photo by Michael Lüth, with permission.

Figure 4. *Sanionia uncinata*, a species in which water limits productivity. Photo by Janice Glime.

Figure 5. Effect of water content on the net productivity of two mosses from Signy Island. Measurements were at 10°C, 500 $\mu\text{e m}^{-2} \text{s}^{-1}$ (400-700 nm). Redrawn from Collins 1976.

Even in bogs, moisture is limiting. Backéus (1988) found that moisture conditions in August explained about 60% of the variation in *Sphagnum* growth the following year. He concluded that the distribution of moisture within the growing season was more important than the mean values. The importance of water in the growth of various *Sphagnum* species is well documented (Asada *et al.* 2003). Rydin and McDonald (1985b) examined the WC₅₀ (% water content at which 50% of the plants would recover if dried to their compensation point) in several *Sphagnum* species (Table 1). These ranged from 198% for *S. balticum* (Figure 6) to 283% for *S. tenellum* (Figure 7). *Sphagnum* typically requires more than 100% water content for photosynthesis.

Table 1. WC₅₀ values for *Sphagnum*. Based on references given in Rydin & McDonald 1985b.

Species	% WC ₅₀	Reference
<i>S. fuscum</i>	227	Rydin & McDonald 1985b
<i>S. fuscum</i>	400	Silvola & Aaltonen 1984
<i>S. balticum</i>	198	Rydin & McDonald 1985b
<i>S. tenellum</i>	283	Rydin & McDonald 1985b
<i>S. nemoreum</i>	400-620	Titus <i>et al.</i> 1983

<i>S. angustifolium</i>	600	Silvola & Aaltonen 1984
<i>S. nemoreum</i>	520	Grace 1970

Figure 6. *Sphagnum balticum*, a hollow species that cannot survive in hummocks. Photo by Michael Lüth, with permission.

Figure 7. *Sphagnum tenellum*, a hollow species that cannot survive in hummocks. Photo by Michael Lüth, with permission.

The strange phenomenon in *Sphagnum* is that there seems to be no correlation between habitat (hummock vs hollow) and photosynthetic rate at low water contents. Titus *et al.* (1983) found the expected relationship was reversed in *S. fallax* (Figure 8) and *S. capillifolium* (*S. nemoreum*, Figure 9), with the hollow-dwelling *S. fallax* having the higher photosynthetic rates at low water content. Silvola and Aaltonen (1984), on the other hand, found that the hummock species *S. fuscum* (Figure 10) was less desiccation-sensitive than the hollow species *S. angustifolium* (Figure 11). Rydin and McDonald (1985a) found that the hollow species *S. balticum* (Figure 6) and *S. tenellum* (Figure 7) cannot grow in hummocks, but that the hummock species *S. fuscum* and *S. rubellum* (Figure 12) can tolerate the wet hollows. It appears that some species have wide niches for water availability.

Figure 12. *Sphagnum rubellum*, a hummock species that can tolerate wet hollows. Photo by Michael Lüth, with permission.

Part of this dependency on water relates to the contact the plant is able to make with its substratum, or at least the water level below its capitulum. Schipperges and Rydin (1998) found that contact between capitula and the basal portion of the moss is essential to the survival of the moss, with isolated capitula being unable to recover from complete desiccation. They determined that the limit seems to be 10-20% of the water content of the compensation point. Maintenance of this level is accomplished by avoidance of desiccation through high capillarity and dense growth forms.

Hanslin *et al.* (2001) examined the effects of plant density on growth rate and water relationships. Increasing the density negatively impacted the relative growth rate and production of green biomass in both boreal forest mosses examined [*Dicranum majus* (Figure 13), *Rhytidiadelphus loreus* (Figure 14)]. However, in the mid-density range and low relative humidity, some of the watering treatments resulted in the best relative growth rates and green biomass production. Although there were no consistent patterns for most treatments, the length of the wet-dry cycle positively affected the relative growth rate when the number of wet-dry days remained equal. This is most likely due to the high cost of repair, with the longer cycles providing more time for positive productivity after the repair. The length of the dry cycle is far less important than having the needed time for repair and gain.

Figure 13. *Dicranum majus*, a species in which density impacts growth. Photo by Janice Glime.

Alpert and Oechel (1987) studied the responses of bryophytes on granitic boulders in the chaparral of San Diego County, California, USA. Even in this dry habitat, the various bryophyte species had significantly different responses to water content, desiccation, and light. Those species in microsites with low water availability achieved maximum net photosynthesis at lower water contents and had a greater ability to recover from prolonged desiccation. Species from microsites with lower light availability achieved higher net photosynthetic rates at lower light intensities. Such studies illustrate the adaptability of bryophytes to a variety of conditions. In this chapter we will examine those limiting factors and the ways that bryophytes cope with them.

Bryophytes adapted to xeric habitats can regain photosynthesis upon rewetting in incredibly short periods of time. In *Grimmia montana* (Figure 15), this occurs in 6-10 minutes (McKay 1935). Equilibrium is reached in 30-40 minutes.

Figure 15. *Grimmia montana*, a xeric species that can regain photosynthesis in 6-10 minutes of rewetting. Photo by Michael Lüth, with permission.

Loss of water can affect not only photosynthesis, but the actual photosynthetic apparatus. As a result, those bryophytes with the ability to achieve non-photochemical quenching have a better chance of survival. In their study of three mosses, Csintalan *et al.* (1999) found that the two rock-dwelling mosses *Grimmia pulvinata* (Figure 16) and

Anomodon viticulosus (Figure 17) had a sharp peak of non-photosynthetic quenching when rewet, whereas quenching seemed to recover slowly in the less desiccation-tolerant *Rhytidiadelphus loreus* (Figure 14). On the other hand, Deltoro *et al.* (1998) suggested that loss of membrane integrity and subsequent loss of potassium might account for the inability to recover its photosynthetic rate.

Figure 17. *Anomodon viticulosus*, a rock dweller that has a sharp peak of non-photosynthetic quenching when rewet. Photo by Janice Glime.

The moss *Rhizomnium punctatum* (Figure 18) experiences damage to PS II at 85% relative humidity (Bartosková *et al.* 1999). This is followed by a functional disconnection of the P680 reaction center from the antenna systems that is evident at higher rates of disconnection.

Water Excess

Silvola (1991) demonstrated that the water needed for photosynthesis varies widely among species. Even within a single boreal forest and peatland system, the minimum water content before net photosynthesis declines ranges from 170% to 500%. On the other hand, these mosses, except for *Polytrichum commune* (Figure 19), also had an upper limit at which photosynthesis would also decline. This limit was imposed by the difficulty of absorbing CO₂ through a water barrier, a phenomenon also observed in *Sphagnum* (Murray *et al.* 1989). Presumably *P. commune* managed to maintain internal air spaces in its leaves among the photosynthetic lamellae (Figure 20), hence permitting it to continue photosynthesis.

Figure 20. *Polytrichum commune* leaf cross section showing spaces between lamellae. Photo by Amelia Merced, with permission.

Liu *et al.* (2001b) found that in the mosses *Thuidium cymbifolium* (Figure 21) and *Chrysocladium retrorsum* (Figure 22) photosynthesis increased in the range of 20-70% water content. Their optimum water content was 70-80%, but then decreased from 80-95%. *Plagiomnium acutum* (Figure 23) had a somewhat broader range, increasing photosynthesis in the water content range of 20-80%, maintaining its highest photosynthetic level in the 80-95% range.

In *Sphagnum*, needed water content is much higher. The limiting water level depends on habitat and associated construction of the leaf. For example, in the hummock species *S. fuscum* (Figure 10), optimum conditions for

photosynthesis occurred at 600-1000% water content, with higher water levels causing a decline in photosynthesis (Silvola & Aaltonen 1984). *Sphagnum angustifolium* (Figure 11), which occurred in wetter locations, had its optimum at a wetter 900-1300%. Nevertheless, it often was too wet for optimum CO₂ absorption, whereas in *S. fuscum* it rarely was. But the relationship is never so simple. Using *Sphagnum*, Jauhianen *et al.* (1998) demonstrated that the negative effect of high water content on photosynthesis disappears at higher CO₂ concentrations, with the optimum water concentration increasing as the CO₂ level increases. At 3000 ppm (10X normal atmospheric CO₂ concentrations), there is no decrease in photosynthetic rate with increasing water content in *S. fuscum* (Figure 10) (Silvola 1990), supporting the conclusion that greater water content creates a barrier to the entry of CO₂.

Similar water content responses occur in *Sphagnum* species from New Zealand (Maseyk *et al.* 1999). Green plants of *S. cristatum* (Figure 24) had an optimum water content of 1200-2000%, whereas brown mosses had a higher optimum content of 1400-3000%. Brown coloration in mosses occurs in response to high light intensity, which usually is accompanied by higher temperatures. This suggests that there is a coordinated suite of responses.

Figure 24. *Sphagnum cristatum*, a species with an optimum water content of 1200-2000%. Photo by Janice Glime.

Seasonal Water Differences

In the tundra of the foothills north of the Brooks Range, Alaska, USA, up to two-thirds of the annual precipitation occurs during summer thunderstorms. In the boreal spruce (*Picea*) forest (Figure 25) in Manitoba, Canada, evapotranspiration was lowest in spring when the ground was still frozen (Betts *et al.* 1999). It was highest in the summer, dropping again in autumn after frost. Evaporation is, predictably, higher when the surface is wet, but it falls with an increase in light level at all temperatures in the summer because of the transpiration resistance of the forest system (*i.e.* guard cells close). But mosses also play a major role in the water evaporation. A wet moss surface lowers the vegetation resistance to water loss at its midmorning minimum by factor of 4. Mosses keep the soil wet and the atmosphere dry by inhibiting evaporation, particularly when they cover pools of standing water.

Figure 25. *Picea mariana* forest in Northern Alberta, Canada, with *Pleurozium schreberi* and *Hylocomium splendens* on the forest floor. Photo by Richard Caners, with permission.

Photosynthetic rate can be directly related to the length of dehydration period (Davey 1997a, b). However, even some bryophytes from very wet habitats in the Antarctic can exhibit some desiccation tolerance. Hydrophytic mosses were more likely to be harmed by repeated wet-dry cycles than were mesophytic or xerophytic bryophytes. Particularly in hydrophytic bryophyte species, the increase in percentage loss of photosynthetic rate following these wet-dry cycles occurred from spring to summer and from summer to autumn sampling periods. Nevertheless, Davey (1997a) could find only broad scale relationships to water availability and drew the same conclusion as Blackman and Smith (1910-1911), that other factors must be important in explaining the distributions of individual species.

Species differ in their responses to humidity. *Plagiomnium acutum* (Figure 23) has higher photosynthetic rates on cloudy and rainy days than does *Herpetineuron toccoeae* (Figure 26), but lower rates on sunny days (Li *et al.* 1999). *Herpetineuron toccoeae* has a lower rate of transpiration and higher water use efficiency than does *P. acutum*, permitting it to have a higher photosynthetic rate on sunny days. It also has a higher temperature tolerance. Interestingly, both species decrease their dark respiration with increases in temperature and decreases in relative humidity.

Figure 26. *Herpetineuron toccoeae*, a species that has reduced photosynthesis in low light. Photo by Li Zhang, with permission.

Nighttime Absorption

Nighttime can be an important time for water absorption in bryophytes. Condensation resulting in dew provides moisture on the surfaces of these small plants and can rehydrate them from the desiccation of daytime. Such moistening will reach its maximum just before dawn, preparing the bryophytes to take advantage of the cool temperatures in the early morning light.

Csintalan *et al.* (2000) demonstrated this phenomenon in the desert moss *Syntrichia ruralis* (Figure 27). They found that water was absorbed progressively by this moss throughout much of the night. This provided sufficient water for the moss to have positive net photosynthesis for about 1.5 hours immediately after dawn. Although the cumulative carbon balance between dark and light on the day of measurement was negative, on those days with greater dew the balance would be positive. They suggested that this short time period was sufficient to permit repair following long-term desiccation damage.

Figure 27. *Syntrichia ruralis*, a species that absorbs moisture from the atmosphere at night. Photo by Des Callaghan, with permission.

CO₂

With all the talk about the greenhouse effect due to elevated CO₂ in the atmosphere, it is hard to think in terms of CO₂ limits on plant productivity. But indeed it is often what limits productivity. In aquatic systems, CO₂ is usually limiting, except perhaps in deep water where sediment decomposition provides CO₂ but light levels are low (Maberly 1985; Wetzel *et al.* 1985).

Zotz *et al.* (2000) found that gas exchange of CO₂ is negatively correlated with cushion size in *Grimmia pulvinata* (Figure 16). Larger cushions have lower rates of photosynthesis and dark respiration, but alternating dark and light periods cause a complicated response that depends at least in part on the state of hydration.

Despite our increasing CO₂ concentrations in the atmosphere, this gas is often limiting to plants, including bryophytes. For this reason, gas spaces associated with the photosynthetic tissue is important (Raven 1996).

Compensation Point

The bottom line on the CO₂ limit for a species is its CO₂ compensation point. But this changes with the water content, temperature, and light intensity. A plant cannot use more CO₂ if there is insufficient excitation of electrons

due to low light levels. Dilks and Proctor (1975) reported compensation points from published studies (Table 2).

Table 2. CO₂ compensation points for bryophytes.

Hanson *et al.* (2002) compared bryophytes with pyrenoids (hornworts) with *Marchantia polymorpha* (Figure 28), a liverwort with no pyrenoids. Pyrenoids are known for their ability to concentrate CO₂, permitting them to store inorganic carbon for later use when levels may diminish. The CO₂ compensation points of the two hornworts with pyrenoids was 11-13 ppm CO₂, whereas in *M. polymorpha* it was 64 ppm, a difference consistent with C₃ photosynthesis in the latter.

Figure 28. *Marchantia polymorpha* with archegoniophores, a species with much higher CO₂ compensation points than hornworts with pyrenoids. Photo by Rudolf Macek, with permission.

CO₂ Environment

The CO₂ environment around a terrestrial plant may be different from that generally found in the atmosphere. Soil bryophytes benefit from CO₂ emitted from soil decomposition. For example, in a New Zealand temperate rainforest where bryophytes blanket the forest floor, those bryophytes had an annual net uptake of carbon of 103 g m⁻², whereas the carbon emitted from the forest floor by bryophytes plus soil respiration was 1010 g m⁻² (Delucia *et al.* 2003). This meant that the bryophytes used only about 10% of the CO₂ coming from the forest soil microbes. The bryophyte contribution to carbon fixation would be considerably higher in the boreal forest.

Bryophytes can actually affect the turbulent fluxes of CO₂ in the forest. The combined effects of moss photosynthesis and respiration reduced those fluxes by a mean of 0.6 $\mu\text{M m}^{-2} \text{s}^{-1}$ (Janssens *et al.* 2001).

For the ground-dwelling *Hylocomium splendens* (Figure 25, Figure 29) in a subarctic habitat, the CO₂

concentration around the plants was 400-450 ppm during the hours when the light intensity was above the compensation point (30 $\mu\text{M m}^{-2} \text{s}^{-1}$) (Sonesson *et al.* 1992). Throughout the growing season, it is light, temperature, and water availability that limit the CO₂ uptake.

Figure 29. Ground-dwelling *Hylocomium splendens*. Photo by Michael Lüth, with permission.

Epiphytes compete with tree leaves for limited CO₂ in the canopy. But wherever the bryophytes are growing, no individual limiting factor is able to work alone. The photosynthetic limits of one are dependent on the levels of the others. Examples of this can be seen in a variety of habitats.

The aquatic moss *Fontinalis antipyretica* (Figure 30) has an especially low CO₂ compensation point, but it was consistent with that of C₃ plants (Maberly 1985). The relationship between the photosynthetic rate and the CO₂ concentration showed a photosynthetic increase as the temperature was increased, typical of plants suffering from boundary layer resistance. It is puzzling that this species had a higher assimilation rate in bicarbonate than in pure CO₂ at the same partial pressure (James 1928). This seems to contradict the studies by Bain and Proctor (1980) that indicate its inability to use bicarbonate. Allen and Spence (1981) independently determined this once more for *Fontinalis antipyretica*. Therefore, in aquatic systems at higher levels of pH, when the CO₂ equilibrium shifts toward bicarbonate or carbonate, CO₂ becomes less available to almost non-existent. In these conditions, perhaps the CO₂ is transformed from bicarbonates in some taxa by lower pH values at the moss-water interface, but no experimental evidence has verified this hypothesis. Thus, the number of mosses growing in alkaline waters is limited, and it seems that many of the ones that do occur in alkaline waters are adapted to grow in the highly aerated water of waterfalls and rapids, as, for example, *Fissidens grandifrons* (Figure 31) (pers. obs.). Others are restricted to the splash zone at the edge of the water, where CO₂ is trapped as the water moves through the air, as in *Cratoneuron* (Figure 32) species (Vitt *et al.* 1986; Glime & Vitt 1987).

Figure 32. *Cratoneuron filicinum*, in a genus in alkaline areas is restricted to the splash zone. Photo by J. C. Schou, with permission.

Silvola (1990) examined the effects of CO₂ on the hummock moss *Sphagnum fuscum* (Figure 10) productivity and determined that maximum productivity occurred at 600-800% dry mass water content at ambient CO₂ levels of about 380 mg L⁻¹, but that at the saturating CO₂ level of 8000 mg L⁻¹, a saturated water content was needed (Figure 33). Since a CO₂ level of 8000 mg L⁻¹ is unrealistic in nature, the curves for 300-1200 mg L⁻¹ CO₂ are more instructive. One might speculate that the present success of *Sphagnum* in full sun and a temperature of

35°C, where most other bryophytes cannot survive, might be related to the elevated CO₂ emitted from peat.

The conclusion from all these studies is that one cannot look at the limits of CO₂, or any other factor, in absolute terms. They must be examined as they are affected by the other potential limiting factors (Maberly 1985). So what does that mean for a statement like the title of a paper by Adamson *et al.* (1990), "Photosynthesis in *Grimmia antarctica* (= *Schistidium antarcticum*; Figure 34), an endemic Antarctic bryophyte, is limited by carbon dioxide"? When considering limits, it is appropriate to consider the range of the natural conditions of the plant and to express the limits that affect those plants under those conditions. Thus, a plant that is limited by CO₂ in the Antarctic might be limited by light if it were growing in England.

Figure 33. The relationship between net photosynthesis and water content (as percent dry mass) in *Sphagnum fuscum* (Figure 10) at two CO₂ concentrations. Constant conditions were maintained at 20°C, 300 μmol m⁻² s⁻¹ PAR photon flux density, and drying at 70% relative humidity. Redrawn from Silvola 1990.

Figure 34. Saturated *Schistidium* (formerly *Grimmia*) *antarctica* with *Ceratodon purpureus* between the hummocks. Photo courtesy of Rod Seppelt.

Silvola (1985) showed that bryophytes can be limited by CO₂ in their natural habitat. In the light range of 70-500 μM m⁻² s⁻¹, raising the CO₂ concentration from 320 ppm to

640 ppm caused a 1.6-2.6-fold increase in the net daily CO₂ exchange.

But short-term studies in the lab or the field may be misleading. Van der Heijden *et al.* (2000) found that initially photosynthesis of *Sphagnum fallax* (= *Sphagnum recurvum* var. *mucronatum*) (Figure 8) was stimulated by elevated CO₂ (700 µL L⁻¹), but that after only three days it had returned to the levels of the controls. Furthermore, at low N deposition levels (6 g m⁻² yr⁻¹) and elevated CO₂, these plants had 17% more biomass after six months, but at high N deposition levels (up to 23 g m⁻² yr⁻¹), there was little effect on biomass increase. High levels of CO₂ caused a suppression of dark respiration, resulting in an accumulation of soluble sugars in the capitulum. Doubling the CO₂ also reduced the total nitrogen content of the capitula, but not the stems, possibly as a result of the increased sugar content. This reduction was seen in reduced amino acid content, but not in protein content. Such shifts in the carbohydrate to amino acid content has sobering implications for the food web, necessitating that more of the same food be eaten to gain the same amino acid content, and consequently increasing the sugar content. Can invertebrates get diabetes?

Within the bryophyte layers, the CO₂ environment differs from ambient. The forest floor efflux of CO₂ beneath *Sphagnum* (Figure 53) and feather mosses such as *Hylocomium splendens* (Figure 25, Figure 29) in the boreal black spruce forest (Figure 25) is ~7 M m⁻² s⁻¹, a loss from the forest floor of 255.4 g C m⁻² during May-October (Swanson & Flanagan 2001). In *H. splendens*, the upper parts may have 400-450 ppm CO₂ while the light conditions are above the compensation point (*i.e.*, while photosynthesis is occurring), but light levels below saturation during most of the growing season limit CO₂ uptake (Sonesson *et al.* 1992). Nevertheless, the higher than normal atmospheric levels of CO₂ that occur within the mat permit the plants to have photosynthetic levels that are higher than would normally occur at the reduced (below saturating) light levels.

As the CO₂ concentration of the atmosphere increases, productivity of various groups of plants are likely to be affected differently. The rate of net photosynthesis in the hummock peatmoss *Sphagnum fuscum* (Figure 10) increases as the CO₂ concentration increases in the range of 350-2000 ppm CO₂ during half-hour exposures (Jauhiainen & Silvola 1999). The rate at light saturation likewise increases. The effect of radiation fluxes, however, is independent of the level of CO₂. When the exposure to high CO₂ is maintained for longer times, the rates of net photosynthesis gradually decrease compared to those at 350 ppm. On the other hand, at high CO₂ levels, the depression of net photosynthesis found at high water contents is no longer present.

Tropical forests have huge competition for CO₂ in the canopy, but so little light reaches the forest floor that competition is greatly reduced. In a submontane tropical rainforest in Panama, diel variations in water content of six studied bryophytes were great, with both high and low water content limiting photosynthesis (Zotz *et al.* 1997). Low photon flux density is less important in limiting CO₂ exchange. More than half of the carbon gained in the daytime (2.9 mg C per g plant) is lost at night as respiration. If the productivity of this study is

representative, the bryophytes gain 45% of their initial carbon content in a year in this environment.

CO₂-Concentrating Mechanisms

Since CO₂ is frequently a limiting resource, a means of concentrating CO₂ for use later or for grabbing it from water is a useful mechanism. Although bryophytes are known only as C₃ plants (Smith & Griffiths 1996), at least some seem to have such mechanisms. Furthermore, both **Cyanobacteria** and many algae are able to accumulate dissolved inorganic carbon through CO₂-concentrating mechanisms (Smith & Griffiths 1996). In the green algae (**Chlorophyta**), this is accomplished by a proteinaceous structure associated with chloroplasts, the **pyrenoid**. And indeed, this structure is present in the phylum **Anthocerotophyta** (Figure 35), but not in all genera.

Figure 35. *Phaeoceros* cells with pyrenoids associated with chloroplasts. Photo by George Shepherd, with permission.

I find it interesting that it is a primarily terrestrial group that has this mechanism. Living on the soil permits bryophytes to take advantage of CO₂ emitted through soil respiration. But living in the water, attaining CO₂ can be a severe problem for some bryophytes not receiving CO₂ from the sediments and unable to use the carbonates and bicarbonates in water with non-acid pH. Something is working to permit some bryophytes to live in these conditions, and the mechanism remains unknown.

pH

On land it is likely that pH has only minimal influence on the uptake of CO₂ from the atmosphere. However, in the aquatic system, pH can be a serious limiting factor. The CO₂ that is dissolved in water seeks equilibrium with the bicarbonate and carbonate. This equilibrium is dependent on pH:

where the pK values are those at 25°C

The pK is the pH at which the dissociated and undissociated forms have the same activity, *i.e.*, the two sides of the arrows in the above equations. It is the equilibrium between the two forms. From this we can derive the level at which inorganic carbon exists in the bicarbonate state. At pH 6.35, the solution would be expected to have half CO_2 and half bicarbonate. Above that it becomes predominately bicarbonate. At even higher levels of 10.3, the bicarbonate and carbonate levels are equal. Above pH 10.3, the carbon is predominately in the form of carbonate. Allen and Spence (1981) calculated that at pH 4.4, 99% of the inorganic carbon is present as H_2CO_3 (making free CO_2 available); only 1% is HCO_3^- , and there is virtually no CO_3^{2-} . At pH 8.4, this reverses and 99% of the total inorganic carbon is HCO_3^- ; less than 1% is in H_2CO_3 ; less than 0.03% is in CO_3^{2-} . At any given moment, some CO_2 will exist as biological and chemical reactions occur to release CO_2 into the water, but as time continues, those small amounts will enter into the equilibrium. Nevertheless, metals and other buffering acids and bases can alter the concentrations.

In aquatic systems, CO_2 is spontaneously hydrated to H_2CO_3 , but this hydration occurs about 2 orders of magnitude slower than the hydration which occurs in the carbonic anhydrase-catalyzed reaction. But remember that the carbonic anhydrase is in the cell where the pH is generally above 6.5. Or is it? There is evidence that carbonic anhydrase acts extracellularly in some algae (Hobson *et al.* 2001), including *Chlamydomonas* (Figure 36) and some diatoms. Thus it is possible that there is extracellular activity in some aquatic mosses. Furthermore, the pH of the cell wall is typically lower than that of the cell, ranging 3-6.

Figure 36. *Chlamydomonas*, a genus that uses carbonic anhydrase extracellularly. Photo by Yuuji Tsukii, with permission.

I am aware of no evidence that this carbonic anhydrase is able to act on water outside the cell in any bryophyte, but then, no one seems to have looked. With such an elevated pH within the cell, the H_2CO_3 is rapidly converted to bicarbonate and the level of carbonic acid is miniscule. But the enzyme RUBISCO is present in the plant photosynthetic cell, ready to place the CO_2 into the photosynthetic pathway where it is bound into the 3-carbon compound, PGA (Rintamäki 1989). Thus, the problem is getting the miniscule amounts of CO_2 from the water in

systems where the pH is too high for the equilibrium to shift toward free CO_2 or H_2CO_3 .

Sphagnum (Figure 7-Figure 12) and other bryophytes have the ability to lower the pH through cation exchange, thus keeping more CO_2 in their environment in readily usable form. Consequently, low pH values in the proximity of bryophytes with polyuronic acid in the cell walls are most likely common, and the cation exchange properties of these acids would provide H^+ ions in the immediate surroundings. This could provide the free CO_2 needed for photosynthesis. In plants living in cool water and low light, such as many aquatic bryophytes, even such low levels of CO_2 are probably adequate. As discussed in the nutrient chapter, this cation exchange and pH -lowering ability have a number of ecological and physiological implications in the peatland habitat. The pH -lowering ability and requirements differ with *Sphagnum* species, with hummock species tending to have requirements for the lowest pH (Haraguchi 1996; Haraguchi *et al.* 2003). After all, it is difficult to have much effect on the pH of an entire lake, but having an effect on the immediate microenvironment of a hummock is not.

Limits to Entry

Water limits the entry of CO_2 into cells. For *Sphagnum fuscum* (Figure 10), Silvola (1990) found the optimal water content at ambient CO_2 levels to be 600-800%. However, if the CO_2 level was raised, that optimal water content increased, an observation consistent with the difficulty of getting CO_2 into a wet cell through the water boundary. By increasing the concentration of CO_2 , more of it is able to penetrate the barrier. At 3000 ppm CO_2 , there was no decrease in the photosynthetic rate with increasing water content.

In aquatic habitats, bryophytes may gain CO_2 from that evolved from sediment respiration. Wetzel *et al.* (1985) found that 25-40% of the CO_2 fixed in leaves of tracheophytes comes from the **rhizosphere** (root area). Bryophytes do not have the **lacunae** (minute cavities) to transmit gases in the manner used by many aquatic tracheophytes, but due to their small size, they are able to incorporate the evolving CO_2 as it escapes from the sediments and before it reaches the awaiting phytoplankton.

Methane

Sphagnum (Figure 7-Figure 12) seems to have an alternative source for gaining carbon (Raghoebarsing *et al.* 2005). It is able to obtain carbon through a symbiotic relationship with endophytic methanotrophic bacteria living in the hyaline cells of both stems and leaves. These bacteria oxidize the carbon from the methane to CO_2 that is then used by the *Sphagnum*. This appears to supply about 10-15% of the carbon used by *Sphagnum*. This and other processes in the peatland system recycle the methane in ways that cause little of the methane to reach the atmosphere.

Light

The majority of bryophytes grow in habitats where the light intensity is less than that of full sunlight. Therefore, it is not surprising that Rincón (1993) found that six forest floor bryophytes all increased their biomass relative to

controls when the light intensity was increased for 36 days. But shoot elongation can have the opposite response. In this study, all species [*Brachythecium rutabulum* (Figure 37), *Eurhynchium praelongum* (Figure 38), *Plagiomnium undulatum* (Figure 39), *Pseudoscleropodium purum* (Figure 40), *Thuidium tamariscinum* (Figure 41)] but *Lophocolea bidentata* (Figure 42) had greater elongation in the lower light intensities. *Dicranum majus* (Figure 13) likewise had its greatest elongation at the lowest light level tested ($20 \mu\text{M m}^{-2} \text{s}^{-1}$) (Bakken 1995).

Figure 42. *Lophocolea bidentata*, a leafy liverwort that exhibits greater elongation in low light. Photo by Michael Lüth, with permission.

Murray *et al.* (1993) found a similar elongation response among Alaskan Arctic tundra *Sphagnum* (Figure 7-Figure 12) species. They experimented by removal of tracheophytes in some plots and by use of shade cloth of others, compared to controls. Moss growth in shaded plots was 2-3 times that of mosses in control plots, whereas significant growth reduction was evident in the canopy removal plots. They suggested that those mosses in the canopy removal plots suffered from photoinhibition. In the

laboratory, such inhibition occurred after only two days of high light treatment and the photosynthetic capacity did not recover during the 14 days of the experiment. They suggested that the low tissue nitrogen levels may have prevented the *Sphagnum* from acclimating to the high light intensity.

Compensation and Saturation Points

Bryophytes in general are shade-adapted plants with low light compensation points and low saturation levels. Gabriel and Bates (2003) showed that bryophytes of the evergreen laurel forest in the Azores were likewise shade-adapted plants that reached their light saturation at $30 \mu\text{M m}^{-2} \text{s}^{-1}$. *Andoa berthelotiana* (Figure 43) had the lowest compensation point at $20 \mu\text{M m}^{-2} \text{s}^{-1}$ and *Myurium hochstetteri* (Figure 44) had the highest at $68 \mu\text{M m}^{-2} \text{s}^{-1}$. The deep shade species *Fissidens serrulatus* (Figure 45) had the extremely low compensation point of $7 \mu\text{M photons m}^{-2} \text{s}^{-1}$. With leaves remaining on the trees, the low light levels of winter often limit the photosynthetic activity of these bryophytes. Contrasting with these evergreen forest species, the pendulous moss *Pilotrichella ampullacea* (Figure 46) in Uganda has a saturating light intensity of $400 \mu\text{M m}^{-2} \text{s}^{-1}$ (Proctor 2002).

It is difficult to compare results from different studies because the units cannot easily be converted to other forms of measure, as discussed in the chapter on light. Older measurements were typically in foot candles or lux, whereas more recent ones are in energy units or PAR (photosynthetically active radiation) units. Conversion is complicated by the composition of the wavelengths of light. For example, Vashistha and Chopra (1989) determined that the optimal growth of the disturbed habitat liverwort *Riccia frostii* (Figure 47) occurred at 3500 lux of continuous light in the lab. But lab light quality differs considerably from that in the field and under fluorescent lights it typically lacks the normal proportion of red light that achieves the highest level of photosynthesis. A light level of 3500 lux is quite low when one considers that full

sunlight is about 70,000 lux. It is likely that at that level of light some other factor became limiting in the lab, perhaps CO₂.

Figure 47. *Riccia frostii*, a species of disturbed habitats. Photo by Rosemary Taylor, with permission.

The interplay of limiting factors becomes the means of niche partitioning in many of the bryophytes. *Plagiomnium acutum* (Figure 23) and *Herpetineuron toccoeae* (Figure 26) occupy different niches because of this interplay. In *P. acutum*, photosynthesis is lower on sunny days but higher on cloudy and rainy days than that of *H. toccoeae*, indicating its greater ability to absorb and use weak light while having a higher CO₂ assimilation efficiency (Li *et al.* 1999). The greater water use efficiency of *H. toccoeae* and lower rate of transpiration permits that species to tolerate higher temperatures and desiccating conditions. One reason for this is the higher respiratory rate of *P. acutum*.

The mosses *Plagiomnium acutum* (Figure 23) and *P. maximoviczii* (Figure 48) have light compensation points of 20-40 $\mu\text{M m}^{-2} \text{s}^{-1}$ and saturation points of 200-400 $\mu\text{M m}^{-2} \text{s}^{-1}$, with lower values in winter and higher ones in summer (Liu *et al.* 2001a). Thus it appears that they acclimate to the conditions of light or temperature or both.

It is intuitively obvious that light intensity will decrease as one penetrates further into the moss layer. In a

study on Antarctic mosses, Davey and Ellis-Evans (1996) found that not only did the light intensity decrease, but the attenuation maxima were at the wavelengths where chlorophyll has the greatest absorption peaks (675 nm and <450 nm). That again seems intuitive, since it is the green plant that is blocking the light penetration, and that green is the result of the chlorophyll pigments. But it is not quite that simple. Species differ in their absorption spectra, with stem orientation, stem density, leaf size, orientation, and pigment content all affecting absorption. While bryophytes all tend to have similar pigments, the relative proportions differ. Drying causes the wavelength variation to disappear and light to penetrate further into the clump or mat. These light penetration and wavelength changes resulted from both structural changes in the cells and pigment changes. This is adaptive, permitting deeper layers to carry out photosynthesis as the upper parts of the plants dry beyond the point where they can photosynthesize.

Because of its thin ozone layer, the Antarctic has some of the highest UV intensities on Earth. Among fourteen species of mosses, the light saturation level was 30-270 $\mu\text{M m}^{-2} \text{s}^{-1}$ (Davey & Rothery 1997). Nevertheless, these shade-adapted bryophytes exhibited no photoinhibition at any light intensity tested, up to 700 $\mu\text{M m}^{-2} \text{s}^{-1}$.

The thallose liverwort *Marchantia polymorpha* (Figure 28) is generally a shade plant, but tolerates at least some direct sun. Nevertheless, its light saturation level was only 2000-3000 lux, with inhibition occurring at higher levels (Mache & Loiseaux 1973). This is a very low saturation level when one considers that full sunlight in the temperate zone is typically about 70,000 lux. Isolated chloroplasts had a rate of photosynthesis about one tenth that of those in whole plants, suggesting that the plant may reduce the light level considerably to achieve its optimum low light level. Furthermore, high light stimulates changes in the chloroplast structure, inducing formation of continuous grana instead of the more typical small grana. By contrast, *Hypnum cupressiforme* (Figure 49), an epiphyte, had not reached saturation at any temperature (0-15°C) at light intensities of 12,000 lux (Kallio & Kärenlampi 1975).

Figure 49. *Hypnum cupressiforme* epiphytic habitat, a species with a wide range of temperatures without reaching light saturation. Photo by Dick Haaksma, with permission.

Rastorfer and Higginbotham (1968) measured the light saturation of *Bryum sandbergii* from Idaho, USA, at 20°C in 3% CO₂ and found that photosynthesis attenuated at

about 8 m watts per cm^2 (Figure 50). However, at 4°C , the photosynthetic rate declined at 8 m watts per cm^2 , suggesting photoinhibition at that low temperature (Figure 51).

Figure 50. Mean effects of light intensity on net photosynthetic rates of *Bryum sandbergii* in the lab and field at 20°C , 3% CO_2 . $n=5$. Redrawn from Rastorfer and Higginbotham 1968.

Figure 51. Mean effects of light intensity in the lab and field on net photosynthesis of *Bryum sandbergii* at 4°C , 3% CO_2 . $n=5$. Redrawn from Rastorfer and Higginbotham 1968.

In *Sphagnum cristatum* (Figure 24) and *S. australe* (Figure 52) from New Zealand, the light saturation point ranges from 111 to $266 \mu\text{M m}^{-2} \text{s}^{-1}$ (Maseyk *et al.* 1999). Color affected the saturation point of *S. cristatum*, with brown coloration causing an elevated saturation point. This, in turn, resulted in lower photosynthetic rates, lower

quantum efficiencies, and higher light compensation points than those of green plants.

Figure 52. *Sphagnum australe*, a species with a wide range of light saturation points. Photo by Tom Thekathyl, with permission.

In the Alaskan foothills of the Philip Smith Mountains, *Sphagnum angustifolium* (Figure 11) has a light compensation point of $37 \mu\text{M m}^{-2} \text{s}^{-1}$ and light saturation between 250 and $500 \mu\text{mol m}^{-2} \text{s}^{-1}$ at 10°C (Harley *et al.* 1989). At 20°C , this relationship shifted upward, with the compensation point increasing to $127 \mu\text{M m}^{-2} \text{s}^{-1}$ and the saturation point to $500 \mu\text{M m}^{-2} \text{s}^{-1}$. *Sphagnum squarrosum* (Figure 53) experienced decreased photosynthetic capacity and chlorophyll bleaching when the tracheophyte cover was removed.

Figure 53. *Sphagnum squarrosum* 1 J. C. Schou, with permission.

Shade mosses have a light compensation point of 20-400 lux and sun species of 1000-2000 lux (Bazzaz *et al.* 1970). Saturation points generally run 10,000-30,000 lux for sun bryophytes (Proctor 1981). The epiphytic *Ulota crispata* (Figure 54) has a saturation point of 40,000 lux (Miyata & Hosokawa 1961). Thus, sun species of bryophytes have compensation and saturation levels about ten times as high as those of shade mosses. In Kansas, USA, the saturating light level for *Dicranum scoparium* (Figure 55), *Leucobryum glaucum* (Figure 61), and *Thuidium delicatulum* (Figure 62) is $200 \mu\text{M m}^{-2} \text{s}^{-1}$ (McCall & Martin 1991).

Figure 54. *Ulota crispa*, an epiphyte with a high light saturation point. Photo by Janice Glime.

Figure 55. *Dicranum scoparium*, a forest floor species. Photo by Janice Glime.

Aquatic plants from deep water are likely to have the lowest compensation points due to the low levels of light penetrating to depths. *Fontinalis* (Figure 30) exhibited a compensation point of 150 lux at 20°C, but this declined to 40 lux at 5°C (Burr 1941). Wetzell *et al.* (1985) found extremely low light compensation points for *Sphagnum auriculatum* var. *inundatum* (Figure 56) and *Juncus bulbosus* (a seed plant; Figure 59) from deeper water and higher values for the red alga *Batrachospermum* (Figure 60) from shallower areas.

Figure 56. *Sphagnum auriculatum*, a species with a very low light compensation point. Photo by Jan-Peter Frahm, with permission.

More recent measurements have put light measurements in terms of energy units or photosynthetically active radiation (PAR). Using energy units, Krupa (1978) found a compensation point of 0.6 and saturation point of 15 W m⁻² for the shade plant *Rhizomnium punctatum* (Figure 18). For the sun plants *Polytrichum piliferum* (Figure 57) and *Funaria hygrometrica* (Figure 58), the compensation points were 1.8 and 1.4 W m⁻², respectively, and the saturation points 55 and 100 W m⁻², respectively.

Even the bryophytes seem to operate below their light saturation points for most of the growing season. *Hylocomium splendens* (Figure 29) in the subarctic had a compensation point of 30 μM m⁻² s⁻¹ and a saturation point of 100 μM m⁻² s⁻¹ during the growing season, but it only experienced its light saturation level 65% of the time in July, 76% in August, and 96% in September (Sonesson *et al.* 1992).

