In the upper montane oak forests in the Cordillera de Talamanca of Costa Rica, Holz *et al.* (2002) found a large diversification of microhabitats and a high diversity of bryophytes. Liverworts (106 species) were slightly more numerous than mosses (100), with 1 hornwort in only 6 ha of forest. The researchers identified three main groups of microhabitats: forest floor, including tree bases, phyllosphere, and other epiphytic habitats. The forest floor was much richer in bryophyte species than in forests of lower elevation zones. These were distributed among tree bases (69 species), rotten logs (70), and soil (69) as the most species-rich habitats (Figure 87), heralding the greater light than that in lowland forests. Trunks (61 species), branches of the inner canopy (35), twigs of the outer canopy (14), and leaves of the understory (14) supported somewhat fewer species (Figure 87).

Figure 87. Number of species on each of the major microhabitats at Los Robles, Costa Rica, in the upper montane forest. Modified from Holz *et al.* 2002.

Holz and coworkers (2002) once again found that **Lejeuneaceae** (Figure 9) was by far the family represented by the most species, reaching ~60 at Monteverde, Costa Rica. The distribution of species among the major families is shown in Figure 88. The life forms are quite varied, with **turfs** and **mats** being the most common strategies (Figure 89). The "pronounced" dry season and host tree characters (tree height, stratification, number of host tree species)

modified this upper montane zone compared to more humid lower altitudes.

Figure 89. Proportions of species in each of the life forms in the major microhabitats at Los Robles, Costa Rica, in the upper montane forest. Modified from Holz *et al.* 2002.

Holz and Gradstein (2005) compared cryptogamic epiphytes in early and late secondary oak (*Quercus copeyensis*; Figure 90-Figure 91) forests and in primary forest in Cordillera de Talamanca, Costa Rica. They found little difference in species richness between the secondary and primary forests. They concluded that the closed canopy of the secondary forests explained the high diversity there, resulting at least in part from the high atmospheric humidity. Nevertheless, even after 40 years one-third of the primary forest species were still absent in the secondary forest. Furthermore, while diversity was similar, the community composition differed markedly between primary and secondary forest, with 40% of all the species restricted to the secondary forests.

In the upper montane in the Central Cordillera of Colombia, rope-climbing techniques permitted assessment of the upper canopy (Wolf 1993b). Using the Braun-Blanquet method, Wolf sampled 15 sites at 200 m intervals on an altitudinal gradient. Wolf sampled four canopy trees, avoiding those with smooth, scaling, or hard bark. As in other studies, location within the host tree and altitude are the most influential characters on the epiphytic vegetation. Based on 59 host trees, Wolf found 187 liverwort and 108 moss species. There is great variability between relevés in

a single community, with a community of ~16%. A rapid change in community structure of the epiphytic vegetation occurs between 2,130 and 2,460 m asl. This is the elevation range where there is a rapid increase in air humidity. As in the Cordillera de Talamanca, *Usnea* (Figure 92) is very abundant in the outer canopy. pH values were somewhat wide-ranging and may have played a role in community composition. For example, at pH 7.1, the dominant community is that of the moss *Hypopterygium tamariscinum* (Figure 93) whereas at pH 3.2 the community of *Scapania portoricensis* (see Figure 46) – *Plagiothecium novogranatense* (see Figure 94–Figure 95) is prominent. The suspended soils of the lower montane rainforest and the upper montane rainforest differ significantly, with the latter having more organic matter and lower nutrient contents. Soils at tree bases in the lower montane rainforest have higher nutrient content than do the canopy soils. The opposite is the case in the upper montane rainforest. Exclusive epiphytic taxa in the upper montane rainforest are the liverworts *Adelanthus pittieri* (see Figure 96), *Bazzania breuteliana* (see Figure 97), *B. hookeri* (Figure 97), *Lepicolea pruinosa* (see Figure 98), *Lepidozia* spp. (Figure 99), *Lophocolea trapezoides* (see Figure 100), *Plagiochila bursata* (see Figure 10, Figure 51–Figure 53), *Riccardia* spp. (Figure 101), and *Trichocolea tomentosa* (Figure 102), and the moss *Sematophyllum insularum* (see Figure 21). In the canopy, the most common exclusive taxa are *Anoplolejeunea conferta*, *Jamesoniella rubricaulis* (Figure 103), *Leptoscyphus jackii* (see Figure 28), *L. porphyrius* (see Figure 28), *Plagiochila echinella*/*P. hansmeyerii*/*P. paludosa* (see Figure 10, Figure 51–Figure 53), *Prionodon fuscolutescens* (Figure 104), *Trachylejeunea dominicensis*, and the lichen *Hypotrachyna laevigata* (Figure 105)/*H. producta*. On tree bases, exclusive taxa for all five tree base communities include *Calypogeia peruviana* (Figure 106), *Cephalozia crassifolia* (Figure 107), *Lophocolea* aff. *connata* (see Figure 100), and *Telaranea nematodes* (Figure 108).

Figure 108. *Telaranea nematodes*, one of the exclusive liverwort taxa on tree bases in the upper montane rainforest of the Central Cordillera of Colombia. Photo by Michael Lüth, with permission.

The most common taxa exclusive for the canopy communities of the upper montane rainforest of the Central

Cordillera of Colombia are *Anoplolejeunea conferta*, *Jamesoniella rubricaulis* (Figure 103), *Leptoscyphus jackii* (see Figure 28), *L. porphyrius* (see Figure 28), *Plagiochila echinella sensu lato* (incl. *P. hansmeyerii* and *P. paludosa*; see Figure 10, Figure 51-Figure 53), *Prionodon fuscolutescens* (Figure 104), *Trachylejeunea dominicensis*, and *Hypotrachyna laevigata* (not separated from *H. producta*; Figure 105).

In Tanzania (Figure 109), the upper montane forest bryophytes capture 50% of the yearly precipitation (Gradstein 1992). That amount is 2.5 times the capture of the lower montane forest. Interception values in the Colombian montane forests were much less, reaching only 18.3% capture in the upper montane forest (Veneklaas & van Ek 1991). This difference is likely to be related to the differences in the forest types, with the Colombian mossy forest being much higher and much more open (Gradstein 1992). Furthermore, bryophytes in the Colombian forest formed discontinuous cover on the branches and usually were in clumps, contrasting with nearly continuous bryophyte cover on the branches in Tanzania.

The leafy liverwort genera *Plagiochila* (Figure 10, Figure 51-Figure 53), *Bazzania* (Figure 97), *Herbertus* (Figure 44, Figure 77), *Lepidozia* (Figure 99), *Lepicolea* (Figure 98), and *Trichocolea* (Figure 102) are the dominant liverworts in the wetter tropical montane forests (Gradstein 1992). In drier forests, mosses are more common. These include *Macromitrium* (Figure 110), *Meteoridium* (Figure 111), *Mittenothamnium* (Figure 112), *Papillaria* (Figure 113), *Porotrichum* (Figure 114), *Porotrichodendron*, *Prionodon densus* (Figure 115), and *Squamidium* (Figure 116). In Asia, one might find more robust mosses such as *Dicranoloma* (Figure 117), *Hypnodendron* (Figure 118), *Braunfelsia*, *Dicnemon* (Figure 119), and various members of the *Pterobryaceae* (Figure 42).

Upper montane forests can have epiphytic bryophyte biomass reaching as much as 44 tons dry weight per hectare (Gradstein 1992), compared to only ~2 tons in the submontane rainforest (Pócs 1982).

Gradstein and Vána (1994) reported that rotten logs in the pine forests in the central highlands of Chiapas, Mexico, exhibited a *Nowellia curvifolia* (Figure 23) community that had many species of boreal liverworts. They found eight species of liverworts and two of mosses. The most abundant of these, forming dense mats, were the leafy liverworts *Fuscocephaloziopsis catenulata* (Figure 120) and *Nowellia curvifolia* and the mosses *Campylopodia stenocarpa* and *Dicranum frigidum* (Figure 26). Other common species were the liverworts *Syzygiella autumnalis* (Figure 121), *Leptoscyphus amphibolius* (see Figure 122), and *Lophozia ventricosa* (Figure 123), with *Crossocalyx hellerianus* (Figure 124) often occurring on the very humid flanks of the logs. The species were all pioneers on the logs except for *Dicranum frigidum*. Six of the liverwort species are characteristic of boreal forest conifer logs. The researchers concluded that this community is probably limited in the tropics to occurrences of conifer forests in the northern parts of Central America.

Figure 125. *Cupressus lusitanica*; the greatest diversity of bryophytes is in the plantations of these species. Photo by Sergio Kasusky, through Creative Commons.

Corrales *et al.* (2010) surveyed secondary montane forest, *Cupressus lusitanica* (Figure 125) plantations, and *Pinus patula* (Figure 126) plantations in the Central Cordillera of Colombia. They used 1 m² random plots along 40 transects. They identified 151 species of bryophytes. Species richness, weighted based on number of samples, was higher in the secondary montane forests and cypress plantations than in the pine plantations. The greatest abundance was in the cypress plantations. Nevertheless, DCA indicated a high degree of floristic similarity. Soil pH, slope, and light availability were the primary factors in determining bryophyte distribution, suggesting that habitat specialization is the main mechanism governing species distribution within a forest type. The similarity of the three forest types suggests that propagule dispersal is also important.

Figure 126. *Pinus patula*; plantations of this species have fewer bryophyte species than those of the cypress (*Cupressus lusitanica*). Photo by Dick Culbert, through Creative Commons.

Veneklaas *et al.* (1990) investigated the effects of epiphytic vegetation in rainfall interception in an upper montane rainforest at 3,370 m asl in the Central Cordillera of the Colombian Andes. This site had ~12 tons dry weight of epiphytes per hectare, comprised mostly of bryophytes and dead organic matter. They learned that the epiphytes were efficient at rainfall capture, gradually releasing the excess. Furthermore, loss through evaporation was slow.

Summary

High mountains throughout the tropics have similar zonation patterns. Canopy tree presence or absence are important determinants of the bryophyte vegetation. Water relations are important, and trees affect the relative humidity. Nitrogen is made available by associated **Cyanobacteria** species. Submontane species are primarily **mat-forming perennial stayers** and **perennial shuttle species**. Liverworts outnumber mosses in humid areas, but the reverse is true in dry areas. Montane regions often have rocky substrata as well as soil, contributing to niche diversity. The montane is also likely to have more temperate plants than the submontane. These regions contrast sharply with the lowland forests by having dense carpets of bryophytes on the forest floor. Trees often support **pendent** bryophytes, and **tall turfs** and **feathers** are common. These more favorable growing conditions support some of the richest diversity of bryophytes in the world and the most exclusive species.

Lejeuneaceae can dominate in all the epiphytic zones. **Meteoriaceae** dominates in montane forests, with **Dicranaceae** typically dominant in the upper montane. The bryophyte communities of the montane have considerable similarity to those of the boreal zones. Bryophytes on logs are predominately liverworts.

Bryophytes lost through disturbances can be replaced through diaspore banks, with liverworts more common than mosses. In the lower montane, water content experiences pronounced daily fluxes. Much carbon is still lost due to respiration at night. Soils at tree bases in the lower montane have higher nutrient content than do the canopy soils. The upper montane bryophytes of Tanzania capture 50% of the precipitation, 2.5 times that captured in the lower montane, but Neotropical bryophytes can be in discontinuous clumps and capture much less water. Upper montane forests can have as much as 44 tons of bryophyte biomass, compared to only 2 in submontane forests. In the upper montane, **cushion**, **short**, and **tall turf** life forms increase in proportion among the typically **perennial stayers** and **perennial shuttle species**.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make this chapter reliable and up-to-date. Her helpful discussions kept me going on this part of the world I know so little about.

CHAPTER 8-10

TROPICS: CLOUD FORESTS, SUBALPINE, AND ALPINE

Figure 1. Ecuadorian mountains and cloud forest. Photo by Arthur Anker, with permission.

Cloud Forests

Neotropical **cloud forests** (Figure 2, often known as **elfin forests** or **mossy forests**, extend from 23°N to 25°S (Churchill *et al.* 1995). These researchers suggested that the cloud forests of the Neotropics are a subset of the montane rainforest. They are isolated in Mexico on the north by xeric vegetation and on the south in Chile and Argentina by temperate rainforest. These cloud forests generally occur at 1000-3000 m asl. But the seasonal variation in precipitation is low and there are no months in which the evapotranspiration exceeds the rainfall. Rather, cloud cover is nearly continuous, with 2,000-4,000 mm precipitation per year. The temperature decreases from 18-22°C at 1,000 m to less than 10°C at 3,000 m asl. The taxa of these cloud forests are strongly influenced by their connections with both North and South America. The low generic level of endemism and high species endemism suggest recent and rapid speciation.

Figure 2. Cloud forest at Parque Nacional Montana de Santa Barbara at 2,180 m asl in Honduras. Photo by Josiah Townsend, with permission.

Cloud forests carry an intrigue that matches their names. Generally perched atop high mountains where they are blanketed in the fog of low-lying clouds or recipients of moisture-laden air that results in a mist zone most of the time (Vitt 1991), these forests must survive the harsh, uninterrupted winds and the continuous moisture that accompanies such a lofty abode. (See also Lawton 1980, 1982.) Consequently, trees there tend to be short compared to forests at lower elevations. For example, in Taveuni, Fiji, the forest trees on top of Mt. Koroturanga at 1,210 m asl were about 3-7 m tall, increasing to 10 m at 1,140 m elevation, and to 30 m at sea level (Ash 1987). Sadly, these dwarfed forests are rapidly disappearing from the face of the Earth before we can begin to understand a fraction of their complexity. In the northern Andes alone, 90% of these remarkable forests have disappeared, compared with 20% loss of the Amazon rainforest (Wuethrich 1993). In Peru alone, the mountainous areas house more than 25,000 plant species.

One problem that keeps these elfin forests out of the public eye is their relative lack of trees. Instead, they are dominated by herbs, shrubs, epiphytic ferns and seed plants, and mosses, with the diversity of all of these increasing with altitude (Wuethrich 1993). Nevertheless, they are the source of more than 3,000 species of plants that are used by the local people and house the ancestors of some of the most important world food crops.

Gotsch *et al.* (2017) showed that vapor pressure deficit could predict the epiphyte abundance in a tropical elevational gradient where the montane cloud forests occupy only a narrow band of microclimate and are thus vulnerable to climate change that changes the heights of the clouds and brings drought to the area. Their predictions are supported by their data showing that epiphyte abundance increases with elevation and leaf wetness and that it decreases as vapor pressure deficit (VPD) increases. VPD differences, however, are not always correlated with elevation and thus serve as better predictors of the epiphyte abundance.

In cloud forests of the Amazon, a high density of 21,900 trees per hectare belies the low tree species richness of 15 species, whereas the lower elevation tabonuco has 170 species with only 1750 trees per hectare (Gorchov & Cornejo 1993). The area behaves as an **ombrotrophic** (low-nutrient) wetland with its 5000 mm rainfall per year and another 10% moisture contributed by clouds. Poor soil oxygenation due to water logging results in most roots being above the soil. These buttress roots are usually covered by numerous bryophytes, and one might suppose that these bryophytes steal most of the nutrients returned by stemflow. Research has begun only recently on the ecological role of these cloud forest bryophytes.

Terrestrial bryophyte cover in the elfin forest is strikingly different from that of the lowland rainforest. The bryophytes are less specialized, with many of the same taxa occurring on the soil and on the trees. And the higher moisture permits bryophytes to grow higher on the bole, often reaching the canopy (Richards 1984).

Russell and Miller (1977) found that at Pico del Oeste in Puerto Rico, 55% of their collections of *Campylopus* (Figure 3) also contained the moss *Hemiragis* (Figure 4), but *Hemiragis* never occurred with *Leucoloma* (Figure 5). As in the submontane rainforest, the leafy liverworts

dominated the upper branches (Russell & Miller 1977). This high humidity no doubt accounts for the high percentage of leafy liverworts, estimated up to 90% of the bryophyte flora (Fulford *et al.* 1970). Yet at Monteverde, Costa Rica, Gradstein *et al.* (2001b) found that 36% of the 190 bryophyte species occurred exclusively in the canopy. The thick, lower branches had the highest diversity, with 99 species, presenting a sharp delineation of communities (Figure 6).

Figure 6. Total bryophyte species richness vs corticolous bryophyte species diversity in the canopy vs the understory in a cloud forest at Monteverde, Costa Rica. Species of rotten logs and epiphylls are not included in the corticolous counts. Redrawn from Gradstein *et al.* 2001b.

Merwin *et al.* (2001) reported 198 epiphytic bryophyte taxa in the Monteverde Cloud Forest Preserve. As is typical, the liverwort species (120) considerably outnumbered the moss species (77), with only 1 hornwort. Of these bryophyte species, 63 occurred in secondary forest and 84 in pastureland, whereas 178 species occurred in the primary forest.

These forests have such dense bryophyte growths on every trunk, branch, and twig that the forests appear "furry" (Gradstein & Pócs 1989). Biomass is high, with 11,000 kg ha⁻¹ dry weight in a Tanzanian elfin forest (80% of total canopy biomass), compared to the lower submontane rainforest with 1,773 kg (Pócs 1982). By comparison, an oak forest in Atlantic Europe had 355 kg (Schnock 1972) and a continental European oak forest had only 41 kg (Simon 1974).

One can find accumulations of organic matter in the crowns of trees of tropical wet forests such as the cloud forests. Bohlman *et al.* (1995) investigated the moisture and temperature patterns of these organic soils in the canopy and on the ground in Costa Rica. These two soil groupings ranged in temperature from 11.5°C to 21.0°C throughout the 42-month study period, but the soil from the two locations generally were within 1°C of each other. Both soils remained moist (>70% water content) during the wet and misty seasons. Nevertheless during dry periods the canopy soils dropped to a water content of 20-40% while the forest floor soils retained 60-70% water content.

Gotsch *et al.* (2016) considered that a shift in the heights of the cloud base or precipitation due to climate change would make a huge impact on the cloud forest epiphyte community.

For a more general understanding of cloud forests one can consult such publications as that of Stadtmüller (1987).

Adaptations and Water Relations

In two Venezuelan cloud forests (Figure 7) in the northern Andes at 2000-2400 m, rainfall in January and February is typically 20 mm or less, but in August to October it can be 200 mm or more (León-Vargas *et al.* 2006). Nevertheless, it is quite variable in all seasons. The longest record for a dry period is only 143 hours. Humidity

typically rises to more than 90% relative humidity at night, with one night in two typically reaching 100%. Six **pendent** (Figure 16) bryophytes were all able to survive at least a few days of desiccation; their recover was, however, better from high humidities. Their ability to reach light-saturation reached 95% at 110-256 $\mu\text{mol m}^{-2} \text{s}^{-1}$, levels only slightly higher than that of typical field levels. The **pendent** and other diffuse life forms are especially able to intercept cloudwater droplets, a feature that permits them to maximise conditions during periods of low rainfall.

Figure 7. Cloud forests, Venezuelan Andes. Photo by Gianfranco Cardogna, through Creative Commons.

The horizontal plane of a **fan** provides maximum surface area to capture light for photosynthesis as well as intercepting water from the moving air (Song *et al.* 2015). In three of the common **fan** bryophytes [moss *Homaliodendron flabellatum* (Figure 8), liverworts *Plagiochila arbuscula* (Figure 9), *P. assamica*] in an Asian subtropical montane cloud forest, the plants experienced high relative humidity coupled with low light and temperatures in the understory. Fog is a major source of water. Data suggest that photosynthetically active periods for these bryophyte are short because they lose most of their free water within an hour. These **fan** bryophytes are further adapted to their low-light understory position by having low light saturation and compensation points for photosynthesis. The researchers expressed concern that these **fan** bryophytes would experience a net carbon loss if the frequency and severity of dry periods increase.

Figure 8. *Homaliodendron flabellatum*, a **fan** form found in the Asian subtropical montane cloud forest. Photo by Jiang Zhenyu, Mou Shanjie, Xu Zawen, Chen Jianzhi, through Creative Commons.

Figure 9. *Plagiochila arbuscula*, a **fan** life form found in the Asian subtropical montane cloud forest. Photo by Peter de Lange, through public domain.

In the Asian subtropical montane cloud forest, there is high relative humidity accompanied by low light levels and temperatures in the understory (Song *et al.* 2015). Fog provides good water availability for the bryophytes. In this habitat, **fan** life forms (Figure 8-Figure 9) thrive. This life form loses its free water within one hour. Without sufficient water content, net photosynthesis can become negative. Song *et al.* (2015b) considered the **fan** life form to be especially suited to the cloud forest regime. The **fan** life form, extending outward from the vertical surfaces of trees (or rocks), is able to capture water from fog efficiently (Song *et al.* 2015). Furthermore, the cell walls have a high elasticity and osmoregulatory capacity that permit these life forms to tolerate desiccation. Additionally, these **fan** species have low light saturation and low compensation points for photosynthesis, all providing shade tolerance. While these characteristics provide ideal adaptations to the humid, low-light conditions of the cloud forest, the inability to tolerate and succeed under desiccating conditions puts these **fan** species at risk under changing climatic conditions that increase both the frequency and severity of droughts.

Biomass

Van Dunne and Kappelle (1998) estimated biomass of epiphytic bryophytes on *Quercus copeyensis* (Figure 10) in a Costa Rican montane cloud forest. They found 22 species each of mosses and liverworts. Biomass of bryophytes was correlated with frequency, with mosses contributing 54-99% of that biomass. Of these, 14% of the species accounted for 90% of the biomass. These bryophytes are important in controlling water flow. Dominant taxa include *Pilotrichella flexilis* (Figure 11), *Rigodium* sp. (Figure 12), *Porotrichodendron superbum* (Figure 13), *Prionodon densus* (Figure 14), *Neckera chilensis* (see Figure 15), and *Plagiochila* (Figure 16).

Nadkarni (1984) was among the early Neotropical researchers who investigated ecology of the epiphytes. Unfortunately for us, these typically included the bryophytes, lichens, and tracheophytes together. Nevertheless, we can generally consider that most of the dead epiphyte biomass that accumulates is comprised of bryophytes. On a single large tree (*Clusia alata*), the standing crop was 141.9 kg, with the nutrient concentrations of N 3062 g, P 97 g, K 678 g, ca 460 g, Mg 126 g, and Na 207 g. Despite contributing only 2% to the biomass of the elfin forest dry weight, they contribute approximately 45% of the nutrients. This gives them a considerable role in the nutrient cycling of the cloud forest.

In a later study, Nadkarni *et al.* (2004) distinguished the role of bryophytes. The canopy organic matter in a primary montane cloud forest of Monteverde, Costa Rica, was 63% dead organic matter. Bryophytes comprised 12% of this. However, in the secondary cloud forest, bryophytes provided 95% of the biomass, with only 3% as dead organic matter. Branch junctions in the primary forest supported only dead organic matter and roots, whereas branch tips, subcanopy, and understory substrates supported only bryophytes. Trunks had diverse organic matter components, but little associated dead organic matter. The secondary forest, on the other hand, exhibited little differentiation between trunks and branches due to the dominance of bryophytes. The absence of bryophytes in branch junctions of both forest types is in stark contrast to their common appearance in these location in temperate forests.

Colonization and Life Strategies

A major problem for tropical bryophytes is that those with the common epiphytic life style must get dispersed and then become established on a vertical or otherwise elevated substrate. It is likely to be even more difficult for seeds of larger plants to become so established, so the bryophytes have an important role in providing a catchment for these propagules. Hence, the establishment of the bryophyte biomass is crucial to the cloud forest ecosystem. Nadkarni and coworkers (2000) attempted to determine how successful the bryophytes were in becoming

established from macroscopic fragments onto branches in a tropical cloud forest in Costa Rica (Figure 17). Not surprisingly, only 1% of the bryophyte fragments managed to land and remain on saplings for the six months of study. However, those dropped on the canopy were more successful. Those branches with intact epiphytes retained 24% of the fragments, whereas stripped branches in the same area retained only 5%. This suggests that larger-diameter branches are more successful at retaining the fragments, as are other epiphytes. After 10 years, the bryophytes showed good recovery (Figure 18) (Nadkarni 2000).

Figure 18. Comparison of component abundance in percent biomass of **original** epiphytic vegetation and percent total cover of **recolonizing** vegetation after 10 years on 75 m segments of inner canopy branches of mature trees at Monteverde, Costa Rica. Redrawn from Nadkarni 2000.

Life forms such as **feather**, **dendroid**, and **large cushions**, and **pendent** forms of *Meteoriaceae* (Figure 72- Figure 73), *Phyllogoniaceae* (Figure 40), *Frullania* (Figure 54), and *Taxilejeunea* (Figure 19) on horizontal branches of small trees and shrubs are often dominant and much more common than in lowland forests (Gradstein & Pócs 1989). Among the cloud forest species is *Fissidens polypodioides* (Figure 20), a member of a very large genus

with more than 500 species (Pursell 1994). In Central America, this is the largest *Fissidens* species, reaching 8 cm. In a Colombian cloud forest (Figure 21), van Leerdam and coworkers (1990) found **tall turfs** and **smooth mats** to predominate in the crowns, with forms differing between the inner and outer canopy. While **smooth mats** are common forms in the higher branches of temperate forests, the **tall turf** would seem to be possible only where moisture is abundant. Surprisingly, they found that growth and life forms differed dependent upon phorophyte species. Epiphyllous forms seem to be limited by frost, occurring up to only about 3,000 m (Pócs 1982).

Figure 20. *Fissidens polypodioides*, a cloud forest species that is the largest *Fissidens* species in Central America. Photo by Janice Glime.

The **perennial shuttle species** take advantage of vegetative reproduction to become very important in the epiphytic communities on Mt. Kanabalu, North Borneo, whereas **perennial stayers** take advantage of the spores ultimately resulting from sexual reproduction or the occasional successful fragment to reach a new substrate, where they can persist for a long time (Frey & Kürschner 1991).

Figure 21. Montane cloud forest of Colombia. Photo courtesy of S. Robbert Gradstein.

Species Diversity

The humid cloud forests are important habitats for the leafy liverworts that typically exceed the mosses in number of species. For example, Russell and Miller (1977) found 60 species of epiphytic liverworts, but only 23 of mosses, in an elfin forest in Puerto Rico.

Mandl *et al.* (2010) questioned whether certain species groups could be used as surrogates for diversity in Neotropical montane forests in Ecuador (Figure 22). To test this, they surveyed 28 plots (400 m² each) of both terrestrial and epiphytic species in the ridge and slope forests in three locations in southern Ecuador. The epiphytic habitat had significantly more liverworts than the ground habitat. Mosses, on the other hand, were predominantly ground dwellers. Liverwort diversity proved to be a good indicator of fern α diversity. Moss α diversity was similar to that of ferns and liverworts only in epiphytic habitats. β diversity of ferns, mosses, and liverworts was similar among ground species, but not among epiphytic species. Thus, α diversity is not a good surrogate for β diversity in these cloud forests.

Figure 22. Montane cloud forest in Ecuador. Photo by Nils Köster, courtesy of S. Robbert Gradstein.

In a lower montane cloud forest at Monteverde, Costa Rica, Gradstein *et al.* (2001b) identified 133 liverwort, 56 moss, and 1 hornwort species. The thick branches of the lower canopy were the most species rich, with 99 species,

whereas trunks 1 m and above supported only 65 species. The lianas, shrubs, saplings, and understory leaves had only 36-46 species. Rotten logs were even more limited, with only 16 species. Roughly 36% of the species were exclusively in the canopy, with half the corticolous ones occurring there. In this case, the percentage of bryophyte species restricted to the canopy differs little from that of lowland and montane rainforests.

The Monteverde cloud forest has many rotting logs and fallen branches (Gradstein *et al.* 2001b). These serve as important habitats for the thallose liverworts *Monoclea gottschei* (Figure 23) and *Riccardia* spp. (Figure 24) and the mosses *Trachyxiphium guadalupense* (Figure 25) (Pilotrichaceae), *Mittenothamnium reptans* (Hypnaceae; Figure 26-Figure 27), *Plagiomnium rhynchophorum* (Mniaceae; Figure 28), and *Pyrrobryum spiniforme* (Rhizogoniaceae; Figure 29). Only one hornwort (*Nothoceros vincentianus*; Figure 30) was found in the study, and this could be found on rotten logs. The rotten log species were also frequently encountered on tree bases, especially rotten humus ones.