Light intensity, coupled with air humidity, seems to be a limiting factor for distribution of tropical epiphytic bryophytes in the Amazon (Frahm 1987). The low light intensities, coupled with high temperatures in the lowland forests, do not permit the bryophytes to reach their compensation points. Energy lost to respiration at such temperatures is greater than that gained in the low light levels of the lowlands. This relationship accounts for the increasing number of taxa and biomass with increased elevation.

Figure 61. *Leucobryum glaucum*, a forest floor species. Photo by Janice Glime.

Figure 62. *Thuidium delicatulum*, a species of open and forest. Photo by Janice Glime.

Excess Light

Excess light can limit bryophyte productivity by causing photoinhibition and damage to the chlorophyll. Dehydration usually protects the bryophytes from this damage by making the plants dormant. When dehydrated, *Grimmia alpestris* (Figure 63) from an alpine habitat had little chlorophyll fluorescence when subjected to high UV light intensity, whereas tracheophytes had high levels of fluorescence under the same conditions (Heber *et al.* 2000). When these mosses were rehydrated, their fluorescence increased, but that of the tracheophytes decreased upon rehydration. These mosses typically do not experience photodamage while dry, apparently using the same protective mechanism while dry as they are able to use successfully while hydrated.

Figure 63. *Grimmia alpestris*, a species that loses its chlorophyll fluorescence at high light intensities. Photo by Michael Lüth, with permission.

Experiments in canopy removal consistently indicate that high light intensities are not favorable to moss growth. In the Alaskan Arctic tundra, Murray *et al.* (1993) found that *Sphagnum*-dominated moss growth (Figure 53) increased by 2-3 times in shaded plots, but had a significant growth reduction in plots where the tracheophyte canopy had been removed. They suggested that the reduced growth was due to photoinhibition.

It is not uncommon for bryophytes to become pale in bright sunlight. Others develop red or other energy-absorbing pigments. But some of the effects of greater exposure to light, such as that seen in canopy removal experiments, is that the temperature and moisture conditions change. More of the daylight hours are at temperatures above that which is suitable for C_3 photosynthesis, forcing the plants to become dormant. And the added light and heat cause a greater loss of water by evaporation.

Continuous Light

As already discussed in Chapter 9-4, we know that continuous light may be deleterious to photosynthesis, causing mosses to lose their chlorophyll (Kallio & Valanne 1975). The stroma thylakoids are destroyed, much like the destruction seen in continuous dark in the cave experiments of Rajczy (1982). However, the continuous light damage observed by Kallio and Valanne occurred in laboratory experiments. Plants living in Polar Regions may acclimate to the seasonal change in continuous photoperiod (Richardson 1981).

It appears that continuous light alters the proportions of sugars and lipids. Sakai *et al.* (2001) found that green portions of the moss *Racomitrium barbuloides* (Figure 64) initially increased their storage of both sugars and lipids, but then they decreased. This decrease was accompanied with a significant decline in photosynthetic capacity. They suggested that the green tissue plays a major role in photoassimilate storage. It appears that accumulation of photoassimilates inhibits photosynthesis, but that such accumulation is unlikely under natural conditions.

Figure 64. *Racomitrium barbuloides*, a species that stores sugars and lipids, depending on environmental conditions. Photo from Digital Museum, Hiroshima University, with permission.

Bryophyte Canopy Structure

A bryophyte canopy is constructed differently from that of tracheophytes. Yet, while the leaf structure is very different, the mat structure may in many ways resemble the leaf structure of a tree leaf. Rice *et al.* (2008) investigated the trait relationships in ten species of *Sphagnum* (Figure 7-Figure 12). They found no relationship between N content and maximum photosynthesis per mass or area, differing from relationships in tracheophytes. Only capitulum area seemed to be relevant to N storage and maximum photosynthesis. Water content and carotenoid

concentration were the strongest predictors of maximum photosynthesis.

Tobias and Niinemets (2010) noted the large variation of light availability within the moss canopy. Furthermore, the lowest light levels are in the lower portions where the oldest tissues reside. Variation within the temperate-boreal forest moss *Pleurozium schreberi* (Figure 25, Figure 65) canopy can be greater than that between locations. Chl, Chl/N, and Chl/Carotenoid ratios increase with decreasing light availability between locations. Upper layers of the moss within habitat vary similarly, but after the light diminishes to 50-60% of the above-canopy levels, the layers demonstrate characteristics of senescence. At these depths, pigment and N concentration and photosynthetic capacity decrease with light availability. Thus, younger tissues are able to acclimate, but older ones do not.

Figure 65. *Pleurozium schreberi*, a common boreal feather moss. Photo by Janice Glime.

Waite and Sack (2010), in studying ten Hawaiian moss species, found that the moss species had low leaf mass per area and low gas exchange rates. The light-saturated photosynthetic rate per mass did not correlate with light levels in the habitat. Rather, microhabitat irradiance had the greatest influence on other photosynthetic parameters and structural traits, causing correlations of traits of leaf area, cell size, cell wall thickness, and canopy density. Costa size, canopy height, and light-saturated assimilation rate per mass correlated with structural allocation. N concentration correlated negatively with canopy mass per area (replacing leaf mass per area used in tracheophytes). The structures are different from those of tracheophytes, but the leaf size and function have been replaced with canopy mass and function.

Photoperiod Effects on Physiology

The effects of photoperiod as an event trigger are well known, but their effects on physiology of vegetative plants has been largely ignored (Cvetić *et al.* 2009). In the forest moss *Atrichum undulatum*, day length had no noticeable effect on photosynthetic pigments in the lab. Protein content and malate dehydrogenase activity were both higher in long day (16h light/8h dark) than in short day (8h light/16h dark) growth conditions. Long days produced higher concentrations of total phenolic compounds, greater peroxidase activity, and higher total antioxidative capacity.

Temperature

Once again we see evidence that limiting factors do not act alone. In *Fontinalis antipyretica* (Figure 30), photosynthesis increases with CO₂ concentration, but the level achieved is further dependent upon temperature (Maberly 1985). As the temperature goes up, boundary layer resistance decreases, permitting more CO₂ to enter the plants.

Aquatic mosses seem to be especially sensitive to high temperature, failing to sustain a healthy state for a prolonged period. Their lethal temperature can be quite low, as illustrated by *Leptodictyum riparium* (Figure 66) with a photosynthetic optimum at 23°C and death at 33°C (Sanford 1979). Several *Fontinalis* (Figure 30) species can do well at 20°C for a period of time; then they lose their green color and stop growing (Fornwall & Glime 1982; Glime 1982, 1987a, 1987b, 1987c, Glime & Acton 1979).

Figure 66. *Leptodictyum riparium*, a species that dies at 33°C. Photo by David Holyoak, with permission.

Interestingly, cold resistance seems to be related to heat resistance, as shown by Balagurova *et al.* (1996) for *Sphagnum* species. For *S. subsecundum* (Figure 67), the lethal temperature of cells was 60.3°C. Lethal cold temperatures ranged -16.1°C to -21.8°C.

Figure 67. *Sphagnum subsecundum*, a species that demonstrates both low and high temperature tolerance. Photo by Michael Lüth, with permission.

But temperature seems to have less detrimental effect on photosynthesis in bryophytes than we might expect from its role in other processes and organisms. While bryophytes have little ability to control temperature physiologically, they do have the ability to respond through

alteration of color that may be induced by day length, light intensity, or temperature itself. Could it be that the red color of the antheridial splash cups of *Polytrichum piliferum* (Figure 68) keeps the sperm warm on cool days in spring?

Figure 68. Antheridial splash cups of *Polytrichum piliferum*. Photo by Janice Glime.

Photosynthetic levels in some Arctic mosses seem to be similar over a wide temperature range. Vilde (1988) interpreted the mosses of the Arctic to be well adapted to their temperature regime. He found that photosynthesis has little temperature limitation and even high light intensity has little effect on these Arctic mosses. Uchida *et al.* (2002) found that the net photosynthetic rate in *Sanionia uncinata* in the high Arctic of Svalbard, Norway, was nearly constant at near-saturating light levels across the range of 7 to 23°C, but these same plants exhibited the extraordinarily high Q₁₀ of 3.0 for respiration in that range. This means that the gross photosynthesis must likewise have experienced a large increase with temperature in that range, with respiration using an increasing differential of that newly fixed carbon.

Temperature can have a threshold effect on bryophyte productivity. Asada *et al.* (2003) found that *Sphagnum* (Figure 7-Figure 12) species in a coastal British Columbia, Canada, peatland had lower temperature thresholds than did *Pleurozium schreberi* (Figure 25, Figure 65) and *Racomitrium lanuginosum* (Figure 69). Winter growth was important in this community, most likely because of greater availability of water; growth was more strongly correlated with precipitation than with temperature.

Figure 69. *Racomitrium lanuginosum*. Photo by Michael Lüth, with permission.

Kallio and Heinonen (1973) found that *Racomitrium lanuginosum* (Figure 69) could photosynthesize at -10°C (compensation point) and that it returned to 60% of its normal photosynthetic rate within three hours after storage at -30°C . Its optimum was at 5°C . They interpreted this moss to be pre-adapted to the wide range of temperatures in which it exists, lacking any clear physiological races with respect to temperature response.

Bryophytes acclimate to temperature, altering their optimum temperature for photosynthesis. This is likely to be accompanied by a shift in the light saturation level. However, the respiration rate does not necessarily acclimate at the same time. Both lowland and highland *Dicranum fuscescens* (Figure 70) showed photosynthetic acclimation to higher temperatures of mid summer, with highland plants having maximum rates of $2.1 \text{ mg CO}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$ and lowland plants having only $0.74 \text{ mg CO}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$ (Hicklenton & Oechel 1976). The optimum temperature shift can occur in as little as 48 hours in this species. The light saturation levels increased from spring to midsummer, then lowered again toward autumn. Dark respiration, however, did not acclimate.

Figure 70. *Dicranum fuscescens*, a species that acclimates to the higher temperatures of summer. Photo by Michael Lüth, with permission.

But even within the normal range of temperatures, bryophytes perform poorly at higher temperatures that favor most tracheophytes, as shown by the rapid drop in growth rate of the temperate pleurocarpous moss *Brachythecium rutabulum* (Figure 37) at temperatures above 15°C (Furness & Grime 1982). On the other hand, at only 5°C their growth is still 40% of their maximum rate at $\sim 19^{\circ}\text{C}$. This moss achieved a growth rate exceeding the maximum reported for seedlings of ten tracheophytes. Furness and Grime show the strong seasonal effects of temperature that help to explain some of the phenology of bryophytes. These results are consistent with its peaks of growth in spring and autumn, allowing it to compete with its tracheophyte neighbors in the British tall herb communities where they grow.

Frahm (1990) determined that high temperatures in tropical lowlands result in high respiration rates. Consequently, at temperatures above 25°C , net assimilation drops sharply. It is that high respiratory loss that limits much of bryophyte distribution in the tropics.

In the New Zealand species *Sphagnum cristatum* (Figure 24) and *S. australe* (Figure 52), the optimum temperatures for photosynthesis are 20 to 25°C (Maseyk *et al.* 1999). Liu *et al.* (2001a) found that *Plagiommium*

acutum (Figure 23) and *P. maximoviczii* (Figure 48) could maintain net photosynthetic gain for 10-30 minutes from -15°C to 45°C . Despite their cold climate, fourteen bryophytes in the Antarctic have a temperature optimum for gross photosynthesis of $10-20^{\circ}\text{C}$ and of $0-20^{\circ}\text{C}$ for net photosynthesis (Davey & Rothery 1997). With the relatively high Antarctic light intensity, these bryophytes are usually temperature limited during the growing season.

Like the experiments on *Fontinalis duriaei* (Figure 71) of Glime and Acton (1979), Dilks and Proctor found that prolonged exposure to high temperatures caused a drop in productivity (Figure 72), thus demonstrating that duration of an experiment would influence the determined optimum temperature. While these curves may indicate the general trend of the response, we must exercise caution because the higher than atmospheric level of CO_2 used would most likely push the temperature optimum to a higher level.

Figure 71. *Fontinalis duriaei*, a species that experiences a drop in productivity after prolonged high temperatures. Photo by Michael Lüth, with permission.

Figure 72. Effect on photosynthesis of prolonged exposure at various temperatures (— 17°C ; - - 25°C ; 30°C ; -.-. 35°C) and responses for net assimilation after 1 hour (●), 12 hours (Δ), and 24 hours (○). Redrawn from Dilks & Proctor 1975.

Rastorfer and Higginbotham (1968) demonstrated an increase in net photosynthesis of *Bryum sandbergii* in the range of 4-24°C, with a drop at 34°C. Dilks and Proctor (1975) compared twenty-three mosses and five liverworts at temperatures varying 5-45°C. These bryophytes typically exhibited fourth order polynomial curves that rose to an optimum, then dropped abruptly (Figure 73). However, not all species showed such a sudden drop and some exhibited a broad optimum, as seen in Figure 74. It is interesting that the more Arctic *Racomitrium lanuginosum* (Figure 69) exhibits the opposite curve shape – a sharp rise with temperature to its optimum at 5°C, and a slow decline above the optimum (Kallio & Heinonen 1973; Kallio & Kärenlampi 1975). *Pleurozium schreberi* (Figure 25, Figure 65) seems to exhibit a nearly bell-shaped curve with temperature, exhibiting an optimum at 10-15°C (Kallio & Kärenlampi 1975).

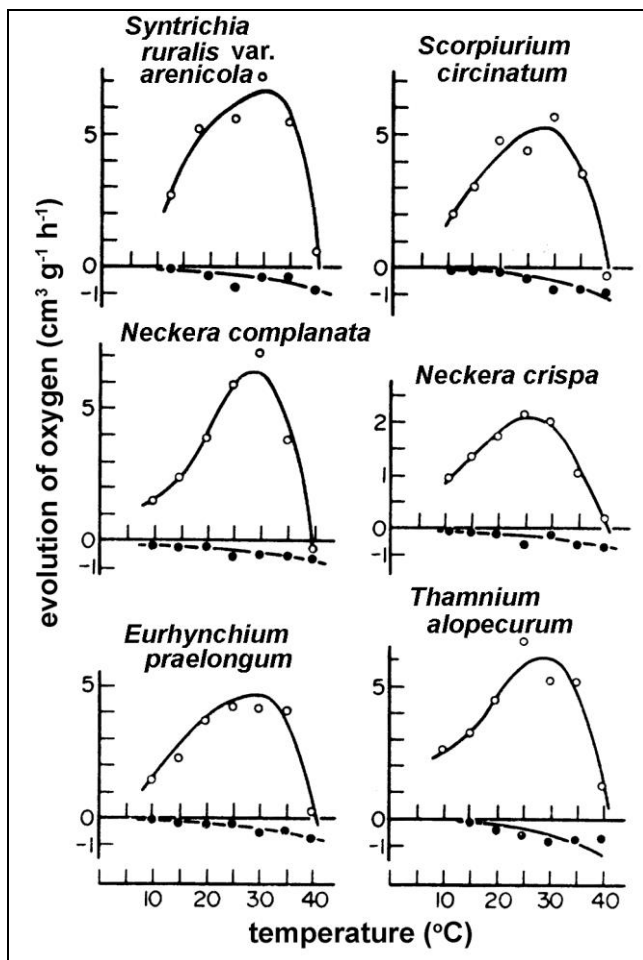

Figure 73. Photosynthesis at various temperatures. O = net assimilation; • = respiration. These responses are modelled with a fourth order curve. Redrawn from Dilks & Proctor 1975.

In the harsh conditions of the Antarctic, we can find some novel responses to temperature and light intensity. The ubiquitous moss *Bryum argenteum* (Figure 75) had a strong dark respiration response to temperature, causing significant changes in CO₂ exchange rates (Green *et al.* 1998). This species had a strong linear correlation between gross photosynthesis and electron-transport rate in PS II. Green and coworkers suggested that this deviation from the curvilinear relationship in tracheophytes might result from

some sort of suppression of dark respiration in the light. In fact, it seems that both bryophytes and C₃ tracheophytes experience photorespiration in the light. Nevertheless, the relationship appears to be different in the bryophytes.

Figure 74. Photosynthesis at various temperatures for several mosses with a northern range. O = net assimilation; • = respiration. These responses are modelled with a fourth order curve but lack the sudden drop seen in Figure 73. Redrawn from Dilks & Proctor 1975.

Compensation Point

In studying 27 temperate bryophytes, Dilks and Proctor (1975) found the high temperature compensation point to be about 35-40°C. However, temperature compensation points are affected by both light intensity and CO₂ concentration and vice versa (Rastorfer 1971).

Acclimation

Acclimation is a physiological change that adjusts to new conditions. It differs from adaptation in that the ability to change is programmed in the genetic code and the changes are temporary and non-heritable. For example, low temperatures can slow down the photosynthetic

apparatus, but in some habitats high light intensities may still cause high excitation of the photosynthetic apparatus. There is evidence [in *Leucodon sciurioides* (Figure 76)] that low temperatures may induce non-radiative dissipation of the absorbed light energy (Deltoro *et al.* 1999). This dissipation is necessary to protect the photosynthetic apparatus from excess excited electrons. This ability to dissipate energy and recover photosynthetically almost immediately upon return to temperatures above freezing permits this bryophyte to survive high light intensity at considerably lower temperature limits. The moss has become acclimated to the new temperature. This moss is one of many examples of preadaptation observed in mosses. This Mediterranean moss is capable of surviving light and temperature conditions that might be encountered in the Antarctic.

Figure 76. *Leucodon sciurioides*, an epiphyte, showing dry branches to the left and wet ones in the middle. Photo by Michael Lüth, with permission.

Even changes in CO_2 concentrations can elicit acclimation in bryophytes. *Riccia fluitans* (Figure 77) lives part of its life floating on lakes and ponds. But some of these plants end up stranded on soil out of water. This environment is much higher in both light and CO_2 than the floating environment from which they came. The relative growth rate under low light and low CO_2 was 0.011 day^{-1} , whereas under high light intensity and high CO_2 it was 0.138 day^{-1} (Andersen & Pedersen 2002). Interestingly, maximum photosynthesis decreased with increasing light intensities, but it increased with increasing CO_2 . The CO_2 compensation point was very low at high light and low CO_2 levels, increasing at low light and high CO_2 levels. These shifts in compensation point are an advantage for plants that live in dense mats in the water with low CO_2 availability and high light intensity at the surface and greater CO_2 and lower light intensity on the lower side of the floating mat.

Figure 77. *Riccia fluitans*, a species in which photosynthetic rate decreases in high light. Photo by Jan-Peter Frahm, with permission.

Glime and Acton (1979) used mosses conditioned for three weeks to a range of temperatures in the lab to demonstrate the effect of temperature on the photosynthesis of *Fontinalis duriaei* (Figure 71). These experiments indicated that the prior history of the moss affected its productivity at a given temperature. Maximum growth occurred in spring and fall and peak assimilation occurred at 5400 lux at 10°C .

Fornwall and Glime (1982) approached the same seasonal question by using field-acclimated plants and showed that *Fontinalis duriaei* (Figure 71) altered its maximum temperature for photosynthesis seasonally. When mosses were brought from the field and their photosynthesis measured in the range of $0.5\text{--}40^\circ\text{C}$, optimal temperatures shifted from 10°C in January to 35°C in August. However, these were short-term measurements of photosynthesis with one hour of acclimation to the respirometer flask and two hours of measurement time. Other experiments with growth at these temperatures over a 15-week period showed that the mosses could only sustain this high level of productivity for a short time and that in fact, temperatures above 20°C caused the mosses to cease growth in the lab (Glime 1982, 1987a, b, c). A more thorough discussion of temperature acclimation is in Chapter 10-1.

The color of these mosses changed with the seasons as well, with the most deep green color in March and April and a brown color in September (Fornwall & Glime 1982). The puzzling result of this study is that not only did mosses from a stream with wide seasonal fluctuations show this acclimation, but those mosses that resided in a stream that maintained a summer temperature of 8.5°C likewise shifted their summer optimum temperature to 35°C in the lab photosynthetic experiments. This suggests that the optimum may not result from acclimating to temperature but that it instead may be stimulated by the lengthening photoperiod or other environmental parameter associated with the seasons.

One might expect temperature acclimation in more northern regions. Oechel *et al.* (1975) demonstrated that subarctic populations of *Dicranum fuscescens* (Figure 70) exhibited a high temperature acclimation (Figure 78). Acclimation to warm temperatures caused a higher temperature optimum (similar to mean field temperatures,

ranging 5-15°C), higher maximum net photosynthetic rate, and a lower photosynthetic max at 0°C.

Figure 78. Acclimation responses of net photosynthesis to temperature in *Dicranum fuscescens* (Figure 70) at Schefferville, Quebec (55°N) after cultivation at warm (18°/7°C) and cool (8°/1°C) temperatures for 1.5 months. Modified from Oechel *et al.* 1975.

Dicranum fuscescens (Figure 70) in subarctic Canada raised its temperature optimum for photosynthesis from 0-10°C in the beginning of June to 10-20°C by 7 July, with net productivity dropping drastically by 29 July (Figure 79), but its dark respiration rates showed no evidence of acclimation (Hicklenton & Oechel 1976). The tissue temperatures fluctuated between a low of 3°C and a high of 26°C during that period. The remarkable drop in productivity by the end of July suggests that the moss could not sustain the high temperature respiratory cost and eventually lost net gain in productivity. At the other end, net productivity was negative at temperatures above 15°C on 5 June. On the other hand, Arctic populations had an optimum temperature that was generally higher than the mean maximum tissue temperature with optima ranging from 12-19°C (Oechel *et al.* 1975). This high optimum commonly accompanies tolerance for lower temperatures.

Even short-term adjustments to changing light levels are possible. The drought-tolerant *Syntrichia ruralis* (Figure 27) experienced increases in F_v/F_m , NPQ, and light-adapted PS II yield [ϕ (PS II)] in sun plants transplanted to the shade, and concurrent decreases in shade plants transplanted to the sun (Hamerlynck *et al.* 2002). But these plants also seemed to have a memory of their old habitat; sun plants performed at a consistently lower level in the shade than did non-transplanted shade plants. Nonetheless, the ability to adjust its photosynthetic apparatus to changing light conditions permits this species to take advantage of a habitat in which the canopy above it changes, changing its exposure to sun vs shade.

One of the changes that occurs on a seasonal basis is a change in the light compensation point and light saturation point. In *Plagiomnium acutum* (Figure 23) and *P. maximoviczii* (Figure 48) from the temperate zone in China, light compensation points switch from 20 $\mu\text{M m}^{-2} \text{s}^{-1}$ in the winter to 40 $\mu\text{M m}^{-2} \text{s}^{-1}$ in the summer (Liu *et al.* 2001a). Likewise, the light saturation ranges from 200 $\mu\text{M m}^{-2} \text{s}^{-1}$ in winter to 400 $\mu\text{M m}^{-2} \text{s}^{-1}$ in summer. The temperature optimum also ranges from a low of 20°C in winter to a high of 35°C in summer.

Figure 79. Mean optimum temperatures and upper temperature compensation points for *Dicranum fuscescens* (Figure 70) photosynthetic activity at Mary Jo lowland near Quebec, Canada, as an effect of acclimation due to increasing and decreasing spring to autumn temperatures. Based on Table 1 in Hicklenton & Oechel 1976.

Aquatic Differences

In streams, the availability of CO_2 varies widely, dependent on the temperature, pH, and rate of flow. In standing water, CO_2 can be even more limiting as temperatures rise and the CO_2 goes out of solution and is lost into the atmosphere. These CO_2 conditions are typically limiting to plant growth, including bryophytes (Madsen *et al.* 1993; Rice & Schuepp 1995). However, structural modifications of leaf spacing, leaf size, and exposure of photosynthetic cells among hyaline cells in *Sphagnum* (Figure 80-Figure 81) all contribute to making aquatic taxa less resistant to CO_2 uptake than are non-aquatic taxa (Rice & Schuepp 1995).

Figure 80. *Sphagnum novo-zelandicum* leaf cells showing hyaline cells and photosynthetic cells. Photo by David Tng, with permission.

Figure 81. *Sphagnum* hyaline cells and pores. Photo from Botany Website, UBC, with permission.

In the aquatic environment, it is the deep water that has the highest CO₂ concentration (Maberly 1985), a product of microbial activity in the sediments. But deep water has the lowest light intensity. A testimony to the CO₂ limits imposed on aquatic mosses is their ability to grow well at extremely low light levels in the bottoms of lakes. These limits change seasonally, with productivity of *Fontinalis antipyretica* (Figure 30) in the North Bay of Esthwaite Water, England, being limited by light in November and by temperature in March. In August, despite microbial decomposition, intense competition for CO₂ from dense phytoplankton limits the moss productivity.

Another problem for aquatic bryophytes is that not only does the intensity of light decrease, but the spectral quality changes with depth. A reduction in water clarity due to increased load of dissolved organic carbon in Grane Langsoe caused a greater attenuation of blue light, relative to red light (Schwarz & Markager 1999). Photosynthesis is most active in red light, with its second peak in blue. However, red light has long wavelengths with low energy and thus is readily absorbed by water, making it diminish quickly with depth. The additional decrease in blue light, which has a short, high-energy light wave, means that the bryophytes are deprived of both of the most active wavelengths. The most abundant moss (70% of biomass) in these conditions was *Warnstorfia exannulata* (Figure 82), which exhibited its maximum absorption in the young parts that were most highly pigmented.

Figure 82. *Warnstorfia exannulata*, a species with relatively low productivity in deep water. Photo from Biopix, through Creative Commons.

Riis and Sand-Jensen (1997) showed that this species and *Sphagnum subsecundum* (Figure 67) grew faster in deep than in shallow water in a low-nutrient lake in Denmark. Their study supported the hypothesis that supersaturated CO₂ as well as low temperatures and higher nutrient concentrations on the bottom of the lake supported the faster growth, despite the lower light intensity. One advantage of the lower temperature is that gases such as CO₂ stay in solution more easily. *Sphagnum subsecundum* exhibited lower dark respiration (1.3-fold) and higher photosynthesis (3.3-fold) at 9.5 m than at 0.7 m conditions.

In lakes, light attenuates with depth, often creating a photosynthetic desert at the bottom. Bryophytes, already adapted to low light, typically grow to greater depths than their macrophytic tracheophyte counterparts. In the Karelia Republic of northwestern Russia, bryophytes dominate at depths in three acidified lakes (pH of water 5.3-5.9) (Ilyashuk 2002). One lake was dominated by a dense carpet of *Sphagnum denticulatum* (Figure 83) at a depth of 5.0-7.6 m, covering about 50% of the bottom. A second lake had only *Warnstorfia exannulata* s.l. (Figure 82) at 5.0-7.0 m, covering 20% of the bottom. The third had only *Fontinalis hypnoides* (Figure 84) at 4.5-5.5 m, covering 13% of the bottom. In these latter two lakes, the net annual production by the mosses was 32-41 g air-dry mass m⁻² yr⁻¹. In the *Sphagnum*-dominated lake, however, the rate was much higher (157 g m⁻²).

Summary

Photosynthesis is limited by light intensity, temperature, CO₂ availability, and water availability. The compensation point is the level of any of these variables at which the CO₂ assimilation is equal to the CO₂ respired by the plant. These are influenced not only by the environment and seasons, but also by plant density and the plants themselves.

Limits are at both ends of the scale. There is a minimal level needed for successful net gain, but there are also upper limits beyond which the plants will lose energy. The saturation level is that level at which increase causes no further photosynthetic gain.

During the growing season, water is typically the limiting factor. However, some bryophytes are able to use water from fog and dew. Given enough water, CO₂ is often limiting. However, in some habitats, such as lake sediments, CO₂ emissions from bacteria and various invertebrates may elevate the CO₂ levels above ambient air CO₂. And some bryophytes, especially *Sphagnum*, may use methane, converted to CO₂ by bacteria, to supply their CO₂. Aquatic bryophytes may use cation exchange to lower the pH in their immediate vicinity, permitting the use of bicarbonate by shifting the equilibrium toward free CO₂. Furthermore, it is possible that some may use external carbonic anhydrase to capture bicarbonate, but experiments to support this in bryophytes are lacking. Light may be limiting, but bryophytes seem to have the lowest light compensation point of any plant group. High light intensity can cause photodamage.

Net photosynthetic activity in many, perhaps most, bryophytes exhibits an abrupt drop above its optimum due to the loss of CO₂ through photorespiration.

Bryophytes acclimate to temperature, CO₂ level, and light intensity. This permits changes in the optimum, compensation point, and upper level limit or saturation point.

Acknowledgments

I appreciate the help of Don Lueking and Heather Youngs, both of Michigan Technological University, in my understanding of *pK* as it might apply to bryophyte CO₂ uptake. Thank you to Weng Zhe for correcting my error.

CHAPTER 12

PRODUCTIVITY

Figure 1. *Pohlia wahlenbergii* var. *glacialis*, a wetland moss that is among the more productive of the acrocarpous mosses. Photo by Michael Lüth, with permission.

Productivity

It is within the framework of productivity that bryophytes are often considered unimportant as components of the ecosystem. As Martin and Adamson (2001) have pointed out, the photosynthetic capacity of mosses is generally considered to be much lower than that of the tracheophytes. However, they contend that this may be a misleading conclusion based on the method of calculating rates of net CO₂ uptake. Rather, they demonstrate that when productivity of bryophytes is calculated on the basis of chlorophyll, differences in rate disappear. It is only when dry mass is used to calculate productivity that bryophytes appear to have a much lower productivity rate than that of tracheophytes. And this depends on whether the senescent portions are included in the calculations.

Ecological Factors

Ability to Invade

There are so many ways in which to measure productivity that one must be careful to consider the purpose for which it is being measured. If it is measured to determine how soon it will grow enough to overtake the pebble path through the garden, a consideration of the linear growth of the stem pointed in that direction is most relevant. But if it is to determine what that particular species is capable of doing, in its own right, we would look at it quite differently, most likely at its biomass gain or CO₂ fixed on an hourly or annual basis. And if we want to know how soon it will fill in as ground cover, we need to know its lateral growth – the growth of its branches as well as its main stem. But it is even more complex than that.

New plants could arise from gemmae or fragments, requiring yet other measurements.

These measures are not easily convertible. For example, Gerdol (1996) expressed the linear growth of *Sphagnum magellanicum* (Figure 2) as 28-31 mm during the growing season, giving a sense of its ability to add to the depth of the peatland. Its dry matter production, however, was 12-13 mg per plant, giving us less of a mental picture of what effect it has on the ecosystem appearance. Does this latter measure reflect new capitula? How much has it increased the mat vertically? Despite these questions, for a peatland harvester, the biomass increase is of more value than the height of the plant.

Figure 2. *Sphagnum magellanicum*, a major peat accumulator. Photo by Michael Lüth, with permission.

Niche Differences

Conditions that favor one species of bryophyte may be detrimental to another. This permits the slow-growing bryophytes to co-exist for a long time, with one species, in this case *Pleurozium schreberi* (Figure 3), advancing more in one year and the other, *Dicranum polysetum* (Figure 4), advancing more in another (Zhang 1998). Arscott *et al.* (2000) demonstrated this with their 13-year experiment in two Arctic streams. An increase in phosphorus caused little difference in the clump-forming *Schistidium agassizii* (Figure 5), whereas the formerly rare mat-forming species of *Hygrohypnum* (Figure 6) increased rapidly. Furthermore, *Hygrohypnum* species had greater tolerance to elevated temperatures (>20°C) than did *S. agassizii*, whereas the latter recovered easily from desiccation, while *Hygrohypnum* was susceptible to damage.

Figure 6. *Hygrohypnum ochraceum* forming mats. Photo by Michael Lüth, with permission.

Growth

Growth is one measure of productivity, but it has two components: **biomass gain** and **increase in length** (including branches). As Schwinning (1993) pointed out, unequal growth rates within a species can result from environmental and other factors independent of the productivity. She attributed these unequal rates to genetic differences, site differences, and competition (both intra- and interspecies).

Growth Measurements

Growth measurement is never easy in a non-linear subject such as a pleurocarpous moss. For example, several authors (Rincon & Grime 1989; Zechmeister 1995; Stark *et al.* 2001) have concluded that measuring stem elongation only may provide an inaccurate picture of true productivity. In fact, biomass accumulation and shoot elongation are uncoupled events and biomass is a better predictor of productivity than is elongation (Stark 2002). As a result, the methods used for measuring bryophyte growth are varied, each having its own purpose for a particular growth habit.

In larger, perennial mosses it is possible to determine growth because the plant provides natural markers (**innate** markers of Russell 1988; Figure 7). In their seminal papers on phenology of bryophytes, Longton and Greene (1969a, b) estimated annual growth rates using attached cotton markers to measure each stem, measuring distances between innate markers (inflorescence position), and measuring the length of the green apical portion of the stem. Hagerup (1935) used the alternating leaf sizes of taxa such as *Ceratodon purpureus* (Figure 8) to measure annual growth.

Figure 7. **Left:** Alternating regions of large and small leaves illustrating natural markers of growth on a species of *Bryum*, based on Hagerup (1935). **Right:** *Hylocomium splendens* – arrows indicate region markers for a new season of growth. Drawings by Margaret Minahan.

Figure 8. *Ceratodon purpureus*, a species with reduced leaf sizes marking the annual growth. Photo by Michael Lüth, with permission.

In others, such as *Philonotis fontana* (Figure 9) and *Aulacomnium palustre* (Figure 10), **innovations** (new

branches just below the apex) often mark new growth, but the first leaves of new growth also cause a constriction compared to the smaller (or larger) leaves ending the previous growing season. In other taxa, there is a wider spacing of the leaves at the beginning of each new season, again causing a clear demarcation between years.

Figure 9. *Philonotis calcaria* showing multiple innovations just beneath the antheridial splash cup. Photo by Michael Lüth, with permission.

Figure 10. *Aulacomnium palustre* showing the branches near the tip. Photo by Kristian Peters through Creative Commons.

In males of **Polytrichaceae** (Figure 11, Figure 13) and others, new growth can arise from a splash cup so that one can trace back through a series of splash cups to measure growth (Figure 11). These various interruptions are useful in many of the acrocarpous moss taxa and at least some leafy liverworts. In pleurocarpous taxa, a new set of branches may arise, providing a marker, as is most exquisitely exhibited in the stair-step moss, *Hylocomium splendens* (Figure 7, Figure 12). But these markers tell us only the total growth for the year, and not the season of growth, and in many pleurocarpous mosses, more than one set of branches can arise in a single year, as in *Fontinalis* (Figure 14) (Glime 1982).

Figure 11. *Polytrichastrum* showing new growth from splash cups (arrows). Photo by Michael Lüth, with permission.

Figure 12. *Hylocomium splendens*, showing annual branching. Photo by Amadej Trnkoczy through Creative Commons.

Changes in color can demarcate the growth of the current season, but these are difficult to discern for more than one year (Figure 13).

Figure 13. *Polytrichum commune* showing change in color from dark green to light green where the current year's growth begins. Photo by Michael Lüth, with permission.

Hawes *et al.* (2002) determined the ages of mosses in a lake bed of the Canadian High Arctic by using annual **growth bands**. These bands were 10-30 mm in length and were apparent due to changes in leaf density and size. The most recent growth provided four – five bands with

recognizable leaves and measurable concentrations of chlorophyll *a*. Another twelve bands were recognizable from leaf scars. However, their attempt to correlate effects of ice cover with growth in a given year failed, and they suggested that the relationship of ice cover to growth (and growth bands) was more complex.

Figure 14. *Fontinalis* showing branching. Photo by Andrew Spink <www.andrewspink.nl>, with permission.

Russell (1988) described eight methods for measuring growth (Figure 15), including innate markers. The **cranked wire** technique is commonly employed for *Sphagnum* (Figure 2), but suffers from the problem of compaction of the mat, particularly as a result of snow, thus underestimating growth, particularly for more than one year. **Tags** can be used to mark a specific point on the moss from which future measurements are taken, but one must be careful not to injure the stem or interfere with water movement. A modification of this method works well for *Fontinalis* (Figure 16) and other aquatics (Glime 1980, 1982); narrow strips of white velcro are placed around the stem as markers (Figure 16) (black velcro seems to have a toxic dye); for terrestrial mosses, the velcro may interfere with water transport, spacing, and drying.

Nets placed over the mosses (Figure 15) likewise provide a starting point for measurements but suffer problems similar to the compaction problems with the cranked wire, although generally it is the older parts that get compacted most. And these might also interfere with water movement, hence giving unnatural readings. **Vital stains** that are not water soluble can serve as markers, including fluorescent dyes and powders; these must be selected not to interfere with photosynthesis or alter nutrient concentrations. **Bags** constructed of nylon mesh can be used to mark a starting point, with an initial measurement of the protruding stems. Russell (1988) recommends cutting the stems to a known length and putting them in the bag, neatly arranged upright; note that this is a flat bag, and the growing tip should not be removed. Gremmen *et al.* (1975) and Russell (1984) used a **coring** method in which they cut horizontally through the

soil beneath the bryophytes, then spread small pieces of polystyrene pellets or other marker before replacing the moss, thus providing a marker from which to measure. This method could again suffer from compaction problems, depending on the species of bryophyte. **Photography** can give rates of advancement of a colony but cannot provide details of growth and provides only horizontal growth (cover), not vertical assessment. Similarly, sheets of clear plastic can be placed over the moss patch and outlines drawn for future comparison. Zhang (1998) used the latter method to show that location of moss patches on the forest floor is quite dynamic.

Figure 15. Methods usable for measuring bryophyte shoot extension growth. **Left** figure of each pair represents the starting condition and time; **right** figure represents end of measuring period. Modified from Russell 1988.

Figure 16. *Fontinalis novae-angliae* on velcro, permitting measurement of growth. Photo by Janice Glime.

Growth rates may include only the dominant stem, or the sum of all the branches as well. Smith (1982) found that the epiphytic *Isoetecium myosuroides* (Figure 17) in England never grew more than 16 mm per year. In an even drier habitat, on dry, exposed, granite ledges in northwestern Ontario, Vitt (1989) measured a yearly growth rate of 2.3-3.1 mm yr⁻¹ for *Racomitrium microcarpon* (Figure 18). Vitt (1990) also measured growth as lateral expansion of a clone. In clumps of *Pylaisia polyantha* (Figure 19) on the bases of poplars, the yearly increase was about 6-8 mm yr⁻¹.

Biomass measurements for living bryophytes are often meaningless because of their tremendous ability to sequester water, not only internally but also externally. Wet mass can be up to 20 times the dry mass of *Sphagnum* (Figure 2), making any wet mass measure meaningless for comparison purposes. Drying the moss, however, creates a new variable that necessarily terminates the experiment and may therefore not be practical. Furthermore, dry mosses can gain sufficient atmospheric moisture to show measurable mass gain during the short time required to weigh them (personal observation). In cases where light availability is the same for all members of a population, biomass and growth in length can be correlated and either might be chosen as a measure of productivity, depending on the goals of the study.

How does the growth occur within the plant and what are the sources of the needed resources? Bisang *et al.* (2008) investigated this question in *Pseudocalliergon trifarium* (Figure 20). This species has discrete annual segments. They found that growth in mass correlates with the segment mass of the previous two years. This relationship declines linearly for the older years. Hence, it appears that growth is limited by reallocation of resources.

Figure 22. Pearson's Product Moment correlation coefficients R between the most recent growth interval (G_0) and consecutively older annual intervals, G_1 to G_4 . Shoots from 12 populations were pooled ($n=44$). Bars indicate ± 1 standard error of R . Data for biomass were log transformed prior to analyses. Redrawn from Bisang *et al.* 2008.

In *Bryum laevigatum*, growth bands are evident, marked by a dark brown color and smaller leaves (Rod Seppelt, Bryonet 16 February 2013). New growth exhibits light green, larger leaves. Rhizoids are often more prominent among the smaller leaves. Are these best referenced as growth bands, responsive to changes in the weather, or are they truly markers of annual increments?

Aquatic forms demonstrate markers that may be indicators of seasonal changes in water level, with cessation or near cessation of growth occurring when the water level is low in summer and they are stranded above water. These seasonal changes may be manifest as changes in leaf size or stem length or branching (Rod Seppelt, Bryonet 16 February 2013).

In Antarctica, *Bryum argenteum* (Figure 23) and *Ceratodon purpureus* (Figure 8) exhibit banding patterns (Rod Seppelt, Bryonet 16 February 2013). These may represent differences between the spring-summer growth and winter dormancy. The internode distance and hyaline leaf apex length differ between Antarctic populations of *B. argenteum* and those of Tasmania. Both produce clusters of branches.

Figure 23. *Bryum argenteum*, a species that exhibits banding patterns. Photo by Rui-Liang Zhu, with permission.

Annual Length Increase

Length increase is generally related to growth form, with acrocarpous mosses exhibiting slow rates of growth in length compared to pleurocarpous mosses (Table 1). The pleurocarpous taxa further increase their biomass by development of new branches, creating an exponential growth pattern. Among these pleurocarpous bryophytes, some can become very long and have high growth rates, with some *Fontinalis* (Figure 24) (Glime 1987b) and *Sphagnum* (Figure 2) species growing 400 mm in a season. *Taxiphyllum barbieri* (Figure 25; Java moss, often mistakenly called *Vesicularia dubyana*) can quickly fill a 50 gallon aquarium through extensive branching and length gain.

Figure 25. *Taxiphyllum barbieri*, a fast-growing species in an aquarium. Photo by Buchling through Creative Commons.

On Signy Island in the Antarctic, the upright *Polytrichum strictum* (Figure 26) grows 2-5 mm, whereas at Pinawa, Manitoba it grows 15-55 mm per year, exhibiting differences due to microclimate and habitat (Longton 1974, 1979). Pitkin (1975) showed wide variation in growth of *Hypnum cupressiforme* (Figure 27), depending on its height on the tree trunk, with mm of growth at 30-100 cm above ground doubling that at 150-200 cm from 23 May to 6 October. Not surprisingly, growth of the upper side of a sloping trunk was more than double that on the lower side.

Uncoupling

In bryophytes, as in some other plants, the increase in height/length may not be well correlated with increase in biomass. For example, in loblolly pine, branching becomes denser in low-density populations, but in high-density populations the trees grow taller. Likewise, self shading or other causes of low light cause elongation without a concomitant gain in biomass, as illustrated by grass elongation under a board on your lawn. It is an interesting phenomenon that biomass increases and elongation may not occur at the same time. Rincon and Grime (1989) showed very clearly that growth in length and increase in biomass of *Brachythecium rutabulum* (Figure 28, Figure 31), *Thuidium tamariscinum* (Figure 29, Figure 31), and *Lophocolea bidentata* (Figure 30, Figure 31) may be almost inverse relationships. When dry matter production declined, there was an increase in length, causing a negative biomass production (Figure 31). This, however, is not true for all species, as seen by *Plagiomnium undulatum* (Figure 31, Figure 32) and *Pseudoscleropodium purum* (Figure 31, Figure 33).

Figure 32. *Plagiomnium undulatum*, a species in which weight gain and elongation can occur together. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

The uncoupling of growth rate in length with that of branches is not surprising. As branches elongate, more distance is available for branch buds to form. In *Leptodictyum riparium* (Figure 34), total growth and growth of branches increase together (Sanford 1979). The rate of main axis growth, on the other hand, decreases as the rate of branch growth increases.

Figure 33. *Pseudoscleropodium purum*, a species in which weight gain and elongation can occur together. Photo by Michael Lüth, with permission.

Figure 34. *Leptodictyum riparium*, an aquatic species in which total growth and that of branches occur together, but main axis growth rate decreases at that time. Photo by Michael Lüth, with permission.

At least in *Sphagnum* (Figure 36-Figure 37), this uncoupling seems to be reflected in seasonal carbohydrate content as well (Shiraishi *et al.* 1996). In the Hakkoda Mountains of Japan, the glucose content of three *Sphagnum* species was highest in summer. Shiraishi *et al.* (1996) attributed this to an uncoupling between the active periods of matter production and growth. Sucrose, however, peaked in autumn in *S. capillifolium* (*S. nemoreum*; Figure 35) and *S. papillosum* (Figure 36), presumably in preparation for winter, and the seasonal changes were different between these two hummock species and *S. tenellum* (Figure 37), a hollow species.

Gaberscik and Martincic (1987) likewise found that net photosynthesis did not correlate with growth. In August, when photosynthesis was maximal, biomass accumulation actually decreased. Chlorophyll content correlated positively with this period of high net photosynthesis, and consequently did not correlate with growth. Rather, the most intensive dry mass increase was at the beginning of the growing season. Winter was a low period for both photosynthesis and growth.

Seasonal Differences

We have assumed maximum growth of most temperate bryophytes to be in the spring when moisture is usually abundant and temperatures are cool. In their study of standing crops, Al-Mufti *et al.* (1977) supported this premise, showing that the peak standing crop in bryophytes occurred in May, the culmination of spring growth, and again in December, following cooler and more moist weather of autumn. The lowest biomass was in August when bryophytes would have suffered respiratory loss in the heat of summer. Zotz and Rottenberger (2001) likewise found this for three moss species [*Grimmia pulvinata*

(Figure 38), *Schistidium apocarpum* (Figure 39), *Syntrichia ruralis* (Figure 40)] on an exposed limestone wall in temperate Europe, with a strong seasonal pattern showing highest carbon fixation in autumn and near zero in summer.

Figure 40. *Syntrichia ruralis*, a rock-dwelling species that is typically dormant in summer. Photo by Darkone, through Creative Commons.

However, we need more field studies to corroborate this assumption of spring growth on a broad scale. Growth in bryophytes has been difficult to measure because it is slow and increments are small, with yearly increments measuring in mm in many taxa.

Kershaw and Webber (1986) approached the seasonal behavior from a different angle, showing that in a forest habitat, chlorophyll was highest in *Brachythecium rutabulum* (Figure 28) in summer when light intensity was lowest. Low light, coupled with high temperatures, contributes to low summer productivity.

In a temperate, semi-arid, sandy grassland, *Syntrichia ruralis* (Figure 40) was strongly dependent on its microclimatic conditions and followed the same general principles I have suggested (Juhász *et al.* 2002). Its highest productivity, however, was in December and January, with carbon gain beginning in October. It was dormant throughout the hot, dry summer. In a different study where the temperate grassland had cover provided by *Juniperus communis* (Figure 41) shrubs, those species that occurred in the open exhibited a decline in photosynthetic efficiency from the humid spring to the hot, dry summer and exhibited lower efficiency (F_v/F_m) than those bryophytes growing in the shade of the shrubs (Kalapos & Mázsá 2001).

Figure 41. *Juniperus communis*, a species that provides shade for bryophytes, permitting them to have greater photosynthesis than plants in the open. Photo by Neva Micheva, through Creative Commons.

Using transparencies to map coverage, Jansová (2006) found that **epixylic** bryophytes in a Bohemian old-growth forest grow faster in winter (October – April) than they do in summer, although some species did not differ in percentage growth (Jansová 2006). Both expansion and local extinction were greater in winter, making stability greater in summer.

But not all habitats create such pronounced seasonal differences. In the subarctic, *Dicranum fuscescens* (Figure 42) exhibited no clear seasonal differences in daily CO_2 uptake, nor were there any apparent differences between lowland and highland sites (Hicklenton & Oechel 1977). Melick and Seppelt (1994) found no seasonal differences in carbohydrate levels in continental Antarctica, although chlorophyll levels did decrease during winter. One reason for this apparent lack of seasonality is the high degree of daily variation that is experienced by bryophytes in Arctic and Antarctic areas.

Figure 42. *Dicranum fuscescens*, a species with no clear seasonal differences in CO_2 uptake. Photo by BBS, with permission.

Nevertheless, seasonal water availability can impose seasonal differences, even in these northern regions. In peatland habitats, productivity may respond to greater water availability in summer, but decrease if the moss becomes submerged (Suyker *et al.* 1997), increasing again as they achieve greater CO_2 exchange with receding water. Skré and Oechel (1981) demonstrated, in their two years of study of the Alaskan taiga, that increased amounts of young, photosynthetically active tissue near the end of the growing season in the mosses *Polytrichum commune* (Figure 13), *Pleurozium schreberi* (Figure 3), *Hylocomium splendens* (Figure 12), and *Sphagnum subsecundum* (Figure 43) accounted for their highest maximum net photosynthesis occurring in August. Williams and Flanagan (1998) reported maximum photosynthetic rates of boreal *Sphagnum* in summer ($14 \mu\text{mol m}^{-2} \text{s}^{-1}$) compared to spring ($5 \mu\text{mol m}^{-2} \text{s}^{-1}$) and autumn ($6 \mu\text{mol m}^{-2} \text{s}^{-1}$). In the same habitat, however, *Pleurozium schreberi* had no seasonal variation, with mean rates of 7, 5, and $7 \mu\text{mol m}^{-2} \text{s}^{-1}$ during spring, summer, and autumn, respectively.

Figure 43. *Sphagnum subsecundum*, a fen species with maximum photosynthetic rates in August. Photo by Jean Faubert, with permission.

Asada *et al.* (2003) showed that winter growth was important for the *Sphagnum* species [*S. austini* (Figure 44), *S. fuscum* (Figure 45), *S. rubellum* (Figure 46), *S.*

papillosum (Figure 36), *S. lindbergii* (Figure 47), *S. tenellum* (Figure 37), and *S. pacificum* (Figure 48)] in the hypermaritime coastal peatland of British Columbia, Canada. Position in the hummock seemed to be important, with lower productivity on the hummocks than in the hollows, again emphasizing the importance of water availability.

In the maritime Antarctic (Figure 49), respiration in *Brachythecium* (Figure 50) is highest in summer and lowest in winter, regardless of temperature, whereas in *Chorisodontium* (Figure 51-Figure 52) and *Andreaea* (Figure 53), there is little difference, perhaps relating to their drier habitats (Davey & Rothery 1996). Photosynthesis rates are generally higher in summer. The optimum temperature for photosynthesis does not change between summer and winter.

False Growth Markers

Growth markers come in many types. C. Robin Stevenson (pers. comm.) reports using sand as a marker in *Campylopus introflexus* (Figure 54-Figure 56). Each growth increment was demarcated by a layer of sand; changes in leaf size also marked the same increments. But are these truly growth markers? Stevenson suggests that they might also be triggered by heavy rain events. This could supply multiple markers in one year, or it could represent the winter growth surge.

Figure 54. *Campylopus introflexus*, a species that shows definite growth markers. Photo courtesy of C. Robin Stevenson.

Figure 55. *Campylopus introflexus* showing growth markers. Photo courtesy of C. Robin Stevenson.

Figure 56. *Campylopus introflexus* showing growth markers. Photo courtesy of C. Robin Stevenson.

Growth Control

Using the open-habitat moss *Physcomitrella patens* (Figure 57), Chodok *et al.* (2010) determined that pH and temperature significantly affected both biomass and a number of polyunsaturated fatty acids (linoleic acid, LA; γ -linolenic acid, GLA; α -linolenic acid, ALA; eicosadienoic acid, EDA; di-homo- γ -linolenic acid, DHGLA; arachidonic acid, ARA; eicosapentaenoic acid, EPA). Sucrose, CaCl_2 , and MgSO_4 affected only some of the polyunsaturated fatty acids. Higher concentrations of sucrose positively affected LA, ARA, and EPA production; higher concentrations of the metals CaCl_2 and MgSO_4 negatively affected ARA and EPA.

Figure 57. *Physcomitrella patens* with capsules, a species in which pH and temperature affect both biomass and polyunsaturated fatty acids. Photo by Hermann Schachner, through Creative Commons.

Growth Tradeoffs

Horsley *et al.* (2011) demonstrated that the allocation to asexual vs sexual reproduction in *Bryum argenteum* (Figure 23) is under genetic control. The allocation to asexual reproduction is negatively correlated with vegetative growth. Protonemal growth rate, on the other hand, is positively correlated with both asexual and sexual reproduction. The sexes did not differ in growth traits, asexual traits, sexual induction times, or biomass, but female sex-expressing shoots were longer than the males. Males, on the other hand, had a much higher number of reproductive structures, causing a much greater rate (24X) of investment in prezygotic tissue in males compared to females.

Etiolation

Elongation can be misleading. Low radiation causes greater elongation, with the highest elongation in *Dicranum majus* (Figure 58) from various polluted areas occurring at the lowest irradiance ($20 \mu\text{M m}^{-2} \text{s}^{-1}$) (Bakken 1995). **Etiolation** (excessive elongation and loss of chlorophyll due to insufficient light) can easily be observed if mosses are collected fresh, then put into a sealed plastic bag and stored in a nearly dark place. More on this phenomenon is discussed in the chapter on light.

Figure 58. *Dicranum majus* exhibiting a large plant size typical of low light conditions. Photo by Michael Lüth, with permission.

Belowground Productivity

It is rather presumptuous to title anything related to bryophytes as "Belowground Productivity" because data reporting such values are woefully lacking. Yet, bryophytes have rhizoids, and much of that biomass exists below ground, so such a title is not absurd. Furthermore, bryophytes have underground rhizomes, particularly in the **Polytrichaceae** (Figure 60). Sveinbjörnsson and Oechel (1981) have shown the respiration in the rhizome relative to whole plant CO_2 gain (Figure 59). Nevertheless, this is but an indirect indication that biomass is in place and active there with no indication of the carbon needed to put it there.

Figure 59. Relationship of aboveground and belowground CO_2 flux in *Polytrichastrum alpinum* (Figure 60) and *Polytrichum commune* (Figure 13) in the Alaskan tundra. Redrawn from Sveinbjörnsson & Oechel 1981.

Figure 60. *Polytrichastrum alpinum* with capsules. Photo by Michael Lüth, with permission.

Sporophyte Productivity

A discussion of the ability of the sporophyte to carry out photosynthesis is in Chapter 2-7, Bryopsida, and in Chapter 5-9, Ecophysiology of Development: Sporophyte. We know that bryophyte sporophytes have chlorophyll, even in thallose liverworts (Bold 1948), but few independent measurements of their rates of productivity seem to exist. These are further complicated by the photosynthetic capacity of the spores inside and the ability of the gametophyte to transport photosynthate to the sporophyte.

Nevertheless, Paolillo and Bazzaz (1968) demonstrated in *Funaria* (Figure 61) and *Polytrichum* (Figure 61) that the shape of the light saturation curve of the sporophyte is close to that of the gametophyte. For *Polytrichum*, the weight of the gametophyte decreases as that of the sporophyte increases and there is no net photosynthetic gain by the sporophyte, but such is not the case in *Funaria*. In *Funaria*, there is a net photosynthetic gain. In *Funaria* the calyptra is perched at the end of the capsule and covers little of it, whereas in *Polytrichum* the capsule is completely covered (Figure 61). The authors conclude that the seta serves as a reservoir for the developing capsule.

Figure 61. **Left:** *Polytrichum* calyptra covering capsule completely. Photo by Janice Glime. **Right:** *Funaria* calyptra covering only the end of the capsule. Photo by Michael Lüth, with permission.

Polytrichum (s.l.) species in particular depend on the gametophyte for their carbon nutrition (Renault *et al.*

1992). The members of this group have large calyptrae (Figure 61) that completely cover the capsule and they are densely covered with hairs. This permits little light to reach the capsule. In *Polytrichastrum formosum* (Figure 62) sucrose is the primary soluble sugar in both generations, with the highest concentrations (~230 mM) occurring in the **haustorium** (cells at base of sporophyte foot; functions in absorption of nutrients from gametophyte to sporophyte). The **vaginula** (part of archegonium of moss enveloping base of embryo or seta after upper part has been torn away), on the other hand, has primarily hexoses.

Figure 62. *Polytrichastrum formosum*, a species that uses sucrose in both generations. Photo by Martin Grimm, through Creative Commons.

Productivity and Aging

The current year's tissues seem to be the primary site of photosynthesis for most mosses. Collins and Oechel (1974) found that early in the season, the photosynthesis of Alaskan mosses relied on tissues produced the previous year, or even previous two years, but those rates were lower than for tissues produced in the current year (75% and 40% for 1 and 2 years earlier, respectively). Callaghan and coworkers (1978) found an even greater reduction in Swedish Lapland mosses. One-year-old tissues had rates 55% lower in *Hylocomium splendens* (Figure 12) and 58% lower in *Polytrichum commune* (Figure 63) than those tissues produced in the current year.

Figure 63. *Polytrichum commune*, a species that has less productivity in the tissues formed the previous year than in that of the current year. Photo by A. J. Silverside, with permission.

Life Span

We have expressed productivity in measurements from seconds to annual, but in consideration of the ecosystem, it is also appropriate to speak in terms of a lifetime. Although our knowledge of life spans is still meager, we do have indications in some species, although they may be minimal rather than maximal ages. For example, Frye (1928) found specimens of *Eurhynchium oreganum* (Figure 64) that were up to six years old. Ulychna (1963) reported mean ages for *Polytrichum commune* (Figure 63) of 3-4 years, with dead parts of 15-17 years age, although if they were not growing in hummocks the dead parts seemed to be only 4-5 years old. (Perhaps that is the age when it starts to become a hummock?)

Figure 64. *Eurhynchium oreganum*, a species that has tissues at least six years old. Photo by Matt Goff <www.sitkanature.org>, with permission.

Corollary to the importance of life span is the effect that age has on growth rate. Ulychna (1963) found no effect in *Hylocomium splendens* (Figure 12) or *Polytrichum commune* (Figure 63). In the same two species, Callaghan *et al.* (1978) found that *Hylocomium splendens* grows its fronds for two years, then produces new segments, a factor that would be misleading in determining its age by its branching. Other factors can mislead age determinations based on growth markers. *Polytrichum commune* continues to have photosynthesis in dry conditions, whereas in *H. splendens* it ceases.

New growth may keep pace with dying portions (Callaghan *et al.* 1978). In *Hylocomium splendens* (Figure 12), normally the new shoot replaces the decomposing distal portion, but if the young segment is damaged, the whole shoot dies. On the other hand, *Polytrichum commune* (Figure 63) has a finite life expectancy which may differ with geographic area, but it also has an underground proliferation that can give rise to new shoots and compensate for lack of branching and death of aboveground parts.

In the maritime Antarctic, *Polytrichum strictum* (Figure 65) can have the extremely high annual mortality rate of 32% in young turfs (Collins 1976). However, in pure older turfs it is closer to 13%.

Figure 65. *Polytrichum strictum* illustrating the protection plants give each other in older tufts. Photo by Michael Lüth, with permission.

In the Arctic, longevity may compensate for the slow growth rates. Sand-Jensen *et al.* (1999) found that the slow, but steady-growing lake bottom mosses could persist for up to 17 years, retaining green leaves for several years, and decomposing slowly. Their growth rate, however, was only 10 mm per year, a relatively slow rate compared to pleurocarpous aquatic mosses elsewhere.

Leaf Production and LAI

Vitt (1990) decided to investigate the number of leaves and other leaf parameters that have been ignored for bryophytes. He did this to illustrate the complexity of moss populations, a fact often not realized by ecological observers. Using *Drummondia prorepens* (Figure 66), a small moss with large leaves, he found about 90 stems per cm^2 . The stems averaged *ca.* 65 leaves each, resulting in 6000 leaves per cm^2 . Considering the available leaf area for photosynthesis, he determined that one cm^2 has $\sim 15 \text{ cm}^2$ of photosynthetic moss surface.

Figure 66. *Drummondia prorepens* on wood, a species in which one cm^2 of substrate has $\sim 15 \text{ cm}^2$ of photosynthetic moss surface. Photo by Dale Vitt, with permission.

The **leaf area index (LAI)** has been used to express the relationship of the leaf-to-light interception (Smith 1990). It is the ratio of the leaf area to ground area, using the same units. Thus, a low LAI indicates wasted sunlight. A value of 1 indicates full usage, and a value of greater than 1 permits maximum usage at more angles of the sun. Since bryophyte leaves generally are not perpendicular to the sun, a higher LAI is required to obtain the same amount of light.

Simon (1987) estimated LAI measurements on *Syntrichia ruralis* (Figure 40), with 2030 leaves cm^{-2} , and *Ceratodon purpureus* (Figure 8), with 27,966 leaves cm^{-2} . These had leaf area indices (LAI) of 44 and 129 respectively. We can state the LAI for *Drummondia prorepens* (Figure 66), based on Vitt's (1990) data, as 15, discounting the portion of the leaf that is non-photosynthetic. Vitt (1990) reported a mean leaf area of 1960 $\text{mm}^2 \text{ cm}^{-2}$ (LAI = 19.6) for mosses in the boreal biome.

Energy Content

One distinction among plants is the amount of their tissue used for storage vs that used for photosynthesis. In this regard, the bryophyte uses nearly all of its tissue for photosynthesis, although I question whether it is as high as the 95% shown in

Table 2. Using the category of cryptogams includes the lichens, club mosses, horsetails, and ferns, complicating the interpretation of the number.

Fungal Partners

Although most bryophytes are self-reliant, photosynthetic organisms, some do benefit from fungal partners. The achlorophyllous thallose liverwort *Cryptothallus mirabilis* (Figure 67) relies totally on an endophytic fungus for its carbon input (Ligrone *et al.* 1993). The fungus is associated with the bases of the rhizoids and does not penetrate the thallus. There is no evidence that a third partner is involved; associated trees have a different fungal partner. Rather, it most likely gains its carbon from the organic nutrients in the soil and litter. Its dependency on this fungal carbon source is supported by its failure to develop beyond a few cells in sterile culture.

Figure 67. *Cryptothallus mirabilis*, an achlorophyllous thallose liverwort. Photo by Michael Lüth, with permission.

In *Aneura pinguis* (Figure 68; Ligrone *et al.* 1993), *Conocephalum conicum* (Figure 69) (Ligrone & Lopes 1989), and *Phaeoceros laevis* (Figure 70) (Ligrone 1988),

it appears that it is the fungus that benefits, not the liverwort.

Table 2. Comparison of biomass devoted to photosynthesis vs storage and respiration for plants from major biomes. From Larcher 1983 and compiled from many sources.

Plant	Green mass (photo- synthetically active organs) shoots	Purely respiratory organs	
		Woody stems above ground	Roots and subterranean
Evergreen trees of tropical and subtropical forests	ca. 2%	80-90%	10-20%
Deciduous trees of the temperate zone	1-2%	ca. 80%	ca. 20%
Evergreen conifers of the taiga and in mountain forests	4-5%	ca. 75%	ca. 20%
Alpine scrubwood	ca. 25%	ca. 30%	ca. 45%
Young conifers	50-60%	40-50%	ca. 10%
Ericaceous dwarf shrubs	10-20%	ca. 20%	60-70%
Grasses	30-50%		50-70%
Steppe plants			
Wet years	ca. 30%		ca. 70%
Dry years	ca. 10%		ca. 90%
Desert plants	10-20%		80-90%
Arctic tundra			
Tracheophytes	15-20%		
Cryptogams (including bryophytes)	>95%		
Plants of the high mountains	10-20%		80-90%

Recent History Effects

Previous conditions have a strong influence on the photosynthetic performance of plants, at least among some Alaskan mosses (Alpert & Oechel 1987). Assemblages of mosses having recent experience with low water availability achieved maximum net photosynthesis at lower water contents than did those that had remained hydrated. Likewise, those mosses that occurred in sites with low light availability achieved higher net photosynthesis at lower light intensities than mosses that had recent history in high light intensities. And a close relationship exists between the lower temperature limit for 85% photosynthesis and the mean maximum tissue temperature for the previous five-day period (Oechel 1976).

Recent history of weather conditions most likely accounts for the considerably lower productivity in spring, compared to summer, in *Atrichum undulatum* (Figure 71), *Plagiomnium affine* (Figure 72), and *Polytrichum formosum* (Figure 62) (Baló 1967). One reason for this is the much higher chlorophyll *a* content in summer, compared to spring. Such previous histories can account for much of the variation we see between measurements of the same species and even the same individuals.

Figure 71. *Atrichum undulatum* fresh growth, a species with lower productivity in spring, compared to summer. Photo by Michael Lüth, with permission.

Figure 72. *Plagiomnium affine*, a species with lower productivity in spring, compared to summer. Photo by Janice Glime.

Mitotic Activity

It appears that mitotic activity, the initial step in new growth, has its own clock. In a study on *Pellia borealis*, a thallose liverwort, the greatest activity occurs between 11:00 and 14:00 hours (Szewczyk 1978). However, further studies are needed to determine if this is an endogenous rhythm or is tied to a daily ecological event in its habitat.

Respiration

Nearly every photosynthetic study includes respiration measurements. However, these may not be reported separately. **Net photosynthesis** is that incorporated carbon that remains after carbon is lost as CO₂ in respiration.

Bryophytes, as C₃ plants, exhibit both dark respiration and photorespiration. **Photorespiration** (respiration in the light) is difficult to measure because of the ability of a plant to put that same lost CO₂ immediately back into carbohydrate through the photosynthetic pathway. Photorespiration in C₃ plants is generally up to three times greater than dark respiration and accounts for the loss of energy at high temperatures. But even dark respiration increases in summer, as noted in *Plagiomnium acutum* (Figure 73) and *P. maximoviczii* (Figure 74) in China (Liu *et al.* 2001).

Figure 73. *Plagiomnium acutum*, a species in which dark respiration increases in summer. Photo by Show Ryu, through Creative Commons.

Figure 74. *Plagiomnium maximoviczii*, a species in which dark respiration increases in summer. Photo by Hiroshima University Digital Museum of Natural History, with permission.

Priddle (1980b) found that dark respiration of two Antarctic species of aquatic mosses [*Warnstorfia sarmentosa* (Figure 75) and *Drepanocladus s.l.* sp. (Figure 76) differed little from that of algal communities in the same lake. At normal lake temperatures (up to 5°C), the mosses respired approximately 0.3 g mg⁻¹ ash-free dry mass h⁻¹.

Figure 75. *Warnstorfia sarmentosa*, a species with respiration rates similar to those of algae in the same Antarctic lake. Photo by David Holyoak, with permission.

Figure 76. *Warnstorfia fluitans*, a genus with respiration rates similar to those of algae in the same Antarctic lake. Photo by Michael Lüth, with permission.

In the high Arctic Svalbard, *Sanionia uncinata* (Figure 77) exhibits a high Q_{10} (ratio of reaction rates for a 10°C rise) of 3 for respiration in the range of $7\text{--}23^{\circ}\text{C}$ (Uchida *et al.* 2002). In the same range, photosynthesis exhibits very little difference, resulting in low temperature optima.

Figure 77. *Sanionia uncinata*, a species that experiences a rapid rise in respiration with temperature in the Arctic Svalbard. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Habitat and Geographic Comparisons

Because of the length of the growing season, temperatures during the growing season, day length, available water, and other geographic and climatic factors, productivity in various biomes differs. Table 3 compares the various biomes to provide a framework for the discussion of habitat differences among bryophytes. Table 4 and Table 5 compare rates on biomass and area bases, respectively.

Although **water** may be a good indicator of productivity of a habitat, the general water availability of the habitat is not a good indicator of the productivity at the time that water is available. In fact, the relationship seems to be inverse. As can be seen in Table 3, the highest productivity seems to be from the driest habitats and from the plants adapted to those habitats. On the other hand, Suba *et al.* (1982) found that hygrophytic and mesophytic mosses of a beechwood community had more photosynthetic intensity than more xerophytic rock-inhabiting mosses. History is probably important here.

In the boreal forest, it appears that the **light use efficiency** of *Pleurozium schreberi* (Figure 3) ($102 \text{ mM CO}_2 \text{ M}^{-1}$) is well above that of most of the plants there ($70\text{--}80 \text{ mM CO}_2 \text{ M}^{-1}$), but its productivity is still lower ($1.9 \mu\text{M m}^{-2} \text{ s}^{-1}$ (Whitehead & Gower 2001). Other understory shrubs and herbaceous plants had productivity mostly between 9 and $11 \mu\text{M m}^{-2} \text{ s}^{-1}$.

For aquatic bryophytes, **depth** affects light intensity. Growth rates of deepwater mosses can be quite slow (10 mm per year in Canadian High Arctic lakes), and vary little between years (Sand-Jensen *et al.* 1999). Martínez Abaigar *et al.* (1994) found that *Scapania undulata* (Figure 78) had a leaf specific area of $317 \text{ cm}^2 \text{ g}^{-1} \text{ DM}$ (dry mass) at 5 cm depth, but at 45 cm depth, the **LSA** (whole-plant leaf surface area) increased to $399 \text{ cm}^2 \text{ g}^{-1} \text{ DM}$. Concomitantly, the leaf specific weight (mass) was reduced from 3.16 mg cm^{-2} to 2.50 mg cm^{-2} . These differences can be interpreted as a response to the lower light availability at 45 cm . Canopy leaf fall, on the other hand, caused an increase in accessory pigments relative to chlorophyll *a*.

Figure 78. *Scapania undulata*, a species in which whole-plant leaf surface area increases with water depth. 1 Michael Lüth, with permission.

Furness and Grime (1982) found that species of disturbed habitats (**ruderal species**) such as *Funaria hygrometrica* (Figure 79) had high relative growth rates, as did perennial pleurocarpous species such as

Brachythecium rutabulum (Figure 28) from fertile habitats. Most species grew best at temperatures of 15-25°C, whereas temperatures above 30°C eventually killed moist mosses.

Figure 79. *Funaria hygrometrica*, a ruderal species with a high growth rate. Photo by Michael Lüth, with permission.

Rates of Productivity

Productivity varies with habitat (Table 3). Mosses, typically living in shaded habitats, are low in productivity compared to other plant groups (Table 6). In the Antarctic, Davey and Rothery (1996) found greater seasonal variation in bryophytes from hydric habitats than from the less hydric sites.

Probably the highest productivity ever measured for a bryophyte is that of *Sphagnum* (Figure 43-Figure 48), with a productivity of 12 tons per hectare per year (Schofield 1985). C₄ plants average a CO₂ uptake of up to 80 mg dm⁻² hr⁻¹, whereas C₃ plants seem to have a max of about 45 (Larcher 1983). Mosses, on the other hand, have a max of only 3! For some reason, perhaps the thick cuticle and other adaptations that reduce the light, CAM plants have a maximum of only 20. However, since measurement time may not coincide with the period of photosynthesis, we may need to interpret these numbers somewhat differently.

Table 3. Comparison of net primary production, biomass, chlorophyll, and leaf surface area in major biomes. From Whittaker *et al.* 1974; Larcher 1983.

Ecosystem Type	Area 10 ⁶ km ²	Net Primary Production			Leaf Surf Area Biomass (dry matter)			Chlorophyll		LAI	
		Normal range g m ⁻² yr ⁻¹	Mean g m ⁻² yr ⁻¹	Total 10 ⁹ t yr ⁻¹	Normal range kg m ⁻²	Mean kg m ⁻²	Total 10 ⁹ t	Mean g m ⁻²	Total 10 ⁶ t	Mean m ² m ⁻²	Total 10 ⁶ km ²

Although the biomass of bryophytes is small, their carbon sequestration is not inconsequential. Cryptogamic covers sequester ~ 3.9 Pg of carbon per year (Elbert *et al.* 2012). This equals about 7% of the net primary production in the terrestrial ecosystem. The uptake of N is ~ 49 Tg per year, accounting for nearly half of the biological N fixation on land.

Latitude Differences

It is difficult to determine if responses of populations in different parts of the world are the result of genetic differences or differences in acclimation history (Sveinbjörnsson & Oechel 1983). *Polytrichum commune* (Figure 13) from five diverse regions from Alaska (71°N) to Florida (29°N) were grown under common garden conditions in constant temperature conditions of 5 and 20°C. In this common set of conditions, plants from lower latitudes had higher photosynthetic rates except for the temperate St. Hilaire population. There was a sevenfold difference between the extreme values. Populations from the lower latitudes had more maximum photosynthetic response to the two temperatures than did populations from higher latitudes. On the other hand, bryophytes from higher latitudes had higher energy contents than those from lower latitudes (Russell 1990; Figure 80).

Figure 80. Comparison of mean energy content of bryophytes related to latitude in several tundra sites in Devon Island and Point Barrow, Alaska; Hardangervidda, Denmark; Mt. Washington, New Hampshire; and Marion Island and South Georgia, Antarctica. Reprinted from Russell 1990.

Antarctic

Temperatures in the Antarctic (Figure 81) have rather large daily fluctuations during the growing season. Therefore, it is not surprising to find that bryophytes growing there show little response to changes in temperature and little acclimation to any temperature (Davey & Rothery 1996). Nevertheless, the species exhibit summer maxima in productivity; no seasonal variation seems to exist for optimum temperature of gross or net photosynthesis.

Figure 81. Antarctic ice on Green Island. Photo by Matt Amesbury, through Creative Commons.

But temperature is not the only limiting factor in the Antarctic climate (Bramley-Alves *et al.* 2014). In addition to temperature, water availability likewise limits productivity. More recently, the ozone hole is limiting productivity, in part due to the increased UV-B radiation, but also because of the associated increase in wind in the ozone hole.

Frigid Antarctic

The **frigid Antarctic**, with mean air temperatures generally below 0°C and very dry air, is entirely vegetated by cryptogams: **Cyanobacteria**, algae, lichens, and mosses. The most conspicuous vegetation is small turf and cushion-forming mosses including *Bryum* (Figure 23) and *Grimmia* (probably *Schistidium*; Figure 82) species (Longton 1979). Standing biomass is similar to the annual production of the tundra, reaching 1000 g m⁻², but more typically 5-200 g m⁻² (Longton 1974, Kappen 1985). Annual production seems to be less than 5 g m⁻² yr⁻¹ (Longton 1974, Ino 1983).

Figure 82. *Schistidium antarctici*, a species with very limited annual production in Antarctica. Photo courtesy of Rod Seppelt.

The **cold Antarctic**, with summer mean air temperatures of 0-2°C, has a production of 200-900 g m⁻² in the larger moss turfs and carpets (Longton 1970, Davis 1981), comparable to temperate grassland (Longton 1992)! In this area, the biomass is more commonly 300-1000 g m⁻² for green shoots, and reaches 20,000 - 30,000 g m⁻² for total biomass, including older brown parts (Longton 1992). It is interesting that the production here is generally higher than in the Arctic tundra (Longton 1988, Russell 1990), exceeding 1000 g m⁻² yr⁻¹ (Russell 1990), perhaps due to greater precipitation and enhanced soil N and P from the marine environment (Longton 1992).

Arctic

Even in the cold Arctic (Figure 83), water is a major controlling factor in photosynthesis. *Sanionia uncinata* (Figure 77) has high photosynthetic activity only when water content is high during or following rainfall (Uchida *et al.* 2002). Temperature has little effect on net photosynthetic rates in this species, with photosynthetic rate being constant in the range of 7-23°C.

Figure 83. Arctic Lapland. Photo by Michael Lüth, with permission.

In Arctic habitats, bryophytes are often poorly represented in models on climate change and carbon balance (Street *et al.* 2012). Nevertheless, they are important components of the vegetation, and their seasonal dynamics are poorly understood. In a system dominated by *Polytrichum piliferum* (Figure 84) and *Sphagnum fuscum* (Figure 45). Street and coworkers found that seasonal changes in bryophyte photosynthetic capacity are important in determining gross primary productivity for both species and in contributing to the Arctic carbon balance. Gross primary productivity of *Polytrichum piliferum* was ~360 g C m⁻² for one year, for *S. fuscum* 112 g C m⁻², figures that represent 90% and 30% respectively of the productivity of tracheophytes in the same area. Furthermore, the bryophytes are not significantly affected by the turf water content during the growing season.

Wetlands

In the Arctic wetlands (Figure 85), mosses account for 91% of the above ground biomass (Oechel & Sveinbjörnsson 1978). Grasses and sedges usually arise from a bed of mosses, including the turf-forming *Meesia* (Figure 86) and *Cinclidium* (Figure 87) and carpet-forming *Calliergon* (Figure 88) and *Drepanocladus s.l.* (Figure 76)

species (Longton 1992). The annual production of 100-300 g m⁻² can be 20-45% bryophyte (Longton 1992) and the biomass is up to 150 g m⁻² (Oechel & Sveinbjörnsson 1978).

Tundra

In the tundra (Figure 89), mosses exhibit about 10% of the productivity of higher plants, despite occupying 50% of the above ground biomass. Whereas *Polytrichum strictum* (Figure 65) can have an annual production of 450-500 g m⁻² in the cool Antarctic grassland (Figure 90), it reaches only 100-150 g m⁻² in the Arctic spruce woodland (Figure 91) (Longton 1979). However, in some areas, the production reaches 50-90% of higher plant production and values up to 1000 g dry wt m⁻² yr⁻¹ can be measured (Clarke *et al.* 1971, Kallio & Kärenlampi 1975, Oechel & Sveinbjörnsson 1978, Russell 1990). More typical values are 1-50 g dry wt m⁻² yr⁻¹. Ratios of biomass to production can be exceedingly high, up to 70:1, illustrating the slow growth and the extreme longevity of the plants (Longton 1992). In heath communities in the tundra of northern Sweden, biomass reaches 156 g m⁻² (Jonasson 1982). However, in below ground biomass, the phanerogams far exceed the bryophytes, with underground parts contributing more than 50% of the total production of all plants (Longton 1984).

Coxson and Mackey (1990) found that the subalpine *Pohlia wahlenbergii* (Figure 1) exhibited strong diel periodicity in midsummer conditions, declining from $8 \text{ mg CO}_2 \text{ g}^{-1} \text{ hr}^{-1}$ to $\sim 5 \text{ mg CO}_2 \text{ g}^{-1} \text{ hr}^{-1}$.

Boreal Forest

In the boreal forest (Figure 92), the dominant mosses are feather mosses, especially *Hylocomium splendens* (Figure 12) and *Pleurozium schreberi* (Figure 93) (Longton 1992). Biomass can reach $170\text{--}290 \text{ g m}^{-2}$ under spruce in Alaska (Figure 92), but only $4\text{--}6 \text{ g m}^{-2}$ under *Betula* (Figure 94) and *Populus* species. Likewise, production was hardly measurable in the *Betula* and *Populus* forests, but reached $70\text{--}150 \text{ g m}^{-2}$ under spruce, often exceeding the productivity of the spruce itself (Longton 1992)! Similar rates to those under spruce are found for feather mosses in other coniferous forests (Tamm 1953; Weetman 1968; Pakarinen 1978). *Pleurozium schreberi* in black spruce forests in New Brunswick, Canada, had an annual productivity of $44\text{--}66 \text{ g m}^{-2}$ (Timmer 1970). Tamm (1953) reported $45\text{--}60 \text{ g m}^{-2}$ for *Hylocomium splendens* in a Swedish spruce forest and Damman reported 50 g m^{-2} for it in Newfoundland black spruce forests. Van Cleve and coworkers (1983), for black spruce forests near Fairbanks, Alaska, reported an even higher value of 100 g m^{-2} .

Figure 93. *Pleurozium schreberi*. Photo by Jan-Peter Frahm, with permission.

Figure 94. *Betula papyrifera* forest. Photo by Nicholas A. Tonelli, through Creative Commons.