Gradstein *et al.* (2001b) elaborated on the species found in the various levels of this Monteverde cloud forest, where they identified 190 species. Unlike some wet forests where *Lejeunea* (Figure 31) presents the most species, in this case that role belonged to *Plagiochila* (Figure 16). In the understory, the most frequent bryophytes on trunks, shrubs, lianas *etc.* were the moss *Porotrichum korthalsianum* (see Figure 32) and the leafy liverworts *Plagiochila* spp. and *Radula antillana* (see Figure 33),

with other common taxa including *Lepidopilum muelleri* (see Figure 34-Figure 35), *Metzgeria leptoneura* (Figure 36), *Omphalanthus filiformis* (Figure 37), *Taxilejeunea pterigonia* (see Figure 38), and *Trichocolea tomentosa* (Figure 39). The well-lit sites were largely characterized by the pendent mosses *Phyllogonium fulgens* (Figure 40) in particular and various *Meteoriaceae* (Figure 54; Figure 72-Figure 73). These often occurred together with the robust liverworts *Porella swartziana* (see Figure 41), *Bryopteris filicina* (Figure 42), *Plagiochila* spp. (Figure 9, Figure 16), and *Radula gottscheana* (see Figure 33).

Trunk bases at Monteverde (Figure 44) typically had the liverworts *Cephalozia crassifolia* (Figure 43), *Lophocolea connata* (see Figure 45), *Telaranea nematodes* (Figure 46), and various species of *Lejeunea* (Figure 31). Mosses here included *Fissidens* spp. (Figure 20) and *Hypopterygium tamariscinum* (Figure 47) (Gradstein *et al.* 2001b). Less common, but nevertheless characteristic trunk base species, were the leafy liverworts *Calypogeia* spp. and the thallose liverwort *Pallavicinia lyellii* (Figure 48), and the mosses *Cyrt-hypnum schistocalyx* (Figure 49), *Leskeodon andicola* (Figure 50), *Octoblepharum erectifolium* (Figure 51), and *Syrrhopodon* spp. (Figure 52). Species of the liverwort *Bazzania* (Figure 53) could also be found, but these are much more common in the forest canopy.

The canopy in the Monteverde cloud forest (Figure 44) demonstrated different communities (Gradstein *et al.* 2001 b). The nearly horizontal branches of the lower canopy displayed these mats of bryophytes. These included the leafy liverworts *Bazzania* (Figure 53), *Frullania convoluta* (Figure 54), *Herbertus* (Figure 55-Figure 56), *Lepidozia* (Figure 57), and *Plagiochila* (Figure 16), and the moss *Macromitrium* (Figure 58). Thick canopy branches added more *Frullania* plus the leafy liverworts *Adelanthus* (Figure 59), *Ceratolejeunea* (Figure 60), *Kurzia capillaris* (Figure 61), *Leptoscyphus porphyrius* (see Figure 62), *Syzygiella pectiniformis* (see Figure 63), and *Acrobolbus latus* (Figure 64).

Figure 64. *Acrobolbus laxus*, a species that occupies thick branches in the canopy of the Monteverde, Costa Rica, cloud forest. Photo by Jan-Peter Frahm, with permission.

Mosses of the canopy included *Acroporium pungens* (Figure 65), *Bryum capillare* (Figure 66), *Campylopus arctocarpus* (Figure 67), *Leucobryum giganteum* (Figure 68), *Leucoloma cruegerianum* (Figure 69), *Pilotrichella flexilis* (Figure 11), *Squamidium nigricans* (see Figure 70), and *Syrrhopodon lycopodioides* (Figure 71) (Gradstein *et al.* 2001). Some moss species were generalists: *Toloxis imponderosa* (Figure 72-Figure 73), the pendent *Phyllogonium* (Figure 40), and *Cheilolejeunea filiformis* (see Figure 74), occurring in both the canopy and the understory. The fine twigs in the outer canopy supported communities of the moss *Daltonia gracilis* (see Figure 75) and many small species of the leafy liverwort family *Lejeuneaceae* (Figure 31, Figure 74). And of course the *Lejeuneaceae* predominated on leaves, especially in the understory. These *Lejeuneaceae* included *Cololejeunea* (Figure 76), *Cyclolejeunea convexistipa* (Figure 77), *C. peruviana* (Figure 78), *Drepanolejeunea* (Figure 79), and *Odontolejeunea lunulata* (Figure 80). Overall, 52% of the species are exclusive to the canopy and 20% to the forest understory.

The epiphytic biomass and the associated canopy humus and canopy water storage capacity vary greatly among old-growth tropical montane cloud forests (Köhler *et al.* 2007). Köhler and coworkers compared the epiphytes in an old-growth cloud forest and a 30-year-old secondary forest on wind-exposed slopes in the Cordillera de Tilarán (Figure 81) in northern Costa Rica where bryophytes were the dominant epiphytes. Epiphyte biomass and canopy humus of the old-growth forest (16,215 kg ha⁻¹) greatly exceeded that of the secondary forest (1,035 kg ha⁻¹). These old-growth forests held water contents of 36%-418% of their dry weights. Stand water storage of the non-tracheophyte epiphytes in the secondary forest was only 0.36 mm, compared to 4.95 mm in the old-growth forest. The bryophytes experienced more dynamic wetting and drying cycles when compared to canopy humus.

Figure 81. Monteverde, Costa Rica, cloud forest, Cordillera de Tilarán. Photo by Peter Andersen, through Creative Commons.

Bubb *et al.* (2004) suggested that bryophytes could serve as indicator species to map the distribution of cloud forests. Because the cloud forest bryophyte species are so sensitive to levels of atmospheric humidity, many have very restricted habitat requirements.

In the Pacific region, many tropical montane cloud forests occur as isolated patches on peaks of volcanoes or rugged upland ridges (Merlin & Juvik 1995). These typically have high rainfall, but also receive "horizontal precipitation" from wind-driven cloud water.

Nadkarni and Solano (2002) expressed concern that climate change models predict reduced cloud water in the tropical montane forests. This could greatly reduce the number of cloud forests in the world. They tested the effects of reduced cloud water on epiphytes by transplanting them, along with their arboreal soil, from the upper cloud forest trees to trees at slightly lower elevation where less cloud water was available. There were no transplantation effects among the controls that remained in the cloud forest. However, those transplanted to the lower elevations had significantly higher leaf mortality, lower leaf production, and reduced longevity. Although these were predominately tracheophytes, it raises the question of survivability of bryophytic epiphytes as well.

Sillett *et al.* (1995) demonstrated a reduction in species when comparing bryophytes in inner tree crowns of *Ficus tuerckheimii* (Figure 82) isolated in a pasture (76 species) with those from an intact cloud forest (109 species) in Costa Rica. Of these, 52 species occurred only on the intact forest trees, whereas only 18 were exclusive to the pasture trees. The intact forest similarly had significantly higher bryophyte species richness, cover, and frequency of **pendants, tall turfs, tails, and fans**. The isolated pasture tree epiphytes experienced higher rates of evaporation and more sunlight compared to those on forest trees. This corresponded with a desiccation gradient from the intact forest to the isolated trees.

Figure 82. *Ficus tuerckheimii*, a species that has more inner crown epiphytes in the forest than when the tree is in the open. Photo by Dick Culbert, with online permission.

Additional studies include those on the microclimate and ecology (Baynton 1968) and ecology of leafy liverworts (Fulford *et al.* 1971a, b) of Puerto Rican cloud forests.

As in so many other studies, Gradstein *et al.* (1977) found "numerous" species of **Lejeuneaceae** (Figure 31, Figure 74), as well as **Plagiochilaceae** (Figure 16). Characteristic species were *Lepicolea pruinosa* (see Figure 83), *Riccardia fucoidea* (Figure 24), and *Scapania portoricensis* (see Figure 84), as well as multiple species of *Bazzania* (Figure 53), *Frullania* (especially **pendulous** species of the section *Meteoriopsis*; Figure 54), *Herbertus* (Figure 55-Figure 56), *Lepidozia* (e.g. *L. wallisiana*; see Figure 57), *Lophocolea* (Figure 45), *Metzgeria* (Figure 36), and *Radula* (Figure 33).

Mount Kenya

Mount Kenya (Figure 85-Figure 86) is the highest mountain in Kenya (5,199 m), exceeded in Africa only by Mount Kilimanjaro (Figure 87). The wettest climate on the mountain is the lower southeastern slopes where the predominating weather system comes from the Indian Ocean (Wikipedia 2018b). This area is dominated by very dense montane forest. The mountain experiences two distinct wet seasons and two distinct dry seasons. Hedberg (1969) described the mountain as having winter every night and summer every day – a challenging climate for most organisms. See also Chamberlin and Okoola (2003) for a discussion of the rainy and dry seasons in eastern Africa.

Figure 86. Near timberline forest with mosses, Mt. Kenya. Photo by Mehmet Karatay, through Creative Commons.

Figure 87. Mt. Kilimanjaro at Amboseli National Park, Tanzania. Photo by Ninara, through Creative Commons.

The mountain straddles the equator, so in the northern summer the sun shines on the north side of the mountain and in the southern summer it shines on the south side (Wikipedia 2018b). There is only a one-minute difference between the shortest and longest day of the year, a phenomenon that eliminates the possibility of photoperiod as a trigger for life cycle events or preparation for seasonal changes.

The summit of the mountain is alpine, with most of the precipitation occurring as snow (Figure 85). However, frost serves as the primary water source. Between 2,400 m and 3,000 m asl (the lower part of the mountain), moist air rising from Lake Victoria forms clouds over the western forest zone (Clemens *et al.* 1991). Winds carry these clouds to the summit, where they protect the glaciers from melting by screening out direct sun (Hastenrath 1984).

Karlén *et al.* (1999) provide an historic climate perspective based on fluctuations in the glacier on Mount Kenya (Figure 85). Coe (1967) discusses the ecology of the alpine zone of Mt. Kenya. A somewhat recent expedition to Mt. Kenya revealed 10 new taxa, with two being new to all of Africa (Chuah-Petiot & Pócs 2003). These researchers found many protozoa living in the lobules of the leafy liverwort *Colura kilimanjarica* (see Figure 88).

Lowland Cloud Forest

Following the lead of Gradstein (2006) in French Guiana, Gehrig-Downie *et al.* (2011) defined this new type of cloud forest in northern South America, the lowland cloud forest (Figure 89). This type of forest occurs in river valleys in hilly areas where high air humidity and morning fog occur (Gradstein *et al.* 2010; Gehrig-Downie *et al.* 2011). The area is a rich epiphyte habitat in central French Guiana (Gehrig-Downie *et al.* 2011). This is most likely a result of the much longer periods of high relative humidity after sunrise. These researchers found significantly more epiphytic biomass in the lowland cloud forest (59 g m^{-2}) than in the lowland rainforest that lacked fog (35 g m^{-2}). Furthermore, epiphyte cover in the lowland cloud forest exceeded that of the lowland rainforest in all forest height zones (Figure 90).

Figure 90. Abundance of all epiphytes as percentage of bark coverage in lowland cloud forest (LCF - white) and lowland rainforest (LRF - grey) in different height zones (1-6) on the tree; N=24 trees per forest type. Boxes indicate upper and lower quartile of data, unbroken line gives the median, dotted line the mean, and whiskers 95th percentile. Levels of significance with unpaired Student t-tests are shown by asterisks, * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$. Modified from Gehrig-Downie *et al.* 2011.

Gradstein (2006) referred to the lowland cloud forest (400 m) of French Guiana (Figure 89) as a "liverwort hotspot." The species richness here is three times that of the Amazonian lowland forest. He found the species

richness of epiphytic liverworts to be similar to that at 2,000 m asl in the Andes. Daytime fog prevents desiccation, permitting a positive net photosynthesis despite the high temperatures. About 30% of the liverwort species are restricted to the canopy and several are obligate epiphylls. Asexual reproduction in the understory is significantly more common than in the canopy. The greater dispersal ability of canopy species, particularly by spores, may explain the greater distributional ranges of species that occur there.

Following up on their earlier studies, Gehrig-Downie *et al.* (2013) described the species differences between lowland cloud forests (Figure 89) and lowland rainforests (Figure 91) in French Guiana. The species composition differs in all height zones, with three times as many indicator species in the lowland cloud forest. The liverwort richness differs more strongly between these two forest types than among the sampled elevations, with lowland cloud forests sometimes being richer in species than even the montane rainforests. Species restricted to the lowland cloud forest and occurring on more than one tree include *Bazzania hookeri* (Figure 92), *Ceratolejeunea coarina* (Figure 93), *Cyclolejeunea chitonia* (see Figure 77-Figure 78), *Metzgeria leptoneura* (see Figure 36), *Pictolejeunea picta*, *Plagiochila cf. gymnocalycina* (see Figure 16, Figure 94), *P. raddiana* (Figure 94), *P. rutilans* (see Figure 16, Figure 94), and *Radula flaccida* (Figure 95). *Ceratolejeunea cubensis* (Figure 60) is the commonest species, occurring in more than 50% of the plots. In the lowland rainforest and collected on more than one tree, the exclusive species are *Anoplolejeunea conferta*, *Diplasiolejeunea cf. cavifolia*, and *D. rudolphiana* (Figure 96). *Cheilolejeunea adnata* (see Figure 74) was present in 80% of lowland rainforest samples, but only in 40% of the lowland cloud forest samples. Liverwort species richness increased with height zone in both forest types. However, in the lowland cloud forest it was the middle and outer crowns where most species occurred, whereas it was highest only in the middle crowns in the lowland rainforest.

Cloud forest life forms are benefitted if they are able to take advantage of the moisture in the clouds. Even in lowland rainforests, such as those found in French Guiana, the clouds increase the diversity of epiphytic bryophytes. Compared to other lowland rainforests, the lowland cloud forest exhibits higher biomass and cover of bryophytes, especially in the mid and outer canopy. These bryophytes likewise exhibit a greater diversity of life forms. Typical cloud forest life forms such as **tail**, **weft**, and **pendants** are nearly absent in the canopies of the lowland rainforest, but these are frequent in the lowland cloud forests.

Role

Bryophytes have another important role in these cloud forests. Bruijnzeel and Proctor (1995) emphasized the importance of the tropical montane cloud forest in the water cycle, even in headwater areas. This role is especially important during dry periods, supplying water to downstream areas. Nevertheless, they are often neglected in vegetation studies.

While interception of rainfall in the submontane rainforest is high, that in the elfin forest is about 2.5 times higher and accounts for intercepting over 50% of the annual rainfall (Pócs 1980). The most effective of these receptive bryophytes were the leafy liverworts *Bazzania*

(Figure 92), *Plagiochila* (Figure 94), *Frullania* (Figure 54), *Lepidozia* (Figure 57), and *Trichocolea* (Figure 39). These bryophytes maintain a humid environment beneath by nearly continuous dripping (Lyford 1969 – Puerto Rico; Pócs 1980 – Tanzania) and this seems to create the necessary conditions for terrestrial bryophyte growth. In

montane rainforests of the Colombian Andes, at 3370 m, the epiphyte mass, primarily of bryophytes, was 12 tonnes of dry weight per hectare and held considerable rainfall (Figure 97), which was likewise released very gradually through drainage as well as slow evaporation (Veneklaas *et al.* 1990).