In addition to feather mosses, *Sphagnum* (Figure 43–Figure 48) is a prominent member of many boreal communities. In a black spruce forest, Swanson and Flanagan (2001) found that *Sphagnum* had higher maximum rates of gross photosynthesis than did the feather mosses and exhibited distinct seasonal changes in its photosynthetic capacity.

Several species of *Dicranum* occur in boreal forests, and Kellomäki *et al.* (1978) found that they differ physiologically in their ability to tolerate desiccation and photosynthesize. Even within the same species, two varieties can differ substantially. For example, the photosynthetic rate of *D. fuscescens* var. *congestum* (see Figure 42) increases more rapidly at 12.5°C than at 17.5°C with increasing light than does that of *D. fuscescens* var. *flexicaule* (see Figure 42), in which the rates at the two temperatures are essentially identical. In *D. fuscescens* var. *congestum*, the rate at 12.5°C is nearly double that at 17.5°C. However, water deficit has a strong effect on the photosynthetic rate. The best photosynthesis seems to occur in the morning when the plants are able to use morning dew while the temperature is still relatively cool.

Temperate Forest

Ground cover of bryophytes in temperate forests (Figure 95) varies widely. In oak forests (Figure 96) in Hungary, production is only 4.3 g m⁻² (Smith 1982). Oceanic European oak forests may reach 35.5 g m⁻² (Pócs 1982). Forman (1969) reported a scant 2-3 g m⁻² in deciduous forests in New Hampshire (Figure 97), USA, whereas Rieley and coworkers (1979) reported 1600-2900 g m⁻² in a Welsh *Quercus petraea* (Figure 98) woods. In these oakwoods, the production was 170-210 g m⁻² for the mosses, whereas the herbs had a production of only 120 g m⁻². Many of the oakwoods in England are on rocky hillsides where litter accumulation is small, whereas many North American temperate forests bury the mosses in litter (Figure 99) just as the fall growth season for mosses begins (Pitkin 1975). However, Rieley and coworkers (1979) offer another explanation. Sheep eat the grasses selectively and leave the mosses behind. On tree trunks and logs (Figure 100), above the litter, temperate forest bryophytes can be significant.

Figure 102. Douglas fir and Ponderosa pine forest, southern Oregon. Photo by Jsayre64, through Creative Commons.

Figure 100. Epiphytes on trees in California. Photo by Michael Lüth, with permission.

In the temperate rainforest (Figure 101) of Washington, USA, biomass can be as great as 800 g m^{-2} of tree surface, translating to 500 g m^{-2} of forest floor. In the Douglas fir forests (Figure 102) of Oregon, USA, bryophyte biomass can be as high as 8.9 kg on a single 65 m tall tree (Pike *et al.* 1972). On Mt. Baker (Figure 103) in Washington, bryophyte biomass averages ca 180 g m^{-2} (Edwards *et al.* 1960). However, in pine forests (Figure 104) in France, the moss *Pseudoscleropodium purum* (Figure 33) has a relatively low annual production of only 39 g m^{-2} (Kilbertus 1968).

Epiphytes

Neckera pennata (Figure 105) demonstrates that colony growth in area is proportional to colony size, thus exhibiting exponential growth (Wiklund & Rydin 2004). Precipitation was an important parameter in determining colony growth. Presence of other species reduced growth. Wiklund and Rydin estimated that the colony needs to attain a size of 12-79 cm² before reproducing sexually, taking 19-29 years to attain that size.

Figure 105. *Neckera pennata*, an epiphytic moss. Photo by Michael Lüth, with permission.

Peatlands

Peatlands (Figure 106) are often 3-d habitats with hummocks and hollows (Figure 107). Grigal (1985) projected that the surface area is 35% greater in a Minnesota peatland due to this 3-d microtopography. In addition to the increase in surface area, three other factors seem to be important in carbon sequestration:

- differences in dominant plant functional type
- interactions between temperature and water table depth
- ecosystem succession (Flanagan 2014).

Figure 106. Bog with *Sphagnum* in Fiordland, NZ. Photo through Creative Commons.

Figure 107. Bohemia bog with *Sphagnum cuspidatum* and *S. denticulatum*, showing hummocks and hollows. Photo by Jonathan Sleath, with permission.

Moore (1989) found a slight tendency for production of *Sphagnum* (Figure 106) to decrease as temperatures decrease northward. Wider differences, however, occur within a single peatland. Hummocks (Figure 108) can have annual production of 100-150 g m⁻², lawns 500 g m⁻², and pools 600-800 g m⁻² (Clymo 1970, Clymo & Hayward 1982), suggesting that water availability is the limiting factor for production. Vitt (1990) reported that production varies from 70 to 400 g m⁻² per year, with fen mosses at the lower half of the range. The highest productivity measured in peatlands seems to be that of *Sphagnum* (868 g m⁻² yr⁻¹) in a recently burned *Eriophorum* (Figure 109) community in Great Britain (Heal *et al.* 1975). Grigal (1985) found a productivity of 320-380 g m⁻² yr⁻¹ in a forested Minnesota bog (Figure 110) and Elling & Knighton (1984) found slightly higher results (390 g m⁻² yr⁻¹) in an open Minnesota bog (Figure 111). These figures of production compare with a standing crop of 500 g m⁻² in west Norway (Laennergren & Oevstedal 1983). Somewhat lower values have been reported for Moor House, England, *Sphagnum*, where the productivity was 213 g m⁻² yr⁻¹ (Forrest & Smith 1975).

Surprisingly, rich fen production is lower. Vitt (1990) found that in Alberta, Canada, at higher elevations it was $47\text{--}93\text{ g m}^{-2}\text{ yr}^{-1}$, whereas in the lower boreal sites it was $125\text{--}131\text{ g m}^{-2}\text{ yr}^{-1}$. Vitt attributes the lack of increased

productivity in rich fens to the similarity of N and P concentrations in the poor, rich, and extreme-rich fens. Nevertheless, in poor fens, Bartsch and Moore (1985) found that productivity of *Sphagnum* (Figure 36-Figure 37) in Quebec was only $58\text{--}73\text{ g m}^{-2}\text{ yr}^{-1}$ in hummocks and $9\text{--}19\text{ g m}^{-2}\text{ yr}^{-1}$ in lawns. It is somewhat puzzling that bog hummocks have less production than carpets, but that poor fen hummocks have double the production of lawns (Vitt 1990).

In peatlands, bryophytes are major contributors to the primary productivity. At a peatland in West Virginia, bryophytes covered 68% of the ground and contributed 43% of the aboveground net primary productivity, with 20, 10, and 27% contributed by herbaceous species, trailing shrubs, and upright shrubs, respectively (Wieder *et al.* 1989). Bryophytes covered 68% of the ground. Precipitation plays a major role in the productivity. Moore (1989) found that growth at the lawn sites was higher than that of hummocks in an average rainfall year, but in a dry year, growth in two of the three lawn sites was less than that in the hummocks.

Species can differ widely in their photosynthetic activity. Dry matter accumulated $141\text{--}206\text{ g m}^{-2}$ in *Sphagnum tenellum* (Figure 37), $32\text{--}190\text{ g m}^{-2}$ in *S. papillosum* (Figure 36), and $187\text{--}219\text{ g m}^{-2}$ in *S. capillifolium* (*S. nemoreum*; Figure 35) at the Takadayachi Moor in Hakkoda Mountains, Japan (Fukushima *et al.* 1995).

Temperature influences the light compensation point of peatland mosses in Alaska (Harley *et al.*). The light compensation point increased from $37\text{ }\mu\text{M m}^{-2}\text{ s}^{-1}$ at 10°C to $127\text{ }\mu\text{M m}^{-2}\text{ s}^{-1}$ at 20°C , despite little increase in the maximum CO_2 uptake rate. Laboratory experiments indicated that responses could be quite different from that in the field, with considerably lower light compensation points and higher light saturation rates of assimilation.

Peatlands can serve as important carbon sinks. In restored peatlands, Waddington and Warner (2000) found that the peatlands resulted in considerable decrease in the atmospheric CO_2 ($\sim 70\%$ decrease due to gross productivity, 30% to decreased respiration). Unfortunately, restoration did not restore the peatlands to a net carbon sink, but it greatly improved the sequestration of carbon.

The peatland bryophytes, especially *Sphagnum* (Figure 36-Figure 37), are particularly sensitive to the direct sunlight of their habitat (Hájek (2014)). Due to the wetness of their habitat, they are unable to go dormant to escape its potential damage, and it can be difficult to obtain CO_2 due to diffusion resistance through water. Many *Sphagnum* species are desiccation avoiders, but are quite sensitive to drought when they actually do dry out. While hydrated, they are subject to photodamage. Slow growth rates are partly the result of allocation of resources to water-holding tissues.

Desert

In the Chihuahuan (Figure 112), Sonoran (Figure 113), and Mojave Deserts (Figure 114) in North America, the highest biomass of mosses (2.24 g m^{-2}) occurred on the north slope of the Mojave (Nash *et al.* 1977).

Figure 112. Chihuahuan Desert at Big Bend. Photo by Adbar, through Creative Commons.

Figure 113. Sonoran Desert at sunset. Photo by Bob Wick, through Creative Commons.

Figure 114. Mojave Desert on Hualapai American Indian Reservation. Photo by Richard Martin, through Creative Commons.

In a sandy semidesert, Juhász *et al.* (2002) found that *Syntrichia ruralis* (Figure 40) exhibited their highest daily carbon fixation rates in December and January, whereas in the summer it went dormant. A net carbon gain did not occur until October. This species is able to maintain its physiological integrity and net photosynthetic gain by changing the surface reflectance and exhibiting thermal dissipation of excess light energy (Hamerlynck *et al.* 2000).

Grimmia laevigata (Figure 115) from the inland chaparral of California, USA, is unable to survive in the most xeric sites because it is unable to maintain a positive carbon balance during repeated wet-dry cycles (Alpert & Oechel 1985).

Figure 115. *Grimmia laevigata*, a species that cannot maintain a positive carbon balance in the most xeric habitats. Photo by Michael Lüth, with permission.

In these dry habitats, cryptogamic crusts (Figure 116) are important producers and protectors of the soil (Coe *et al.* 2014). These are mixed communities of **Cyanobacteria** (Figure 117), algae, fungi, lichens, and bryophytes. Mosses comprise up to 30% of this crust cover. They are highly tolerant of desiccation and may remain dry for extended periods of time. They also are able to tolerate larger ranges of temperature, light, and cellular water content than mesic species.

Figure 117. *Scytonema* (Cyanobacteria) in cryptogamic crusts. Photo from inactive website on Desert Ecology.

Elevated CO_2 stimulates the biocrust mosses, but it appears that they do not acclimate to long-term exposure by continued high rates of photosynthesis (Coe *et al.* 2014). Rather, the elevated levels might favor stress tolerance at the expense of growth, especially at high temperatures. Nitrogen appears to be an important limiting factor, but N deposition can be toxic, increase competition by tracheophytes, and interfere with nitrogen fixation by **Cyanobacteria** (Figure 117).

Dulai *et al.* (2014) used cryptogamic crusts containing **Cyanobacteria** (Figure 117) to test survival under Mars-like conditions. Those organisms that survived best were the ones from very salty and very dry habitats.

Savannah

In such dry habitats as the savannah (Figure 118), the life cycle can be shortened to accommodate the lack of water. Mosses such as *Archidium ohioense* (Figure 119), *Bryum coronatum* (Figure 120), *Fissidens minutifolius*, and *Trachycarpidium tisserantii* develop protonemata and gametophytes in March – April; by September and October the spores are being dispersed (Makinde & Odu 1994). All of these events occur within the rainy season, permitting maximum photosynthesis.

Temperate Rainforest

Although the rainforest has its season of daily rain, it also has periods of continued dryness. Under these circumstances, respiration may exceed photosynthesis, causing negative photosynthetic gain (DeLucia *et al.* 2003). Forest floor bryophytes in a New Zealand rainforest (Figure 121) have an annual net carbon uptake of 103 g m^{-2} , compared to annual carbon efflux from the forest floor (bryophyte + soil respiration) of -1010 g m^{-2} . Bryophytes were unable to recover more than 10% of carbon lost from the forest floor. Water is the most likely limiting factor in their productivity.

Figure 121. New Zealand rainforest. Photo by Stomac, through Creative Commons.

Tropical Rainforest

The biomass of bryophytes in the tropics rises sharply with elevation. Frahm (1990a) found standing biomass of bryophytes to be less than $10\text{--}12 \text{ g m}^{-2}$ of tree trunk at low elevations (up to 1000 m), up to 140 g m^{-2} in Peru (Figure 122), and $400\text{--}800 \text{ g m}^{-2}$ in Borneo (Figure 123). Exceptionally high biomass of bryophytes, up to 1030 g m^{-2} , can occur in high altitude epiphytes in Tanzania (Figure 124) (Pócs 1982). The astonishingly high figure of 1400 g m^{-2} productivity occurs among the epiphytic bryophytes of a Tanzanian cloud forest (Figure 125) (Pócs 1980).

Figure 124. Western Usambara Mountains and rainforest in Tasmania. Photo by David Ashby, through Creative Commons.

High temperatures and low light place severe limitations on tropical net productivity (Frahm 1990b). Temperatures above 25°C drastically decrease the net assimilation. Coupled with the low light, temperature causes productivity of bryophytes in tropical lowlands to be the lowest of any tropical altitude, with high rates of respiration often resulting in no net carbon gain.

Tropical Altitudinal Relationships

Wagner *et al.* (2014) emphasized the importance of altitude (Figure 126) in affecting bryophyte diversity and productivity in the tropics, asserting that the bryophytes and lichens demonstrate a conspicuous increase with altitude in the tropics (Wagner *et al.* 2013). In the lowland rainforests (Figure 127), frequent fast drying events and low light greatly limit productivity, even for bryophytes (Wagner *et al.* 2014). These detriments are further enhanced by the warm, moist conditions at night, promoting high dark respiration. The optimum temperatures for net photosynthesis of the species at sea level, 500 m asl, and 1200 m asl in Panama were closely related to the mean temperatures in their habitats at each of those elevations (Wagner *et al.* 2013). However, the ratio of dark respiration to net photosynthesis did not decrease with altitude. Water, light, and CO₂ responses did not vary systematically with altitude. Lowland species often had near-zero carbon balances, most likely due to the rapid evaporation rate that restricts the time available for photosynthesis. This relationship seems to be consistent on a worldwide scale.

Figure 126. Gannett Peak alpine. Photo by Summitcheese, through Creative Commons.

Figure 127. Lowland Rainforest, Masoala National Park, Madagascar. Photo by Frank Vassen, through Creative Commons.

When comparing bryophytes across an elevation gradient on Mauna Loa (Figure 128), Hawaii, Waite and Sack (2011) found that nutrient concentrations in the bryophytes increased with soil nutrient availability. Nutrient concentrations on an area basis were related to irradiance, mediated by the bryophyte canopy mass per area. N and P behaved similarly to those nutrients in tracheophytes. Phosphorus increased and the N:P ratio decreased with elevation, a relationship that is consistent with increasing cold tolerance.

Problems in the Water

Productivity in aquatic systems is dependent on sufficient CO₂, suitable temperatures, and sufficient light (Glime 2014). Red light becomes negligible in deeper water, and even the CO₂ that is present is slowed by boundary layer resistance, all problems that are greater in water than in terrestrial habitats. Even pH is important in the availability of CO₂, with little or no dissolved CO₂ in alkaline water. Temperature becomes a problem when the bryophytes are wet and hot at the same time, a problem that can occur when the bryophytes are moist but not submersed (Figure 129). N and P are often limiting as well. The already limited light can be further reduced by sediments and algae on the plants (Figure 130-Figure 131).

Figure 129. *Platyhypnidium riparioides* experiencing hydrated conditions but not submersed. Photo by Michael Lüth, with permission.

Figure 130. *Fontinalis hypnoides* with sediments and detritus. Photo by Janice Glime.

Figure 131. *Fissidens fontanus* with periphyton (algae) on its leaf. Photo by Dick Haaksma, with permission.

But there are some advantages not known in terrestrial systems (Glime 2014). The water serves as a UV filter. This can be enhanced in high light by production of protective pigments.

Rivers and Streams

Naiman (1983) considered mosses in 4th order or higher streams to be the most productive autotrophic members of the stream community in boreal forest

watersheds (Figure 132), producing $3.9 \times 10^{10} \text{ g yr}^{-1}$. This compares to periphyton productivity of only $2.1 \times 10^{10} \text{ g yr}^{-1}$ in the same watersheds. These higher order streams occupy 76.8% of the lotic surface area and are responsible for 86.3% of the gross productivity, demonstrating the importance of bryophytes in the stream ecosystem.

Figure 132. Boreal forest in Canada. Photo by Rich Bard, with permission.

But stream habitats can be rather unfavorable, especially for mosses. In one study in Oregon, *Fontinalis* (Figure 24) only had positive photosynthesis in the winter (Naiman & Sedell 1980). It was negative the rest of the year.

Despite their slow growth and low nutrient requirements, higher nutrients can favor enhanced growth in some bryophyte taxa. In Alaskan streams (Figure 134), *Hygrohypnum alpestre* (Figure 133) and *H. ochraceum* (Figure 135) increased in cover following phosphorus enrichment, whereas *Schistidium agassizii* (Figure 136-Figure 137) showed little response (Arscott *et al.* 2000). Although the *Hygrohypnum* species were intolerant of desiccation, they were more tolerant of high temperatures than *S. agassizii*, having the higher productivity ($1676\text{--}6342 \mu\text{g O}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$) compared to that of *S. agassizii* ($428\text{--}1163 \mu\text{g O}_2 \text{ g}^{-1} \text{ dry mass h}^{-1}$).

Lakes and Ponds

Bryophytes in lakes enjoy the presence of constant water, permitting photosynthesis at any time other factors are favorable. Instead of being at the mercy of water availability like most bryophytes, these bryophytes face the limits of low light intensity, rapidly attenuated red light, and limited CO₂ availability. In most lakes, temperature is not a problem, with bottom temperatures of deep lakes generally not going below 4°C, and summer temperatures often not exceeding 10°C. In more shallow lakes and ponds, summer temperatures may become a problem if they reach 20°C and sustain that temperature for extended periods. Under those conditions, hydrated bryophytes not only lose more energy to respiration than they gain by photosynthesis, but they must compete with aquatic tracheophytes and algae that benefit from the higher temperatures. Sediment CO₂ can often contribute to the productivity of bottom-dwelling bryophytes in lake systems.

The floating liverwort *Riccia fluitans* (Figure 138) increased its relative growth rate from 0.011 d⁻¹ at low light and CO₂ to 0.138 d⁻¹ at high light and CO₂ (Andersen & Pedersen 2002). There was strong acclimation to light and CO₂ conditions. Nevertheless, high light intensities resulted in decreased maximum net photosynthesis while increasing CO₂ continued to increase the maximum net photosynthesis. The CO₂ compensation point for photosynthesis was strongly depressed by high light and low CO₂ and increased in low light and high CO₂. High levels of CO₂ within the floating mat permits photosynthesis at greater depths where the light intensity attenuates.

Wagner *et al.* (2000) found that in Waldo Lake, Oregon, liverworts, comprising 98% of the bryophyte biomass, exhibited growth similar to that of upland plants (1.5-3 cm annually).

Problems with Bryophyte Measurement

The first problem one faces is measuring productivity in the field vs the lab. In the field, logistics are difficult and effects of CO₂ from the soil may be measured along with respiratory CO₂ from the bryophyte. Even putting the equipment in place can disrupt the bryophyte canopy morphology and change light, temperature, moisture, and CO₂ relationships within the canopy. On the other hand, if

we take the mosses into the laboratory, we have disrupted the canopy morphology, lost the normal variation of the field, altered light quality, and in other ways failed to mimic the conditions that occur in the field. And furthermore, laboratory experiments often use only a branch, losing all the effects of the bryophyte canopy and mechanisms of external transport. While these may be useful for physiological studies, they can be misleading when measuring productivity is the objective.

Figure 138. *Riccia fluitans*, a floating thallose liverwort. Photo by Michael Lüth, with permission.

Past history matters. Some bryophytes have inducible desiccation tolerance. Others provide it as a constitutive trait. Hence responses to various manipulations will behave differently depending on the recent environmental weather.

Summary

Productivity can be considered in many ways, including ability to invade, linear growth, biomass increase, CO₂ uptake, O₂ production, C¹⁴ incorporation, chlorophyll concentration, and surface expansion. Biomass gain may often be uncoupled from linear growth, with the former typically occurring first.

Likewise, annual growth of the plant can be measured in many different ways, including length of branch internodes; distance between splash cups on a stem; height above a cranked wire, tag, nylon net, plastic bubbles, or dye, growth out of a nylon bag; photographic record of expansion on a grid. Pleurocarpous mosses typically exhibit exponential growth, whereas unbranched acrocarpous mosses have linear growth, thus requiring different measures of growth.

Etiolation (excessive elongation and loss of chlorophyll due to insufficient light) may occur in low-light environments, giving a false measurement of length as an indication of productivity.

Productivity is generally highest when there is a good supply of water and ceases when the bryophyte is desiccated, causing seasonal differences. Once the moisture requirement is met, temperature and light are important in determining maximum productivity, with most bryophytes diminishing in productivity above 20-25°C and dying at prolonged exposure above 30°C if hydrated. The lower limit varies geographically and

with species, with some species having their compensation point as low as -10°C . In water, bryophytes are limited by low light and low concentrations of CO_2 , but those on the bottom can take advantage of CO_2 from the sediments.

Belowground productivity may be extensive in some bryophytes, such as those in the Polytrichaceae. Capsules, and even spores, can contribute to overall productivity, but at the same time, they typically reduce productivity of the leafy gametophyte.

Life span may be months to centuries, but unlike tracheophytes, generally only the upper portion of the stem supports active productivity. Mortality of the whole stem can be high, reaching 32% in Antarctic young populations of *Polytrichum strictum*. On the other hand, longevity may reach 17 years in the Arctic, compensating for the slow growth, and apparently is even higher in some cold lakes.

The **Leaf Area Index** (LAI) indicates that bryophytes are well adapted to take advantage of the many angles of the sun, reaching such levels as 44 and 129 for sun-adapted species, whereas a value of 1 indicates full usage; anything higher than 1 permits maximum usage at more angles of the sun. Mosses in the boreal biome have an LAI of about 20. Light use efficiency can be very high, but productivity still remains low, perhaps due to CO_2 limitation. Mosses have a maximum CO_2 uptake of about $3 \text{ mg dm}^{-2} \text{ hr}^{-1}$, whereas C_3 tracheophytes reach 45 and C_4 plants reach 80.

Some bryophytes, especially *Cryptothallus mirabilis*, rely on fungal partners for their carbon input. Other thallose liverworts can lose energy to fungi.

The **highest productivity**, when it occurs, seems to be from bryophytes in the driest habitats. On the other hand, yearly productivity seems to be highest in *Sphagnum*, reaching 12 tons per hectare.

Striking differences occur among **latitudes** and **habitats**. For example, Antarctic bryophytes have drastic daily temperature fluctuations and show little response temperature differences. Cool tundra populations of *Polytrichum strictum* may have only 1/4 – 1/3 the production they exhibit in the cool Antarctic grassland. The ultimate limit to productivity, hence to distribution, is achieving a positive carbon balance. Heat causes respiratory loss and frequent wet-dry cycles require excessive repair, both reducing the net carbon gain in some habitats to 0 and ultimate death.

Acknowledgments

Klaus Weddelling, Brian O'Shea, and Marshall Crosby helped me find the new name for *Hylocomium parietale*. It appears to have been *H. parietinum*, now *Pleurozium schreberi*. Several bryonettors helped me locate the current name of *Homaliodendron scalpellifolium*, which is now *H. flabellatum*.

CHAPTER 13

DECOMPOSITION

Figure 1. *Adelanthus decipiens* with fresh, green branches and older, decomposing brown branches. Photo by Michael Lüth, with permission.

Decomposition

If you were to ask the average person to name a plant that decays at the bottom while the top is green and continues to grow, most would have no clue or tell you that's not possible. These people, like most of my beginning students, when defining plants, have forgotten about bryophytes. This group of plants is unique in its ability to die at its base and continue life for years, or even centuries, from the parts above.

Although bryophytes are generally quite small, their slow rate of decomposition and their effect on decomposition of other plants can be important influences on ecosystem dynamics. For example, the genus *Sphagnum* (Figure 2), well known for its preservative properties, occupies 1/3 of the land on the planet and stores more carbon than any other single genus of plants

(Turetsky *et al.* 2002). Decomposition in that system necessarily is important.

Although they lack the lignin that resists decay in tracheophytes, bryophytes are replete with many kinds of secondary compounds – compounds with no known metabolic function, but that seem to deter herbivores from consuming them. These same compounds, including many phenolics, are likewise active in inhibiting the organisms that would normally facilitate decomposition. In fact, bryophytes do have a slower decomposition rate than do tracheophytes (Scheffer *et al.* 2001). Turetsky (2003) considers this to result not only from the secondary compounds, but also from the low nitrogen concentrations in many taxa, an interpretation shared by Aerts *et al.* (1999), who demonstrated that *Sphagnum* (Figure 2)

leaves had lower N and P concentrations than other taxa and likewise had lower rates of litter decomposition.

Figure 2. *Sphagnum fuscum* hummock. Photo by Oscar Gran, through Creative Commons.

Aerts *et al.* (1999) also found that cellulose decomposition in bogs was lower than in fens and that the nutrient mineralization rate was greater in forested peatlands than in herbaceous peatlands. On the other hand, Coulson and Butterfield (1978) found that the rate of decomposition depended not on the substrate of peatland vs. mineral substrate, but on the kinds of plants being decomposed. Peat mosses can play a major role in determining what kinds of plants can live there, so they do play a role in the sequestration of carbon and the decomposition rate by limiting available nutrients and encouraging growth of evergreen shrubs.

It is not surprising that decomposition rates are affected by nutrient levels in the plants. The availability of nutrients influences the kinds of decomposers and the rate at which they act. Aerts *et al.* (2001) found that higher N concentrations caused higher potential rates of decay of *Sphagnum* litter (Figure 3); the rates were actually not significantly affected by nutrient additions. Rather, the higher N levels in *Sphagnum* and other litter led to lower P concentrations. Changes in these ratios can have serious effects on the carbon balance. *Sphagnum*, as an ecosystem engineer, seems quite important in the decomposition process.

Figure 3. *Sphagnum fimbriatum* with capsules and senescent tissues. Photo by J. C. Schou, with permission.

Tsuneda *et al.* (2001) studied the degradation of cell walls in *Sphagnum fuscum* (Figure 2). They found that the *Ascomycota* fungi *Acronium cf. curvulum* (Figure 4) and *Oidiodendron maius* were able to degrade the leaf cell walls in this species. *Acronium cf. curvulum* first fragmented the outer wall layer, then removed it. Then the inner wall was mostly degraded and removed, the middle wall layer, consisting of bundles of microfibrils embedded in an amorphous matrix, experienced degradation and disappearance of the amorphous matrix. Finally, the microfibrils were degraded, causing holes in the cell wall. *Oidiodendron maius*, on the other hand, did not degrade the wall in layers. Rather, it degraded all the components in a nearly simultaneous manner.

Figure 4. *Acronium* ascospores, a fungus able to degrade *Sphagnum fuscum* leaf cell walls. Photo by Ninjatacoshell, through Creative Commons.

Decomposers

A wide array of organisms typically contribute to decomposition of plant material, with invertebrates, especially arthropods, breaking up the tissues into smaller fragments, and fungi and/or bacteria attacking the cellulose and other parts. This is not necessarily the order of activities, which can vary with habitat and available species. **Protozoa** can contribute in some habitats and complete the major groups generally involved.

But bryophytes do not seem to encourage all of these organism groups. Consumption of bryophytes is limited, most likely due to the many secondary compounds they produce (Asakawa 1990). Among liverworts, a variety of volatile oils may be the deterrent (Lohmann 1903, in Frankland 1974). It appears that animals play little role in the decomposition process of bryophytes (Frankland 1974; Coulson & Butterfield 1978).

On the other hand, a wide variety of parasitic and saprophytic fungi are known from bryophytes. Frankland (1974), reporting on earlier work of Racovitza (1959, in Frankland 1974), considered the decreasing order of importance of fungi to be **Ascomycetes** > **Fungi Imperfecti** > **Phycomycetes** > **Basidiomycetes** > **Mycelia Sterilia** > **Archimycetes**. Although some common fungi, like the Loculoascomycetes, may not penetrate the bryophyte host (Henderson 1972, in Frankland 1974), other studies have demonstrated the ability of fungi to penetrate and decompose bryophyte cells (Parke & Linderman 1980; Redhead 1981; Grasso & Scheirer 1981).

There are some indications that the number of fungal species on bryophytes is lower than the number on tracheophytes (Frankland 1974). Longton (1992) found that more than 50% of the bryophytes tested produced microbial inhibitors, perhaps explaining the reduced number of decomposer species found on *Sphagnum* (Figure 2), where pH is often too low for most bacteria to survive.

However, it appears that even on *Sphagnum* (Figure 2), the number of taxa can be large. In a boreal bog in Alberta, Canada, 55 species of fungi were identified on *S. fuscum*, 36 of which were new records for *Sphagnum* (Thormann *et al.* 2001). It appears that this may be a poorly investigated habitat for fungi with many more taxa awaiting discovery. One reason for the large number of fungal taxa on *Sphagnum* may be their ability to utilize a wide range of carbon sources, including cellulose, tannic acid, and pectin.

The concentration of ergosterol is an indication of fungal presence (Uchida *et al.* 2001). Fungi are common among bryophytes, and Uchida *et al.* found that not only the brown moss litter of *Hylocomium splendens* (Figure 5), but also its living green shoots exhibited ergosterol. The interesting relationship for this species is that the ergosterol content of its litter from boreal and subalpine forests was about twice that of the cool temperate forest where the decomposition rate was faster.

Figure 5. *Hylocomium splendens*, showing senescent brown portions and green shoots. Photo by Michael Lüth, with permission.

Penicillium (Figure 6) seems to be a common inhabitant of bryophytes. Mikola and Hintikka (1956) found it to be one of the more abundant fungi (3 species) on *Pleurozium schreberi* (Figure 7), along with *Mucor* (Figure 8) (3 species; 50% of the number of molds) and *Trichoderma* (see Figure 9-Figure 10) (40% of the number of molds). In the same experiment, a grass had the same species plus four more genera. Leaf litter lacked *Trichoderma*, but had 8 species not found on the *P. schreberi*, suggesting certain fungi may have a specificity for bryophytes.

Clymo (1965) concluded that micro-organisms were the chief agents in *Sphagnum* (Figure 2) decomposition, albeit slowly. As suggested earlier, the acidic conditions in most *Sphagnum* habitats do not encourage bacterial growth (Frankland 1974). Williams and Gray (1974) found that when the pH drops below 5, decomposers drop proportionally to the drop in pH. Nevertheless, in an acid peatland, even a four-year addition of simulated acid rain had no effect on the decomposition rate (Rocheftort *et al.* 1990). Furthermore, *Sphagnum* itself is bacterial resistant, as noted by those using it for bandages in World War I. For example, only 6-8% of dry weight was lost in six months incubation of *Sphagnum* inoculated with *Trichoderma lignorum* (see Figure 9-Figure 10) or *Penicillium spinulosum* (see Figure 6) (Minchevich 1969,

in Frankland 1974). *Collybia dryophila* (Figure 11), a fungus, causes a 30% loss of bryophyte dry mass in only four months; this fungus caused 53-56% loss in bryophytes while angiosperm litter lost only 46-69% (Mikola & Hintikka 1956, in Frankland 1974). Benda (1957, in Frankland 1974) found that associated organisms could be important. In her experiments, bacterial decomposition of *Sphagnum* protein occurred only when fungal symbionts of *Erica* were present.

Figure 11. *Collybia dryophila*, a species that is able to decompose bryophytes. Photo by Dan Molter, through Creative Commons.

Küster (1968), on the other hand, did not consider peat to be the microbe-poor community that its antibacterial properties might suggest, reporting that the numbers were "much higher than originally assumed." He concluded that chemical composition, structure, moisture, and other factors determined the occurrence and nature of the microorganisms on peat.

Satake and Miyasaka (1984) reported the penetration of bacteria into the cell walls of the leafy liverwort *Jungermannia vulcanicola* (Figure 12-Figure 13). Satake and Shibata (1986) supported the role of bacteria in at least some bryophytes by demonstrating that the leafy liverwort *Scapania undulata* (Figure 14) exhibits bacterial invasion of its cell walls at both pH 6.4 and pH 4.2. Furthermore, they found no evidence of fungal presence on these aquatic leafy liverworts.

Figure 14. *Scapania undulata*, an aquatic leafy liverwort that seems to be free of fungi. Photo by Michael Lüth, with permission.

Frankland (1974) suggested that *pH* may not be the limiting factor and concluded that the chemical composition of *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18) walls determined its rate of decomposition. They are rich in pectin. Their cellulose and "lignin" are unusual. The cellulose actually hydrolyzes more readily than that of seed plants, but phenolic compounds such as sphagnol may serve as a microbial retardant. Reports of a lignin of unusual composition probably represent another phenolic compound, but its resistance to decay is still of importance.

Decomposition is not the only factor contributing to the disappearance of bryophyte tissue. Other factors in the Antarctic and elsewhere include wind erosion, leaching, and removal by skuas (Davis 1981). The losses to invertebrates are assumed to be minimal, but for some bryophyte taxa, it could be significant.

Phaeopigments

Phaeopigments have been used to indicate the degree of decomposition in algae and bryophytes. Bastardo (1980) examined *Fontinalis* (Figure 15) and other aquatic plants, demonstrating that the ratio of chlorophyll *a* to phaeopigment can be used to indicate plant vitality, with a ratio of less than 1 indicating irreversible decomposition.

On the other hand, use of phaeopigments as an indicator of decomposition may be misleading. Martínez Abaigar *et al.* (1994) found that the degradation of chlorophyll in immersed bryophytes did not produce phaeopigments.

Figure 15. *Fontinalis antipyretica*, a species in which a high phaeophytin to chlorophyll ratio can be an indicator of decomposition. Photo by Misha Ignatov, with permission.

Influential Factors

We have already seen that water is a major factor in the rate of photosynthesis. It appears that it may be the major factor in decomposition as well, with different taxa having different moisture requirements. Belyea (1996) showed that for *Sphagnum capillifolium* (Figure 16) this ideal water content was achieved in the zone of water fluctuation; for *Racomitrium lanuginosum* (Figure 17), it was just above the highest water level. For epiphytes, it appears that living on the north side of a tree may incur an advantage that increases the decomposition rate (Van Tooren 1988).

Figure 17. *Racomitrium lanuginosum*, a species that decomposes best just above the water level. Photo by Janice Glieme.

Depth in the peat profile seems to have a major influence on *Sphagnum* (Figure 16) decomposition (Hogg 1993; Johnson *et al.* 1990). At a depth of 7-10 cm, nearly all hollow species had completely fragmented into stems and leaves. On the other hand, the hummock species, especially *S. fuscum* (Figure 2), remained completely intact to a depth of at least 25 cm. This relationship further supports the contention that hollow species decompose more rapidly than do hummock species (Limpens & Berendse 2003). But as observed by Belyea (1996), those in the zone of water fluctuation disintegrated the most rapidly and completely. Even when samples were moved from deep peat (50-100 cm), the hummock species still decomposed more slowly than did the hollow species (Hogg 1993). In older peat, decomposition reduces to 0%.

Peat seems generally to resist decay. Karunen (1981) demonstrated that *Sphagnum* (Figure 2) cell walls were resistant to both **autohydrolysis** and microbial decomposition. Some organisms, such as insects and fish, accomplish autohydrolysis by releasing enzymes (from dead cells) that cause them to digest themselves from the inside out. Nevertheless, not all species of *Sphagnum* exhibit equal resistance. Johnson and Damman (1991) indicated that the species are important in determining the decay rate. *Sphagnum cuspidatum* (Figure 18) in the hollows have a decay rate (16.9% mass loss) 1.5 times as fast as that of *S. fuscum* (Figure 2) (11.3% mass loss) in the hummocks. Even when the species were placed in each others' habitats, *S. cuspidatum* continued to have the faster rate. They suggested that the more rapid decay rate of hollow species like *S. cuspidatum* may initiate and maintain the hummock and hollow complex. In a separate experiment, Johnson *et al.* (1990) found that among three species, *S. fuscum* stems were the most decay resistant, *S. rubellum* (Figure 19) next, and *S. balticum* (Figure 20) least. Rochefort *et al.* (1990) likewise found that the decomposition rate was least at the top of the hummock and greatest for hollow species, suggesting that it was the slower decomposition rate that maintained the hummocks, not high production.

Figure 18. *Sphagnum cuspidatum*, a hollow species with a faster decay rate than that of the hummock species *S. fuscum*. Photo by Jutta Kapfer, with permission.

Figure 20. *Sphagnum balticum*, a species with lower decay resistance than *S. fuscum* or *S. rubellum*. Photo by Michael Lüth, with permission.

Water is not the only factor that differs at the top of the hummock. Because the hummock is not submersed often, if at all, it has only the small task of lowering the pH of the adhering water, whereas the hollow species may have their efforts of acidifying diluted by an entire lake. The result is that the hummocks exhibit the lowest pH in the peatland (Clymo 1963, Vitt *et al.* 1975; Clymo 1986), and this acidity most likely contributes greatly to the lower breakdown rate there.

Kälviäinen *et al.* (1985) supported the difference between species by demonstrating biochemical differences. The two ectohydric forest mosses underwent a rapid decay and possessed a dominance of short-chain hydroxy acids. The two ectohydric *Sphagnum* species were highly resistant to decay and possessed a dominance of long-chain hydroxy acids in their walls. Changes in biochemistry may result in differences in rates. *Sphagnum fuscum* (Figure 2) has considerably more hydroxy acids in the 9-12 cm segments than in the 0-0.5 cm segment (Ekman & Karunen (1982).

Fontinalis seems to be somewhat different in this regard. The sterolesters of *Fontinalis antipyretica* (Figure 15) are rapidly hydrolyzed during decay (de Leeuw *et al.* 1976).

Rate

Decomposition rates of bryophytes have been difficult to measure. The tiny bryophyte leaves are often lost through the holes of mesh bags, making the litter bag method used for tree leaves less reliable for bryophytes. Nakatsubo *et al.* (1997) used the annual rate of litter production and the amount of litter accumulated to calculate the decomposition rate in *Hylocomium splendens* (Figure 5) in boreal and subalpine forests. They estimated the litter production rate based on the moss shoot growth. While this method gave larger estimates than those usually obtained by the litter bag method, it relies on the assumption that litter production occurs at the same rate as shoot production. Over a long period of time, this assumption probably provides a fairly accurate estimate, but in any given year the estimate could be quite disparate.

Bryophytes are known for their slow decomposition. For example, *Pseudoscleropodium purum* (Figure 21) has a much slower rate than does the grass *Brachypodium pinnatum* under the same conditions (Kilbertus 1968). The feather moss *Pleurozium schreberi* (Figure 7) can require 5-12 years to decay (Weetman & Timmer 1967). But *Hylocomium splendens* (Figure 5) lost 10-24% of its biomass per year in Northern Hemisphere boreal and subalpine forests (Nakatsubo *et al.* 1997).

Figure 21. *Pseudoscleropodium purum*, a species with a much slower decay rate than the grass *Brachypodium pinnatum*. Photo by Janice Glime.