Figure 97. The biomass and interception of water by epiphytes, including bryophytes, and tree leaves in the cloud forest, showing their positions in the forest layers in Tanzania. Modified from Pócs 1980.

Martin *et al.* (2011) remind us that the moisture in a cloud forest reduces fire risk. This same cloud immersion fosters the growth of epiphytic bryophytes (Proctor 1982; Frahm & Gradstein 1991). These bryophytes, in turn, serve as sponges that strip moisture from the air and retain it, further lowering the flammability (Bruijnzeel & Proctor 1995).

Ah-Peng *et al.* (2017) reported excellent cloud water interception ability by the bryophytes in the cloud forest on Reunion Island, using *Bazzania decrescens* (Figure 98) and *Mastigophora dicladus* (Figure 99) as study organisms. *Mastigophora dicladus* had the greater ability to intercept water, but *Bazzania decrescens* had a far greater water storage capacity. Despite having less than half the abundance of *M. dicladus*, *B. decrescens* stored more than twice the water per hectare. The two species combined stored approximately 34,500 L ha⁻¹, the equivalent of 3.46 mm rainfall.

Figure 98. *Bazzania decrescens*, one of the bryophytes that intercepts cloud water in cloud forests on Reunion Island. Photo by Jan-Peter Frahm, with permission.

Figure 99. *Mastigophora dicladus*, one of the bryophytes that intercepts cloud water in cloud forests on Reunion Island. Photo by Claudine Ah-Peng, with permission.

In the cloud forests of Papua New Guinea, Norris (1990) found that disturbance could cause serious reduction in the moisture within an epiphytic bryophyte colony. The epiphytes in these tropical cloud forests and rain forests have a much larger biomass than those of temperate forests. He suggested that larger **colonies** might maintain moisture longer than small **colonies**. Furthermore, contiguous clones will allow lateral conduction of water, whereas separated **tufts** result in little if any transfer across the host surface.

That water trapping is not always beneficial to the trees. In places where there are trees, the bryophytes can contribute to their demise. Encircling and hanging from branches, the bryophytes often capture 25% of the precipitation and absorb up to four times their own weight

(Schofield 1985). With this added weight, they can break the branches upon which they rest.

Epiphytes have another interesting role as well in the development of some forest trees. Bryophytes, along with other components (filmy ferns, dead organic matter) of the humus on the branches, provide the moisture and nutrients needed to stimulate adventitious roots, that is, roots that develop from locations other than the base of the stem, in this case from the trunk or branches (Nadkarni 1994b). Using the shrub-tree *Jessia cooperi* (Figure 100), an inhabitant of landslides, she determined that wet epiphytes or nutrient solutions with foam sponges would stimulate the production and growth of adventitious roots, whereas dry epiphytes, distilled water with foam sponges, and dry sponges would not.

Figure 100. *Jessia cooperi*, a species that responds to wet sponges to form adventitious roots, suggesting a possible role for epiphytic bryophytes. Photo by Dick Culbert, through Creative Commons.

As with epiphytes in general, the epiphytes in the cloud forest can provide substrate, water reserves, and nutrient release that are available to tracheophytes. Orchids frequently become established in these mats (Frei 1973).

As with any thick bryophyte mat, the tropical bryophyte assemblages are home for numerous invertebrates. In the cloud forest of Costa Rica, these are likely to include amphipods, isopods, mites, Collembola, larvae, adult beetles, and ants (Nadkarni & Longino 1990). Interestingly, Nadkarni and Longino found that the composition of the fauna was basically the same in the canopy as that on the forest floor, but the ground had a mean density that was 2.6 times as great as that in the canopy, with the exception of ants, which were similar in both.

Subalpine

The sub-alpine (Figure 101) can act like an island, presenting a temperature regime that is more like the Arctic than the tropics. This makes mountaintop extinctions and a

loss of biodiversity a danger under the influence of global climate change (Ah-Peng *et al.* 2014). On Réunion Island, Ah-Peng and coworkers found a relatively high species richness for bryophytes in the subalpine habitats, with diversity peaking at 2750 m asl for the ground-dwellers. They found that the functional richness with elevation differed between ground-dwellers and epiphytes, suggesting differences in the processes that structure these two community types. The ground-dwellers have a higher functional redundancy; the researchers interpreted this to indicate that the ground-dwellers may be more robust than the epiphytes when disturbances occur in this subalpine system.

Figure 101. Tropical subalpine dwarf forest in Peru at 3,200 m asl with Jan-Peter Frahm among the epiphytes. Photo courtesy of S. Robbert Gradstein.

Alpine

Luteyn *et al.* (1999, p. 1; see also Smith & Young 1987) list the different local names applied to the band of vegetation between the upper limit of continuous, closed-canopy forest (**timberline**; Figure 102) and the upper limit of plant life (**snowline**; Figure 103). In tropical regions of Mexico, Central and South America, Africa, Malesia including New Guinea, and Hawaii, this zone typically has tussock grasses, large rosette plants, evergreen shrubs, and cushion plants. These areas have different local names, including *zacatonales* (Mexico, Guatemala; Figure 104), *páramo* (Central and northern South America; Figure 105), *jalca* (northern Peru; Figure 115), *puna* (drier areas of the

altiplane of central Andes; Figure 106), *Afro-alpine* or *moorland* (East Africa; Figure 107), and *tropical-alpine* (Malesia; Figure 108-Figure 109).

Bader *et al.* (2007) examined the role of bryophytes in tree regeneration above treeline in Ecuador (Figure 110). It is difficult for tree seedlings to become established there, and the researchers hypothesized that bryophytes could facilitate that establishment. First, they found that the number of naturally occurring tree sprouts (seedlings, saplings, and ramets) was highest just outside the forest, and decreased with distance to the forest edge. They transplanted seedlings into the alpine vegetation. The forest floor is totally covered with mosses, including species of *Sphagnum* (Figure 111), especially at the forest edge, and has a peaty organic layer of 30-100 cm on top of the dark mineral soil. The transplanted seedlings had negligible growth after 2.5 years, and some decreased in size due to damage of upper parts. Others seemed to be shorter due to the growth of fast-growing forest floor mosses that served as the measurement base. The seedlings that were planted in the mosses were sometimes overgrown by the mosses. The researchers concluded that seedlings can grow among mosses in the forest where that is the only available substrate, but that they are not favored by mosses.

Figure 111. *Sphagnum magellanicum*; the genus *Sphagnum* occurs on the forest floor near treeline in Ecuador. Photo by Michael Lüth, with permission.

In the Neotropics, Gradstein *et al.* (2001a) recognized páramo, Puna, and Zacatonal as the alpine habitats. Smith and Young (1987) noted how few studies existed on tropical alpine bryophytes and emphasized their importance in tropical mountain communities.

Páramo

The **páramo** (sparsely vegetated alpine zone on tops of high mountains of Andes and other high-elevation South American mountains; Figure 112-Figure 114) is generally considered to occur in Venezuela, Colombia, and northern Ecuador, with a pocket in Costa Rica (Luteyn 1999; Daniel Stanton, pers. comm. 4 December 2011). In northern Peru, wetter grasslands are known as **jalcas** (Figure 115). As pointed out by Daniel Stanton (pers. comm. 4 December 2011), the differences in naming may be more political or cultural than a reflection of real differences.

Figure 115. **Jalca** district, Chachapoyas, Peruvian Amazon Region. Photo by Pitxiquini, through Creative Commons.

There is a striking shift in the substrate of bryophytes as one goes up in elevation in many parts of the tropics. Lower elevations, ranging up through the condensation zone and only slightly into the **páramo**, one can find most of the bryophyte cover as epiphytes on trees and shrubs. However, beginning at in the lower montane and increasing dramatically in the páramo, the major bryophytic cover is found on soil and rock for both mosses and liverworts (van Reenen & Gradstein 1983).

Central America enjoys the interesting flora that is a product of influence from both North and South America. In the Cordillera de Talamanca of Costa Rica, Holz (2003) and Holz and Gradstein (2005) identified 191 liverworts, 209 mosses, and 1 hornwort. Of these, 128 liverworts, 122 mosses, and 1 hornwort occur in the oak (*Quercus*) forests. The bryophytes are represented by proportionally more tropical species than are the tracheophytes. In the páramo, by contrast, the bryophyte flora is more similar to that of temperate regions. There are fewer endemics than are found in the oak forests.

Table 1. Ten largest families and genera of páramo mosses and liverworts. From Holz & Gradstein 2005.

Family (no. genera/spp.)	Genus (family) (no. spp.)
Mosses (prepared by Steve Churchill and Dana Griffin III)	
Dicranaceae (17/67) – Figure 3	Sphagnum (Sphagnaceae) (37) – Figure 111

One reason for the low number of bryophyte taxa at lower elevations might be due to nighttime respiratory losses. High nighttime temperatures in the lowlands elevate the loss of CO₂ and prevent the bryophytes from attaining a net positive carbon balance (Proctor 1982; Richards 1984; Frahm 1987, 1990, 1994; Zotz *et al.* 1997; Zotz 1999). This is consistent with observations that the distribution correlates with increased moisture and lower temperatures at higher elevations (Pôrto 1992), permitting more time per day for photosynthetic gain.

Other studies on the páramo include liverwort diversity in the Neotropics (Gradstein 1998) and bryophytes and lichens of the páramo (Griffin 1979). Cleef (1978) described the Neotropical páramo vegetation and its relationship to that of the subAntarctic. Mägdefrau (1983) described bryophyte vegetation in the páramo of Venezuela and Colombia.

Moss Balls

Moss balls, also known as **vagrant plants**, erratic, solifluction floaters, and errant cryptogams (Pérez 1997b), are unattached plants that are blown about by the wind or moved by water or frost-heaving. Because of their movement, they frequently change their upward direction and consequently begin growth in a different direction (Shacklette 1966). This, and the tumbling that can break off extruding parts, forms them into balls. These are somewhat common on bare soils where climate conditions are subarctic, creating lenticular to spherical moss balls that are completely unattached and free to blow about on the snow and ice (Beck *et al.* 1986). These moss balls are particularly abundant in the alpine zone of high mountains of tropical Africa, especially on Mt. Kenya. In that location, the balls are formed by *Grimmia ovalis* (Figure 127-Figure 128). These are formed by continual motion of fragments of cushions that have been broken by frost or by single plants or small aggregations that occur on bare soil. These vulnerable bryophytes can be moved by wind and solifluction that occurs due to nocturnal needle-ice formation and subsequent thawing in the daytime. The outer layer of the balls that are formed is the living part; next is a layer of dead plant sections, whereas the core is a peaty material of disintegrated leaflets, rhizoids, stems, and minute soil particles.

Figure 127. *Grimmia ovalis*, a species that is able to form moss balls. Photo by Michael Lüth, with permission.

Figure 128. *Grimmia ovalis* forming balls that can break away to form moss balls. Photo by Barry Stewart, with permission.

Others, in particular *Marsupella* (Figure 129-Figure 130), occur on small soil buds and nubbins that are common on the ground surface in the high páramo (Pérez 1994). The moss balls are known in many biomes where wind or water create them. In the superpáramo zone, frost-heaving creates such moss balls, as also seen in the fruticose lichen *Thamnolia vermicularis* (Figure 131) and the acrocarpous moss *Grimmia longirostris* (Figure 132) (Pérez 1991, 1994). Members of *Grimmiaceae* seem to be suited to making vagrant populations. Shacklette (1966) reported unattached polsters (known as glacier moss) of *Schistidium apocarpum* (Figure 133) on sandy soil on Amchitka Island, Alaska, where they become detached by wind erosion.

Afro-alpine

In most people's minds, the combination of African and alpine (Figure 134) seems like an oxymoron. Nevertheless, **Afro-alpine** (high mountains of Ethiopia and tropical East Africa, which represent biological 'sky islands' with high level of endemism) zones exist and present unique communities (Hedberg 1964). The *Dendrosenecio* (Figure 135) woodlands present *Breutelia diffracta* (Figure 136), *B. stuhlmannii* (Figure 137), *Brachythecium ramicola*, *Campylopus nivalis* (Figure 138), *Sanionia uncinata* (Figure 139), and *Leptodontium viticulosoides* (Figure 140). The bottom layer is characterized by the mosses *Brachythecium ruderae* (Figure 141), *B. spectabile*, and *Hypnum bizotii*, and the liverworts *Chiloscyphus cuspidatus* (Figure 142), *Lophocolea martiana* (see Figure 45), *Metzgeria hamata* (Figure 143), *M. hedbergii*, *Mylia hedbergii* (see Figure 144), and *Plagiochila haumanii* (see Figure 16, Figure 94).

Figure 144. *Mylia anomala*; *M. hedbergii* is a species of the bottom layer in the *Dendrosenecio* woodlands in the Afro-alpine zones. Photo by David T. Holyoak, with permission.

Older stems of the *Dendrosenecio* (Figure 135) commonly support thick cushions of moss, with lichens being relatively rare (Hedberg 1964). These include numerous bryophyte species, but the moss *Antitrichia curtispindula* (Figure 145-Figure 146) is the most abundant.

Figure 145. *Antitrichia curtispindula* habitat. This species is the most abundant on *Dendrosenecio* in the Afromontane. Photo by James K. Lindsey, with permission.

Accompanying species include the moss *Hypnum cupressiforme* (Figure 147-Figure 148) and the leafy liverworts *Anastrophyllum auritum* (see Figure 149), *Lophocolea mollerii* (see Figure 150), *Plagiochila colorans* (Figure 16, Figure 94), and *Radula boryana* (see Figure 151) (Hedberg 1964). These moss mats support several tracheophytes, including *Polypodium moniliforme* var. *rigescens* (see Figure 152), *Poa schimperiana* (see Figure 153), *Cardamine obliqua* (see Figure 154), *Arabis pterosperma* (Figure 155), and juvenile *Senecio* sp. The ground layer has a nearly continuous carpet of mosses that also cover boulders and decaying stems of *Senecio/Dendrosenecio* and *Lobelia* (Figure 156). The important bryophytes in these carpets include the mosses *Brachythecium spectabile* (see Figure 141), *Breutelia diffracta* (Figure 136), *Hylocomium splendens* (common in boreal forests; Figure 157), *Pogonatum urnigerum* (Figure 158), *Syntrichia cavallii* (see Figure 159), and the liverwort *Metzgeria hamata* (Figure 143). Stones typically had a thin cover of *Homalothecium sericeum* (Figure 160). Many additional species were identified on the *Dendrosenecio*. The dominant *Sphagnum* species in the sedge (*Carex*) peatland was *S. strictum* subsp. *pappeanum* (Figure 161), with additional species on and among the grass tussocks.