All indications are that bryophyte decomposition is slow [Russell 1990 – tundra (Figure 22); Verhoeven & Toth 1995 – *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18); Hobbie 1996 – tundra; Sand-Jensen *et al.* 1999 – Arctic lakes (Figure 23); Liu *et al.* 2000 – montane moist evergreen broad-leaved forest (Figure 24); Moore *et al.* 2007 – temperate peatlands (Figure 25); Turetsky *et al.* 2008 – *Sphagnum* in boreal peatlands (Figure 23); Lang *et al.* 2009 – subArctic]. As a result, bryophytes become a nutrient sink compared to other plant species in most ecosystems. This implies that they get most of their decomposition nutrients from litter decomposition of tracheophytes, not from recycled nutrients from their own tissues.

Rejment-Grochowska and Misztal-Cieliczko (1975) examined the decomposition of the moss *Climacium dendroides* (Figure 26). They found that moss decay increases with depth in the 12 cm examined. Temperature undoubtedly plays a role, with an increase from April to August, then decreasing to November when the study ended. Nakatsubo *et al.* (1997) demonstrated that rates of decomposition of the moss *Hylocomium splendens* (Figure 5) decreased with altitude, but at boreal sites the rates were similar to those of the subalpine sites, despite the lower mean annual temperatures. They found a log-linear relationship between the annual mass loss rate and the cumulative value of monthly mean air temperatures higher than 0°C.

In the Antarctic, where ground at 20-30 cm is permanently frozen, decomposition above the frozen portion is less than 1% per year. By the time it becomes part of the permafrost zone, about half the original material has decomposed (Fenton 1980). It took approximately 40 years to decompose half of the moss *Polytrichum strictum* (Figure 27) in the upper 15 cm. But this low rate may not be representative. This species has an intrinsically low decomposition rate.

Time, of course, has an effect on the rate. Johnson and Damman (1991) found a much faster rate during the first 10 months than in the months 10-22 after the onset of the experiment. When tested in the anoxic (submerged) zone, *Sphagnum fuscum* (Figure 2) actually had less total decomposition (9.1%) in months 10-22 than in the first 10

months (10.6%), whereas *Sphagnum cuspidatum* (Figure 18) increased slightly from 15.1% to 16.1%.

Figure 27. *Polytrichum strictum*, a moss that forms deep cushions. Photo by Michael Lüth, with permission.

Extreme heat may have a negative effect on decomposition in bryophytes (Ohlson 1987). In a Swedish mire, rates of decomposition differ spatially. This may in part be due to temperature differences. Clymo (1965) showed that *Sphagnum papillosum* (Figure 28) that was dried at 105°C exhibited less subsequent decay than did material that dried in air. This may have been due to death of associated microorganisms.

Figure 28. *Sphagnum papillosum*, a species that decays less after being subjected to 105°C. Photo by 1 James K. Lindsey, with permission.

One explanation for the slowdown in decay rate may be types of constituents that still remain (Coulson & Butterfield 1978). In *Hylocomium splendens* (Figure 5), the oldest and most decomposed tissues exhibited a slight increase in polymerized lipid monomers (Kälviäinen *et al.* 1985).

Cellulose and hemicellulose content change during decomposition (Küster 1968). For *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18) the hemicelluloses changed from 16% in relatively undecomposed peat to 10% in well-decomposed plants. Celluloses had a similar decline from 19% to 11%. Such changes affect the kinds of organisms required for or attracted to the moss for decomposition and these changes affect the rate of decay.

As readily obtainable nutrients are consumed by the decomposers, more recalcitrant kinds become a greater proportion of the remaining components. Nadkarni (1984) demonstrated considerably higher nutrient content of N, P, Ca, Mg, K, and Na in live compared to dead parts of epiphyte mats [including bryophytes, *Selaginella* (Figure 29-Figure 30), and *Polypodium* (Figure 31) on *Acer macrophyllum* (Figure 32). However, these changes in concentrations could reflect re-distribution of nutrients to growing parts of the plants. But one of the biggest decreases is in Ca, an insoluble nutrient that is not readily moved within plants, suggesting that some of these changes may result from loss during decomposition. During (1990) demonstrated that bryophytes in calcareous grasslands released nutrients in summer as a result of partial die-back and decomposition. Damman (1988) found that as the age of decomposing *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18) increases, tissue N concentrations increase. Malmer and Wallén (1993) supported this observation with their evidence that N is conserved in decomposing *Sphagnum*. N becomes depleted in the litter at the bottom layer where decomposition has led to disintegration, but below that layer (litter deposition level) the concentration of N increases once more with depth (in the decay decrease level).

Damman suggested that P deficiency might limit the decomposition rate. However, Coulson and Butterfield (1978) found that for *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18), increased concentration of P caused a reduction in its decomposition rate. Such releases could favor different groups of organisms for subsequent decomposition. Increased N levels, on the other hand, seemed to increase the decomposition rate.

It appears that in *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18) the ratio of N:C is more important than the absolute level of N in the plants (Limpens & Berendse 2003). This ratio affects the litter quality, with greater decomposition when the N:C ratio is higher.

Habitat within an ecosystem can play a significant role. Decomposition of epiphytic bryophytes in a tropical montane forest at Monteverde, Costa Rica, was significantly less than that of forest floor taxa (Clark *et al.* 1998). The first year, the epiphytes were reduced by 17%, reaching only 19% reduction by the end of the second year. At the same time, forest floor bryophytes lost 29% to decomposition the first year and 45% by the end of the second year. These differences most likely reflect differences in water availability, but they also support the N story. Within the first three months the bryophyte forest floor litter lost 47% of its N; the remaining N seemed to be

recalcitrant. Similar recalcitrance occurred in epiphytes, which typically trap significant amounts of N-containing dust from the atmosphere, then convert it to biomass and lock it up. Reduction in available N could contribute to the slowdown of decomposition with time.

The decomposer population likewise changes with time, further modifying the decay rate. For *Pleurozium schreberi* (Figure 7), Mikola and Hintikka (1956) found bacterial densities of 10 million per ml after 20 days, a reduction to 1 after 50 days, up to 40 after 80 days, and back down to 10 after 130 days. The molds had a more consistent pattern, exhibiting declining numbers with time.

The decline in decomposition rate with time seems to be a fairly common occurrence among bryophytes. Clark *et al.* (1998) showed a decline in rate from the first to second year in various northern hemisphere populations of *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18), *Dicranum* (Figure 33), mixed bryophytes (from Costa Rica), and *Calliergonella* (Figure 34). Only a population of *Sphagnum* from North Sweden deviated, increasing its decomposition rate in the second year. Van Tooren (1988) likewise demonstrated a decline in the decomposition rate of *Calliergonella cuspidata* (Figure 34) after six months. Concomitantly, there was a drastic drop within the first two months in both N and P as a percent of that originally present. Nevertheless, after the first two months, both the N and P content eventually increased as a percent of the remaining dry weight.

Decomposition rates of *Hylocomium splendens* (Figure 5) varied with site (Uchida *et al.* 2001). The most recent two years of growth were green from all sites. However, two-year-old segments were green in the Canadian boreal forest and the Mt. Fuji subalpine forest, but were senescing from Mt. Tsurugi. By the third year, decomposition had slowed in the boreal and subalpine forests, with the 5-year-old segments on Mt. Fuji exhibiting ~80% of the weight of the largest segment. On Mt. Tsurugi, on the other hand, rapid decomposition had rendered the 5-year-old segment to be less than half the weight of the largest segment.

Figure 33. *Dicranum fragilifolium* showing older brown parts that will decompose slowly over time. Photo by Michael Lüth, with permission.

As we can see from these examples, decomposition rates vary widely between habitats and geographic areas. Likewise, the onset of senescence and decomposition

varies with locality and habitat. *Eurhynchium oreganum* (Figure 35) in Douglas fir forests (Figure 36) of Oregon, USA, begins decomposition at age 3 (Binkley & Graham 1981), whereas those in Washington don't turn brown until age 6 (Frye 1928). In the same Washington forest, *Hylocomium splendens* (Figure 5) lives 8 years before its lower parts begin to decompose. But moss tissue may remain alive even after it has become brown (Longton 1972), moving nutrients to younger parts (Eckstein & Karlsson 1999).

Figure 36. Douglas fir forest in Vancouver, BC, Canada. Photo by Janice Glime.

We might expect decomposition in the Antarctic to be slow. Baker (1972) found that *Chorisodontium aciphyllum* (Figure 37-Figure 38) on Signy Island had an approximately linear decomposition rate, averaging 2% per year.

Figure 37. *Chorisodontium aciphyllum*, a species that decays at approximately 2% per year in the Antarctic! Photo by Peter Convey, with permission.

Figure 38. *Chorisodontium aciphyllum*, a species that decays at the rate of 2% per year in the Antarctic. Photo by Jan-Peter Frahm, with permission.

It may be fairly typical that decomposition of forest floor bryophytes is at a pace similar to that of growth. For example, *Hylocomium splendens* (Figure 5) exhibits apical growth equivalent to the loss from the distal segments (Callaghan *et al.* 1978). Zhang (1998) used mapped permanent plots on Isle Royale, Michigan, to track yearly changes in boreal bryophytes for four years. He likewise found that decomposition was approximately replaced by new growth, resulting in little change in cover from one year to the next, but often considerable change in position of the clump.

As might be expected, temperature is an important contributor to the rate of decomposition, as shown for peat decomposition in Scotland (Chapman & Thurlow 1998).

Habitat Differences

Forests

Forests are known for their relatively rapid decomposition of deciduous leaf litter. Decomposition in conifer forests is notably slower (Berg 1984). But where do the bryophytes fit in?

Liu *et al.* (2000) compared decomposition of bryophytes [*Homaliodendron scalpellifolium* (Figure 39),

Symphiodon perrottetii, *Herbertus* sp. (Figure 40), and *Bazzania albicans*] with that of three dominant non-conifer tall tree species and an understory bamboo in southwest China. The tracheophyte decomposition rates seem to be controlled by initial concentrations of lignin, N, and P rather than by leaf morphology. Nutrient and lignin concentrations were less important in bryophyte decomposition. Furthermore, the trees all decayed faster than the bamboo, and the bamboo decayed faster than the bryophytes. The rate constants of canopy litter ranged 0.50-0.64, that of bamboo 0.40, and that of bryophytes 0.22. Turnover time for the canopy species ranged 1.55-2.0 years, for bamboo 2.50 years, and for bryophytes 4.55 years.

Peatlands

It seems that more is known about decomposition of bryophytes in peatlands than from all other ecosystems combined (Collins 1973; Heal & French 1974; Heal *et al.* 1981; Davis 1986; Grandmaison & Laflamme 1986; Lieffers 1988; Russell 1990; Chmielewski 1991; Johnson & Damman 1991; Santelmann 1992; Gignac & Vitt 1994; Bowden *et al.* 1999; Table 1). That is attributable to the

large area of the Earth's surface covered by peatlands and their importance in those ecosystems.

Table 1. Percent decompositional rates of peatland bryophytes. From Bowden *et al.* 1999.

Rate (% y ⁻¹)	Species	Location	Reference
0.04-3	moss	Arctic	Russell 1990
5	<i>Sphagnum fuscum</i>	Arctic	Roswall <i>et al.</i> 1975
4	<i>S. balticum</i>		
7	<i>S. lindbergii</i>		
5	<i>Drepanocladus schulzii</i>		
7	<i>Dicranum elongatum</i>		
1.5	moss	Antarctic	Davis 1986
1.3-2.4			Baker 1972
0.1-8.3			Fenton 1980
2	<i>Chorisodontium aciphyllum</i>	Signy Island	Collins 1973
14	<i>Sanionia uncinata</i> (dry)		
25	<i>S. uncinata</i> (wet)		

Thomas and Pearce (2004) suggest that cation exchange may be responsible for preventing decay in deep peat. Conditions in the deep peat are anoxic. When mono- and di-valent cations were added to deep peat, a reduction in emissions of methane and CO₂ follows. Decay could be stimulated by adding a carbon source, but not by added NH₄⁺. The researchers concluded that the cation limitation is limited to the deep peat and could explain the decay rate differences between anoxic surface and deep peat.

In northern peatlands, the maintenance of unfrozen bogs and fens creates habitat heterogeneity where these wetlands are interspersed among areas of permafrost mounds. Thus, their presence affects the hydrology, topography, thermal regime, and community structure (Turetsky 2004). Turetsky determined that the internal lawn peat produces more CO₂, hence has more decomposition, than other peatland types. The composition of the peat, as suggested earlier, plays a major role in the rate of decomposition, with acid-insoluble material and the ratio of this material to nitrogen being of primary importance when looking at the broadscale of peatlands. However, within a given peatland, the soluble proximate fractions are better predictors of the decompositional rate. Permafrost stability is important in determining the plant and soil environment, which in turn controls litter inputs, quality of organic matter, and ultimately, decomposition rates.

Peatlands are famous for their emission of methane, causing concerns that global warming will raise the methane emission, which will in turn increase the global warming effect (Weltzin *et al.* 2001). But peatlands can also consume methane. Yavitt *et al.* (1990) demonstrated that *Sphagnum* (Figure 2-Figure 3, Figure 16, Figure 18) -derived peat from 0-40 cm exposed to aerobic conditions consumed methane (CH₄), presumably due to consumption by aerobic microorganisms, whereas the same peat maintained under anaerobic conditions at 19°C for 40 hours produced 0.5-1.0 μM L⁻¹ peat h⁻¹. Under these two conditions, CH₄ emission of 6.8 mmol m⁻² d⁻¹ and CH₄ consumption of 5.4 mmol m⁻² d⁻¹ demonstrate a net increase of CH₄ to the atmosphere.

Methane emission could experience further enhancement due to various environmental pollutants that

enhance the rate of decay. among these concerns are increasing temperature and acid precipitation. Rochefort *et al.* (1990) examined the effects of simulated acid rain on *Sphagnum fuscum* (Figure 41), *Sphagnum magellanicum* (Figure 42), and *Sphagnum angustifolium* (Figure 43). During the first two years, production of *Sphagnum* was enhanced, but after that it declined to its original rates. Decomposition was unaffected during the four years of application. Furthermore, it appears that the hummocks are maintained by a higher rate of production and lower rate of decomposition than that of the hollows in that Ontario, Canada, poor fen.

Figure 43. *Sphagnum angustifolium*, a species in which acid rain does not affect decomposition rate. Photo by Jan-Peter Frahm, with permission.

In a *Betula*-carr, conditions were suitable for growth of *Sphagnum recurvum* var. *mucronatum* (Figure 44) (Brock & Bregman 1989). This species proved to have one of the highest productivity rates of peatmosses. On the other hand, loss of mass during breakdown in this species in the wetland forest was low. N, P, and especially K reduced faster than did the biomass during decomposition, but a large proportion of N and P remained after 12 months. This was consistent with the observation that little damage had occurred to the cells, and colonization by microorganisms was poor.

Figure 44. *Sphagnum recurvum* var. *mucronatum*, a species in which N, P, and especially K reduce faster than the biomass during decomposition. Photo by Jan-Peter Frahm, with permission.

The role of *Sphagnum* (Figure 42-Figure 45) in slowing decomposition is emphasized by the experiments of Verhoeven and Toth (1995). Using litter bags and laboratory experiments, they compared the decomposition rates of *Carex* litter from a base-rich fen with that of *Sphagnum fallax* (Figure 45) from a base-poor fen. In all experiments, the *Carex* litter decomposed significantly faster than did the *Sphagnum* litter. But more to the point, when *S. fallax* was added to *Carex* litter, the rate of loss of *Carex* mass slowed significantly. They concluded that *Sphagnum* acid, a phenolic compound, was responsible by inhibiting the growth of microorganisms.

Figure 45. *Sphagnum fallax* with capsules, a species that has not only a slow decomposition rate, but it reduces decomposition in litter of other species in contact with it. Photo by David T. Holyoak, with permission.

Arctic

Mass loss of non-*Sphagnum* Arctic mosses correlated with the initial N in the plants, a phenomenon that may relate to their nutritive value to the decomposers (Lang *et al.* 2009).

Tundra

Freeze-thaw cycles in the tundra can affect the microbial activity on peat and other bryophytic substrata. Wynn-Williams (1982) compared dry and wet sites in the Signy Islands of Antarctica under *Polytrichum strictum* (Figure 27) and *Chorisodontium aciphyllum* (Figure 37-Figure 38). In the tundra biome, bryophytes are of major biomass importance, averaging 30% cover, but often reaching 100% in wetter areas (Russell 1990), so their decomposition rates have a major influence on those ecosystems. A high standing crop biomass results from low decompositional loss rates, with initial annual loss rates commonly below 10%. The long growing season at sub-Antarctic wet sites can support up to 1000 g m⁻² yr⁻¹.

Antarctic

In the Antarctic, it appears that substrate and moisture are the primary regulators of the decomposition rate, with temperature having little effect (Wynn-Williams 1985; Smith & Walton 1986). Using *Polytrichum* (Figure 27) and *Drepanocladus* (*sensu lato*) (Figure 46) peat, Wynn-Williams demonstrated consistent differences in respiration rates. Furthermore, the lack of correlation between O₂ uptake and CO₂ release suggests that anaerobic CO₂ production occurs under wet conditions.

Figure 46. *Drepanocladus longifolius*. In the Antarctic, CO₂ production in this genus occurs under wet conditions and temperature has little effect on rate. Photo by John Game, through Creative Commons.

Davis (1986) examined the decomposition of Antarctic mosses using litter bags. In a 2-year period, *Polytrichum strictum* (Figure 27) and *Chorisodontium aciphyllum* (Figure 37-Figure 38) from a moss turf community and *Sanionia uncinata* (Figure 47), *Calliergon sarmentosum* (Figure 48), and *Cephaloziella varians* (Figure 49) from a moss carpet community exhibited a decomposition rate of 1.5% per year. This was consistent with the low rate of decomposition of cotton strips inserted into the bryophyte clumps, indicating a low decomposition potential. The decomposition potential, from highest to lowest, for the

five species was *S. uncinata*, *C. aciphyllum*, *C. sarmentosum*, *P. strictum*, and *C. varians*. The time required for 50% decomposition of the cotton strips buried among these bryophytes varied from 1-2 years for *S. uncinata* and *C. aciphyllum* to 3-4 years for *P. strictum* and *C. varians*, with low temperatures, low pH, and short active season contributing to their slowness. Other differences affecting differing rates among sites, depth, and species resulted from temperature, nutrient status, water content, and available oxygen.

Streams

While impacts of grazers and other decomposers on leaf litter in streams are relatively well known, virtually nothing is known about decomposition of bryophytes in streams (Bowden *et al.* 1999). Yet bryophytes often comprise the predominant in-stream vegetation and must therefore play a significant role in its internal nutrient cycling.

Bowden *et al.* (1999) suggested that stream bryophytes may not produce litter in the traditional sense. Rather, biomass is lost to fragmentation, consequently dispersing tissues that could potentially form new plants in new locations. But in slower streams, fragmentation is less extensive, and accumulations of senescing and dead tissues could contribute significantly to ecosystem structure.

Suren and Winterbourn (1991) compared common bryophytes in and near New Zealand streams, revealing that content of lipids, carbohydrates, and N is similar to that of grasses, shrubs, and tree foliage. However, content of holocellulose, crude fiber, and ash may be slightly higher overall in bryophytes, suggesting there might be slightly more resistance to decomposition. Furthermore, antibiotic compounds such as phenolics, terpenes, and flavonoids may inhibit decomposition (Markham & Porter 1983; Geiger 1990; Gorham 1990; Herout 1990; Markham 1990; Russell 1990; Glime 2006).

It appears that the only study designed to measure the rate of decomposition of stream bryophytes [*Schistidium agassizii* (Figure 50); *Hygrohypnum* spp. (Figure 51)] is that described in Bowden *et al.* (1999) for the Kuparuk River, Alaska, USA (Figure 52). These bryophyte rates are far faster than the yearly rates presented in Table 1 and furthermore show that the rates do not differ greatly from those of the tracheophyte leaves in the same study.

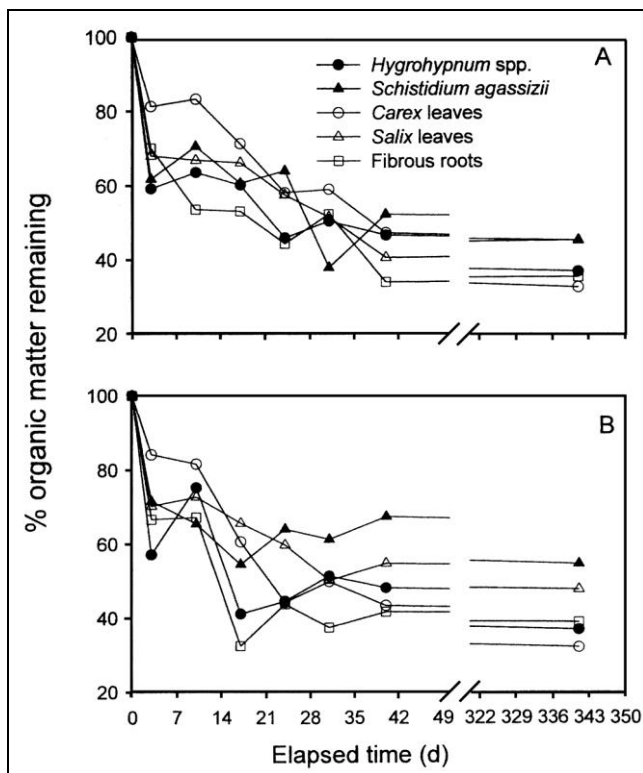

Figure 52. Mean percent of original organic matter of bryophytes, tracheophyte leaves, and roots remaining after six weekly intervals and one year when placed under rocks in the Kuparuk River, Alaska, USA. $n = 5$. **A** = control; **B** = fertilized portion of stream. Modified from Bowden *et al.* 1999.

Ecologists have traditionally considered that consumption of bryophytes by invertebrates was minimal. Nevertheless, consumption does occur and contributes to the removal of bryophyte tissue. Suren and Winterbourn (1991) found that of 23 invertebrate taxa in alpine streams in New Zealand, only 14 contained bryophytes in their guts. Furthermore, only the cranefly *Limonia hudsoni* (Figure 53; Tipulidae) and caddisflies *Zelandopsycha ingens* and *Oeconesus similis* (Figure 54) commonly consumed them. Suren and Winterbourn (1991) showed that bryophytes (*Fissidens rigidulus* (Figure 55), *Cratoneuropsis relaxa* (Figure 56), *Bryum blandum*

(Figure 57), *Plagiochila retrospectans* (Figure 58), and *Hepatostolonophora paucistipula*) contained more refractory and indigestible compounds than did the common riparian tracheophyte plants nearby (*Chionochloa pallens*, *C. flavescens*, *Hebe subalpina*, *H. odora*, *Nothofagus solandri* var. *cliffortioides*, *Blechnum capense*, and *Marsippospermum gracile*), making the bryophytes less nutritious.

Lakes

In cold lakes, particularly those in polar regions, bryophytes may be the only form of macrovegetation (Sand-Jensen *et al.* 1999). In these frigid waters, with their low nutrients and short ice-free season, bryophytes are able to form dense stands, occupying great depths. Sand-Jensen and coworkers used changes in the size and density of leaves as markers to indicate growth and decomposition in Char Lake and North Lake in the Canadian High Arctic. The annual growth was remarkably constant (~ 10 mm shoot⁻¹), combined with slow decomposition. The slow growth rate, however, is at least partly offset by the greater longevity of the mosses in these communities.

Epiphytes

Of all the ignored bryophytes in the world, epiphytic taxa (Figure 59) have probably been most ignored by ecologists. However, in the tropics, a number of ecologists have recognized their importance in nutrient retention and cycling. Clark *et al.* (1998) examined the ecological role of epiphytic bryophytes in a tropical montane forest of Monteverde, Costa Rica. They found net production to be $122\text{--}203$ g m⁻² yr⁻¹ while decomposition from litterbags after one and two years in the canopy was $17 \pm 2\%$ and $19 \pm 2\%$ mean ± 1 SE), suggesting that the bryophytes may have a significant retention time for nutrients. However, approximately 30% of the N content was released rapidly, contributing short-lived spikes in the N input to the underlying ecosystem. On the forest floor, approximately 47% of the N was lost in the first three months from green shoots! However, the N that remained in the litter was recalcitrant. Since bryophytes retain inorganic N from atmospheric deposition, they play a major role in altering the amount of available N to the system by transforming it to highly recalcitrant forms.

Figure 59. In the tropics even small branches can sport bryophytic epiphytes like *Schlotheimia tecta* growing with a bromeliad. Photo by Michael Lüth, with permission.

Role

It is too early to define a clear role for bryophytes in nutrient cycling through decomposition in ecosystems. Evidence from epiphytes suggests that leakage of N compounds from senescing bryophytes may be a significant

contribution of the nutrient pool for other epiphytes and throughfall recipients (Clark & Nadkarni 1992).

While our understanding of such roles in the terrestrial ecosystems is meager, our understanding in aquatic systems is nearly non-existent, as noted by Bowden *et al.* (1999). Their role in the regeneration of nutrients in streams is essentially unknown and there seem to be almost no published rates of bryophyte decomposition in stream ecosystems.

Summary

Bryophytes, unlike tracheophytes, die from the bottom up, with apical regions continuing to live and grow as their lower parts decompose. Compared to tracheophytes, their decomposition rate is relatively low, most likely due to recalcitrant cell wall components and secondary metabolites acting as antiherbivore/antibiotic compounds. Loss of nitrogen appears to be initially rapid, then becomes relatively unavailable, further limiting attractiveness to decomposers. Changes in the internal composition of the decomposing bryophyte appear to slow its rate of decomposition after the first year.

Bacterial decomposition may be limited in peatlands by the low pH, but it appears that fungi can be abundant, some being unique to bryophytes. Nevertheless, bacteria are able to penetrate the cell walls of at least some aquatic leafy liverworts, presumably contributing to their decomposition.

Phaeopigments may be an indicator of degree of decomposition, but their use for such purposes appears to be unreliable in aquatic systems.

Water seems to be the primary factor affecting rate of decomposition, but it acts in consort with pH, cell constituents, temperature, species of bryophyte, and available microorganisms.

Rates of decomposition vary widely, with peatland decomposition ranging from 0.04 to 25% per year. Similarly, the Antarctic exhibited a low rate of 1.5-2% per year. Tropical epiphytes may reach about 18% in a year.

CHAPTER 1

THE FAUNA: A PLACE TO CALL HOME

Figure 1. A bird nest of the New Zealand fantail (*Rhipidura fuliginosa*) in a New Zealand *Nothofagus* forest, exhibiting a potpourri of vegetal material, including bryophytes. Could that be *Dawsonia* on the left? Photo by Rosemary Lovatt, with permission.

Types of Interactions

When I first became interested in bryophytes, I turned to the aquatic habitat, a place I had loved as a child and young adult. This soon led me to the organisms that lived among them. But literature on the subject was extremely difficult to find. This did not seem to be a high priority topic among bryologists, and those who studied animals seemed to think bryophytes were unimportant.

It is with great pleasure that I write this book, because there are now many fascinating stories of bryophyte – animal interactions, from housing to building materials (Figure 1) to food to safe sites. It appears that ecologists are beginning to recognize the importance of bryophytes, including them in studies, and publishing their studies in a very wide array of journals. That literature is easier to find now due to the internet, and when contacted, these wonderful scientists have been willing to share their stories and their photographs with all of us.

Bryological Fauna

Imagine yourself as a tiny mite in the forest. Everything around you must seem gigantic! But there, amidst the rocks and pine needles, a miniature forest beckons. It is a moss. This moss is your home. Here you can feel secure, protected from the drying wind and flecks of sun, hidden from the hungry birds, yet able to find tiny morsels for your own diet.

The bryophyte world is full of life, creating a habitat unlike any other (Ramazzotti 1958). Yet we know almost nothing of it. What loss might there be if the mosses were to disappear? What bird might be unable to construct a nest? What ant would have no place to hide its winter cache of seeds? What lemming might freeze its feet? The animals of the forest and field, stream and rock, have a very different view of the mosses and liverworts from that of the human inhabitants of the planet. These relationships will begin to unfold in this volume.

The habitats provided by mosses and liverworts are widely varied and worldwide, from mosses on roofs (Corbet & Lan 1974) to epiphytes (Fly *et al.* 2002) to turf-forming moss polsters (von der Dunk & von der Dunk 1979). In this volume we will explore the wide-ranging sizes and uses of the bryophyte dwellers and users. We will compare the terrestrial habitat, where nematodes are often most abundant, closely followed by rotifers (Figure 2), to the aquatic habitat, which can be quite different, and where Chironomidae (midges) are often the most abundant.

Figure 2. Comparison of relative abundance (log scale) of common bryophyte-inhabiting invertebrate fauna. Redrawn from Sayre & Brunson 1971.

Dispersal

Dispersal is necessary for both bryophytes and their inhabitants. Some, perhaps most of the microinhabitants, ride on a magic flying carpet, transported to their new location as a passenger on the bryophyte. Janiec (1996) trapped microfauna that were transported by the wind to areas with established plants near a glacier on King George Island of the South Shetland Islands. After six weeks of exposure, 859 individuals were trapped. Nematodes comprised 71%, tardigrades 22%, and rotifers 7%. The number of individuals caught depended on the distance from a colonized area and the presence of plant parts, suggesting that the plant parts contributed to their dispersal.

Limitations

Bryophytes provide a habitat with a number of constraints that can prove to be of value to their tiny inhabitants. Most obviously, their small size limits the organisms that can live there. This affords small organisms protection from larger predators. And the bryophytes have a slow growth rate, permitting them to be a nursery to organisms that are initially small, but forcing these youngsters to leave before they are large enough to turn cannibal and consume their own offspring. The perennial nature of most bryophytes, rendering them present when many tracheophytes are absent or unable to provide cover, also provides a suitable overwintering habitat for numerous organisms, from the small ones living among the stems and leaves to the larger ones that live under them or use them as nesting material. Their C_3 habit permits the bryophytes to survive and sometimes even grow when the environment is

cold and other plants are dormant, often absent above the substrate surface. Thus, in a world of predators, the bryophytes offer a safe site to numerous organisms that dominate this miniature world.

In the Antarctic, water limits the flora and fauna (Kennedy 1993). Kennedy suggested that water, rather than dispersal or temperature may limit many organisms from colonizing in the Antarctic. He demonstrated that there was a close relationship between the substrate biota and gradients in meltwater, seepage, and upwelling. Furthermore, microarthropod abundance is "directly proportional" to microvariation in relative humidity. Even the algal food source migrates upward in response to added water.

The Inhabitants

Large bryophyte mats typically host a wide variety of micro and macroinvertebrates (Ino 1992; Glime 1994; Peck & Moldenke 1999). The presence of a wide diversity of feeding strategies in a moss community suggests that the moss serves as a site of multiple pathways for nutrient cycling (Merrifield & Ingham 1998).

Fauna of bryophytes may be divided between those that are **bryophilous**, *i.e.*, those that typically live among bryophytes, and the casual visitor, sometimes referred to as **bryoxenous** (Ramazzotti 1958; Gadea 1964). Gerson (1982) divided these bryofauna into four categories:

- bryobionts:** animals that occur exclusively associated with bryophytes, *e.g.* *Cyclidium sphagnetorum* (a ciliate protozoan) on *Sphagnum* (*cf* Figure 3)
- bryophiles:** animals that are usually associated with bryophytes but can be found elsewhere
- bryoxenes:** animals that regularly spend part of their life cycle among bryophytes
- occasionals:** animals that may at times be found associated with bryophytes but do not depend on them for survival

Figure 3. *Cyclidium* sp. This genus includes *C. sphagnetorum*, a species that occurs only on *Sphagnum*. Photo by Yuuji Tsukii, with permission.

Chernov (1985) named the bryophyte-dwelling invertebrates **semi-edophores**, a term that means partly living in soil. This naming is consistent with the treatment of mosses as part of the litter, a practice common in soil biology. In aquatic systems, those tiny organisms that live on the bed of a river or lake and are barely visible to the human eye are termed **meiofauna** – those that pass through a 0.500 mm sieve and are retained on a 0.045 mm sieve (International Association of Meiobenthologists 2008).

Usage of this term has expanded to include organisms living on bryophytes that provide a moist film of water during at least part of the year. Maggie Ray (Bryonet 7 July 2005) stated that there are three groups of meiofauna that commonly live in the film of water on the bryophyte surface and that can achieve an **ametabolic** state. These are tardigrades, free-living nematodes, and rotifers. This **cryptobiotic** or **ametabiotic** state permits them to join the bryophytes in being dormant during those periods when the bryophyte is dehydrated or under a blanket of snow. She states that these cryptobiotic animals are "virtually indestructible." This permits them to survive environmental extremes such as high and low temperatures, high and low pH, very high pressure and very low vacuum, and low moisture. Upon return of the habitat to a "livable" and hydrated state, the animals absorb water, expand, and return to an active life. Hence, one might find eggs, "tuns" (stage in which body metabolism is undetectable), and cysts. Maggie points out that they do not age while they are in their cryptobiotic state and can remain that way for decades, making ideal study organisms for those interested in space travel and cellular research.

Bryophytes are such an important part of the **niches** of some invertebrates that their name indicates they are "of the moss." A Google search for *muscorum* has revealed 33 of these names among the protozoa and invertebrates (Table 1), and there are probably more, as well as those with *bryophila* or *muscicola* and other bryological epithets such as *Cyclidium sphagnetorum* or *Bryometopus sphagni*.

One particularly important **xerophytic** community is the **cryptogamic crust** (Figure 4) found in prairies and deserts. These bryophyte masses are associated with lichens and algae and inhabited by fungi, bacteria, and other micro-organisms. Among 38 taxa (nematodes, tardigrades, mites, arachnids, springtails, other small insects) in New Mexico, 29 occurred on mossy patches (Brantley & Shepherd 2002). Twenty-seven species occurred on mixed lichen and moss patches, and 21 on lichen patches. Fifteen taxa occurred on all three types. Mosses supported the highest abundance, followed by mixed lichen and mosses, then by lichens. Richness and abundance were both higher in winter (March) than in summer (August) for all crust types in these dry habitats, reflecting differences in moisture stress.

Table 1. Names of protozoa and invertebrates including *muscorum* as the specific epithet. The list was derived from an internet Google search, especially ITIS search, for *muscorum*. Accessed on 7 October 2008 at <<http://www.itis.gov/servlet/SingleRpt/SingleRpt>>.

Protozoa

Assulina muscorum (Rhizopoda)
Chilodontopsis muscorum (Ciliophora)
Gastrostyla muscorum (Ciliophora)
Histriculus muscorum (Ciliophora)
Holosticha (= *Keronopsis*) *muscorum* (Ciliophora)
Oxytricha (= *Opistotricha*) *muscorum* (Ciliophora)
Pusilloburius (= *Pseudoglaucoma*) *muscorum* (Ciliophora)
Rhabdostyla muscorum = *Opercularia coarctata* (Ciliophora)
Sathrophilus (= *Saprophilus*) *muscorum* (Ciliophora)
Steinia muscorum (Ciliophora) name validity not verified
Strongylidium muscorum (Ciliophora) name validity not verified
Stylonychia muscorum (Ciliophora)
Urostyla muscorum (Ciliophora)

Nematoda

Hemiplectus muscorum (nematode)
Prionchulus muscorum (nematode)

Arthropoda: Arachnida

Gnaphosa (= *Pithonissa*) *muscorum* (Araneae – spider)
Liochthonius muscorum (Araneae – spider)
Tegeocranellus muscorum (Acari – mite)

Arthropoda: Isopoda

Philoscia (= *Oniscus*) *muscorum* (moss wood louse)

Arthropoda: Pseudoscorpiones

Neobisium muscorum (Neobisiidae – moss scorpion)

Arthropoda: Insecta

Acerella muscorum (Protura)
Acrotona muscorum (Coleoptera: Staphylinidae)
Bombus (= *Apis*) *muscorum* (Hymenoptera: Bombidae – moss carder bee)
Anthrenus museorum = *Byrrhus* (= *Anthrenus*) *muscorum* (Coleoptera: Dermestidae)
Entomobrya (= *Degeeria*) *muscorum* (Collembola – springtails)
Leptothorax (= *Myrmica*) *muscorum* (Hymenoptera: Formicidae)
Liothrips muscorum (Thysanoptera: Thripidae)
Lissothrips muscorum (Thysanoptera: Thripidae)
Mniophila muscorum (Coleoptera – leaf beetle)
Neanura muscorum (Collembola: Neanuridae)
Peromyia muscorum (Diptera: Cecidomyiidae)
Tetramorium muscorum (Hymenoptera: Formicidae – Guinea ant)

Mollusca

Pupilla muscorum (Gastropoda – snails)

Bryophytes can be especially important in contributing to species diversity of ecosystems. Sudzuki (1971) found that among 17 stations along five lakes on Mt. Fuji in Japan, the populations of rhizopods, gastrotrichs, rotifers, and nematodes were richest in the mosses. The mosses by Lake Kawaguchi had the highest overall species richness, ranging as high as 77 species, whereas gravels had richness as low as 19 species.

Varga (1992a, b) has found that some rare bryophytes in Sweden [*Plagiobryum zierii* (Figure 5) & *Saelania glaucescens* (Figure 6)] harbor a bryofauna that helps in monitoring air pollution. Not only do the invertebrates have high concentrations of lead, but the fauna in polluted

cushions is diminished compared to that from unpolluted sites.

Figure 5. Lead accumulates in the fauna of this *Plagiobryum zierii*. Photo by Michael Lüth, with permission.

Figure 6. *Saelania glaucescens* is a moss whose bryofauna can be used to monitor air pollution. Photo by Michael Lüth, with permission.

Cover and Nesting Materials – Terrestrial

Moss mats and cushions can make ideal cover and nesting material for a variety of organisms. They serve to buffer both temperature and moisture, while providing sufficient spaces for gas exchange. There are many tiny spaces ideal for laying eggs and protecting young larvae from predators or desiccation. For larger organisms, the leafy stems are easily woven into suitable nests, and the projecting leaves render stability to the completed product. Thus it is not surprising to find that many organisms actually depend on bryophytes for their homes and shelters.

Bryophyte Individuality

But to what extent do individual bryophyte species differ in their provisions for these animals? Learner *et al.* (1990) found no relationship between taxon richness and macroinvertebrate fauna on bank slopes of river corridors where bryophytes were included in the assessment. This suggests that bryophytes might form functional groups that differ in their form from other plants but otherwise differ little within the functional group in the means by which they shelter organisms.

Two communities of bryophytes on Signy Island in the Antarctic support this growth form or functional group suggestion for richness. Davis (1981) found that there was little difference in assimilation or respiration of the plant

and faunal components of the *Polytrichum strictum* (Figure 7) and *Chorisodontium aciphyllum* (Figure 8) turf compared to the *Calliergidium austro-stramineum* (Figure 9), *Calliergon sarmentosum* (Figure 10), and *Sanionia uncinata* (Figure 11) mat with *Cephaloziella varians* (Figure 12), but among the faunal taxa (protozoa, Rotifera, Tardigrada, Nematoda, Acari, and Collembola) of these bryophytes, the standing crops of Collembola and Acari differed between the two associations. Thus, while richness differed little, the types of species did differ. Interestingly, it appeared that no bryophytes were eaten by these organisms. Rather, the bryophytes form unique habitats that provide safe sites for the small invertebrates that seek shelter there.

Figure 7. *Polytrichum strictum*, a turf-former that provides habitat for invertebrates on Signy Island in the Antarctic. Photo by Michael Lüth, with permission.