Summary

The cloud forests have dwarfed trees that are typically covered with bryophytes. Seasonal variation in rainfall in cloud forests can be low or high. **Pendent** bryophytes and **fans** effectively trap water droplets and expose maximum surface area to the light; bryophytes can intercept over 50% of the annual rainfall in cloud forests. Water conservation within the bryophytes is facilitated by elastic cell walls. **Fan** species have low light saturation and low compensation points. Because of the high moisture requirements, the bryophyte species are often restricted to these cloud forests.

Liverworts typically outnumber mosses, but mosses can contribute 54-99% of the biomass. Whereas this biomass is relatively low compared to woody biomass, the bryophytes can contribute 45% of the nutrients through nitrogen fixation and entrapment of nutrients from the air, fog, and precipitation.

Dispersal may occur by fragments, and these are more successful when landing among epiphytes. **Tall turfs** and **smooth mats** predominate in crowns. **Meteoriaceae**, **Phyllogoniaceae**, **Frullania**, and **Taxilejeunea** are the most common taxa on horizontal branches of small trees and shrubs. These are among the typically **perennial shuttles** and **perennial stayers** that dominate the life strategies. Mosses predominate on the ground, liverworts as epiphytes. Instead of the typical **Lejeunea**, **Plagiochila** predominates among the epiphytes at Monteverde, Costa Rica. Nevertheless, the **Lejeuneaceae** is common. Thallose liverworts are common on logs.

Lowland cloud forests are a recent discovery and have a similar high humidity to mountain cloud forests and a species richness often exceeding them. Life forms such as **tail**, **weft**, and **pendants** are nearly absent in the canopies of the lowland rainforest, but these are frequent in the lowland cloud forests. Bryophytes play a major role in the water cycle, with **Bazzania**, **Plagiochila**, **Frullania**, **Lepidozia**, and **Trichocolea** maintaining a humid environment beneath by nearly continuous dripping.

The canopy bryophytes serve to trap dust and contained nutrients, hold moisture, and in some cases provide rooting media. Their cushions hold massive amounts of water, thus maintaining a humid environment long after rainfall ceases. This minimizes fire danger. Unfortunately, their weight sometimes causes the branches to break. The bryophytes also provide habitat for a number of invertebrates.

The subalpine and alpine areas can act as islands because most of their species cannot grow at lower elevations. As one goes up into the alpine region, bryophytes are increasingly found on the soil and rocks. Glaciers and windy alpine tundra provide conditions that create moss balls that blow about on the substrate. Other moss balls are created by and carried by **solifluction** – movement by water. Members of **Grimmiaceae** are particularly common among these moss balls.

Acknowledgments

My appreciation goes to Noris Salazar Allen for her efforts to make this chapter reliable and up-to-date. Her helpful discussions kept me going on this part of the world I know so little about.

CHAPTER 8-11

TROPICS: HYDRIC AND XERIC HABITATS

Figure 1. Várzea in Brazil. Photo by D. N. Santos, through Creative Commons.

Inundated Forests

The classification of inundated forests has been inconsistent even by botanists, particularly in different regions (Prance 1980), making descriptions of the vegetation based on literature difficult and confusing. Prance divided these forests into periodically inundated (seasonal várzea, seasonal igapó, mangrove, tidal várzea, flood plain forest) and permanently waterlogged (permanent white water swamp forest, permanent igapó).

Inundated forests are forests that are constantly or periodically in water and include the **igapós** (Figure 2-Figure 3) and **várzeas** (Figure 1, Figure 7) (Pires & Prance 1985). These flood forests cover 2% or more of Brazilian Amazonia, excluding the rivers themselves. For example, the palm *Astrocaryum jauari* is, in various places, flooded 30-340 days a year (Piedade *et al.* 2005, 2006). The **igapós** are black and clearwater areas, whereas the **várzeas** are muddy waters. In the black and clearwater areas, the **igapó**

gives the water a golden appearance (Figure 4) (Pires & Prance 1985). In flood season, the igapó trees are flooded so that their trunks are completely submerged (Figure 5), permitting one to canoe through the canopy (Figure 6).

Figure 2. Diagram of igapó showing water level fluctuation for a mound of trees. Modified from Piedade *et al.* 2006.

Várzea and Igapó Forests

The classification of Amazonian floodplains is based on water and vegetation types (Ferreira *et al.* 2005, 2013). The **igapó** (Figure 8) and **várzea** (Figure 1, Figure 7) are the most common of these. The **várzea** is a seasonally whitewater-flooded forest growing along rivers in the Amazon. The **igapó** forests are seasonally inundated with freshwater and typically occur along the lower reaches of rivers and around freshwater lakes, whereas the **permanent igapó** forest is in water year-round, but with fluctuating water levels.

Using 100 plots, each of 20 x 20 m, within 4 hectares, Ferreira and coworkers (2013) identified all trees and lianas greater than 10 cm diameter at breast height. They identified a total of 97 species, with 75 in igapó and 48 in várzea forests. Only 26 species occurred in both forests, indicating that these are distinct forests. The várzea forests have more soil nutrients, more light availability, and greater natural disturbance, perhaps helping to explain the plant diversity differences.

Figure 8. Igapó in Brazil. Photo by Lisa Cyr, through Creative Commons.

Cerqueira *et al.* (2017) studied the epiphytic bryophytes on *Virola surinamensis* (baboonwood; Figure 9) in igapó (Figure 8) and várzea (Figure 7) forests in the Caxiuanã National Forest. They found a greater richness in the igapó forest (44 species) compared to that of the várzea forest (38 species) (Figure 10). Furthermore, the composition of the bryophyte communities differed between the várzea and the igapó, but did not differ between dry and rainy periods. Although Cerqueira *et al.* (2016) studied only seven species in detail, two species were associated with the forest type and two species to the seasonality of flooding. They identified 54 bryophyte species in 502 samples; 34 were fertile. Sexual reproduction predominated over asexual (Figure 10).

Figure 10. Reproduction of bryophytes in inundated forests. Numbers refer to number of species. Modified from Cerqueira *et al.* 2016.

Lopes *et al.* (2016) compared the bryophyte communities as they relate to degrees of flooding in the igapó and várzea. They sampled eighteen transects each in the igapó and várzea forests of São Domingos do Capim, Pará State, Brazil. As in many rainforest studies, they found that the leafy liverwort family **Lejeuneaceae** (Figure 28) was the predominant family, with 63 species. Among the mosses, the **Calymperaceae** (Figure 11, Figure 30) had the most species, with 8 species. In total, they reported 118 bryophyte species, 82 liverworts and 37 mosses. Live bark was the most colonized substrate, with 45 species exclusive to it, but 101 species in total on bark. Decomposing bark followed, with 66 species, 16 of which were exclusive to it.

Floodplains and Mangrove Forests

Mangrove forests and floodplains are subject to inundation by salt water (Pires & Prance 1985). They are species-poor and typically quite uniform. Among the primary tree species is the mangrove, *Rhizophora mangle* (Figure 12).

Figure 11. *Calymperes tenerum*, one of the common species on mangroves in eastern Thailand. Photo from Auckland Museum, through Creative Commons.

Figure 12. *Rhizophora mangle*, a primary species of the mangrove forest. Photo by Steve Hillebrand, through public domain.

In Thailand there are about 40 tree species in the mangrove forests (Thaithong 1984). Among these, only 10 species support epiphytic bryophytes. Thaithong found only 5 species of mosses and 21 species of leafy liverworts. *Rhizophora apiculata* (Figure 13) was the most favorable phorophyte for bryophyte species richness, with 23 bryophyte species found on this host. She found 22 of the 111 specimens of bryophytes belong to only 5 species of mosses [*Calymperes tenerum* (Figure 11), *Calymperes hampei*, *Octoblepharum albidum* (Figure 14), *Leucophanes albescens* (see Figure 15), and *Dixonia orientalis*]. The remaining 89 specimens were represented by 21 species of leafy liverworts in the genera *Frullania* (Figure 26), *Lejeunea* (Figure 16), *Acrolejeunea* (Figure 17-Figure 18), *Mastigolejeunea* (Figure 19), *Lopholejeunea* (Figure 20), *Pycnolejeunea* (Figure 21), *Thysananthus* (Figure 22), *Schiffneriolejeunea* (Figure 23), *Caudalejeunea* (Figure 24), and *Cololejeunea* (Figure 25). The most common bryophytes, occurring in both the eastern and western mangrove forests, were *Frullania meyeniana* (Figure 26), *Acrolejeunea fertilis* (Figure 27), *Cheilolejeunea intertexta* (Figure 28), and *Lopholejeunea subfusca* (Figure 29), all leafy liverworts and all but *Frullania* in the *Lejeuneaceae*. In the eastern mangrove forests, the moss *Calymperes tenerum* (Figure 11) is also common, whereas in the western mangroves *Calymperes erosum* (Figure 30) is common.

Frangi and Lugo (1992) used 10-year-old wooden stakes to examine bryophytes on the microtopographic gradient of a floodplain forest in the Luquillo Experimental Forest, Puerto Rico. They assessed biomass and nutrients, finding 210-1400 kg ha⁻¹ of ash-free biomass. Nutrient levels for bryophytes in the floodplain floor in kg ha⁻¹ were N (9.1), P (0.5), K (3.3), Ca (1.7), Mg (1.7), Mn (0.33), Fe

(11.6), and Al (13.8). These accumulations are in the same order of magnitude as those of the fine litter, suggesting passive accumulation. On streambank slopes or slopes of tree mounds, the biomass and nutrient accumulation were greater than in other microhabitats. Frangi and Lugo concluded that the floodplain bryophytes serve as biotic filters of flood waters, helping in retention of nutrients in these habitats.

Studies on bryophytes of tropical floodplains and mangrove forests seem to be minimal. Yamaguchi *et al.* (1987) listed the terrestrial bryophytes in mangrove forests of Japan. Windolf (1989) analyzed the bryophyte species in sub-tropical mangroves in southern Queensland, Australia. Windolf made 337 collections and described the host-substrate relationship, comparing bryophyte occurrences to those on the adjacent non-mangrove trees. There seems to be an absence of ecological studies for this habitat.

Hydropogon fontinaloides occurs in periodically inundated locations in the Orinoco and Amazon River floodplains (Mägdefrau 1973).

Pirizal

The **pirizal** vegetation occurs only in small, restricted areas. These are shallow lakes or puddles and the water is stagnant, dark, and transparent. This tropical habitat is not typically a habitat for bryophytes.

Peatlands

Gates (1915) reported on *Sphagnum* (Figure 31-Figure 33) bogs in the tropics, noting that these had only been described from higher altitudes. Eddy (1977) provided a treatment of the *Sphagnum* species of tropical Asia.

McQueen (1991) considered the *Sphagnum*-dominated peatlands in southern Ecuador to be similar to the intermediate or transitional poor fens in the Northern Hemisphere, based on levels of pH, conductivity, and concentrations of Fe, K, Mg, Mn, Na, and P. Species included *S. magellanicum* (Figure 31), *S. recurvum* (Figure 32), *S. sancto-josephense*, and *S. denticulatum* (Figure 33).

Figure 31. *Sphagnum magellanicum*, a species found in *Sphagnum*-dominated peatlands in southern Ecuador. Photo by Michael Lüth, with permission.

Figure 33. *Sphagnum denticulatum*, a species found in *Sphagnum*-dominated peatlands in southern Ecuador. Photo by Michael Lüth, with permission.

Wolfe and McQueen (1992) noted that few tropical studies of *Sphagnum* (Figure 31-Figure 33) habitats had been published and that these were restricted to the páramo in the northwestern part of South America. Cleef (1981) distinguished four kinds of *Sphagnum* bogs in the Cordillera Oriental of Colombia, distinguished on the basis of vegetation, pH, altitude, and peat depth. In addition, Cleef described *Sphagnum* habitats including wet seeps, peaty lake shores, floating mats, and boggy glacial valleys at 3,600-3,850 m asl.

Peatlands are not always *Sphagnum* (Figure 31-Figure 33) habitats. In the high elevation tropical Andes of Colombia, similar conditions to those of *Sphagnum* bogs prevail, but these peatlands are *Distichia muscoides* (Juncaceae – rushes; Figure 34) cushion bogs. These cushions provide similar function and structure to those of *Sphagnum* in boreal and austral regions (Cleef 1981; Fritz *et al.* 2011). Even the dead parts of these cushions fall to the bottom of the pool and are converted to turf, as does *Sphagnum* (Cuatrecasas 1968). In the high Andes, such cushion plants are restricted to areas with poor drainage or that have a positive water balance (Cleef 1981; Kleinebecker *et al.* 2010). Benavides *et al.* (2013) concluded that cushion plants are "capable of reducing

methane emission on an ecosystem scale by thorough soil and methane oxidation," whereas *Sphagnum* lawns had substantial methane emissions. These mountaintop peatland habitats are in danger of extinction under most climate change scenarios (Colwell *et al.* 2008; Ruiz *et al.* 2008).

Figure 34. *Distichia muscoides*, a member of the rush family Juncaceae that resembles moss cushions and is forming a cushion bog like those found in the Andes. Photo by Sergej – Bofedal, through Creative Commons.

Likewise, despite geographic differences, the niche width and overlap values of *Sphagnum* (Figure 31, Figure 35) species in tropical Costa Rica are similar to those for *Sphagnum* species in North America (McQueen 1995). In Costa Rica, *S. magellanicum* (Figure 31) and *S. sparsum* have the broadest niche widths. Despite its relatively narrow niche with, *S. sancto-josephense* is one of the most common *Sphagnum* species accompanying the other two. The niche overlap values are high, except for that of *S. platyphyllum* (Figure 35). This species occurs in habitats rich in iron. The pH, conductivity, and concentrations of Ca, Fe, K, Mg, Mn, Na, and P in these peatlands are similar to those of the páramo habitats in South America.

Figure 35. *Sphagnum platyphyllum*, a species with small niche overlap in Costa Rica. Photo by Michael Lüth, with permission.

In Bolivia, McQueen (1997) determined that, based on pH, conductivity, and concentrations of Ca, K, Mg, Na, and P, the *Sphagnum* habitats in páramo and cloud forests of Bolivian Andes are ombrotrophic. In these habitats, the *Sphagnum* forms small, scattered carpets. The species include those from Ecuador and Costa Rica. Common species are *S. alegrense*, *S. boliviae*, *S. cuspidatum* (Figure 36), *S. magellanicum* (Figure 31), *S. oxyphyllum*, *S. recurvum* (Figure 32), *S. sancto-josephense*, and *S. sparsum*.

Figure 36. *Sphagnum cuspidatum*, a common species in the páramo and cloud forests of the Bolivian Andes. Photo by Michael Lüth, with permission.

Bosnian *et al.* (1993) described cushion mires in the páramo. Two types are dominated by tracheophytes, with *Campylopus reflexisetus* (Figure 37) occurring on the cushions. Two are dominated by bryophytes. The mosses *Sphagnum sparsum*, *Breutelia* sp. (Figure 38), and *Campylopus cuspidatus* var. *dicnemoides* (Figure 39) dominate one of these, and the leafy liverwort *Lophonardia laxifolia* along with the tracheophyte *Cortaderia sericantha* (Figure 40) dominate the other. The *Sphagnum sparsum* type requires higher conductivity of ground water, higher NO₃ and PO₄ levels, and lower Fe levels. The *Lophonardia laxifolia* type requires lower levels of K and Al. A fifth type is dominated by submerged *Sphagnum cyclophyllum* (Figure 41), whereas the sixth has only the aquatic vegetation of *Equisetum bogotense* (Figure 42) and algae. Moss cover is low in the water-filled depressions among the cushions.

Liu *et al.* (2014) examined population structure of *Sphagnum tumidulum* (Figure 43) on tropical Reunion Island. Using genotypes at 10 microsatellite loci, they determined the species to be highly variable. They identified 31 multilocus genotypes. This variability suggests that sexual reproduction is successful on the island, although capsules have not been found. On the other hand, gene flow among populations appears to be very limited.

Oxygen deficiency is important for the survival of *Sphagnum* spores (Figure 44) (Feng *et al.* 2018). After 60 days of storage, those spores that experienced oxygen injection had lower germinability than those that lacked it. High pH further diminished the germinability. These requirements make *Sphagnum* peat suitable substrate for retaining viable spores.

Aquatic

In the tropics, aquatic bryophytes grow in periodically inundated habitats such as river beds, marshes, and waterfalls (Gradstein *et al.* 2018). Permanently submerged bryophytes are rare, occurring primarily at high altitudes. Their modifications of morphological traits (de Winton & Beever 2004; Rankin *et al.* 2017), sometimes induced by changing water conditions, make identification difficult.

Lowland tropical habitats are especially challenging for bryophytes. Because the bryophytes are continuously hydrated, they continue respiration even when the temperatures are high. This results in net carbon loss as respiration exceeds photosynthesis, especially in low light conditions.

The red-listed liverwort *Colura irrorata* (Figure 45) was known only from its type collection from the Ecuadorian Andes in 1857 (Gradstein *et al.* 2004). But Gradstein and coworkers found the species along two tributaries of the Rio Pastaza, Ecuador. It is in fact abundant along the Rio Topo, where it lives on the periodically submerged *Cuphea bombonasa* (Figure 45) shrubs along with the rare *Myriocoleopsis gymnocolea* (see Figure 46). In the Ecuadorian Andes, *Colura irrorata* occurs almost exclusively on the small, woody subshrub *Cuphea bombonasa* where it is very close to torrential water (Gradstein & Benitez 2014). Three other rare rheophytic bryophytes [*Lejeunea topoensis* (see Figure 47), *Myriocoleopsis gymnocolea*, and *Sematophyllum steyermarkii* (see Figure 48)] typically occur with it. The species *Colura irrorata* is distinguished by a very high number of clustered gynocidia as well as numerous antheridia per male bract (Gradstein *et al.* 2004).

Rheophytes

Our knowledge of bryophytic **rheophytes** (aquatic plant that lives in fast moving water currents) in the tropics is somewhat limited. It is greater for Asia than for Africa or South America (Shevock *et al.* 2017). In Malesia, studies of floristic works have elaborated the bryophytes of such habitats (Koponen & Norris 1983; Eddy 1988, 1990, 1996). In Borneo Island, bryophytes are species rich above 1,000 m asl. In lower elevations, heavy deposits of sediments can be detrimental to rheophytic bryophytes.

The seemingly ever-present **Lejeuneaceae** even ventures into rheophytic habitats. Reiner-Drehwald (1999) reported *Potamolejeunea polyantha* [now considered to be a subgenus of *Lejeunea* (Gradstein & Reiner-Drehwald 2007)] as a rheophyte from South America, noting that it was poorly known.

At higher elevations, one can find *Neckeropsis beccariana* (see Figure 49), *Thamnobryum ellipticum* (see Figure 50), and *Fissidens beccarii* (see Figure 51) on boulders; *Calymperes tahitense* (see Figure 52) occurs on hardwood branches or exposed tree roots; and *Sclerohypnum littorale* on branches of rheophytic shrubs (Akiyama 1992a). In a separate paper, Akiyama (1992b) described the morphology and ecology of these rheophytes. Along the river and streambanks, one can find carpets of bryophytes that are actually rheophytic, surviving high water levels and rapid flow (Ma *et al.* 2014). Above this flooding zone, the same shrub species lack these rheophytic bryophytes. In many areas of the tropics, these bryophytes are submerged multiple times through the year, especially during monsoon season.

Despite the cosmopolitan nature of many rheophytes in the temperate zone, new tropical species are still awaiting exploration. For example, Shevock *et al.* (2011) named *Yunnanobryon* as a new genus of rheophytic moss from southwest China. *Yunnanobryon rhyacophilum* (Figure 53-Figure 54) occurs in fast-flowing rivers. As is typical of mosses in fast-flowing water, it is pleurocarpous. It is slender with stoloniform primary stems and intricately much-branched secondary stems that become flagellate-attenuate at the tips.

Figure 54. *Yunnanobryon rhyacophilum* from a stream in Yunnan, China. Photo by Li Zhang, with permission.

Neotropical bryophyte families with at least some species that can be found as rheophytes include the mosses **Amblystegiaceae** (Figure 78, Figure 81), **Andreaeaceae** (Figure 55), **Brachytheciaceae** (Figure 56), **Fissidentaceae** (Figure 51), **Hydropogonaceae**, **Leucomiaceae** (Figure 57), **Pilotrichaceae** (Figure 58), **Pottiaceae** (Figure 86-Figure 87), **Seligeriaceae** (Figure 76), **Sematophyllaceae** (Figure 48), **Sphagnaceae** (Figure 31-Figure 33, Figure 35-Figure 36), and the liverworts **Aneuraceae** (Figure 73), **Balantiopsidaceae** (Figure 70), **Cephaloziellaceae** (Figure 59), **Fossombroniaceae** (Figure 62-Figure 63), **Jungermanniaceae** (Figure 75), **Lejeuneaceae** (Figure 27-Figure 29), **Lophocoleaceae** (Figure 60), and **Pelliaceae** (Figure 61) (see Mägdefrau 1973; Griffin *et al.* 1982; Bartlett & Vitt 1986; Gradstein & Vána 1999; Reiner-Drehwald 1999; Gradstein *et al.* 2001a, 2004, 2011; Gradstein & Reiner-Drehwald 2007; Hedenäs 2003; Crandall-Stotler & Gradstein 2017). Permanent submergence is less common in the tropics compared to temperate and Arctic zones (Gradstein *et al.* 2018).

Gradstein and Reiner-Drehwald (2007) described a new rheophytic liverwort, *Lejeunea topoensis* (Figure 16), from the Andes in Ecuador and southern Brazil. Crandall-Stotler and Gradstein (2017) found a new riverine species in Ecuador, *Fossombronia jostii* (Figure 62). It seems to be restricted to limestone boulders, where one can also find *F. texana* (Figure 63) and *F. wrightii*. These species experience major flooding events that appear to wipe out the entire population, but given a little time, these species return, regenerating from remaining shoot apices of plants that have otherwise been killed by the flooding.

Figure 63. *Fossombronia texana*, one of the species on the limestone rocks in Ecuador. Photo by Bob O'Kennon, through Creative Commons.

Racomitrium lamprocarpum (= *Bucklandiella lamprocarpa*; Figure 64) is a rheophytic moss from the central and northern Andean countries (Bednarek-Ochyra 2015). Ochyra concluded that *Racomitrium bartramii* should be included within this species. *Racomitrium lamprocarpum* is an austral cool-adapted species that has spread deep into the tropics, where it finds suitable habitat at high elevations in the Neotropics and in East and Central Africa.

Figure 64. *Racomitrium lamprocarpum*, Cape Horn, a rheophyte in both Africa and the Neotropics. Photo by Juan Larrain, through Creative Commons.

Ochyra *et al.* (1998) reported a new moss species from subtropical Tenerife as *Gradsteinia torrenticola*, considering it to be most closely related to the Andean *Gradsteinia andicola* from Colombia. But instead it was later placed in *Platyhypnidium* (*P. torrenticola*; Figure 65) (Ochyra & Bednarek-Ochyra 1999). In the Neotropics, *Platyhypnidium torrenticola* is known only from a single waterfall.

Figure 65. *Platyhypnidium torrenticola*, a species from waterfall habitats in Colombian Andes. Photo by BBS website, with permission from Barry Stewart.

So why are we seeing so many new species in a relatively restrictive habitat? Gradstein *et al.* (2011) attributed the unusual morphology of river bank species to habitat specialization and isolation. Such is the case for *Cololejeunea stotleriana* (Figure 66) from Ecuador. This species is both rheophilous and epiphytic. It was the first member of the subgenus *Chlorolejeunea* to be found in the Neotropics, with the other known member occurring in Asia. Furthermore, it occurs with the rare mosses *Fissidens hydropogon* (Figure 67) and *Lepidopilum caviusculum* (Figure 68), both previously known only from their type collections 150 years ago. But rarity and new species are probably products of the isolation between mountaintops, with unsuitable habitat in between.

Lakes

Like the rheophytic habitat, Andean and other high-altitude lakes are isolated from those on surrounding mountains by inhospitable habitat surrounding them. Since aquatic bryophytes are transported mostly by fragments, this effectively isolates them.

In high altitude lakes in the Neotropics, one can find the liverworts *Clasmatocolea vermicularis* (Figure 69), *Gymnocoleopsis cylindriformis*, *Herbertus sendtneri* (Figure 83), *Isotachis obtusa* (Figure 70), *Jensenia spinosa* (Figure 71), *Lophonardia laxifolia*, *Marchantia plicata* (Figure 72), *Riccardia cataractarum* (see Figure 73), *Ricciocarpos natans* (Figure 74), and *Syzygiella*

sonderi (see Figure 75) (Gradstein *et al.* 2018; see also Cleef 1981; Gradstein *et al.* 2001b; Hedenäs 2003; Churchill 2018). Mosses include *Blindia gradsteinii* (see Figure 76), *Ditrichum submersum* (see Figure 77), *Drepanocladus* spp. (Figure 78), *Fontinalis bogotensis* (see Figure 79), *Gradsteinia andicola*, *Philonotis andina* (see Figure 80), *Pseudocalliergon* spp. (Figure 81), *Scorpidium* spp. (Figure 82), and *Sphagnum* spp. (Figure 31-Figure 33). Most of the mosses and all of the liverworts also can grow out of water in wet situations. Only the mosses *Blindia gradsteinii*, *Ditrichum submersum*, *Fontinalis bogotensis*, and possibly some *Sphagnum* species are restricted to submergence. *Blindia gradsteinii* is known from only one locality, a small pond at 4,090 m asl in the páramo de Sumapaz in Colombia (Churchill 2016). *Gradsteinia andicola* has been found only once, in a dried-up lake at 3,650 in the same páramo (Gradstein *et al.* 2018). These two rare species suggest that they are restricted by temperature.

In the Andes of Colombia, at 4,120 m asl, Gradstein *et al.* (2018) found a large population of *Herbertus sendtneri* (Figure 83) in a glacial lake. The researchers speculated that a rock-inhabiting population had washed into the lake by vegetative branches or other fragments.

Figure 83. *Herbertus sendtneri*, a species found in a glacial lake of the Colombian Andes. Photo by Michael Lüth, with permission.

In seven páramo lakes above 3,800 m asl on Volcán Chiles, Ecuador, Terneus (2001) found that moss species (not including *Sphagnum*) were the most abundant and most frequent vegetation, exhibiting a 71.4% frequency among the lakes and a 70% frequency among the transects. They provided a mean cover of 26.7% and occupied maximum depths greater than 100 m. They had a wide depth range (>100 m) compared to other vegetation types.

In Lake Titicaca in the Andes on the border of Peru and Bolivia, *Drepanocladus longifolius* (Figure 84) is another deep-water moss (Richards 1984). It is not as deep as the moss occurrences reported by Terneus (2001), but reaches depths to 29 m and dominates one of the submerged vegetation zones in the lake.

Seepage Areas

Volk (1979) reported *Riccia cavernosa* (Figure 85) (a nitrophilous species), *R. runssorensis*, and *R. volkii* from seepage areas around dams in southwest Africa. Similarly, Pettet (1967) reported several species of *Riccia* from seepage areas in the Sudan. In addition, Pettet found *Tortula bogosica* (see Figure 86), *Barbula unguiculata* (Figure 87), *Physcomitrium niloticum* (Figure 88), *Funaria* (Figure 89), and *Bryum* (Figure 90) from such areas.

Xeric Habitats

Subtropical Israel provides us with a glimpse of the importance of climate, particularly water availability. Distribution of bryophytes there depends on climate, altitude, other vegetation, and shelter (Bischler 2002). Israel is one of the drier sites on the Mediterranean, and the low liverwort species richness reflects this fact. Within Israel, species richness of liverworts is lowest in the arid region and highest in the Mediterranean zone. Those liverworts that are able to grow in the arid zone are also able to grow under less severe conditions and have a wide geographic distribution, whereas many of the Mediterranean species are absent in the arid zone, but otherwise widely distributed. The flora of the country tends to be cosmopolitan and no endemics are known.

To succeed in habitats that have long dry periods interrupted by short periods of moisture, bryophytes must be able to recover quickly from desiccation. Di Nola *et al.* (1983) found that the **Pottiaceae** mosses *Tortula brevissima* (Figure 91) and *Trichostomopsis aaronis* (see Figure 92) are able to resume photosynthesis and respiration rapidly after prolonged desiccation.