Bryophytes can play a role in the larger ecosystem picture as well, affecting organisms in other niches. Some mosses in the Antarctic provide habitat for a variety of arthropods indirectly rather than directly by modifying the underlying soil (temperature, moisture, structure) in ways that make it suitable for a variety of arthropods (Gerson 1969).

Are Bryophytes an Important Food Source?

The answer to that question seems to depend on who you are. But there is clear evidence that some organisms do eat bryophytes. And they seem to have their preferences for both species and parts.

For example, in *Ulota phyllantha* (Figure 13), the consumer (apparently an isopod) has a preference for the lamina, leaving behind hair-like structures that are the costa remains (Robin Stevenson, pers. comm. 19 February 2014). In others, gemmae are preferred. Stevenson has suggested that in *Orthotrichum lyellii* (Figure 14), where gemmae are prolific, being edible might be an adaptation for dispersal of the gemmae.

Figure 13. *Ulota phyllantha* very badly affected by grazing. Those hair-like structures are remaining costae – the leaf lamina has been eaten. Photo courtesy of Robin Stevenson.

Food Value of Bryophytes

Because most bryophytes exist uneaten in herbaria around the world, biologists have long held the view that bryophytes are not effectively a part of the food chain. They have low caloric value (3.7–4.8 Kcal/g; Forman 1968, 1969; Rastorfer 1976a, b), large quantities of holocellulose

and crude fiber (Walton 1985) that makes them hard to digest, and are often endowed with a plethora of secondary compounds (Asakawa 1981; see chapter on antiherbivory).

In comparison to evergreen and deciduous shrubs in the alpine tundra, with ~5,560 cal/g ash-free dry mass, bryophytes would seemingly provide considerably less energy (Bliss 1962). Nevertheless, the caloric values for twenty herbaceous tracheophyte species had a mean of $4,601 \pm 29$ cal/g ash-free dry mass, whereas seven species of moss averaged $4,410 \pm 70$ cal/g, ranging from a high of 4,780 in *Polytrichum juniperinum* (var. *alpestre*) (Figure 16) to 4,211 in *Sphagnum girgensohnii* (Figure 17), a difference hardly worth noting.

Figure 16. *Polytrichum juniperinum*, a moss with 4780 measured calories/g ash free dry mass. Photo by Janice Glime.

Ecologists have long considered that bryophytes had little to offer in nutritional quality (Pakarinen & Vitt 1974). Furthermore, some bryophytes even prevent their consumers from obtaining the nutrition from the non-bryophyte food they have just eaten by complexing the protein in ways that make it indigestible. Liao (unpublished) has found lignin-like protein-complexing tannin compounds in all the boreal forest mosses, except for *Sphagnum* (Figure 17), in his study.

In further support of this concept of low food value, we find that in the Antarctic, where bryophytes form the bulk of the vegetation, the invertebrates (protozoa, Rotifera, Tardigrada, Nematoda, Acari, & Collembola) form a diverse fauna among the bryophyte cushions. Yet despite the paucity of non-bryophyte plant food organisms, most invertebrates apparently do not eat the bryophytes (Davis 1981).

Nevertheless, some animals seem to include liverworts (Barthlott *et al.* 2000), mosses (Smith 1977), and hornworts (Bisang 1996) in their diets. Even among the **apparent** (conspicuous) Antarctic bryophytes, which should be expected to have the highest quantity of antifeedant secondary compounds, some invertebrates are adapted to consume them. Weevils (*Ectemnorhinus similis*) eat 37% of their body weight daily of the moss *Brachythecium rutabulum* (Figure 18), consuming 1.67 mg per day per individual weevil on Marion Island (Smith 1977). Tardigrades worldwide are adapted to living among and consuming mosses. Perhaps antifeedants are not as

important to these organisms as we might suppose. How little we know of the physiological mechanisms that make these feeding relationships successful!

Figure 17. *Sphagnum girgensohnii*. Photo by Janice Glime.

Figure 18. *Brachythecium rutabulum* with capsules, a moss that provides 37% of the body weight daily to the weevil *Ectemnorhinus similis*. Photo by Andrew Spink, with permission.

We know even less about the nutritive value of sporophytes. Yet several instances are known where capsules are a preferred food, especially for snails and slugs (Davidson *et al.* 1990). Stark (1983) found that 14% of the expanded capsules of *Entodon cladorrhizans* (Figure 19) exhibited signs of grazing. Spores can have a lipid content of 30% while vegetative portions may have only 5% (Gellerman *et al.* 1972; Pakarinen & Vitt 1974). Even flowering plants have a lipid content of only 5% in the Arctic (Pakarinen & Vitt 1974).

Figure 19. *Entodon cladorrhizans*, a moss where capsules are grazed. Photo by Bob Klips, with permission.

Not all functions of food are directly for nutrition. Particularly in northern climates, mammals, and perhaps other animals, seem to benefit from the large quantities of arachidonic acid in bryophytes (Al-Hasan *et al.* 1989). With a melting point of -49.5°C , this fatty acid provides greater pliability for cell membranes at low temperatures. Prins (1981) suggested that this property may help to keep foot pads of Arctic rodents from freezing.

In any case, bryophytes appear to form an important component of the diet for a number of invertebrates and some Arctic mammals and birds. Gerson (1969) included among these the **Collembola**, **Diptera**, **Hemiptera**, **Hymenoptera**, **Orthoptera**, **Cryptostigmata**, and **Acarina**. These and many others will be discussed further in the succeeding chapters on individual groups.

Vitamins

Bryophytes may fill specific needs of animals when fresh food is scarce. For example, vitamin B₂ is not available in most plants, but *Barbella pendula* has a high content and causes no noticeable side effects when fed to puppies and chickens (Sugawa 1960). In fact, Sugawa claims that the animals thrive. Asakawa (1990) lists the species used by Sugawa, citing *Barbella pendula*, *B. enervis*, *Floribundaria nipponica* (Figure 20), *Hypnum plumaeforme* (Figure 21), *Neckeropsis nitidula* (Figure 22), and *Ptychanthus striatus* (Figure 23) as all resulting in weight gain in chickens and puppies, implying that the presence of B₂ in these bryophytes may have been instrumental in that gain.

Food Chain Effects

Of concern when bryophytes enter the food web is the ability of bryophytes to retain high levels of radiation. When the Chernobyl accident occurred, bryophytes for hundreds of miles had elevated radiation (Daroczy *et al.*

1988), measurable in mosses two years after the accident (Elstner *et al.* 1987, 1989). These concentrated levels are further concentrated when they enter the food web, and lemmings, which consume them rather extensively in areas affected by the high radiation (Ericson 1977), are but one step into the food web of higher carnivores.

Seasonal Differences in Habitat and Diet

We know virtually nothing about the seasonal changes in diet of invertebrates that might involve bryophytes. And it is likely that bryophytes also change their nutritive value seasonally, but again we are ignorant. We do know that both invertebrates and vertebrates change habitats to survive or take advantage of the seasons (Ovezova 1989). Crafford and Chown (1991) hypothesized that curculionid beetles (**Curculionidae**: Ectemnorhini) would gain a nutritional advantage by eating bryophytes at low temperatures. Indeed, the cryptogams provided the main source of energy for five out of six of these species on sub-Antarctic Marion Island.

While we seem to know nothing about seasonal diet changes of moss-dwelling invertebrates, we have, however, observed changes in the eating habits of the more conspicuous rodents. Lemmings are known to switch to bryophytes as winter approaches (Prins 1982a), perhaps taking advantage of the high content of arachidonic acid in bryophytes to maintain pliability of cell membranes in their footpads as they run around on frozen ground and snow.

Habitat Differences in Nutrient Availability

Even desert mosses form habitats for a variety of invertebrates (Kaplin & Ovezova 1986). Habitat can play a major role in food value (Figure 24). The avoidance of bryophytes as food seems to be supported where bryophytes form a dominant feature of the physiognomy, *i.e.* the Antarctic, so perhaps apparency theory, the theory that more visible plants contain more antiherbivory compounds, does apply.

Davis (1981) reported that moss was eaten at a rate of less than 0.2 g m⁻² yr⁻¹ by two Antarctic moss invertebrate communities, despite tardigrades, nematodes, rotifers, protozoa, mites, and insects living among them. If such is the case, it supports the model of **apparency**, discussed regarding antiherbivory later in this volume, where the Antarctic bryophytes indeed are the most conspicuous photosynthetic food items available. One would suppose that to avoid herbivory where the slow-growing bryophyte is so conspicuous to would-be consumers, it must either have a high component of secondary compounds to inhibit feeding or lack sufficient food value to make consumption profitable.

This nutritional profitability, as in tracheophytes, differs with habitat. In the high Arctic, not only do the percentages of N and C differ (Figure 24), but the hydric mosses tend to have a higher caloric value (4.57-4.97 kcal/g) and lipid content than do the mesic and terrestrial ones (4.50-4.69 kcal/g) (Pakarinen & Vitt 1974).

Caloric contents likewise differ among terrestrial habitats, with those of alpine regions seemingly lower than those of either coniferous forests (4169 cal/gdw) or northern hardwoods (4179 cal/gdw) (Figure 25; Forman

1968). Oakwoods have the least (3773 cal/gdw) among these studies.

Despite their seemingly lower caloric content, Arctic bryophytes seem to experience greater consumption by mammals than elsewhere (Prins 1982b). Prins (1982a) reported that mosses were found in 20% of Arctic stomach analyses but were only about 1% of the total amount of food consumed. It is clear that a lower proportion of net bryophyte production is grazed than for tracheophytes, and Longton (1984) concluded that bryophytes are utilized primarily via the detritus pathway. Ugh! If they have little caloric content when alive, it would seem that only the microbes could benefit when they are dead. Of course, once eaten they can go up the food chain. It appears that certain temperate animals eat mosses in very limited amounts. Unfortunately, our knowledge of feeding relationships with bryophytes in the tropics is meager.

Figure 24. Mean food values (\pm 95% C.I.) of green (living) tissues based on ash-free dry mass of 35 species of Arctic bryophytes. Redrawn from Pakarinen & Vitt 1974.

Markham and Porter (1978) were among the first to take a global approach to examining the constituents of bryophytes. The differences are strongly influenced by the climate, especially temperature. In the Antarctic, bryophytes have higher C:N ratios than do tracheophytes, with larger amounts of holocellulose and crude fiber and lower energy levels, contributing to their undesirability as a food source (Walton 1985). Pakarinen and Vitt (1974) found that even within the Arctic, ratios could differ considerably, with mesic habitats having a higher carbon ratio (Figure 24). Furthermore, as the moss ages, its cellulose content increases, whereas in grasses it decreases (Walton 1985).

Long after Bliss (1962) initiated the study of Arctic and alpine plants and their nutritional value by examining the caloric and lipid content of alpine tundra plants. Sveinbjornsson and Oechel (1991) found little seasonal difference in lipid or carbohydrate content of *Polytrichum*

commune (Figure 26) or *Polytrichastrum alpinum* (Figure 27). Nevertheless, the variability they did find suggests that seasonality of nutrients bears further investigation. Sugar and starch content were negatively associated with each other, with high starch contents occurring in rhizomes and high sugar contents in shoots, suggesting that starch serves as a storage compound.

Figure 25. Caloric values (per gram dry weight) of bryophytes (open circles) compared to other plants and plant parts (solid circles). Non-bryophyte data are from Golley 1961; redrawn from Forman 1968.

Consumption Rates

There are few quantitative studies of bryophyte consumption. Duke and Crossley (1975) calculated that a rock grasshopper, *Trimerotropis saxatilis* (Figure 28), consumed the moss *Grimmia laevigata* (Figure 29) at a rate of 391 mg m⁻² yr⁻¹ in SE USA. On Marion Island in the Antarctic, an individual beetle, *Ectemnorhinus similis*, ate a mean of 1.67 mg of *Brachythecium rutabulum* (Figure 18) per day in feeding trials, equivalent to 37% of its body weight (Smith 1977). Davidson and Longton (1987) quantitatively investigated the consumption of several moss species by slugs [*Arion rufus* (Figure 30-Figure 31) and *A. subfuscus* (Figure 32)], as discussed in the chapter on invertebrates.

Moss litter is not easily broken down and depends on the moss fauna for consumption, returning to the ecosystem as feces (Frak & Ponge 2002). In alpine areas, other litter generally does not depend on fauna for its breakdown. The same secondary compounds that discourage herbivory also interfere with bacterial and fungal decomposition.

New and Exciting Directions

I am excited – a young researcher decided to examine *Funaria hygrometrica* (Figure 33) to see who lived there. This was a great challenge because there are few resources to help in the identification of terrestrial protozoa and algae, especially those that might find mosses to be particularly suitable as homes. But Alen Alex Philip ventured into the realm of the microscopic to explore this cryptic fauna.

What Philip (Philip & Thomas 2016) found was more than he could identify among the 120 kinds of organisms, including Cyanobacteria, algae, Protozoa, Rotifera, Nematoda, and Tardigrada, but he did manage to identify

16 of them to genus. In each of the 15 Indian locations of *Funaria hygrometrica* (Figure 33) collections he found six constant genera: **Cyanobacteria** – **Oscillatoria** (Figure 34); **Protozoa** – **Aspidisca** (Figure 35), **Chilodonella** (Figure 36), **Holosticha** (Figure 37), and **Rotifera** – **Habrotrocha** (Figure 38), **Philodina** (Figure 39). For a short-lived fugitive moss species of exposed, disturbed habitats, this is to me a surprising number of constant genera!

This volume will be a new adventure. In the words of Donald Rumsfeldt, then US Secretary of Defense, in a statement to the press in February 2002, "There are known knowns: there are things we know we know. We also know there are known unknowns; that is to say we know there are some things we do not know. But there are also unknown unknowns – the ones we don't know we don't know." This volume will certainly venture toward the ones we don't know we don't know, and hopefully it will take us to places where we begin to discover those unknowns.

Summary

The small size of bryophytes affords protection from predators to small organisms. This also makes them a good nursery for many kinds of invertebrates. Their perennial nature also provides winter cover, not only for tiny invertebrates, but for larger amphibians and reptiles. Therefore, their potential for contributing to the biodiversity of the planet is enormous.

Bryophyte inhabitants may be classified as **bryobionts** (animals occurring exclusively on bryophytes), **bryophiles** (animals usually but not exclusively among bryophytes), **bryoxenes** (animals that spend part of their lives among bryophytes), and **occasionals** (animals that occur among bryophytes but do not depend on them for survival). **Meiofauna** are the tiny organisms on the bed of a river or lake, or in the moist film of a bryophyte.

One reason for the success of many invertebrate inhabitants is their ability to achieve an **ametabolic** or **cryptobiotic** state, thus becoming dormant when the bryophyte becomes dehydrated or frozen.

Bryophytes buffer both temperature and moisture, not only within the bryophyte community, but in the soil beneath them. Bryophytes differ considerably in their form, yet we know little about differences in communities among different species of bryophytes.

Scientists have assumed that bryophytes have little or no food value, but, nevertheless, isopods, lemmings, and a variety of other organisms do eat them. We know virtually nothing about seasonal changes in nutritive

value of bryophytes, nor of seasonal diets of animals that feed on them. Only a few small rodents are known to switch to bryophytes in preparation for winter. Dangers lurk in areas with radiation accumulation in the bryophytes.

Habitat may select for nutritional quality, with alpine taxa having lower caloric values, hydric mosses having higher values and also higher lipid content. Coniferous and northern hardwood forest bryophytes have higher caloric values, bryophytes of oakwoods the least. As bryophytes age, cellulose content increases, further reducing palatability and energy availability.

Acknowledgments

Thank you to Rod Morris for providing the name of the bird that made the nest in the frontispiece. Throughout this volume, Google and Wikipedia have been invaluable. Without the search capabilities of Google, I would never have discovered many of the stories in this volume. With Wikipedia, I could find general information and leads to important primary literature. Members of Bryonet have kindly sent me stories and publications. This volume is the product of worldwide cooperation of scientists of many kinds. Without their help in providing literature, comments, and images, the richness of the forthcoming stories would be lost.

CHAPTER 2-1

PROTOZOA DIVERSITY

Figure 1. *Actinophrys sol*, a heliozoan that can sometimes be found among mosses in quiet water, with a diatom. Photo by Yuuji Tsukii, with permission.

Moss-Dwelling Micro-organisms

Bryophytes are truly an elfin world, supporting diverse communities of organisms that we often can't see without a microscope. As one might expect, micro-organisms abound (Figure 1) (e.g. Leidy 1880; Maggi 1888; Penard 1908; Heinis 1910; Sandon 1924; Bartos 1946, 1949a, b; Ramazotti 1958; Torumi & Kato 1961; Matsuda 1968; Smith 1974a, b; Schönborn 1977; Sudzuki 1978; Bovee 1979), traversing the crevices like fleas among a dog's hairs. Bovee (1979) reported 145 taxa of protozoa from bogs in the Lake Itasca region, Minnesota, USA. In fact, there are sufficient of these organisms associated with *Sphagnum* that there have been books published on their identification (e.g. Hingley 1993). From forest bryophytes, Bovee found only 68 taxa. Ciliates and testate amoebae dominate the protozoa in both habitats. Even floating liverworts like *Ricciocarpus natans* have their associated microfauna (Scotland 1934).

Gerson (1982) suggests that protozoa have evolved into the bryophyte habitat. Water that wets the mosses permits the protozoa to complete their life cycles. Moist

bryophytes easily accumulate windborne dust, providing even epiphytic species with a source of nutrient matter to serve as food for bacteria and ultimately protozoa. Colonization of aerial bryophytes by micro-organisms could likewise be accomplished by wind. Dispersal of these small organisms may be similar to dispersal of spores of mosses, and the implications of their small size will be discussed later in this chapter.

Terminology

It has been a while since I examined the classification of the micro-organisms, so organizing this chapter turned out to be a bigger mire than I had bargained for. I am sure some of my classification is old-fashioned, but practicality has won out if I am ever to approach completion of this volume. I have tried to update where possible, but some things just don't fit there in my mind, or seem more appropriate to write about in a different place. I have decided to avoid kingdom arrangements completely, so you may find some traditional algae here and others in a chapter labelled algae.

Organisms living "firmly attached to a substratum," but not penetrating it, are known by the German term **Aufwuchs** (Ruttner 1953), introduced in 1905 by Seligo (Cooke 1956). Later the term **periphyton** (literally meaning "around plants") was introduced for organisms growing on artificial objects in water. This term was later expanded to refer to all aquatic organisms growing on submerged surfaces. Young (1945) restricted the definition to "that assemblage of organisms growing upon free surfaces of submerged objects in water and covering them with a slimy coat" (in Cooke 1956). The use of the term has varied, including not only **epiphytes** (those living on plants and algae), but also organisms on non-plant substrata. Although the term Aufwuchs has enjoyed a less confusing history of meanings, Americans tend to use periphyton more frequently to refer to those micro-organisms living upon a substrate. By whatever term, this group of micro-organisms often creates a rich community in association with bryophytes. This chapter will concentrate on the protozoa.

Abundance

One difficulty in describing the micro-organisms of bryophytes is the tedious task of sorting through and finding the organisms. Methods for finding and enumerating protozoa are discussed later in this chapter. Often identification and quantification requires culturing the organisms, which will bias the counts to those most easily cultured. Testate rhizopods are most easily located because the presence of the test permits recognition even after death. These limitations must be remembered in any discussion of abundance.

Tolonen and coworkers (1992) found up to 2300 individuals per cm³ among the bryophytes in Finnish mires. These include **rhizopods** – those with movement by protoplasmic flow, **ciliates**, and **flagellates** (Gerson 1982). The most abundant seem to be the rhizopods (Beyens *et al.* 1986b; Chardez 1990; Balik 1994, 2001), especially those with shells (**testate**) (Beyens *et al.* 1986a, b; Chardez & Beyens 1987; Beyens & Chardez 1994). Among these, *Diffugia pyriformis* (Figure 2), *D. globularis*, *Hyalosphenia* (Figure 3), and *Nebela* (Figure 4) are the most common among *Sphagnum* at Itasca, Minnesota, USA (Bovee 1979). In Pradeaux peatland in France, *Nebela tinctoria* (Figure 4) numbered an average of 29,582 L⁻¹ active individuals, with another 2263 in encysted form (Gilbert *et al.* 2003).

Figure 2. *Diffugia pyriformis* test. Photo by Yuuji Tsukii, with permission.

Schönborn (1977) actually estimated the production of protozoa on the terrestrial moss *Plagiomnium cuspidatum* (Figure 5) and found a yearly mean of 145×10^6 individuals per m² ($0.11 \text{ g m}^{-2} \text{ d}^{-1}$). Rainfall played an important role in the dynamics of protozoa among the mosses, contributing to dislocation and modifying production. Many of the protozoa were testate amoebae that carry sand houses around with them. Heavy rains easily knock these loose and carry them to deeper layers in the soil. On the other hand, the daily death rate of these testate amoebae is lower (only 3.0% per day) than in the river itself. Furthermore, the turnover rate in mosses is much lower than in the river. The higher drying rate (higher than in soil) decreases the number of generations to about half that in soil in the same time period.

Figure 3. *Hyalosphenia papilio* showing test and ingested algae. Photo by Ralf Meisterfeld, with permission.

Figure 4. *Nebela tinctoria* test. Photo by Yuuji Tsukii, with permission.

In temperate forests of northeastern USA, Anderson (2008) identified 50 morphospecies of non-testate amoebae, averaging 17 per sample, based on lab cultures. Densities ranged 3.5×10^3 to $4.3 \times 10^4 \text{ gdm}^{-1}$ of moss. As in other studies, numbers were highly correlated with

moisture content of the mosses ($p < 0.001$). These numbers exceeded those of soil, perhaps due to the heavier weight of soil per unit volume. As expected, number of encysted forms was inversely related to moisture content.

Figure 5. *Plagiomnium cuspidatum*, a terrestrial moss habitat. Photo by Michael Lüth, with permission.

Peatlands

Peatlands are unique habitats dominated by mosses. Because of their moist nature, they are home to numerous micro-organisms (Warner 1987; Kreutz & Foissner 2006) and will warrant their own sections as we talk about many of the groups of organisms that inhabit mosses.

In addition to the moist habitat of the peatland mosses, peatlands provide numerous small pools, hollows, channels, and small lakes that are ideal habitats for some micro-organisms. Using glass slides, Strüder-Kypke (1999) examined the seasonal changes in these micro-organisms in dystrophic bog lakes at Brandenburg, Germany. May brought ciliates and choanoflagellates and the highest degree of species diversity for the year. This community was replaced by one dominated by peritrich ciliates from August to October. Their decline coincided with early frost, yielding to a winter periphyton of small heterotrophic flagellates. The pioneers on the slides were bacterivorous ciliates.

Peatlands typically have **vertical community** differences, as will be seen as we discuss the various groups. Diminishing light restricts the photosynthetic organisms and those protozoa with **zoochlorellae** (algal symbionts) to the upper portion of the *Sphagnum*. In the German bog lakes, Strüder-Kypke (1999) found that this zone was characterized by autotrophic cryptomonads and mobile ciliates. Deeper portions were colonized by heterotrophic flagellates and sessile peritrich ciliates.

Cyclidium sphagnetorum (Figure 6) is known only from *Sphagnum* and is thus a **bryobiont** (Grolière 1978 in Gerson 1982). In fact, *Sphagnum* usually has the richest bryofauna of any moss, as shown by Bovee (1979) in Minnesota. In Canada, a single gram of *Sphagnum girgensohnii* (Figure 7) housed up to 220,000 individuals of protozoa, mostly flagellates, while *Campylium chrysophyllum* (Figure 8) had a maximum of only 150,000 in the same habitat (Table 1; Fantham & Porter 1945), suggesting there might be important microhabitat differences among bryophyte species. In Westmorland, the numbers translate to a mere 16 million of these animals in a single square meter of *Sphagnum* (Heal 1962).

Figure 6. *Cyclidium* sp. (Ciliophora). Photo by Yuuji Tsukii, with permission.

Sphagnum is a particularly common habitat for micro-organisms (Chacharonis 1956; deGraaf 1957). It appears that even the surface of *Sphagnum* may offer a unique community. Gilbert *et al.* (1998, 1999) considered that these surface organisms might play an important role in recycling nutrients using the **microbial loop**, an energy/carbon pathway wherein dissolved organic carbon re-enters the food web through its incorporation into bacteria. Changes in these bryophyte protozoan communities could alter the return of nutrients through the microbial loop and indicate the degree of human disturbance.

Figure 7. *Sphagnum girgensohnii*, a peatmoss that can house up to 220,000 individuals in 1 gram of protozoa. Photo by Michael Lüth, with permission.

Figure 8. *Campylium chrysophyllum*, a peatland species that may be less hospitable to protozoa than *Sphagnum*, but still can house 150,000 in just 1 gram. Photo by Michael Lüth, with permission.

Table 1. Number of individuals occupying *Sphagnum* per gram dry moss. From Fantham & Porter 1945 in Hingley 1993.

	naked amoebae	testate rhizopods	flagellates	ciliates	rotifers	nematodes
<i>S. papillosum</i>	440	3640	9920	1000	160	120
<i>S. subsecundum</i>	1344	1712	26672	2224	176	64
<i>S. palustre</i>	240	3360	5880	2080	120	360
<i>S. girgensohnii</i>	over 220,000				1160	4680

In their comparison of the protozoan groups and other small invertebrates on four *Sphagnum* species, Fantham and Porter (1945) found that *Sphagnum girgensohnii* supported the most protozoa, rotifers, and nematodes, and that flagellates were the most common on all four *Sphagnum* species (Table 1). Unfortunately, most extraction techniques do not work well for examining the flagellates, so it is likely that they are more common than most studies indicate.

We might well ask why *Sphagnum girgensohnii* was the preferred moss. This species tends to occur on higher ground and in forests where it is not submersed for significant periods of time and it is usually possible for protozoa and other small invertebrates to seek out higher parts of the plants to escape drowning. Water is not always a good thing.

The richness of the invertebrate fauna in peatlands is rather astounding in view of the antibiotic properties of *Sphagnum*. Its polyphenolic compounds could not only discourage herbivory on the moss, but reduce the availability of micro-organisms, especially bacteria, that might otherwise live there and serve as food for invertebrate inhabitants (Verhoeven & Liefveld 1997). Smirnov (1961) could find only one invertebrate species that ate the *Sphagnum* – *Psectocladium psilopterus* – a chironomid (midge) larva. Other fauna ate mostly algae from the surface. Nevertheless, microfauna seem to abound in a wide diversity of species and numbers among the *Sphagnum* (Smirnov 1961; Tolonen *et al* 1992; Gilbert *et al.* 1999), despite the fact they are on the menu at this mossy restaurant.

Protozoa

Although **Protozoa** was once a recognized taxonomic unit, it is now only a convenient name used to describe the heterotrophic flagellates, ciliates, and amoebae. Of the now-recognized four major groups of protozoa, three can be found in association with bryophytes. These are **Sarcodina** – rhizopods (amoebae), **Ciliophora** – ciliates, and **Mastigophora** – flagellates (Chiba & Kato 1969; Gerson 1982). Bamforth (1973) described two nutritional protozoan groups associated with plant communities. The naked taxa are primarily **bacterivores** (consume bacteria) and depend on the decomposability of the litter (including bryophytes) where they live. The **Testacea** (those rhizopods living in a shell of their own making) are more slow growing, associate with humus and mosses, and live where the humus is of slow decomposability. These characteristics make bryophytes suitable substrates.

The most important factor in determining the habitation by the protozoa is moisture. This determines which species can occur there, what food is available, and whether the protozoan is active or dormant. Mosses act much like a sponge, absorbing water that is available from

the soil, rain, and atmosphere, and retaining it. As such, they provide a moist safe haven for protozoans to continue an active life long after other surfaces are dry. But they also help to slow the drying of their underlying substrate and provide insulation against heat, cold, and wind, increasing the utility of the substrate, especially soil, as well (Das 2003).

Gerson (1982) has described four categories of bryophyte fauna, based on their occurrence among bryophytes: **bryobionts** – animals that occur exclusively in association with bryophytes; **bryophiles** – animals that are usually found among bryophytes but may survive elsewhere; **bryoxenes** – animals that regularly spend part of their life cycle on bryophytes; **occasional** – animals that may at times be found among bryophytes but do not depend on them for survival.

In a study of Polish peatlands, Mieczan (2006) named four categories of protozoa that inhabited the peatlands, based on percent presence: **very constant species** (in 61-100 percent of the samples), **constant species** (in 41-60 percent), **accidental species** (in 21-40 per cent), **accessory species** (in less than 20 per cent). Although this system aligns closely with that of Gerson (1982), it has the advantage that one does not need to know the occurrence of the species elsewhere and it is more quantitative. On the other hand, that quantification requires considerable time to determine.

As already noted, the richest protozoan habitat among the mosses is considered to be *Sphagnum*, with up to 16 million individuals m⁻² (Richardson 1981). Whereas *Sphagnum* provides a moist habitat, *Drepanocladus* (*sensu lato*; Figure 9), a rich fen species, may be a better habitat by trapping more nutrients (Gerson 1982). In that habitat, the amount of available nutrients determined the numbers of protozoa, due to the greater availability of microbes and organic matter that served as food sources.

Figure 9. *Drepanocladus* (=Limprichtia) *revolvens*, a species among the brown mosses that live in rich fens. Photo by Michael Lüth, with permission.

In his study of Polish peatlands, Mieczan (2006) found 24 taxa of ciliates and 6 of testate amoebae among mosses. But he considered the majority of these to be accidental or accessory species.

Even dry cryptogamic crusts of prairies and deserts sport a diverse fauna of protozoa. In the Grand Canyon, Arizona, USA, 51 species of ciliates, 28 of amoebae, 17 of Testacea, 4 metazoan taxa, and a number of flagellate morphotypes were present in the water film among just 28 microbiotic crust samples (Bamforth 2003). These crusts were composed of Cyanobacteria, lichens, and bryophytes. In the predominating non-flagellated protozoan groups, **r-selected** (high level of reproduction, small body size, short generation time) bacterivores respond rapidly to wetting, quickly exploit resources, then encyst when unfavorable conditions return. It seems that these protozoan groups and bryophytes were made for each other (Kunz 1968).

Zoomastigophora (Flagellates) and flagellated Chlorophyta

Like Euglenophyta, flagellated green algae (flagellated Chlorophyta) are placed in this sub-chapter because of their movement capability and ecological relationships, especially with peat.

The flagellates, known as Zoomastigophora, swim by means of 1-4 long flagella and thus require at least a film of water. Fortunately, some are able to encyst, enabling them to become dormant when that film of water is absent.

As one might suspect, *Sphagnum* can provide long periods when leaves have a thin film of water. Numbers of flagellates can reach 10^7 cells L^{-1} (Gilbert & Mitchell 2006). For the green alga *Carteria sphagnicola* (Figure 10) *Sphagnum* provides an unique habitat, with its cation exchange making its surrounding water acid. This would be particularly true of a thin film of water that is not diluted by lake or fen water.

Figure 10. *Carteria sphagnicola*, a peatland inhabitant. Photo by Yuuji Tsukii, with permission.

Chlamydomonas (Figure 11), a green alga, is a relatively common genus in peatlands. *Chlamydomonas acidophila*, as its name implies, lives at low pH and is common among *Sphagnum* plants with a pH of 2-6, where as many as 50,000 individuals may exist per cm^2 (Hingley 1993). Another *Chlamydomonas* species, known first from *Sphagnum*, has been named *C. sphagnicola*.

Figure 11. *Chlamydomonas moewusii*. Photo by Yuuji Tsukii, with permission.

One advantage that the widely known genus *Chlamydomonas* shares with many of the bryophyte-inhabiting protozoa is the ability to form a **palmelloid** stage (Figure 12) – a stage that can remain dormant during dry spells (Rajan 2002). This stage is named because of its resemblance to the green algal genus *Palmella*. In *Chlamydomonas*, to form the palmella stage, the cells lose their flagella, divide, and form a gelatinous ball in which the cells are embedded. Each cell is still capable of individual function. When favorable conditions return, individual cells are freed and continue an active life.

Figure 12. *Chlamydomonas*, a genus that can inhabit the hyaline cell of *Sphagnum*. **Upper:** vegetative cell. **Lower:** palmelloid stage. Photos by Jason Oyadomari, with permission.

Chlamydomonas reinhardtii is known to form gelatinous masses or a **palmelloid** stage (Figure 13) when confronted by the predator *Brachionus calyciflorus*, a rotifer (Lurling & Beekman 2006). The reaction to form a palmelloid stage can occur within 25 hours and apparently affords some protection against rotifer grazing. The low pH of the *Sphagnum* habitat may contribute to this ability; calcium can cause the palmelloid stage to dissociate, but phosphorus can negate the dissociation (Iwasa & Murakami

1969). Iwasa and Murakami suggest that organic acids (such as those produced by *Sphagnum*) chelate calcium and permit the formation of the palmelloid stage. Nakamura *et al.* (1976) have shown that there are other biochemical/chemical interactions that can inhibit the formation of the palmelloid stage in *Chlamydomonas eugametos*, suggesting that rotifers, and other organisms, could emit biochemicals that stimulate or interfere with palmelloid formation. Among bryophytes, cohabitation with rotifers is likely to occur frequently, so one should look for these special reactions.

Figure 13. *Chlamydomonas* close view of palmelloid stage. Photo by Jason Oyadomari, with permission.

Henebry and Cairns (1984) found the flagellated Chlorophyta *Chilomonas*, *Monas*, and *Monasiga* associated with *Sphagnum* in peatlands. Additional members of bryophyte associations are listed in Table 2.

Euglenophyta

Euglena (Figure 14) is one of those organisms that caused consternation among early classifiers because of its combination of animal and plant traits. It can engulf food, but it also has chlorophyll and a flagellum. I have stubbornly used its algal name here but am writing about it with the protozoa because of its flagella. Additional Euglenophyta are listed in Table 2.

Figure 14. *Euglena* in a poor fen collection at Perrault Fen, Houghton County, Michigan, USA. Photo by Jason Oyadomari, with permission.

Euglena mutabilis (Figure 15) can withstand pH as low as 1.8, numbering 50,000-70,000 per cm² of ground surface (Hingley 1993). Its numbers, like those of many other *Sphagnum* organisms, correlate positively with moisture content of the peat. *Euglena mutabilis*, common in the upper 2 cm of peat, lacks the flagellum that is typical of euglenoids and has only two chloroplasts. Of special interest is its ability to live inside hyaline cells of the *Sphagnum* leaves (Figure 16, Figure 17). *Sphagnum* species with hooded leaves seem to house more euglenoids than do other kinds of *Sphagnum*. The "hood" most likely helps to create a micro-basin for trapping water. Some of these tiny unicellular organisms, like *Euglena mutabilis*, enter through the *Sphagnum* leaf pores and live within the hyaline cells (these are non-living), dining on organic debris left by former residents.

Figure 17. SEM of *Sphagnum* hyaline cells, showing pores. Photo from <<http://www.botany.ubc.ca/bryophyte/LAB8.htm>>, with permission.

Despite their lack of a test, *Euglena acus* (Figure 18) and *Phacus longicaudatus* (Figure 19) can survive desiccation for more than seven years with no test to protect them (Hingley 1993).

Figure 19. *Phacus longicauda*, a not-so-common member of the bryophytic protozoan fauna. Photo by Yuuji Tsukii, with permission.

Pyrrophyta (=Dinophyta)

The name **Pyrrophyta** literally means fire plants, and these organisms are so-named because of the ability of some species to produce flashes of light through bioluminescence. Sadly, these spectacular show-offs are rarely known from bryophytes (Table 2). I have located only one Pyrrophyta species known commonly to inhabit bryophytes – *Hemidinium ochraceum* (Hingley 1993; Figure 20). But that gives me an excuse to write about these remarkable organisms, also known as **dinoflagellates**. *Hemidinium ochraceum* lives among the *Sphagnum* in hollows of peatlands where they give the *Sphagnum* a yellowish-rusty color (Hingley 1993).

Figure 20. The dinoflagellate *Hemidinium* sp. Photo by Yuuji Tsukii, with permission.

Whereas some **dinoflagellates** (so-named because of their twirling motion) attract attention by their brilliant displays, others attract it by their deadly toxins. They are the apparent cause of the water that "turned to blood" as reported in Exodus of the *Bible* – red tide organisms known today for the resulting unpleasant odors of dying fish and in some cases very strange effects on humans. Some wear

plates of armor and others do not. Their two flagella lie in grooves, one around the middle of the cell like a sash and the other extending from that line down the "back" and up the "front," resulting in their characteristic twirling motion. It is not surprising that they avoid peatlands because most of them prefer alkaline conditions (Hingley 1993).

Ciliophora (Ciliates)

These organisms use a series of fine cilia instead of flagella to achieve movement. Some of these, despite their cilia, attach themselves to *Sphagnum* leaves (Hingley 1993). The cilia can serve more than one function. Whereas the primary one is to direct food into the cell, many also use them for locomotion.

Numbers of ciliates among *Sphagnum* water range 0-4.2 x 10⁶ cells L⁻¹ (Gilbert & Mitchell 2006). Many of these organisms may simply use the bryophytes as a substrate. Such is probably the case for the stalked *Vorticella* (Figure 21, Figure 22). Nevertheless, detrital matter that accumulates and algae and bacteria that take up residence among the leaves most likely provide food for ciliates, whether confined by an attachment or free-moving.

Some ciliates occur only among *Sphagnum* (Figure 23), including *Bryometopus* (Figure 24) and *Climacostomum* (Figure 25), the latter often with **symbionts** (Figure 26) (Gilbert & Mitchell 2006). Other taxa that Mieczan (2006) found to be very constant in Polish peatlands include *Askenasia* sp., *Chlamydonella* spp., *Enchelyomorpha vermicularis* (70%), *Gastronauta* spp. (89%), *Paramecium putrinum*, and *Trochilia minuta*.

Figure 23. *Sphagnum obtusum* showing the wet capillary spaces among the leaves that support ciliate protozoan communities on these drooping branches. Photo by Michael Lüth, with permission.

The ciliates have a distinct zonation within the peatland, and different communities, fewer in number of individuals and species, occur at the depth of the non-green *Sphagnum* parts (Hingley 1993). Those with **symbiotic** algal partners require light and are thus restricted to areas near the surface where the *Sphagnum* likewise is green. However, some symbiotic ciliates are also able to ingest food and can thus also live farther down the stems.

Figure 26. *Climacostomum virens* with dense symbionts. Photos by Yuuji Tsukii, with permission.

Like many other protozoa, the ciliates can survive drought by encysting. *Paramecium aurelia* (see Figure 27- Figure 28 for genus) can survive more than seven years with no test to protect it (Hingley 1993).

Figure 27. *Paramecium*, the slipper animal, is a ciliate that is larger than most protozoa. Photo by Jason Oyadomari, with permission.

Figure 28. *Paramecium* showing two of its round contractile vacuoles that permit it to regulate its water content. Photo by Jason Oyadomari, with permission.

The *Sphagnum*-dwelling ciliate *Podophyra* sp. (Figure 29) has tentacles that are necessary in its capture of prey. These have a knob at the end that excretes substances that narcotize the prey (Samworth). The interesting part of this trapping mechanism is that the cytoplasm is sucked down these tentacle arms to the body and the prey, such as the ciliate *Colpidium* (Figure 30), remains alive during the journey! The prey organism is finally absorbed into the body of the *Podophyra*. But stranger still it is that the prey organism may be released, still alive, after the *Podophyra* has finished feeding!

Michael Plewka (Michael Plewka, pers. comm. 29 November 2016) finds the ciliate *Phacodinium metchnikoffi* (Figure 31-Figure 33) to be common among mosses. Other inhabitants include *Bryophyllum tegularum* (Figure 34-Figure 35) and *B. loxophylliforme* (Figure 36).

Symbionts

Many of the ciliates have their own **symbiotic** residents. Those ciliates living near the surface of bryophyte communities where there is ample light often incorporate photosynthetic algae inside their cells (Figure 37), benefitting from the oxygen and photosynthate, and contributing CO₂ to the algae (Hingley 1993). The algae can also transfer organic nitrogen, phosphorus, and sulfur and excrete glycerol, glucose, alanine, organic acids, and carbohydrate released as maltose (Arnold 1991; Dorling *et al.* 1997). In return, the symbiotic algae can gain inorganic forms of nitrogen, phosphorus, and sulfur and may gain vitamins, while enjoying the safety of a moist cell. Wang (2005) reported that protozoa with algae seemed to be favored by higher oxygen concentrations with concomitant higher concentrations of CO₂. This higher CO₂ undoubtedly aided the algae in their photosynthesis inside the diffusion barrier of the protozoan cell.

Figure 37. *Colpoda* with Chlorophyta symbionts. Photo by Yuuji Tsukii, with permission.

When the alga is to be used as a symbiont, it is protected within a vacuole by a double membrane. Somehow the host cell knows not to digest these, whereas those doomed as food are located in vacuoles that merge with lysosomes and are digested (Karakashian &

Rudzinska 1981). In *Hydra*, it is the maltose that apparently signals the host not to digest its symbiont (McAulay & Smith 1982 in Arnold 1991), and this may also be the means of recognition in the protozoa. Anderson (1983) suggests that the protozoan may still later digest some of the symbionts, making these photosynthetic organisms into an internal garden to be harvested as needed.

In *Frontonia*, the alga may survive with or without symbionts (Figure 38). Among the ciliate symbiotic hosts, *Cyclidium sphagnetorum* (see Figure 39) is one of the common ciliate species among peatland bryophytes (Grolière 1977). The common *Paramecium bursaria* is likely to be home for numerous cells of *Chlorella* (Figure 40), but it can also have the alga *Scenedesmus* (Figure 41) as a partner (Arnold 1991). Others include *Frontonia vernalis* (Figure 42), *Platyphora similis* (Figure 43), and *Prorodon viridis* (Figure 44). Additional species are listed in Table 2.

One possible additional advantage to having symbionts, aside from the added energy availability, is that it permits these ciliates to live where the oxygen supply is low, deriving their oxygen from their symbionts (Lawton 1998). This strategy provides them the opportunity to avoid the more oxygen-dependent larger metazoans that might otherwise have them for dinner. In the words of Lawton, it provides "enemy-free space."

Coleps hirtus (Figure 46-Figure 47) is a facultative host to the *Chlorella* symbiont (Auer *et al.* 2004), but it grows faster when it is in the light and endowed with endosymbionts (Stabell *et al.* 2002). Even when it has endosymbionts, it will ingest organic matter, including smaller protozoa and algae (Figure 48-Figure 49; Auer *et al.* 2004). The alga maintains a coordinated growth rate with the host by its rate of leakage of products to the host.

In Addition to the taxa listed here, Kreutz and Foissner (2006) have listed many additional taxa from *Sphagnum* ponds in Germany. Many of these are figured with wonderful color images, but pool species are not

distinguished from those actually on mosses in or adjoining pools.

Summary

There is a rich diversity of protozoans among the bryophytes, much of which has never been explored. **Ciliates** and **testate amoebae** (rhizopods with houses) predominate in both peatlands and forests, but some flagellates and other minor groups occur as well. Bryophytes are especially suitable habitats for these organisms that can **encyst** when dry. And both depend largely on wind for dispersal, with protozoa often dispersing with fragments of their hosts.

Aufwuchs, or **periphyton**, are those organisms that live on aquatic substrata, including bryophytes, without being parasites. **Epiphyte** is a broader term that includes terrestrial associates as well. Identification is difficult and often requires culturing. But more than 2000 organisms per cm³ make the effort worthwhile.

Rainfall can dislocate the protozoa, especially those with heavy testae, and modify their production. Not surprisingly, numbers are highly correlated with moisture.

Some taxa, known as **bryobionts**, occur only on mosses (e.g. *Cyclidium sphagnetorum*). The naked taxa are mostly **bacterivores**. In *Sphagnum* the numbers of protozoa are so high (up to 220,000 per gram) that they are important in the **microbial loop**.

In addition to bryobionts, **bryophiles** are usually found among bryophytes, **bryoxenes** live elsewhere but regularly spend part of the life cycle among bryophytes, and **occasionals** are typical elsewhere, but occasionally are found among bryophytes.

The **Zoomastigophora** (flagellates) include *Chlamydomonas*, *Euglena*, and *Phacus* among the bryophyte inhabitants. These organisms can swim around in the hooded tips of *Sphagnum* leaves and may inhabit the hyaline cells. The low pH may contribute to the formation of the **palmelloid** stage in their life cycle, protecting them from rotifer predation. Among the **Ciliophora** (ciliates), *Stentor* and *Vorticella* may attach themselves to bryophyte leaves. Other members swim about in the surface water film. Some of these have chlorophyll-bearing **symbionts** and thus must live near the surface; the symbionts leak maltose and provide oxygen while gaining CO₂.

Acknowledgments

Edward Mitchell provided me with a large number of papers and photographs and William Bourland provided me with wonderful photographs of taxa on my special needs list. Yuuji Tsukii and Jason Oyadomari permitted me to use any of their numerous images. Edward Mitchell and Paul Davison were invaluable in helping me with areas where I was often not personally familiar with the subject.

CHAPTER 2-2

PROTOZOA: CILIOPHORA AND HELIOZOA DIVERSITY

Other Ciliophora Known from Bryophytes

Figure 1. *Amphileptus pleurosigma*, a free-swimming, predatory ciliate. Photo by William Bourland, with permission.

Figure 2. *Chilodontopsis depressa*, an algivorous ciliate (Risse-Buhl & Küsel 2008). Photo by William Bourland, with permission.

Figure 3. *Cinetochilum margaritaceum*, a bryophyte-inhabiting ciliate that Mieczan (2007) found in peatland ponds of Poland with pH of 5.0. Photo by William Bourland, with permission.

Figure 4. *Cinetochilum margaritaceum* stained to show organelles. Photos by William Bourland, with permission.

Figure 5. *Didinium nasutum*, a bryophyte-dwelling ciliate that feeds on *Paramecium*. This species is capable of encysting to avoid unfavorable conditions. Photo by William Bourland, with permission.

Figure 6. *Oxytricha fallax*, a ciliate, has a complex grouping of cilia that are used for sweeping food into the gullet. It lives among bryophytes, as well as other habitats. Lower organism has been stained. Photos by William Bourland, with permission.

Figure 7. *Stentor multiformis*, a ciliate that occurs in peatlands (Mieczan 2006) and can attach to moss leaves. Photo by William Bourland, with permission.

Figure 8. *Stentor* showing green algal symbiont. Photo by Wim van Egmond, with permission.

Figure 9. *Colpoda steinii*, a constant member of *Sphagnum* communities in two Polish peatlands (Mieczan 2006). Photo by Yuuji Tsukii, with permission.

Figure 10. Two *Holophyra* species, ciliates that can inhabit *Sphagnum* in peatlands (Mieczan 2006). Photos by Yuuji Tsukii, with permission.

Figure 11. *Monodinium*, a ciliate that sometimes occurs on *Sphagnum* in peatlands (Mieczan 2006), showing ring of cilia. Photo by Yuuji Tsukii, with permission.

Figure 12. *Monodinium* dividing. Photo by Yuuji Tsukii.

Figure 13. *Paramecium bursaria*, a common species that can occur on *Sphagnum* in peatlands in Poland (Mieczan 2006). This one has algal symbionts. Photo by Yuuji Tsukii, with permission.

Figure 14. *Spathidium muscicola*, a ciliate that can live among mosses. Photo by Yuuji Tsukii, with permission.

Figure 15. *Steinia sphagnicola*. Normal cell. Photo by Yuuji Tsukii, with permission.

Figure 16. *Steinia sphagnicola* cell dividing. Photo by Yuuji Tsukii, with permission.

Michael Plewka kindly sent me the names of several **Ciliophora** that commonly occur on bryophytes. These include *Phacodinium metchnikoffi* (Figure 19-Figure 20), *Bryophyllum tegularum* and *B. loxophylliforme* (Figure 21).

Figure 21. *Bryophyllum loxophylliforme*, a common species on wet moss. *Bryophyllum tegularum* likewise is common there. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Figure 20. *Phacodinium metchnikoffi* showing ribs. Photo by Michael Plewka <www.plingfactory.de>, with permission.

Heliozoa

The heliozoans look like a sunburst with their sticky, wirelike pseudopods. About 20 species live among *Sphagnum* in pools with pH ranging 5-5.6 (Hingley 1993). The sticky pseudopods, known as **axopods**, are used to ensnare food such as algae and smaller protozoa, and to protect the organisms. They also facilitate a slow movement, since these organisms lack cilia or flagella. The beautiful and delicate moss dwellers include *Actinophrys sol* (Figure 23) and *Actinosphaerium eichhorni* (Figure 24-Figure 25).

Figure 22. *Actinophrys sol*, a moss dweller, showing radiating pseudopodia. Photo by Yuuji Tsukii., with permission

Figure 23. *Actinophrys sol* showing radiating pseudopodia. Photo by William Bourland, with permission.

Figure 24. *Actinosphaerium eichhorni*. Photo by William Bourland, with permission.

Figure 25. *Actinosphaerium eichhorni*. Photo by William Bourland, with permission.

Summary

Although they are more difficult to detect, the **Ciliophora** are quite common among bryophytes. They are best detected by culturing, and then the many species seen in this chapter become active. **Heliozoa** are not common among bryophytes, and only the few species shown here are familiar ones in a bryophyte habitat.

Acknowledgments

This chapter would not have existed without my new, but never seen, friends, William Bourland and Yuuji Tsukii. William Bourland provided me with a set of his pictures of bryophyte inhabitants. Yuuji Tsukii gave me unlimited permission to use his many, many images on the Protist Information Server website. Michael Lüth reported his observations on Protozoa on bryophytes.

CHAPTER 2-3

PROTOZOA: RHIZOPOD DIVERSITY

Figure 1. *Arcella vulgaris*, a testate amoeba (**Rhizopoda**) that is dividing. Photo by Yuuji Tsukii, with permission.

Rhizopoda (Amoebas)

The **Rhizopoda** are a phylum of protozoa with a name that literally means "root feet" (Figure 1). They include both **naked** and **testate** amoebae. **Testate amoebae** are encased in "houses" of their own making (Figure 2) by way of organic secretions (Hoogenraad & Groot 1953; Wilmschurst 1998). Imagine a tiny pile of sand grains moving across a liverwort leaf.

Despite being only one-celled, testate species construct houses made of various materials such as small sand grains cemented by their own secretions, and even diatoms (Figure 4) may be included among the sand grains. Some even manufacture silica plates that they meticulously arrange into housing. Others may include such items as mineral particles, pollen grains, and the recycled plates and remains of their microscopic food organisms. Such testate rhizopods include *Diffugia* (Figure 5-Figure 6), *Arcella vulgaris* (Figure 8-Figure 9), and *Centropyxis* (Figure 11) among the most common moss-dwellers (Bartos 1949a).

Figure 2. This testate amoeba is among the many testate amoebae that live among the bryophytes. This one dwelt on the moss *Sanionia uncinata* (Figure 3) on the Barton Peninsula of King George Island, Antarctica. Photo by Takeshi Ueno, with permission.

Although naked amoebae are sometimes numerous on submerged *Sphagnum* (Figure 13) plants, the testate amoebae seem to be particularly common among the bryophytes (Richters 1908 a, b, c, d, e; Heinis 1908, 1910, 1911, 1914, 1928; Penard 1909; Roberts 1913; van Oye 1936; Bartos 1938a, b, c, 1939, 1940, 1946a, b, 1947,

1949a, b, 1950, 1951, 1963a, b, c; Jung 1936 a, b; Jung & Spatz 1938; Hoogenraad & Groot 1940, 1948, 1951, 1952a, b; Fantham & Porter 1945; Bonnet 1961, 1974, 1978; del Gracia 1964, 1965a, b, c, 1966, 1978; Chardez 1965, 1990; Golemansky 1967; Chiba & Kato 1969; Coûteaux 1969; Decloître 1970, 1974; Corbet 1973; Chardez 1976, 1979; Coûteaux & Chardez 1981; Richardson 1981; Beyens & Chardez 1982; Tolonen *et al.* 1985; Schönborn & Peschke 1990; Charman & Warner 1992; Balik 1996; Mitchell *et al.* 2004, 2008; Mieczan 2007). In one Swedish bog, 40 species of testate amoebae were found (Mitchell *et al.* 2000). However, it is interesting that in two Polish peatlands, Mieczan (2006) found only six taxa, compared to 24 ciliate taxa.

Species Diversity

The diversity of testate amoebae among mosses is quite remarkable. Those dwelling in peatlands are so species-rich and numerous that I have devoted an entire subchapter to them. But terrestrial bryophytes have rhizopods as well.

Török (1993) examined six species of terrestrial mosses in Hungary to compare their rhizopod fauna species diversity. He found 46 testate species, six of which were new for Hungary. The dominant taxa are reviewed in Table 1. The Hungarian diversity exceeded that reported for Arctic mosses (Beyens *et al.* 1986b). Török found *Plagiopyxis labiata* on most of the mosses in the study as well as finding them on *Sphagnum*. Some differences in protozoan species composition seemed evident among

moss species. For example, *Phryganella acropodia*, a soil species, had its highest moss occurrence in *Brachythecium velutinum* (Figure 14). *Trinema penardi*, a common *Sphagnum* inhabitant, was a characteristic species to be found in *Cirriphyllum tommasinii* (Figure 15). The rhizopod genera with the most species among these six mosses were *Centropyxis* (Figure 11-Figure 12) and *Euglypha* (Figure 18). The six mosses are listed with their diversity and numbers in Table 2.

<i>Atrichum undulatum</i>	2.80	14	285

In the southeastern Alps in Italy 25 species occurred on the forest moss *Hylocomium splendens* (Figure 16) in the altitudinal range from 1000-2200 m asl (Mitchell *et al.* 2004). The most frequent taxa on *H. splendens* included *Assulina muscorum* (Figure 17), *Centropyxis aerophila* (Figure 18), *Corythion dubium* (Figure 19), *Euglypha ciliata* (Figure 20), *Euglypha laevis*, *Nebela tinctoria* (Figure 21), *Phryganella acropodia*, and *Trinema enchelys* (Figure 22), all with a frequency greater than 10 among 21 samples. Densities per gram of a single species were as high as 12,666 (*Corythion dubium*, Figure 19). It is interesting that every one of these species is also among the common peatland taxa elsewhere (Table 3); they are all cosmopolitan, a phenomenon suggested by Vincke *et al.* (2004) and discussed in a later subchapter. *Nebela collaris* (*sensu lato*) is not only common on the leaf surfaces of

Sphagnum, but can occur within the hyaline (colorless) cells as well (Gilbert *et al.* 2003).

Mieczan (2006) found that the testate species *Difflugia oblonga* (Figure 23), *Euglypha* sp. (Figure 24), and *Nebela longeniformis* comprised more than 25% of the total numbers in the two Polish peatlands he studied.

In contrast to studies on moist peatland bryophytes (e.g. Table 3), Nguyen *et al.* (2004) found only 9 rhizopod species in 30 samples of the xerophytic moss *Syntrichia*

ruralis (Figure 25). Mitchell *et al.* (2004) attributed this depauperate number to the dry conditions and restriction of samples to the photosynthetic tips of the moss.

Figure 23. *Difflugia oblonga*, a testate amoeba that was common in the Polish peatlands studied by Mieczan (2006). Photo by Yuuji Tsukii, with permission.

Figure 24. Test of *Euglypha bryophila*, a species whose name means "moss loving." Photo by Yuuji Tsukii, with permission.

Other studies on species richness generally include mosses as a group, rather than examining individual species, with rhizopod richness ranging 9-53 species (Beyens *et al.* 1986a, b; 1990; Beyens & Chardez 1994; Todorov & Golemansky 1996; Van Kerckvoorde *et al.* 2000). Additional bryophyte inhabitants from around the world are shown in Figure 26 - Figure 59. A complete list of bryophyte-inhabiting rhizopods is in Table 4.

Testate amoebae that live on bryophytes are mostly cosmopolitan taxa (see discussion of the Baas Becking hypothesis in Chapter 2-5). Even more remarkable than the Northern Hemisphere similarities seen in Table 3 is that the Antarctic displays similar communities. In the Antarctic, where mosses are the dominant flora, testacean protozoa are particularly rich in species. Vincke *et al.* (2004) found 83 taxa, representing 21 genera, among the mosses on Île de la Possession of the sub-Antarctic. Smith (1974) found them in carpets of the moss *Sanionia uncinata* (Figure 3) in the severe climate of the South Orkney Islands and near Rothera Station, Adelaide Island, both in the Antarctic.

On Île de la Possession of the sub-Antarctic, the bryophyte communities were dominated by *Euglypha laevis*, *E. rotunda* (Figure 60), *Trinema enchelys* (Figure 61), and *T. lineare* (Figure 62, Figure 63), (Vincke *et al.* 2004). These four taxa are among those listed in Table 3 as common in the Northern Hemisphere.

Figure 60. Test of *Euglypha rotunda*. Photo by Yuuji Tsukii, with permission.

Figure 61. *Trinema enchelys* test and living cell. Photo by Yuuji Tsukii, with permission.

Figure 62. *Trinema lineare* test and protoplasm. Photo by Yuuji Tsukii, with permission.

Figure 63. SEM photo of *Trinema lineare* test. Photo by Edward Mitchell, with permission.

Upon analysis, three communities of testate amoebae emerged for Île de la Possession: the *Corythion dubium* (Figure 39) **community** occurred in drier and slightly acidic terrestrial moss communities; the *Arcella arenaria* (Figure 29) and the *Diffugiella crenulata* **communities** were both in wetter, circumneutral habitats, with the former occurring in standing water and the latter community typically on submerged mosses of running water. In those habitats, the bryophyte species was important in describing the testate protozoan community. Among these dominant organisms, only *Diffugiella crenulata* is absent from the Northern Hemisphere taxa listed in Table 3. A word of caution, though: the taxa are difficult to distinguish and one name may have been applied to several taxa, or several names from different regions may actually apply to the same taxon. Morphologies can differ between regions, making the same species appear different (Bobrov *et al.* 1995). And within a region, cryptic species ("hidden" species that look the same but are reproductively isolated and genetically distinct) can exist.

Many of the known bryophyte inhabitants are never reported as such in the literature. In gathering information for this chapter, I have been able to add several taxa to the published literature I uncovered. Some, like *Euglypha bryophila* (Figure 64), are suggested by their names. Others, like *Tracheleuglypha dentata* (Figure 65), have come to me among the images of bryophyte-inhabiting protozoans sent by protozoologists. William Bourland has provided me with images of several moss inhabitants that I

have not found in the literature: *Cyphoderia trochus* (Figure 66); *Quadrullella symmetrica* (Figure 67). I also found many among the Perrault Fen, Michigan, USA images of Jason Oyadomari. Many more taxa are probably lurking among the **non-Sphagnum** taxa.

Summary

The rhizopods (amoebae) can be naked or testate (living in a self-made house), with testae made of sand, diatoms, pollen, or mineral particles put together with secretions. Testate species are cosmopolitan and are particularly common on bryophytes, especially in peatlands. These common species even extend to the Antarctic. *Euglypha laevis*, *E. rotunda*, *Trinema lineare*, and *T. enchelys* are among the dominant taxa in both hemispheres. More taxa may be in common but are currently understood as multiple species. Many others undoubtedly remain to be discovered, especially among the **non-Sphagnum bryophytes**.

Acknowledgments

The protozoologists have been especially helpful in preparing this subchapter. Edward Mitchell and Paul Davison helped me find appropriate people to contact to get good images, and Edward Mitchell contributed several of the excellent SEM images used here. William Bourland provided a CD that filled some of my hard-to-find image needs. Images from Jason Oyadomari helped me to expand the list of known bryophyte inhabitants. The images by Yuuji Tsukii, provided through the Protist Information Server website, were invaluable.

CHAPTER 2-4

PROTOZOA: RHIZOPOD ECOLOGY

Figure 1. Test of *Centropyxis ecornis* with desmids that are common cohabitants in peatlands. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Geographic Distribution

Testate amoeba communities not only are diverse in themselves, but they typically occur with a diversity of algae and other micro-organisms (Figure 1). Moss-dwelling testate amoebae have been reported from the Antarctic (e.g. Richters 1904, 1908a, b; Sudzuki 1964; Smith 1973a, b, c, 1974a, b, 1986; Beyens *et al.* 1988; Balik 1994), to The Czech Republic (Balik 2001), to the Canadian Arctic (Beyens *et al.* 1986a, b), to name only a few. Beyens and Chardez (1994) thought that the amoebae formed specific assemblages related to the moss habitats. Working in the Mt. Kurikoma district of Japan, Chiba and Kato (1969) likewise suggested that the testacean community structure is related to the bryophyte habitat.

Bartos (1949) reported on the moss-dwelling Rhizopoda of Switzerland. Most of his samples were from aerial mosses, but the Rhizopoda belonged to damp moss associations. The largest numbers of individuals belonged to the testate amoeba genus *Centropyxis*, including *C. aerophila* (Figure 3), *C. eurystoma*, *C. kahli*, and *C. ecornis* (Figure 4), in all the mosses. Smith (1992) reported *Arcella arenaria* (Figure 2), *Centropyxis aerophila* (Figure 3), *Corythion dubium* (Figure 5), *Diffugia lucida*, *Diplochlamys timida*, *Heleopera*

petricola (Figure 6), and *Trigonopyxis arcula* (Figure 7) from Antarctica, where numbers were generally low compared to Northern Hemisphere studies. Only *Bryum* exhibited larger populations, those of *Arcella arenaria*. *Centropyxis aerophila* seems to prefer more calcareous situations (Coûteaux 1969), although its distribution in South Georgia (Antarctica) occurs at pH 4.5-5.6 (Smith & Headland 1983). This species is variable, whether due to geography or ecology (Chardez 1979).

Figure 6. *Heleopera petricola*. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Figure 7. *Trigonopyxis arcula*. Photo by Yuuji Tsukii, Protist Information Server, with permission.

As for most of the invertebrates, the highest numbers seem to occur in peatlands. Gilbert *et al.* (2003) reported $29,582 \pm 9650$ active individuals per liter of *Nebela vas* and 2263 ± 1620 for the encysted ones at Pradeaux peatland (Puy de Dôme, France), with the greatest abundance at the end of June (almost 40,000), dropping to the lowest number in July (less than 15,000).

Communities

Although most of the information regarding rhizopod communities is for peatlands (Subchapter 2-5), a few studies have discussed communities in other types of bryophytes. Beyens *et al.* (1990) compared communities from the coastal lowlands on Devon Island, NWT, Canadian Arctic. These encompassed 57 taxa on mosses, soils, and lichens. The dry, acidic moss habitats were characterized by *Assulina muscorum* – *Corythion dubium* assemblages. In wet, neutral pH habitats, *Paraquadrula irregularis* was dominant. Sedge moss meadows had a soil fauna association of *Plagiopyxis callida* – *Plagiopyxis declivis*. *Centropyxis minuta* was mostly on coarsely textured soils in this study, but is known from mosses elsewhere.

Mazei and Belykova (2011) found 29 rhizopod species/forms associated with mosses at the water edge in seven streams of the Sura River basin (Middle Volga region, Russia). The dominant species are *Centropyxis aerophila*, *Centropyxis cassis*, *Corythion dubium*,

Euglypha ciliata glabra, *Tracheleuglypha dentata*, *Trinema complanatum*, *Trinema enchelys*, and *Trinema lineare*. The species richness in these communities varies from 2 to 11 per sample, with an abundance of 100 to 4000 individuals per gram dry moss. Mazei and Belykova suggested that the character of the community could be influenced by forest cover, water hardness, "biogenic elements," stream size, and environmental contamination.

Davis (1981) reported that the testate rhizopods were the dominant form of non-photosynthetic life among mosses in the maritime Antarctic. Smith (1986) reported ten species on the moss *Sanionia uncinata*: *Assulina muscorum*, *Corythium dubium*, *Diffugia lucida*, *Nebela lageniformis*, *Nebela walesi*, *Phryganella acropodia*, *Trigomopyxis arcua*, and a species of *Diffugia*, possibly *D. mica*. The most abundant of these were *Diffugia lucida* and *Assulina muscorum*. The species richness was low, similar to that found in other southern latitudes.

Moisture Relationships

Moisture plays an important role in survivorship. Like many other bryophyte inhabitants, the testate amoebae among the bryophytes survive the wet-dry changes so common among the bryophytes (Chardez 1990). When conditions are dry, many rhizopod amoebae can encyst (Sacchi 1888 a, b; Heal 1962), thus escaping the need for water during long periods of drought (Hingley 1993). Some have survived 5-8 years in dry moss (Hingley 1993).

Chlamydomyxa montana is one such encysting protozoan. In its amoeboid state it feeds on diatoms, but it is photosynthetic in bright light in its encysted state (Pearlmutter & Timpano 1984). Cysts of this unusual amoeba occur on the branches of *Sphagnum* (Lankester 1896). These cause the moss to be ruddy brown, with a glistening surface due to olive-brown disk-like or ovoid cysts about 1-2 mm in diameter. When these are awakened, a network of threads appears, signifying the amoeboid stage.

In Germany, the death rate of testaceans in the river exceeded that in mats of the terrestrial *Plagiomnium cuspidatum* (Figure 8) (3%/day) (Schönborn 1977). This is perhaps due to the greater resistance to desiccation among the terrestrial taxa and represents a time of optimal conditions. With *Euglypha ciliata* (Figure 9, Figure 10) (429,000 individuals/m²; 15.5 mg/m²) and *Assulina muscorum* (Figure 11) (406,000 individuals/m²; 2.9 mg/m²) dominating, the production rate on the mosses is 40,600 individuals m⁻² day⁻¹ and a biomass of 0.3 mg m⁻² day⁻¹. In drier times, generation time increases as amoebae go dormant, causing fewer generations to be produced and reducing the productivity. Soil organisms spend only half the time for one generation compared to those living on the bryophytes. Not only is the moss subject to more frequent drying, but the number of *Aufwuchs* on the mosses is lower, thus providing less food.

Rhizopod communities are determined by the moisture and temperature conditions available to them (Chiba & Kato 1969). This affects not only the clumps of moss they inhabit, but also their vertical distribution within the clump. For example, in the Canadian Arctic, *Trinema lineare* (Figure 12) occurs deep in the moss mat where conditions are more humid (Beyens *et al.* 1986b).

Rhizopods are able to inhabit ponds, lakes, marshes, and swamps where there is likewise sufficient moisture to support moss growth (Cash *et al.* 1905). They are constant members of the community near ponds among the mosses *Drepanocladus* spp. (*sensu lato*), *Philonotis fontana*, and *Aulacomnium palustre*, where they are typically associated with diatoms. Rhizopods also subsist among mosses on tree trunks and roots in shaded forests.

Figure 11. *Assulina muscorum*, a common bryophyte inhabitant. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Figure 12. *Trinema lineare*. Photo by Yuuji Tsukii, PIS, with permission.

Bartos (1949) found that in those mosses that were often dry, *Centropyxis labiata* occurred, with *C. platystoma* and *C. constricta* (Figure 13) in somewhat damper ones. The very dry mosses housed *Trigonopyxis arcula* (Figure 14) and *Bullinularia indica* (Figure 15). Several species occurred in all moss probes: *Trinema enchelys* (Figure 16), *Nebela collaris* (Figure 17), *Euglypha ciliata* (Figure 10), and *Assulina muscorum* (Figure 11).

Case Building

The large, shell-forming *Arcella* is a common genus among bryophytes, particularly *Sphagnum* (Hoogenraad & De Groot 1979; Chardez & Beyens 1987). *Arcella* builds a case that is completely organic (Meisterfeld & Mitchell 2008; Figure 18) and resembles a tiny doughnut in bottom view (Figure 19). *Arcella crenulata* and *A. mitrata* (Figure 20) tend to occur together on *Sphagnum* that is constantly wet, low in nutrients, and in a pH range of 4-6. Others such as *A. arenaria* (Figure 19), *A. catinus* (Figure 21), *A. artocrea* (Figure 22, Figure 23), and *A. microstoma* "prefer" *Sphagnum*, but also occur elsewhere.

Food

The Rhizopoda have long been considered to be bacterivores, but it appears that this conclusion may be somewhat short-sighted. Although most are heterotrophic, a few are mixotrophic, housing photosynthetic algae as symbionts (Gilbert *et al.* 2000). The ability of some taxa to ingest a wide size range (0.2-1000 μm) of organisms and particulate organic matter (POM) offers a potential competitive advantage.

Figure 21. Test of *Arcella catinus*. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Wilmshurst (1998) found protozoa so common in New Zealand *Sphagnum* peatlands that she estimated that more than 50,000 protozoans could "eke out a living" in a gram of fresh moss. The amoebae survive by consuming particulate organic matter, algae that grow epiphytically on the mosses, bacteria, fungi, plant cells, and even smaller amoebae (Richardson 1981; Gilbert *et al.* 2000). Although bacterivorous taxa are the most frequent, some taxa eat algae and other protozoa almost as large as they are.

Deriu *et al.* (1995) challenged earlier studies that suggested that *Sphagnum* served as a reservoir of mycobacteria as a food source, citing the medicinal properties of *Sphagnum* as evidence of the near absence of mycobacteria. Nevertheless, it is likely that bacteria serve

as the primary food source. Mieczan (2006) found that among the *Sphagnum* in Poleski National Park in Poland the bacterivorous protozoa had the greatest numbers, whereas those that ate algae were least common.

Figure 22. Test of *Arcella artocrea*. Photo by Edward Mitchell, with permission.

Figure 23. Test of *Arcella artocrea*. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Symbionts

Despite their habitation within a case or test, some of the Testacea also have **symbionts**. Among those inhabiting bryophytes, symbiotic taxa include *Amphitrema flavum* (Figure 24), *Diffflugia oblonga* (Figure 25), *Hyalosphenia papilio* (Figure 26), and *Heleopera sphagni* (Figure 27) (Burkholder 1996; Charrière *et al.* 2006; Meisterfeld & Mitchell 2008). Their dependency on light forces them to live in the upper few cm where the algae live both independently and within the rhizopod, and are able to photosynthesize. A more detailed discussion of algal symbionts is in the subchapter on Protozoa Diversity (Chapter 2-1).

Bryophyte Chemistry

Moss chemistry appears to play an important role in at least some cases in determining species richness. Testate amoebae occupying *Hylocomium splendens* (Figure 28) in the Italian Alps were distributed largely in accordance with differences in C, P, Ca, Mg, Al, Fe, and Na of the moss tissues (Mitchell *et al.* 2004). The researchers suggested that the chemistry affected the prey organisms, thus affecting their consumers, the amoebae. Surprisingly, there was no relationship to the important nutrients N and K. Both Mitchell *et al.* (2004) and Bonnet (1973b) concluded that distribution of testate amoebae among wefts of *H. splendens* was independent of soil type.

Figure 26. *Hyalosphenia papilio* densely impregnated with symbiotic algae. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Figure 27. *Heleopera sphagni* with what appear to be algal symbionts. Photo by Yuuji Tsukii, Protist Information Server, with permission.

In addition to the taxa mentioned above, Mieczan (2006) also found *Codonella cratera* (Figure 29) in two Polish peatlands. There is surely a wealth of species waiting to be discovered in the little-explored bryophyte microcosm. Corbet (1973) managed a 38-page article on the testate species of *Sphagnum* at a single location, Malham Tarn, Yorkshire. Other bryophytes have received much less attention.

Figure 29. Test of *Codonella cratera*. Photo by Yuuji Tsukii, Protist Information Server.

Pollution – Heavy Metals

Rhizopods, as well as bryophytes, can serve as indicators of pollution damage to a community. In a study of the moss *Barbula indica* in Viet Nam, both richness and abundance of rhizopods were reduced by lead (Nguyen-Viet *et al.* 2007). Shannon diversity was negatively correlated with cadmium. Although several species of rhizopods were negatively correlated with lead, cadmium, zinc, and nickel, lead was the only pollutant that caused a significant change at the community level. Other effects will be discussed in the sub-chapter on Peatland Rhizopods.

Summary

Centropyxis and *Arcella* are among the most common of the testate amoebae among epiphytic bryophytes. Communities vary seasonally as moisture changes. Moisture is also the greatest determinant of the choice of bryophyte and vertical location within it, but for some pH also plays a role. Construction of cases may help them to survive brief dry periods, but most encyst until favorable moisture returns. Terrestrial taxa are more resistant to desiccation than are aquatic ones. Generation time is longer on mosses because of the time spent encysted.

Many of the rhizopods are bacterivores, but they also consume fungi, algae, plant cells, and smaller amoebae. Chemistry may affect the available food organisms, but N & K do not seem important. Several of the rhizopods harbor *Chlorella* as symbionts. Their need for light causes these taxa to live in the upper few cm of the bryophyte layer.

Rhizopods often have a negative correlation with pollutants, especially some of the heavy metals.

Acknowledgments

Yuuji Tsukii was most helpful in giving me permission to use his images from the Protist Information Server. Edward Mitchell helped me to find literature and provided me with a number of images I couldn't find elsewhere.

CHAPTER 2-5

PROTOZOA: PEATLAND RHIZOPODS

Figure 1. A peatland with *Sphagnum magellanicum* that serves as habitat for protozoa. Photo by Michael Lüth, with permission.

Peatlands Taxa: *Sphagnum*

Protozoa, and especially Rhizopoda, are apparently most abundant in peatlands (Figure 1) and were among the earliest of the moss fauna to be examined (Jung 1936). But few other bryophyte protozoans have been studied in detail. Among the abundant **sphagnicolous** taxa (growing in *Sphagnum* moss) are *Nebela* (Figure 2), *Hyalosphenia* (Figure 3), *Diffugia pyriformis* (Figure 4), and *D. globularis* (Bovee 1979; Gerson 1982). Table 1 summarizes the species I have found in the literature.

Figure 2. *Nebela collaris*, a sphagnicole. Photo by Yuuji Tsukii, with permission.

Figure 3. *Hyalosphenia papilio*, a sphagnicole. Photo by Yuuji Tsukii, identified by Matthieu Mulot, with permission.

Mitchell *et al.* (2000b) compared testate (with a house) amoebae in peatlands of Switzerland, the Netherlands, Great Britain, Sweden, and Finland. They found that the plant species differed more than the species of amoebae. The high number of rhizopod species among *Sphagnum*, compared to that of other mosses or tracheophytes, supported the usefulness of rhizopods as indicators of both past and present conditions. Furthermore, the mosses were

less affected by the chemistry of the ground water than were such taxa as *Carex* and *Eriophorum*. But when Booth and Zygmunt (2005) compared the testate amoeba communities of the Great Lakes in North America with those of the Rocky Mountains of North America, the communities differed, perhaps due to differences in climate and the trophic state of the peatlands. Even so, these two regions had many species in common, and these species occupied similar moisture positions in both regions. In the Rocky Mountains, USA, distribution of these testate amoebae in *Sphagnum*-dominated peatlands is dictated primarily by surface moisture (Zygmunt *et al.* 2003). Communities in the western Great Lakes region are similarly distributed, with 50% of the species also occurring in the Rocky Mountain peatlands, and similar communities exist for Yellowstone National Park.

Figure 4. *Diffflugia pyriformis*, a sphagnicole. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Testate amoebae abound in peatlands all over the world. Because of their abundance there, testate amoebae have been widely studied in peatlands all over the world (*e.g.* Leidy 1879; Harnish 1924, 1925, 1927, 1948, 1950, 1951; Hoogenraad 1934, 1935; Jackzo 1941; van Oye 1941, 1951; Conra, 1943; Heinis 1945; Hoogenraad & de Groot 1946; Paulson 1953; Rose 1953; Hoppman 1954; Chacharonis 1956; Varga 1956; Bonnet 1958; Thomas 1959; Heal 1961, 1964; Schönborn 1962, 1963, 1965; Martin 1963; Buttler *et al.* 1966 a, b; Tolonen 1966, 1994; Coûteau 1969; Bovee 1979; Seis 1971; Corbet, 1973; Laminger 1975; Vucetich 1975; Grospietsch 1976; Ruitenburg & Davids 1977; Meisterfeld 1978, 1979a, b; Beyens & Chardez 1984; Tolonen *et al.* 1985, 1992, 1994; Warner 1987; Hendon & Charman 1997; Gilbert *et al.* 1998a, b, 2003; Woodland *et al.* 1998; Bobrov *et al.* 1999; Strüder-Kypke & Schönborn 1999; Mitchell *et al.* 1999, 2000a, b; Charman *et al.* 2000; Booth 2002; Langdon *et al.* 2003; Laggoun-Défarge *et al.* 2008).

Bobrov *et al.* (1999) studied their ecology in peatlands of Russia. Bousquet (1950) studied them in southwestern France, Mieczan (2006) in Poland, and Wilmschurst (1998) in New Zealand. Robson *et al.* (2001) reported on *Sphagnum* bog microfauna in Tierra del Fuego, South America, demonstrating several of the same familiar genera as those in Switzerland (Bartos 1949a). Among those Northern Hemisphere taxa also identified in Tierra del Fuego were *Assulina* (Figure 5), *Corythion* (Figure 6), *Euglypha* (Figure 7), and *Heleopera* (Figure 8). Just as peatland plants are more cosmopolitan than other plants, these rhizopod assemblages seem to be more affected by

ecology than by geography. This is reflected in the small-scale vertical gradients seen among the amoebae, rotifers, and other invertebrates. As noted above, it appears that the number of species of these rhizopods is generally much greater among *Sphagnum* (Figure 1) than among other mosses or tracheophytes (Mitchell *et al.* 2000b). Nevertheless, Tolonen *et al.* (1992) found little difference in rhizopod taxa between *Sphagnum* communities and those of bryalean mosses in Finnish mires. Unfortunately, few studies have compared fauna on these two groups of bryophytes at the same location.

The nature of peatlands may account for their prominent testate amoeba fauna (Booth & Zygmunt 2005). *Sphagnum* itself is particularly rich in species (Hingley 1993; Mazei *et al.* 2007). The amoebae are able to live in the thin film of water in the concavity of *Sphagnum* leaves (Figure 9; Corbet 1973). Mazei *et al.* (2007) found 59 species of testate amoebae among the *Sphagnum* plants of a bog in Volga Highland in Russia. Among these, 24 were common and the minimal richness was three species in a sample. Interestingly, the highest densities of organisms occurred in the driest bog habitats, but predictably, the diversity was lowest (3 species), with *Arcella arenaria* (Figure 10) the most common. At medium levels of humidity, the number of species was greater (13-16), with *Nebela tenella* (Figure 11) and *Hyalosphenia elegans* (Figure 12) being the most common. Low oxygen concentrations reduced densities by 50-65%. When oxygen was not limiting, however, both abundance and species richness increased with depth. At high humidity, the dominant taxa were *Hyalosphenia papilio* (Figure 13) and *Helopera sphagni* (Figure 14). But not all of these testae were occupied by live amoebae. The number of living individuals ranged 35-75% of the testae found.