Furthermore, they suffer little high light intensity damage. The chlorophyll is ready to resume photosynthesis without additional chlorophyll synthesis first. This is true for some temperate species as well, as seen in the Mediterranean moss *Didymodon fallax* (Figure 93), whereas *Homalothecium aureum* (Figure 94) has a slower recovery and is more sensitive to desiccation. But the temperate *Pohlia* (subgenus *Mniobryum*; Figure 95) sp. was unable to survive prolonged desiccation, exhibiting a lack of drought tolerance.

Figure 95. *Pohlia melanodon*; temperate species in this subgenus (*Mniobryum*) are unable to survive desiccation. Photo by Jan-Peter Frahm, with permission.

Frey (1986) noted the large percentage of endemic species in the arid parts of southwest Asia. Notable genera with endemic species include *Tortula* (Figure 86, Figure 91), *Crossidium* (Figure 122), and *Targionia* (Figure 102).

Pócs *et al.* (2007) reported on dry-land communities in Kenya. They described a community of *Mannia capensis* (Figure 96) that was accompanied by *Exormotheca pustulosa* (Figure 97), *Gongylanthus ericetorum* (Figure 98), *Plagiochasma rupestre* (Figure 99), *Riccia congoana* (Figure 100), *Riccia crinita* (Figure 101), and *Targionia hypophylla* (Figure 102), all liverworts. They identified several other associations in the dry lands. *Plagiochasma microcephalum* (see Figure 99) was accompanied by *Asterella cf. linearis* (see Figure 103), *Exormotheca pustulosa*, and *Riccia albolimbata* (Figure 104-Figure 105). *Riccia lanceolata* is widespread in tropical Africa, where it reaches a high diversity. This genus is particularly adapted to the seasonal rain, going dormant, then springing to growth when the rain arises. Other important *Riccia* species include *Riccia microciliata* (Figure 106), accompanied by *Riccia congoana*, *Riccia crinita*, and *Riccia okahandjana* (Figure 107). Widespread species include *Riccia congoana* and *Riccia atropurpurea* (Figure

108), accompanied by *Exormotheca pustulosa*, *Riccia crinita*, *Targionia hypophylla*.

Savannahs

In their study of savannah bryophytes in southwest Nigeria, Makinde and Odu (1994) found little bryophyte diversity. Liverworts were rare.

Oyesiku and Egunyomi (2001, 2002) have explored savannah bryophytes in southwestern Nigeria. They likewise found that mosses were far more common than liverworts in the dry savannah. The intense dryness is unfavorable to liverworts. Tree bark, however, provides some protection, permitting corticolous bryophytes to live in areas with bush burning. On the trees in relatively closed stands, bryophytes, particularly **mat**-forming species, are able to spread from the base to locations under 3 m height. Some of these bryophytes [*Hyophila* (Figure 109), *Erythrodontium* (Figure 110), *Riccia* (Figure 85)] are specialists at specific heights. Generalists with no height preference include the mosses *Fissidens* (Figure 51, Figure 67), *Calymperes* (Figure 11, Figure 30), *Thuidium* (Figure 111), and the leafy liverwort *Lejeunea* (Figure 47). Among these epiphytes, 60% of the mat species are dominant on host trees; the co-dominant tuft species comprise 34%.

Figure 114. *Sematophyllum subpinnatum*, a savannah moss in the Cerrado, Brazil. Photo by Michael Luth, with permission.

Silva Bonfim *et al.* (2018) collected bryophytes from a Cerrado fragment in Caxias, Maranhão, Brazil. This area is mostly savannah. They identified 175 bryophyte samples in 12 families (10 mosses, 2 liverworts), 17 genera (15 mosses, 2 liverworts), and 23 species (21 mosses, 2 liverworts). The **Sematophyllaceae** was best represented (*Trichosteleum subdemissum*, *Sematophyllum subsimplex* (Figure 113), *Sematophyllum subpinnatum* (Figure 114), and *Taxithelium planum* (Figure 115). **Dicranaceae**, **Fissidentaceae** (Figure 51, Figure 67), and **Pottiaceae** (Figure 86-Figure 87, Figure 91-Figure 93) followed with three species each.

Figure 112. Cerrado savannah in Brazil. Photo by Conrado, through Creative Commons.

Figure 115. *Taxithelium planum*, a savannah moss in the Cerrado, Brazil. Photo by Scott Zona, with permission.

Succession

In their study of epiphytes in an Amazonian savannah in Brazil, Gottsberger and Morawetz (1993) noted that lichens and bryophytes have a successional relationship with their host trees. Young trees have lichen dominants. These lichens usually are diminished in older trees and bryophytes assume abundance, apparently supressing the lichens.

Life Cycle Strategies

Makinde and Odu (1994) followed the reproductive cycles of four species [*Archidium ohioense* (Figure 116), *Bryum coronatum* (Figure 117), *Fissidens minutifolius* (see Figure 51, Figure 67), *Trachycarpidium tisserantii*] that reproduce predominately sexually. They found that the protonemata and gametophytes are produced in the field in March-April. Capsule dehiscence and spore dispersal occurs in September-October. The development of gametangia through the completion of dispersal all occur within the rainy season. **Cleistocarpous capsules** (capsules with no operculum and that open irregularly) of *A. ohioense* and *T. tisserantii* do not disperse their spores easily. All species experience only a short period between the formation of sex organs and the dehiscence of the capsule.

Figure 116. *Archidium ohioense*, a species with cleistocarpous capsules and a short period between fertilization and ripe capsules. Photo by Li Zhang, with permission.

Figure 117. *Bryum coronatum*; in the Nigerian savannah, development of gametangia through the completion of dispersal all occur within the rainy season in this species. Photo by Jan-Peter Frahm, with permission.

When long periods of drought are a regular part of the environment, reproduction can be challenging. Spore longevity would help to solve this problem. However, when Egunyomi (1979) tested spore viability of 20 tropical moss species, only 7 germinated after more than two years of storage, and only 4 species had as much as 50%

germination. Freezing for 1 week or more was detrimental to all 20 species. *Microcampylopus nanus* (see Figure 118) had the highest spore longevity and germination after desiccation. Other species that survived desiccation for at least two years were *Weissia papillosa* (see Figure 119), *Mittenothamnium overlaetii* (Figure 120), and *Weisiopsis nigeriana*. What is interesting is that these four species are from a locality that is persistently wet.

Although we cannot rule out spore longevity, we need to find other means to explain reproductive success in these dry-habitat mosses. During and coworkers (During 1998, 2007; During & Moyo 1999) examined the diaspore bank in a savannah in Zimbabwe. They determined at least 2 hornworts, 10 liverworts, and 22 mosses that emerge from these soil samples. Some of these were in large numbers. Some of these species, such as *Micromitrium tenerum* (Figure 121), were rare or previously unknown in Africa or Zimbabwe. An added advantage for these diaspores is that they are able to survive above-ground burning.

Tropical Deserts

Deserts are not very friendly to bryophytes, and this habitat is likewise unfriendly for bryologists. Tropical deserts are often among the worst of these due to their even higher temperatures. Hence, systematic studies of bryophytes in these habitats are rare. Nevertheless, the guileless bryophytes and their adventurous observers can occur in these inhospitable places.

O'Shea (1997) reported over 3000 taxa of mosses in sub-Saharan Africa. Of these, 77% were considered endemic at the time. Because of the small number of bryologists exploring the vast area of Africa, it may still be a long time before we understand the African flora well enough to know how many of these are truly endemic.

The moss *Crossidium laevipilum* (Figure 122) occurs in semidesert conditions in Kenya, where it is associated with many xeric species (Pócs *et al.* 2007). *Didymodon revolutus* (Figure 123) occurs on vertical volcanic cliffs. This species has both axillary and rhizoidal gemmae, contrasting with American plants that are only known to have axillary gemmae. This species is known as a xerophyte in the desert and semidesert of southern United States, Mexico, Guatemala, and Ecuador.

At the edge of the Tunisian Sahara, Pócs (2007) found the community of *Crossidium laevipilum* (Figure 122)-*Tortula atrovirens* (Figure 124) to be dominant. Only the tips of the plants and apical hair points, if present, extended above the sand. The hair points can protect against UV light and collect moisture. Most of the bryophytes, like these two, are in the **Pottiaceae**. The rock cliffs can support a community dominated by *Grimmia capillata* (Figure 125)-*Tortula revolvens* (Figure 126). The association of *Eucladium verticillatum* (Figure 127-Figure 128) and *Didymodon tophaceus* (Figure 129) occurs only near waterfalls of the Tamerza oasis. North-facing cliff bases provide enough shelter to support *Bryum funckii* (Figure 130)-*Didymodon australasiae* (Figure 131) associations. On the exposed limestone gravel scree and loess cliffs one can find the pioneer community of *Crossidium squamiferum* (Figure 132) and *Aloina bifrons* (Figure 133). The northern part is less extreme in climatic conditions and one can find the *Didymodon australasiae*-*Tortula revolvens* community.

The thallose liverworts in such dry areas are "tiny" and become practically invisible during the dry season, reappearing when the rains arrive. This ability is particularly common in the **Ricciaceae** (Pócs *et al.* 2007). The *Riccia* species (Figure 100-Figure 101, Figure 104-Figure 106) in these dry habitats exhibit 20% endemism while another 20% are widespread, often cosmopolitan xerophytes. Most of the mosses are in the **Pottiaceae** (Figure 122-Figure 123). These xerophytic mosses have crispate, often contorted leaves with inrolled or recurved margins (Kürschner 2004).

Kürschner (2000) described the bryophyte flora of the Arabian Peninsula (Figure 135) and Socotra (Figure 136), much of which is desert. Prior to 1980, no bryophytes were known from the entire peninsula. The bryological flora is characteristic for the monsoon-influenced peninsula, including 1 hornwort, 50 liverworts, and 173 mosses, with many Palaeotropical and Afro-montane taxa. On the other hand, the arid and semi-arid regions, with winter rainfall, are dominated by species that are drought adapted and drought tolerant. These include many **Pottiaceae** and thalloid liverworts that go dormant during the drought.

Later, Kürschner (2003) conducted a phytosociological analysis of the *Riccietum jovet-astii-argenteolimbatae* association as a new association found in the Jabal Arays area of Yemen. This association consists predominantly of *Riccia jovet-astiae* and *Riccia cf. albolimbata* (Figure 104-Figure 105). Kürschner identified this association as being grouped within the alliance of *Mannia androgyna* (Figure 137) with *Barbula unguiculata* (Figure 87). The new association typically occurs on shallow soils that overly volcanic rock outcrops, where it occurs in the understory of *Sterculia africana arabica* (Figure 138) woodland in monsoon-affected areas. The life strategy here is that of a shuttle species with large spores. Thus dispersal is short range. Spores in a diaspore bank help to maintain the presence of these liverworts. Of minor importance is their colonist strategy and they live on the soil where they can go dormant until monsoon season.

Summary

Neotropical floodplains include the **igapó** and **várzea** habitats, seasonally inundated, and supporting different bryophyte communities. Sexual reproduction predominates among the bryophytes. The leafy liverwort family **Lejeuneaceae** predominates in species richness, while the family **Calymperaceae** has the most moss species.

Mangrove forests are limited in bryophyte species because of saltwater. Nevertheless, **Calymperaceae** are among the few moss species present, with **Lejeuneaceae** being the most species-rich among the liverworts. Bryophytes in these floodplains are passive accumulators of nutrients and help to retain them within the floodplain.

Tropical peatlands are effectively restricted to higher altitudes and include some of the well-known high latitude species such as *Sphagnum magellanicum* and *S. recurvum*. *Sphagnum platyphyllum* is common in peatlands rich in iron. Two mire types are dominated by tracheophytes, with the moss *Campylopus reflexisetus* occurring on the cushions. Two are dominated by bryophytes, differing in vegetation with differences in conductivity and nutrients. Genetic variation within species may be highly variable, as seen in *Sphagnum tumidulum* from Reunion Island. At least some *Sphagnum* spores have greater longevity in the absence of oxygen, permitting them to survive in the peat.

Few tropical bryophytes live permanently submerged except at high elevations. In low elevations, high temperatures, low CO₂ levels, and low light intensities result in negative carbon gain. But in the Andes, several rare species are associated with torrential waters.

In **rheophytic** habitats, one can find leafy liverworts in the **Lejeuneaceae**, with a number of moss species on rheophytic shrubs, roots, and rocks where they are seasonally submerged. The absence of tropical studies on rheophytes leaves species awaiting discovery. Nevertheless, a number of families with rheophytic representatives are known.

Glacial lakes may have such species as *Herbertus sendtneri*. These lakes and other high-altitude tropical lakes are isolated by the hot valleys that are unsuitable as vegetative dispersal avenues for bryophytes.

Seepage areas often have species of **Riccia** and mosses that are typical of disturbed areas such as *Barbula unguiculata*, *Funaria*, and *Bryum*.

The tropics create a number of xeric habitats. These have low liverwort diversity but are able to support desiccation-tolerant mosses, particularly members of the **Pottiaceae**. These mosses are able to resume photosynthesis quickly upon rewetting. Among the liverworts, **Riccia** species can become dormant for prolonged periods of time, then expand and resume growth. Among these xeric habitats are savannahs, where liverworts are rare and little diversity is common. Nevertheless, the liverworts **Riccia** and **Lejeuneaceae** can occur as epiphytes. The meager evidence on life cycle strategies suggests that the sexual cycle takes advantage of the short wet periods, with spore dispersal

likewise occurring in wet periods. Some mosses have **cleistocarpous** capsules. Spores in 20 tested species exhibit limited longevity. However, spores seem to survive better in diaspore banks. Deserts, as might be expected, have their highest bryophyte diversity in the **Pottiaceae** and **Ricciaceae**. Canyon and shaded cliffs have a higher diversity.

Acknowledgments

Thank you to Tatiany Oliveira da Silva for her contributions of papers, images, and comments. Her helpful discussions kept me going on this part of the world I know so little about and clarified some of the terminology of the inundated forests. Thank you to Claudine Ah-Peng for helping me obtain an image of *Sphagnum tumidulum*. And my appreciation to all the photographers who have put their images in Creative Commons.

CHAPTER 8-12

TROPICS: ROCK OUTCROPS AND INSELBERGS

JANICE M. GLIME AND TATIANY OLIVEIRA DA SILVA

Figure 1. Inselbergs in Mozambique, Africa. Photo by Ton Rulkens, through Creative Commons.