Lamentowicz and Mitchell (2005) found 52 taxa of testate amoebae in *Sphagnum* peatlands of northwestern Poland. In a later study, in Poland's largest peatland

complex, Lamentowicz *et al.* (2007) found 32 taxa of testate amoebae. In most of the ten sites in this complex, species composition was dominated by *Hyalosphenia papilio* (Figure 13), *Cyclopyxis arcelloides* (see Figure 15), and *Hyalosphenia elegans* (Figure 12); *Amphitrema flavum* (Figure 16, Figure 17) was among the most numerous.

Lamentowicz and Mitchell (2005) identified three groups of testate taxa, based on depth to water table (DWT) and pH: **high DWT & low pH**, **low DWT & low pH**, and **high pH & mid-range DWT**. Species tolerance increases with dryness, with a pattern that reflects that of *Sphagnum*. That is, changes in the water table depth have more effect on those species in wet habitats than on those in drier microhabitats. This appears to indicate that those in dry microhabitats are specialists for drought.

Figure 15. *Cyclopyxis*, a testate rhizopod. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Corbet (1973) found several species that are apparently confined to the *Sphagnum* habitat: *Amphitrema flavum* (Figure 16-Figure 17), *A. wrightianum* (Figure 18-Figure 19), *A. stenostoma* (Figure 20), *Hyalosphenia elegans* (Figure 12), and *H. papilio* (Figure 13). *Cryptodiffugia ovalis* (Figure 21) and *Amphitrema flavum* (Figure 16) can live within the hyaline cells of *Sphagnum* leaves, entering through the pore and experiencing constant moisture.

Those species that characterize *Sphagnum* hummocks (Figure 22) in the western Carpathians [*Nebela militaris* (Figure 23), *N. tincta* (Figure 24), *Assulina muscorum* (Figure 25), *Heleopera petricola* (Figure 26)] seem intolerant of the mineral-rich fens (Opravilová & Hájek 2006). Only *Corythion dubium* (Figure 27) and *Nebela bohémica* occupy both. The Euglyphidae were dominant in all these habitats and were nearly the exclusive testate inhabitants of the moderately rich fens. Hyalospheniidae, on the other hand, characterized the extremely acid habitats, particularly in *Sphagnum* hummocks. The overall vegetation was the best predictor of the testate protozoan composition, and the composition of the bryophyte assemblage was the second most important predictor.

Mazei and Tsyganov (2007/08) reported on a number of taxa in the *Sphagnum* peatlands of Russia. In a single bog, they found 63 taxa comprising 21 genera. They found two different communities, one that lived in the *Sphagnum* "quagmire" and one that lived in the bottom sediments of the drainage. The detritivores from the bottom sediments included *Arcella gibbosa*, *A. vulgaris*, *A. hemisphaerica*, *A. discoides*, *A. intermedia*, *A. mitrata*, *Centropyxis aculeata sphagnicola*, *Cyclopyxis kahli*, *Diffflugia glans*, *Lesquereusia spiralis*, *Netzelia tuberculata*, and *Phryganella hemisphaerica*. Those species typical of *Sphagnum* were *Archerella flavum*, *Euglypha cristata*, *Diffflugia juzephiniensis*, *Cryptodiffflugia compressa*, *Nebela militaris*, and *Sphenoderia fissirostris*. Those inhabiting both the *Sphagnum* mats and the quagmire included *Assulina seminulum*, *A. muscorum*, *Bullinularia indica*, *Centropyxis aculeata*, *Diffflugia globulosa*, *D. parva*, *Euglypha ciliata*, *Hyalosphenia elegans*, *Nebela tenella*, and *N. tinctoria*. Other species are not so specific and occur in both of the major bog communities: *Arcella arenaria*, *Euglypha laevis*, and *Trigonopyxis arcuata*.

But even within the *Sphagnum* quagmire, Mazei and Tsyganov (2007/08) found three types of testate amoebae communities. The **xerophilous** (dry-loving) community could be found in hummocks made of *Polytrichum strictum*, *Sphagnum papillosum*, and *S. angustifolium*. These dry hummocks house a community characterized by *Assulina muscorum*, *A. seminulum*, and *Cryptodiffflugia compressa*. The lawns of *Sphagnum palustre* and *S.*

magellanicum make a wet community characterized by *Heleopera sphagni*, *Hyalosphenia papilio*, *H. elegans*, and *Nebela tenella*. Submerged *Sphagnum riparium* is characterized by an association of *Cyclopyxis eurystoma*, *Heleopera sphagni*, *Hyalosphenia papilio*, and *Phryganella hemisphaerica*. Available moisture, determined by depth from the water table, separated the communities. The greatest homogeneity occurs in the moist areas in the middle of the quagmire, whereas dry habitats have the greatest diversity. On the other hand, a greater proportion of amoebae were alive in the moist areas (36-45%) compared to 22-27% of those in dry habitats.

Medium and Rich Fens

Bryophytes of rich fens (Figure 28) differ greatly from those of *Sphagnum* bogs and poor fens, and so do the protozoa. To utilize fully the testate protozoa to reconstruct peatland history, as discussed later in this chapter, it is important to understand these faunal differences. Opravilová and Hájek (2006) studied the spring fens of the Western Carpathians in the Czech Republic and Slovakia to fill in this rather large gap in our knowledge. They found that two species [*Paraquadrula irregularis* (Figure 29, Figure 30) and *Centropyxis discoides* (see Figure 31)] were essentially restricted to fens, while seven rhizopod species characterized the bryophytes there. In moderately rich *Sphagnum* fens, *Arcella discoides* (Figure 32) was characteristic. In poor fens, testate protozoan species of bryophyte lawns were closely tied to moisture and overlapped widely with those of poor fen sediments and moderately rich fens: *Nebela collaris* (Figure 33), *Phryganella acropodia*, *Sphenoderia fissirostris*.

The protozoan species of *Sphagnum* fens in the Czech Republic and Slovakia are very similar to those known elsewhere, with *Amphitrema flavum* (Figure 34), *A. wrightianum* (Figure 34), and *Hyalosphenia papilio* (Figure 35), being optimal in wet microhabitats, but also tolerating higher mineral concentrations (Meisterfeld 1979b; Charman & Warner 1992; Tolonen *et al.* 1992; Booth 2001; Schnitchen *et al.* 2003; Booth & Zygmunt

2005; Lamentowicz & Mitchell 2005; Opravilová & Hájek 2006). In the drier poor fens, the dominant species are *Assulina muscorum* (Figure 25), *A. seminulum* (Figure 36), *Arcella catinus* (Figure 37), *Nebela militaris* (Figure 23), *N. bohémica*, *Trigonopyxis arcula* (Figure 38), and *Corythion dubium* (Figure 39). *Corythion dubium* also occurs in moderately rich fens (Beyens *et al.* 1986; Tolonen *et al.* 1994; Bobrov *et al.* 1999; Mitchell *et al.* 2000b; Opravilová & Zahradková 2003; Vincke *et al.* 2004).

Figure 38. *Trigonopyxis arcuata*. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Figure 39. Test of *Corythion dubium*. Photo by Yuuji Tsukii, Protist Information Server, with permission.

Among the "brown mosses" (Figure 40, Figure 41,) of calcareous fens, *Centropyxis cassis*, *Cyclopyxis kahli*, *Cyphoderia ampulla* (Figure 42), *Diffugia glans*, *Quadrullella symmetrica* (Figure 43), and *Trinema enchelys* (Figure 44) often predominate (Mattheeussen *et al.* 2005; Opravilová & Hájek 2006). There is indeed a gradient of species from poor to rich fens, with moisture being an important variable in the poor fens and bogs (Opravilová & Hájek 2006; Hájek *et al.* 2011). Interestingly, the sediments of poor acidic fens support a species composition similar to that of bryophyte tufts of mineral rich fens (Opravilová & Hájek 2006).

Successional Stages

Differences occur not only between peatlands, but also in different stages of the same peatland, an important factor in permitting us to reconstruct the past history of peatlands. Mazei and Bubnova (2007) demonstrated 42 species in the initial stage of a transitional bog. Early stages were characterized by widespread species such as *Assulina muscorum*, *Arcella arenaria*, *Phryganella hemisphaerica*, and *Euglypha laevis*, whereas the sphagnobionts such as *Nebela*, *Hyalosphenia*, and *Heleopera* were absent. Vertical differences had not developed because the species that characterize the different depths had not yet become established.

Kishaba and Mitchell (2005) carried out a 40-year study on the *Sphagnum*-inhabiting rhizopods to determine successional trends in the Swiss Jura Mountains. They took their first samples in 1961 following peat cutting and lateral drainage that resulted in an increase in tree cover, especially at the edges. By the second sampling date in 2001, three species had increased significantly in mean relative abundance: *Nebela tinctoria* s. l. (+97%), *Bullinularia indica* (+810%), and *Cyclopyxis eurytoma* (+100%; absent in 1961), while two species decreased significantly: *Assulina muscorum* (-63%) and *Euglypha compressa* (-93%). Furthermore, testate amoebae communities differed among hummocks, lawns, and hollows. Nevertheless, there were no significant changes in the overall community structure between the two sampling dates.

Recent, moist stages of succession in the Jura Mountains of Switzerland were dominated by *Hyalosphenia papilio*, with *Archerella flavum* indicating wet, acidic conditions at one site (Laggoun-Défarge *et al.* 2008). Drier acid conditions supported a greater abundance of *Nebela tinctoria* and *Assulina muscorum*. *Corythion dubium* also indicated dry, acid conditions.

Habitat Needs

Mieczan (2007) examined the habitat preferences of eleven testate amoebae in Eastern Poland peatlands. He found that low pH (4.5) favored the amoebae (see also Warner & Chmielewski 1992; Tolonen *et al.* 1994; Charman & Warner 1997; Mitchell *et al.* 1999; Bobrov *et al.* 2002; Booth 2002; Lamentowicz & Mitchell 2005). These acidophilic taxa were dominated by ubiquitous and common taxa, with *Arcella vulgaris*, *Assulina muscorum*, *Euglypha* sp., and *Hyalosphenia* sp. having a distinct preference for low pH. The distribution pattern seemed to be controlled by moisture (no surprise there), whereas the total numbers and biomass had a positive correlation with pH and total organic carbon content of the water. Heal (1964) found that pH was a major factor accounting for differences between bog and fen communities in Great Britain. In addition to moisture and pH, the trophic status and concentration of mineral nutrients, including calcium, can play a role in determining numbers (Tolonen *et al.* 1992).

In the Western Carpathians along the border between the Czech Republic and Slovakia, Hájková *et al.* (2011) attempted to ascertain the factors that determined which micro-organisms comprised communities at two sites within mineral-rich *Sphagnum*-fens and four within mineral-poor *Sphagnum*-fens. They found that community composition correlated with water pH, conductivity, calcium concentration, and *Sphagnum* dominance. The types of mosses often played a major role, with a significant positive correlation between testate amoebae and *Sphagnum* (*S. fallax*, *S. flexuosum*, *S. palustre*, *S. papillosum*). On the other hand, there was a significant negative correlation with "crawling dense tufts" of bryophytes (*Cratoneuron filicinum*, *Palustriella commutata*, *P. decipiens*). There was no correlation with crawling loose tufts (*Brachythecium rivulare*, *Calliergonella cuspidata*, *Plagiomnium ellipticum*, *P. elatum*) or erect species (*Bryum pseudotriquetrum*, *Fissidens adianthoides*, *Philonotis caespitosa*). These community distinctions suggest that growth form was an important factor. Growth form often determines water-holding ability, a strong factor in distribution of testate amoebae.

Food

Although many of the protozoa associated with bryophytes are detritus/bacterial feeders, some common species prefer a different diet. In one *Sphagnum* peatland 17.4% of *Nebela collaris sensu lato* most frequently preyed upon micro-algae (45%, with diatoms comprising 33% of total prey), spores and fungal mycelia (36%), and large ciliates, rotifers, and small testate amoebae in smaller numbers (Gilbert *et al.* 2003). However, 71% of the food content could not be identified because it was partially decomposed. It appears that when the mosses are

sufficiently wet, most of the food organisms are immobile, senescent, or dead. However, as the water film on the moss becomes thin, it constrains the ciliates and micro-Metazoa, causing them to be a more easily consumed part of the diet.

Vertical Distribution

Peatlands have both horizontal and vertical differences in moisture, light availability, nutrient availability, and pH (Figure 45). The testate rhizopods are distributed both vertically and horizontally with respect to these differences (Meisterfeld 1977).

Figure 45. *Sphagnum teres*, demonstrating the zonation from light to dark within the peat. Photo by Michael Lüth, with permission.

Perhaps because of the multiple factors involved in vertical and horizontal distribution, distinct patterns are difficult to discern. Mazei and Tsyganov (2007/8) considered the aggregations of species to blend into each other in patches of varying sizes. For *Assulina muscorum* and *A. seminulum*, patch size seemed to correlate with shell size. As sample size increases, heterogeneity increases. Communities can be distinct on as small as a 1-cm patch, but more typically the minimum size does not exceed several cm. In their study in the Middle Volga region of Russia, Mazei and Tsyganov found that associated with the upper parts of *Sphagnum* the typical species were *Assulina flavum*, *A. muscorum*, *A. seminulum*, *Heleopera sphagni*, and *Hyalosphenia papilio*. Among these, *Assulina flavum*, *Heleopera sphagni*, and *Hyalosphenia papilio* were mixotrophs, requiring light for their algal symbionts (see sub-chapter 2-4), whereas *Hyalosphenia elegans* lacked symbionts and lived in a deeper community. The upper 0-3 cm layer typically had low rhizopod species richness but the highest abundance in the peatlands. And among those tests the proportion of living organisms was highest (75%). Species of *Amphitrema* likewise occur in the upper layer because of the need for light by their symbionts (Gilbert & Mitchell 2006).

When conditions are somewhat drier, the vertical structure of the communities is more pronounced (Mazei & Tsyganov 2007/08). Low moisture typically resulted in empty tests, especially in *Assulina* species. Survival of the rhizopod species is facilitated by the **r-strategies** of reproduction in which these small organisms are able to increase rapidly in response to the return of favorable conditions.

One additional factor that may play a role in distribution for some species is available nitrogen (Mitchell & Gilbert 2004). In cutover peatlands fertilized with N for three years, richness of the peatland was high (22 taxa of testate amoebae), but diversity of individual samples was low (6.6), attesting to the diversity of the habitat. Species richness increased with depth, but there was little response to differences in N levels in the tested range of additions of 0, 1, 3, or 10g N m⁻² yr⁻¹ for three years. Only *Bullinularia indica* was significantly more abundant in N-fertilized plots. Although the vertical distributions differed among species, there seemed to be no relationship to either shell type or metabolism type. In the top segment (0–1 cm), *Assulina muscorum* was most abundant. At 3–5 cm *Heleopera rosea*, *Nebela militaris*, and *Phryganella acropodia* were most abundant.

It is not surprising that the taxa with zoochlorellae occur in the green portions of *Sphagnum*. In Obersee near Lunz, Austria, the dominant taxa hosting zoochlorellae are *Amphitrema flavum*, *Heleopera sphagni*, *Hyalosphenia papilio* (Laminger 1975). *Centropyxis aculeata* likewise lives there, but without zoochlorellae. Activity among the rhizopods extended down to 18 cm, with some of the less mobile testate species extending to a depth of 45 cm. Some of the species that lived down to depths of 12 cm were species that also inhabited forest mosses (*Euglypha laevis*, *Trinema enchelys*, and *T. lineare*). At 18 cm, several sediment species of *Diffugia* occurred (*D. amphora*, *D. corona*, *D. acuminata*, *D. lebes*). Furthermore, the populations of *Centropyxis aculeata* exhibited characteristics of sediment-inhabiting taxa, *i.e.* tests covered with mineral particles and no spines.

Horizontal Differences

Not only do the testate amoebae have a vertical zonation in peatlands, but their horizontal distribution varies as well, reflecting habitat patchiness (Meisterfeld 1977; Mitchell *et al.* 2000a; Mazei and Tsyganov 2007/8). In the Swiss Jura Mountains, spatial structure accounted for 36% of the observed variation. Imbedded in the horizontal variability, Mitchell *et al.* found that microtopography played an important role, indicating that in just 0.25 m² conditions are not uniform and present a different picture from that seen on a macroscale. In this case, the horizontal scale responds to differences in distance from the water table, whereas vertically within a *Sphagnum* mat, light, moisture, and detrital accumulation all differ. The horizontal scale also differs in pH and ion concentrations, both of which are lower on hummocks than in hollows. These differences in turn cause differences in the bacteria, fungi, algae, and other protozoa available for food. And hummock *Sphagnum* species are usually different from hollow species, having different morphologies that provide different sorts of spaces and different abilities to retain water and detritus.

Seasonal Differences

Communities of protozoa can differ among seasons, just as moisture and other conditions change in their habitat. As a result, species richness will fluctuate, as will abundance. In a *Sphagnum* bog in the Middle Volga region of Russia, species richness increases as the vegetation increases during May to September (Mazei &

Tsyganov 2007/2008). At the same time, evenness and species diversity have little variation. Species abundance changes are less well defined seasonally, most likely being more responsive to available moisture that is not directly tied to season.

Spring brings melting snow in most peatlands (Figure 46), with dormant protozoa awakening as the environment becomes more hospitable. In spring, dominant **hygrophilous** (water-loving) species in the Middle Volga region included *Heleopera sphagni*, *Hyalosphenia papilio*, and *Nebela tincta* (Mazei Tsyganov 2007/08). This dominance is replaced in summer and autumn by *Hyalosphenia elegans* and *Nebela tenella*. The **xerophilous** (dry-loving) community is slightly different and the diversity is somewhat greater. In spring, *Assulina muscorum*, *Heleopera sphagni*, and *Nebela tincta* dominate, being replaced in summer by a community of *Assulina seminulum*, *Euglypha ciliata*, *Hyalosphenia elegans*, and *Nebela tenella*. Yet another community appears in autumn, dominated by *Assulina seminulum*, *Cryptodiffugia compressa*, and *Trigonopyxis arcuata*.

Figure 46. As the snow recedes, the *Sphagnum* habitat will witness the awakening of water-loving protozoa that have remained dormant throughout the winter. Photo courtesy of Andres Filipe Baron Lopez in Alaska.

Heal (1964) found slightly different species in his study of six fen and bog sites in Great Britain, but the patterns were similar. Three species – *Amphitrema flavum*, *Hyalosphenia papilio*, and *Nebela tincta sensu lato* – had peak numbers from May until October. They then either encysted or died. For *Hyalosphenia papilio*, light is a controlling factor because this protozoan typically contains photosynthetic zoochlorellae (Figure 47). Although many of these rhizopods can reproduce every eight days by cell division, field evidence suggests that they have fewer than ten generations per year. This low number of generations limits their ability to respond to improved environmental conditions. These three species thus accounted for a biomass of 1.0 g m^{-2} and 30.2×10^6 individuals m^{-2} in Great Britain. Nevertheless, Heal found 98 species and varieties in these six sites with a distribution similar to that found in northern fens and bogs.

One mechanism that maintains closely related species in different niches is their seasonal requirements. For example, *Hyalosphenia papilio* is dominant in spring, *H. elegans* in summer-autumn. *Nebela tincta* occurs in spring, *N. tenella* in summer. *Assulina muscorum* appears in spring, *A. seminulum* in summer.

Figure 47. This protozoan, possibly *Bryometopus*, contains zoochlorellae. Photo by Yuuji Tsukii, with permission.

Pollution

Pollution can alter the peatland rhizopod communities. Mitchell *et al.* (2003) found that CO_2 enrichment caused a change in structure, but not in total biomass. Heterotrophic bacterial biomass increased by 48%, whereas that of the testate amoebae decreased by 13%. They suggested that the increase in CO_2 may have caused an increase in *Sphagnum* exudates that in turn stimulated an increase in bacterial biomass.

Ozone Loss and UV-B Radiation

One of the effects of pollution with refrigerants has been the destruction of ozone in the upper atmosphere. This loss of ozone itself is not dangerous; it is not an oxygen source for life on Earth. But it is a critical shield of the UV rays from the sun, high energy wavelengths that are lethal to many forms of life. This is especially realized in polar regions.

Searles *et al.* (1999) examined the effects of this "ozone hole" in regions of Tierra del Fuego, southern Argentina, and Chile. Their study was experimental. They chose areas with an ozone hole and used plastic film filters to reduce the UV-B reaching the habitat, in this case a *Sphagnum* bog. The growth and pigment concentrations of *Sphagnum* (*S. magellanicum*) were virtually unaffected during the three months of the experiment. The surprise was that both **testate amoebae** and **rotifers** in this *Sphagnum* habitat became more numerous under the near-ambient UV-B radiation (*i.e.*, under the reduced ozone filter of the ozone hole) than they were under reduced UV-B radiation resulting from the plastic filter (Figure 48). The protozoa were dominated by *Assulina muscorum* with some individuals of *A. seminulum*, *Nebela*, *Heleopera*, and *Euglypha* species.

Protozoan communities are also sensitive to other pollutants (Nguyen-Viet *et al.* 2008). As in testate amoebae on *Barbula indica* in Viet Nam, the testate amoebae on *Sphagnum fallax* declined in species richness, total density, and total biomass and community structure was altered with added lead (Nguyen-Viet *et al.* 2007, 2008). NO_2 also caused a decline in diversity, but not in density in the more heavily polluted city center of Besançon, France ($34.8 \pm 9.5 \mu\text{g m}^{-3}$) compared to the peripheral area ($14.6 \pm 4.7 \mu\text{g m}^{-3}$) (Nguyen-Viet *et al.* 2004). *Paraquadrula irregularis* differed dramatically, being present in all peripheral samples and completely

absent in the city; no other species differed significantly between the two areas.

Figure 48. Effects of UV-B radiation on **protozoa** and **rotifers** living among *Sphagnum magellanicum* in the Antarctic ozone hole. Vertical lines represent standard error of differences between treatments. Redrawn from Searles *et al.* 1999.

Reconstruction of Past Climate

Diatoms and siliceous protozoan plates and scales are common in peat preparations (Douglas & Smol 2001). However, these are seldom used in peatland reconstruction because it is nearly impossible to identify the species from these fossils. Fortunately, rhizopod tests are often present in the same samples and require the same preservation techniques as the diatoms and scales. Since the species are generally identified by their shells, there has been considerable recent interest in using these testate shells for determining the past history of the peatlands.

Both the mosses and the amoebae are well conserved over time, *Sphagnum* because of its resistance to decay, and for testate amoebae it is the unique test (housing) that likewise resists decay (Meisterfeld & Heisterbaum 1986; Coûteaux 1992). Both can be identified thousands of years later.

Even fossil evidence supports the richness of the *Sphagnum* fauna (Douglas & Smol 1988). Fortunately, the species are cosmopolitan (Smith & Wilkinson 2007) and community structure varies little with geography (Mitchell *et al.* 2000b; Booth & Zygmunt 2005), differing much less between geographic areas than does the tracheophyte community (Mitchell *et al.* 2000b). Even if species have diverged into sister species and become endemic (Mitchell & Meisterfeld 2005), it will often be possible to use these species complexes as indicators. On the other hand, we may be plagued by species that have diverged physiologically without changing morphologically, thus permitting them to live under different conditions but without being recognizable as different taxa.

As already implied, the testate amoebae have a distribution pattern that mimics that of *Sphagnum*

(Lamentowicz & Mitchell 2005). Wet habitat species of both are more sensitive to changes in the water table depth than are those of dry habitats such as hummocks. Species of dry habitats are more tolerant of desiccation. Consequently, the testate amoeba shells from the past permit us to reconstruct the past history of peatlands (van Geel 1976; Beyens & Chardez 1987; Warner 1991; Wilmshurst 1998; Bobrov *et al.* 1999; Charman *et al.* 1999; McGlone & Wilmshurst 1999a, b; Foissner 1999; Mauquoy & Barber 2002; Schnitchen *et al.* 2003; Zygmunt *et al.* 2003; Booth *et al.* 2004; Gilbert & Mitchell 2006; Payne *et al.* 2006; Payne & Mitchell 2007; Mitchell *et al.* 2008). Payne *et al.* (2008) demonstrated that even such diverse regions as Turkey, North America, and Europe have similar testate communities. Because of the unique assemblages of testate amoebae associated with moisture conditions of the peat mosses worldwide and the effects of climate change on them, the testate amoebae are useful for reconstructing past climate.

Surface moisture of **bogs** (with only precipitation as a water source), in particular, is controlled by climate. Reconstruction of the testate amoeba history permits reconstruction of the historic surface moisture, and that permits reconstruction of past rainfall. The amoebae are so fine tuned to the water table that they can help a researcher to predict the water table within less than 2 cm (Payne & Mitchell 2007). For example, Hughes *et al.* (2006) used testate amoebae to identify fourteen distinct phases of near-surface water tables in a coastal plateau bog in eastern Newfoundland, with corresponding time periods beginning 8270, 7500, 6800, 5700, 5200, 4900, 4400, 4000, 3100, 2500, 2050, 1700, 600, and 200 calibrated years BP. The final drainage of glacial Lake Agassiz accounts for the first major phase of pool development at 8400 calibrated years BP, followed by the Ungava lakes ca 7500-6900 calibrated years BP. From 7500 BP to the present the reconstructed bog surface water and the stacked ice rafted debris of the North Atlantic Ocean correlate well. At the same time, long-term changes in air masses may have been a contributing factor. Records of "cosmogenic isotope flux," when compared to the bog surface wetness reconstruction, suggest that reduced solar radiation presents a consistent link with increased bog surface wetness during the Holocene.

But the models are not always so accurate. Payne *et al.* 2006) were only able to estimate within 9.7 cm of water table depth, and that was after exclusion of selected data. They attributed the less than ideal fit to inaccuracies in water-table measurements, very large environmental gradients, and recent climatic change in the study area. Their pH estimates were only off by 0.2, which is within the error range of many pH measuring techniques.

Using weighted averaging to model species abundance as measures of water table depth and soil moisture, Bobrov *et al.* (1999) calculated optima and tolerance of species niches. They found that each group of taxa tends to have a gradient of hydrological preference. For example, a wet to dry gradient is exhibited among species of the *Trigonopyxis arcuata* group: *T. arcuata* var. *major* > *T. arcuata* > *T. minuta*. Likewise, the *Assulina-alkanovia* group exhibits wet to dry as *A. seminulum* > *A. muscorum* > *Hyalosphenia elegans* and the *Trinema lineare* group appears as *T. lineare* var. *truncatum*/*T. lineare* > *T.*

lineare var. *terricola*. Interestingly, these species gradients also follow a large to small size gradient, indicating that small taxa survive better than large ones under dry conditions. It appears that having spines is a disadvantage in dry habitats. Within the genera *Euglypha* and *Placocista*, the spined forms (Figure 49) are typical of wetter habitats than are those with shorter spines or no spines. These relationships suggest that the most effective use of these rhizopods for reconstruction of the past water regime is to use the lowest possible level of identification, i.e. species and varieties.

One interesting question that arises is whether these spined taxa are really different species and varieties, i.e., genetically different, or if they represent ecotypes – morphological representations of the microenvironment where they occur. For example, Laminger (1975) found that *Centropyxis aculeata* from greater depths lacked spines and their tests were covered with mineral particles. To test the possibility of ecological morphs, Booth (2001) examined four of the most common taxa in two Lake Superior coastal wetlands: *Arcella* spp., *Assulina* spp., *Centropyxis cassis* type, and the *Nebela tinctoria-parvula-collaris* group. Using 74 microsites, Booth compared testate amoeba assemblages based on percent moisture, depth to water table, pH, porosity, depth of living moss, and associated bryophyte and tracheophyte species. He used such parameters as test length and aperture diameter for amoebae from at least ten microsites. In general, there was little correlation between morphological variation and microenvironmental parameters. However, in the *Nebela tinctoria-parvula-collaris* group, the test size correlated significantly with pH ($r^2 = 0.68$). Booth concluded that these testate rhizopods are sensitive indicators of water-level and pH changes.

Figure 49. *Placocista spinosa*, a rhizopod typical of wet habitats. Photo by Yuuji Tsukii, with permission.

Many more studies on testate amoeba ecology have been conducted in the Northern Hemisphere than elsewhere (Mitchell & Meisterfeld 2005), making their comparisons somewhat easier. In the East Carpathian peatlands of eastern Europe, species such as *Amphitrema flavum* (Figure 17) and *Hyalosphenia papilio* (Figure 12) indicate wet conditions were present (Schnitchen *et al.* 2003). *Assulina muscorum* (Figure 50), *Diffugia pulex*, and *Nebela militaris* (Figure 23) indicate that conditions were dry.

Figure 50. Test of *Assulina muscorum*. Photo by Edward Mitchell, with permission.

In *Sphagnum* peatlands of the Rocky Mountains, USA, surface moisture determines the distribution of fossil rhizopods (Zygmunt *et al.* 2003). As suggested by the ecological studies of Lamentowicz and Mitchell (2005) and others (Booth & Zygmunt 2005), Booth and Jackson (2001) could track the history of an ombrotrophic peatland in northeastern Lower Michigan, USA, through 2800 years of changes using the moisture preferences of these organisms. Such fossils as these testae of rhizopods permit us to determine past changes in water table depth (Warner 1991; Woodland 1998; Woodland *et al.* 1998). Booth and Zygmunt (2005) further argued that the widespread geographic nature of the rhizopod relationships makes interpretation of their community structure widely applicable.

Charman and Warner (1997) used 60 samples from 14 peatlands in Newfoundland, Canada, and found 40 species that occurred in more than six samples. They used these to model the relationships between the species and the water table depth. Species with narrow tolerances provided the best indicators. These include *Amphitrema stenostoma*, *Arcella discoides*, *Cryptodiffugia sacculus*, *Diffugia bacillifera*, *Nebela carinata*, *Nebela griseola*, *Nebela marginata*, *Quadrullella symmetrica*, and *Sphenoderia lenta*. Charman and Warner recommend that for most accurate results modern constructs from wide regions should be used to interpret the data from peatland cores that represent palaeoecological time series.

Fortunately, most of the testate amoeba taxa are cosmopolitan, permitting the studies from the Northern Hemisphere to be used in less-studied areas such as New Zealand (Charman 1997; Wilmschurst 1998). In fact, Charman (1997) modelled the hydrologic relationships of protozoa and *Sphagnum* in peatlands of New Zealand and suggested that "palaeohydrology could be accurately inferred from fossil faunas."

Schoning *et al.* (2005) used peatland amoebae to reconstruct 125 years of peatland amoebae in Sweden. Unlike the cases in other areas in Europe, the changes in water table correlated primarily with changes in mean annual temperature, whereas in most other studies, precipitation was also an important factor. They caution that spatial differences must be considered in these historic interpretations and thus more study is needed on these influences.

In a Michigan, USA, study, Booth (2002) found that most of the eleven peatlands he studied had similar testate assemblages. As in most other studies, depth to water table was the best predictor of the protozoan assemblages. Nevertheless, within a given peatland, community variability was correlated with environmental heterogeneity, adding support to the suggestion of Schoning *et al.* (2005) regarding spatial considerations. But the testate amoebae in bog/fen habitats also had distinct differences in species between May and late summer-early autumn. Testate amoebae in the swamp community, on the other hand, had no clear difference in community structure between dates. They attributed these differences to the more constant water table and moisture conditions in the swamp.

Warner *et al.* (2007) add further support to the importance of considering seasons, particularly for living rhizopods. In southern Ontario, Canada, the usual factors of soil water content and water table influenced the distribution of amoeboid species and these differ with seasons. But the big differences were in the open bog/fen community, whereas in the swamp community there was no clear seasonal difference between May and August or October.

The historical record will not take us back forever. In their study on bogs in Ontario and Minnesota, Warner and Charman (1994) found that cores spanning the entire Holocene era only exhibited rhizopods present in the last 6500 years. They indicated that the fauna changed from the early rich fens with sedges and brown mosses. At those early stages, the protozoan communities were dominated by *Cyclopyxis* and *Centropyxis*. By 5000 BP, the habitat had become *Sphagnum*-dominated and the predominant protozoan taxa had shifted to *Amphitrema flavum*, *Assulina muscorum*, *Heleopera sphagni*, and *Hyalosphenia subflava*. As the habitat became drier, taxa again shifted to *Nebela griseola*, *N. militaris*, and *Trigonopyxis arcuata*.

Geographic Differences

Despite a considerable number of studies indicating usefulness of these organisms, use of testate amoebae to determine past habitats can at times be misleading. Harnish examined mires in Central Europe (1927 in Paulson 1952-53) and in Lapland, North Sweden (1938 in Paulson 1952-53), and found that the communities were not similar. Rather, associations from Central Europe did not exist in raised bogs in Lapland. In fact, the *Amphitrema* association existed in Lapland, but in different habitats, not raised bogs, whereas in Central Europe it was confined to raised bogs. The *Hyalosphenia* type was also absent in the Lapland raised bogs.

Problems in Using Rhizopods

There are caveats in using fossilized amoeba tests to assess past communities of testate rhizopods. Not all tests are equally preserved (Mitchell *et al.* 2007). The Euglyphida, which includes the common *Euglypha* species (Figure 51), are an **idiosome** group that secretes its own test and its biosilica plates (Beyens & Meisterfeld 2001). This biological test decays more readily than the testae of the other groups (Mitchell *et al.* 2007). In *Sphagnum* peatlands, this differential decay seems to make little

difference in the estimations of water table depth. However, in minerotrophic peatlands, with large numbers of this Euglyphida group, the loss of these tests leads to an underestimation of the water table depth. Data on more alkaline fens are lacking, and the community structure there is not well known. If this idiosome group is not dominant there, reconstruction may be more accurate.

Swindles and Roe (2007) likewise found that under conditions of low pH, such as found in peatlands, the degree of dissolution was highly variable, but it did not seem to relate to **xenosomic** (using "foreign" materials) vs. **idiosomic** tests. *Euglypha* (Figure 51) is particularly susceptible, whereas *Assulina muscorum* (Figure 50), *Amphitrema flavum* (Figure 34), and *Trigonopyxis arcuata* (Figure 52) are affected little by acidity. Payne (2007) found similar results by subjecting rhizopod tests to weak acid, nutrient enrichment, and desiccation over 28-months, and used shorter-term experiments with stronger acids in peatlands. He determined that during dry periods the record may be altered by differential preservations of the tests, as demonstrated by significant effects of long-term desiccation and short-term acid treatment at two different concentrations. This consequence could lead to overestimating water table depths.

Figure 51. SEM detail of biosilica plates of *Euglypha penardi*, a protozoan for which the test is especially susceptible to dissolution. Photo by Edward Mitchell, with permission.

Human Influence on Development

In New Zealand, it appears development of *Sphagnum* bogs has been dependent on human activity such as clearing or modifying the vegetation, resulting in *Sphagnum* dominance (Wilmshurst 1998). In other places, clearing of a peatland means that without human intervention it is gone forever. After such loss, it is often desirable to reconstruct the peatland. Testate amoebae have been used to define the past nature of the peatland for reconstruction purposes (Charman 1997; Charman & Gilbert 1997).

In a Polish peatland, a rapid shift in peat accumulation and lower pH occurred ~110-150 years ago, with a shift to

a *Sphagnum*-dominated poor fen (Lamentowicz *et al.* 2007). The protozoa supported this history. Researchers interpreted this to be a result of forest clearance in surrounding areas. Whereas peatlands are often destroyed by human activity, in some cases those activities make conditions more favorable to peatland development. In this case, *Sphagnum* peatland replaced a species-rich poor fen.

Figure 52. *Trigonopyxis arcula* test showing opening for pseudopod. This test is more stable than that of *Euglypha*. Photo by Yuuji Tsukii, with permission.

Laggoun-Défarge *et al.* (2008) found testate amoebae can be used to reflect disturbances that result from peat harvesting. Where better carbohydrate preservation was present, along with more heterogeneous peat composition, the testate amoebae exhibited a higher diversity, thus serving as a biological indicator of conditions.

Use in Peatland Regeneration

Regeneration of peatlands can use remains of testate amoebae to determine the species to re-introduce or to follow the progress in a less labor-intensive fashion by monitoring the amoebae. In the Jura Mountains, Switzerland, Laggoun-Défarge *et al.* (2008) examined a peatland that had been mined for heating fuel until World War II and found that amoeba communities changed as peatlands changed during regeneration. The *Sphagnum* habitat shifted from moderately acidic, wet conditions to more acidic, drier conditions. During these changes, biomass and mean size of amoebae declined while remaining higher at the undamaged site. At the same time, species richness and diversity increased while density declined. As reported by Mitchell *et al.* (2004), changes in the amoeba community lagged behind that of the returning *Sphagnum* community. Moreover, during the forty years of 1961-2001, overall amoeba richness (33) remained unchanged, but richness per sample decreased from 11.9 to 9.6 (Kishaba & Mitchell 2005). Relative abundance changed, with three species increasing significantly [*Bullinularia indica* (Figure 53) (+810%), *Cyclopyxis eurytoma* (+100%, 0 in 1961), *Nebela tinctoria* (Figure 54) (+97%)] and two species declining [*Assulina muscorum* (Figure 50) (-63%), *Euglypha compressa* (Figure 55) (-93%)]. The researchers concluded the expected changes in richness were complete before the 1961-2001 study began.

Jauhianinen (2002) demonstrated in an ombrotrophic bog that the testacean shells were present throughout the

vertical profile, whereas in the minerotrophic fen they were numerous only at the surface. As in other studies, moisture conditions were important, but peat composition and minerals also played important roles. Following restoration, species that indicated dry conditions disappeared, whereas the moisture gradient seemed to result in less defined community differences. In fact, the minerals seemed to have a greater effect.

Lamentowicz *et al.* (2008) demonstrated that the testate amoebae record in a Baltic coast peatland in Northern Poland correlated well with the stable isotope data in the same core. The large number of testate protozoans known from peatlands, their relatively cosmopolitan distribution, and the understanding we have of the water table requirements for many of these species provide us with a useful tool for understanding the past history of many peatlands.

Summary

Peatlands support an abundant bryophyte fauna, with *Amphitrema*, *Assulina*, *Corythion*, *Diffugia*, *Euglypha*, *Heleopera*, *Hyalosphenia*, and *Nebela* typically being the most common genera. *Sphagnum* sports more species than those found among other mosses or tracheophytes. These taxa are widespread and thus are very reliable indicators of moisture conditions in the peatlands and are less affected by water chemistry than are the tracheophytes.

Diversity is lowest in the driest peatland habitats, but the number of individuals is highest. Abundance increases with depth if oxygen is not limiting. Dry habitat species are more tolerant of changes in water depth than are wet habitat species. Rich fen amoeba species differ from those of acid bogs, but Euglyphidae are prominent in all these habitats. *Paraquadrula irregularis* and *Centropyxis discoides* are restricted to fens, with *Arcella discoides* indicative of rich fens. Detritus forms a major portion of the protozoan diet in the peatlands.

Vertical zonation presents the symbiotic taxa in the light zone at the top of the moss, with those requiring more moisture occurring at the greatest depths. Shell size, pH, moisture, light, nutrients, and available food all contribute to the distribution. Horizontal variation results from differences in bryophyte species and microtopography, resulting in differences in distance from water table and in pH. Seasonal differences reflect some of these same changes in moisture and food availability and are effective in separating niches of closely related species.

CO₂ enrichment may cause a reduction in testate amoebae while at the same time increasing bacterial biomass. Loss of the ozone filter and consequent increase in UV-B radiation may actually favor some testate amoebae in *Sphagnum* peatlands.

Amoebae form more constant associations in peatlands than do the plants. And testate species, with few exceptions, are well preserved even after death. Therefore, they can serve as appropriate markers of past climates as well as indicators of predisturbance conditions, although tests of some species, especially Euglyphidae, decompose more easily than others and can skew the results. The best indicators are those with narrow tolerance ranges, especially for moisture.