Rock outcrops and inselbergs provide unique habitats, usually being more xeric than surrounding habitats. An **inselberg** (Figure 1) is distinguished as "those isolated rock outcrops that stand out abruptly from surrounding plains" (Potembski & Barthlott 2012). The term appears to have been introduced by Bornhardt (1900). Both outcrops and inselbergs can differ in rock types, and this can promote different vegetation groupings. Potembski and Barthlott noted that study of the widespread granite inselbergs has been neglected, yet it is "remarkably" rich in plant life. Porembski (2007) identified the three hot spots of inselberg plant diversity on a global scale as southeastern Brazil, Madagascar, and southwestern Australia; the first two of these are tropical.

Barthlott *et al.* (1993) note that the flora of the inselbergs differs almost completely from that of the surrounding area, behaving like islands. They concluded

that the bare rock is covered almost completely by **Cyanobacteria** in French Guyana, but by lichens in the Ivory Coast. Nevertheless, the life forms are similar in the Palaeotropics and Neotropics. It would be interesting to make these same comparisons for bryophytes.

It is interesting that tracheophytes in such dry habitats may mimic some of the traits of bryophytes. These adaptations include forming **mats** and **poikilochlorophyllous** (lose chlorophyll and cease photosynthesis and transpiration when dry) behavior (Porembski & Barthlott 2000). It is incredible that of the approximately 330 species (in only 13 families) of tracheophytes that are desiccation-tolerant, close to 90% occur on inselbergs.

In Brazil, ironstone rock outcrops provide an adverse environment where daily temperatures vary widely, UV exposure is elevated, constant winds are present, and soils

are impermeable and have low water retention with high levels of iron (Peñaloza-Bojacá *et al.* 2018b). Such conditions favor a very rich and endemic community where xerophilic plants thrive.

Rock outcrops are not just bare rock, even in their earliest stages. These topographic differences include shallow depressions that can fill with water (Figure 2), drainage channels (Figure 3), vertical faces with directional N-S exposures (Figure 4), and horizontal plains (Figure 5). In Guinea, mats of *Afrotrilepis pilosa* (Figure 6) create protected habitats, habitats with extremes (*e.g.* Figure 5) that support ephemeral plants, and areas experiencing flushes that have their own distinct vegetation (Porembski *et al.* 1994). Sandstone outcrops of Fouta Djallon in Guinea (Figure 7) are species-rich and have a large number of endemics. Porembski and coworkers suggested this may be due to the combination of vertical differentiation, large area, long-term climate stability, and isolation. The granite inselbergs and **ferricretres** (hard, erosion-resistant layer of sedimentary rock, usually conglomerate or breccia, cemented into a duricrust by iron oxides), on the other hand, lack local endemics and have a lower species richness. The greatest diversity of inselberg vegetation of tropical Africa seems to occur in Tanzania, Malawi, Mozambique, Zambia, Zimbabwe, and Angola.

Inuthail and Sridith (2010) examined the structure of plant communities on the granitic inselberg in Songkhla Province in Peninsular Thailand. They identified seven microhabitat types: rock crevices and clefts (Figure 8), rock falls (Figure 7), shallow depressions (Figure 2), deep depressions, exposed rock slopes (Figure 4), shady flat rocky slopes (Figure 3, Figure 9), and rock platform fringes. They recorded 73 species of tracheophytes, with Orchidaceae, Rubiaceae, and Poaceae predominating. The highest number of plant species occurred on the fringes of the rock platforms where soil conditions and light intensities vary.

Although some researchers disagree about which formations belong to the inselberg category, Porembski *et al.* (1997) considered granitic inselbergs to be present in all the climatic and vegetational zones of the tropics. Because of the harsh edaphic and microclimatic conditions, the vegetation of inselbergs differs greatly from that of their surroundings. The habitats on these rocks can be defined by vegetation groups including cryptogamic crusts, rock pools, monocot mats, and ephemeral flush vegetation. **Stochastic** (randomly determined) environmental disturbances promote greater species richness due to prevention of competitive exclusion. Other processes are deterministic, creating high temperatures and light levels and extended periods of drought. Moss cushions are able to take advantage of seepage water. In West Africa, *Bryum arachnoideum* (Figure 10) is able to take advantage of such wet areas (Frahm & Porembski 1994).

Figure 10. *Bryum arachnoideum*, a moss that colonizes wet seepage areas on rock outcrops in West Africa. Photo by Jan-Peter Frahm, with permission.

Sarthou *et al.* (2009, 2017) described tropical inselbergs as rocky outcrops protruding from a plain landscape. These are hot spots of plant and animal biodiversity that result from the high turnover of species between sites and the presence of organisms mostly

restricted to the inselberg habitat. Thus they are isolated patches of tracheophytic vegetation surrounded by bare rock or cryptogamic vegetation (algae, lichens, and bryophytes).

Sarthou and Villiers (1998) remind us that tropical inselbergs are surrounded by rainforest, but that they have their own special vegetation. They describe six such associations on French Guianan inselbergs. These respond to different environmental characteristics, including local relief, insolation, water availability, and soil depth. Species diversity is low in all of these associations. They found striking similarities in the vegetation units when comparing those of South American and African inselbergs.

It is only recently that ecological studies of bryophytes on inselbergs have emerged. Ribeiro *et al.* (2007) provided a comprehensive summary of vegetation on rock outcrops in Brazil and outlined the three needs they considered most urgent for study:

1. inselbergs and high mountains in the Amazon and the Brazilian northeast
2. long-term studies, which are almost totally unavailable, hindering global change monitoring and assessment
3. national and international networking to speed up scientific production about such habitats.

Frahm (2000) summarized early studies in the volume by Barthlott and Porembski on inselbergs. Valente and Pôrto (2006) described the bryophytes from a rocky outcrop in Bahia, Brazil. Even in 2018, Peñaloza-Bojacá *et al.* (2018a, b) commented on the paucity of bryophyte studies on rock outcrops and inselbergs.

To elucidate outcrop vegetation in the northeastern Brazil, Silva *et al.* (2014a, b) looked at both tracheophytes and bryophytes on rocky outcrops there. They noted that for these small plants, the large outcrops served as islands amid a "sea" of soil, resulting in a floristic composition that results from **stochastic processes** (unpredictable events) at a regional scale. However, such stochastic processes did not show any clear relationship with the communities on a local scale.

Adaptations

Watson (1933) gave an early view of adaptations to terrestrial adaptations of bryophytes. He suggested that these included **cushion** life forms, the arrangement of the leaves to be imbricated or twisted upon drying, hair points or hyaline leaf apices, leaf borders, infolded leaf margins, thickened cell walls, cell size, and papillae. Some store water and others prevent evaporation. Capillarity was accomplished by spaces between leaves, at leaf axils, between leaf folds, and specialized water folds (lobules as in *Frullania*; Figure 11-Figure 12) and storage cells as in *Leucobryum* (Figure 13). Although at that time there was little experimental evidence to support his suggestions, we now find that these traits often describe adaptations of bryophytes of rock outcrops and inselbergs.

Life Cycle Strategies

Life cycle strategies can be particularly important in these severe environments. As noted by Benassi *et al.* (2011) for the desert moss *Syntrichia caninervis* (Figure 14), those in the most extreme environments have lower frequencies of sexual expression, fewer sexual branches per individual, and a lower male:female ratio. Sexual reproduction is infrequent. They suggested that male rarity may be due to a lower desiccation tolerance in males. Males have a higher energetic requirement for their sex expression, and this may make them less tolerant to repeated cycles of hydration and desiccation. While rock outcrops and inselbergs are not deserts, many of their microclimate characteristics are similar, so we might expect similar life cycle restrictions.

Figure 14. *Syntrichia caninervis* (Pottiaceae), a xerophytic moss that has lower frequencies of sexual expression, fewer sexual branches per individual, and a lower male:female ratio. Photo by John Game, through Creative Commons.

Frahm (1996) found that bryophytes from the inselbergs he examined in the Ivory Coast and Zimbabwe had a conspicuous lack of both sexual and vegetative propagules. They lacked both the animal and wind dispersal found in inselberg tracheophytes.

Kürschner (2003) found that the life strategy for the *Riccia* liverwort association on thin soil over volcanic rock in Yemen was that of a **shuttle** species. These liverworts produce large spores with short-range dispersal. Disturbances could result in exposure of these spores that have been stored in the diaspore bank. **Geophytes** (plants with short, seasonal lifestyle and some form of underground storage organ) and colonists also occur, but are of only minor importance.

Kürschner (2006) elucidated the ecology of the **saxicolous** (growing on rocks) *Grimmia ovalis* (Figure 15)-*G. laevigata* (Figure 16)-*G. longirostris* (Figure 18) association on Socotra Island of Yemen. The bryophytes on these sun-exposed, acidic rock formations appear to be mostly endemic and are dominated by *Schlotheimia balfourii* (see Figure 19). The life strategy is that of drought-tolerant **cushions**, **short turf**-forming generative **perennial shuttle species**, **perennial stayers**, and **pauciennial** (short-lived) **colonists**.

In her study of bryophytes on rock outcrops in Brazil, Silva found that most species were monoicous (26 spp. compared to 20 dioicous species) (Silva 2012; Silva *et al.* 2014b). Nevertheless, the three most frequent species were dioicous. But of these three, two rarely produced sporophytes and one had them only occasionally.

Peñaloza-Bojacá *et al.* (2018a) found that asexual reproduction was important for several of the key species of mosses on Brazilian ironstone outcrops. Surprisingly, dioicous mosses had the highest sexual expression and reproductive success, with most of these species having a female bias. Of the 108 species, 70% were reproducing. A total of 50% of the specimens were reproducing either sexually or asexually. Mosses exhibited mostly asexual reproduction, whereas liverworts mostly exhibited sexual reproduction. Of the asexually reproducing species, 31% had gemmae and 69% had other deciduous propagules. Among the dioicous species, the majority had a female bias.

Pôrto *et al.* (2017) specifically studied the life cycle strategies of the widespread moss *Bryum argenteum* (Figure 20) from a rock outcrop in northeastern Brazil. They noted that despite the severe water constraints of the inselbergs, dioicous mosses are able to colonize rock outcrops and inselbergs. Previous researchers had found

that in northeastern Brazilian rock outcrops, only *Bryum argenteum* frequently had sporophytes (Valente & Pôrto 2006; Silva & Germano 2013; Silva *et al.* 2014a, b). This dioicous species has several asexual strategies – axillary bulbils, rhizoidal gemmae (tubers), and caducous shoot apices (Frey & Kürschner 2011), complemented with numerous small spores when it reproduces sexually (Söderström 1994). Despite its asexual options, 93% of the rock outcrop colonies were expressing sex (Pôrto *et al.* 2017). Although there was a slight female bias, the ratio was only 56:44 female to male. The relationship of number of sporophytes to male:female sex ratio is shown in Figure 21.

Figure 20. *Bryum argenteum* with capsules on rock outcrop in Brazil. Photo of Tatiany Oliveira da Silva.

Figure 21. Probability of sporophytes based on sex ratio in *Bryum argenteum*. Modified from Pôrto *et al.* 2017.

So why is *Bryum argenteum* (Figure 20) so productive with sporophytes on the rocks when most other dioicous species are unable to succeed on these rocks? Cronberg *et al.* (2006, 2008) may have the answer. They found that mites are able to disperse the asexual propagules and that springtails (*Collembola*; Figure 22) and possibly mites as well facilitate fertilization. Another factor that may contribute to the success of *B. argenteum* on the rocks and

elsewhere is the ability of antheridia to survive desiccation and rehydration, then to release viable sperm (Shortlidge *et al.* 2012; Stark *et al.* 2016).

Figure 22. *Folsomia candida* (Collembola) on *Ceratodon purpureus* in fertilization study. Photo courtesy of Erin Shortlidge.

Dispersal

Dispersal can limit the species that reach inselbergs because the surrounding vegetation is of a completely different type (Burke 2002a). Frahm and Porembski (1994) considered the inselbergs of western Africa to be refugia for dry-adapted bryophyte species. Burke (2002a) investigated the role of inselbergs in Namibia as refugia for tracheophyte species. These inselbergs are considered to have a high recolonization potential and a high diversity relative to the landscape. Burke found that gene flow and nutrient flow occur from the inselbergs to the surrounding lowlands. The granite inselbergs support longer-lived species of stable communities, whereas the dolerite inselbergs support transient communities of short-lived species. Regional differences relate to climate, with differences in climate and geology contributing. Altitude is likewise an important variable. Species of granite inselbergs are more closely allied to the surrounding habitats than are those of dolerite inselbergs. Burke concluded that conserving groups of inselbergs is more important to conserving their unique species than conserving isolated mountains. "Stepping stone" inselbergs have greater potential for conserving those species with short dispersal ranges.

These principles should likewise apply to bryophytes, but most likely at a greater distance scale. One way that bryophyte dispersal is facilitated to boulders and inselbergs is having a large number of propagule sources nearby. This can be other boulders and inselbergs, but for many species, it is the ability to grow on other types of substrates. Pócs (1982) demonstrated that many of the tropical species of **Meteoriaceae** (Figure 69-Figure 70), **Neckeraceae** (Figure 23-Figure 24), **Pterobryaceae** (Figure 25), **Plagiochila** (Figure 26), and **Lejeuneaceae** (Figure 37) that are typically corticolous (growing on bark) may also be abundant on rocks.

Desiccation Recovery

One area of adaptations that was usually ignored in early studies was physiological adaptations. Lüttge *et al.* (2008) reported strong quenching of chlorophyll fluorescence in the three desiccated bryophytes in their study of three poikilohydric, homiochlorophyllous moss species from sun-exposed rocks of a Brazilian tropical inselberg. Using *Campylopus savannarum* (Figure 27- Figure 28), *Rhacocarpus fontinaloides* (see Figure 29), and *Ptychomitrium vaginatum* (see Figure 30), they concluded that these species have photo-oxidative protection that permits them to live on exposed rocks that experience high light intensity. They achieve this by a reduction of the base chlorophyll fluorescence to nearly zero. Upon rewetting there is a rapid recovery to higher values in the first 5 minutes, requiring more than 80 minutes to reach equilibrium. These adaptations help to define their niches, with *C. savannarum* forming an inner belt and *R. fontinaloides* forming an outer belt around the vegetation. *Ptychomitrium vaginatum*, on the other hand, lives in small cushions on bare rock. Nevertheless, these three species differ little in their reduction of fluorescence or rewetting recovery and have only slight differences in photosynthetic capacity. The researchers suggest that CO₂ acquisition is a greater problem in *P. vaginatum* than in the other two species, with water films causing limitations in CO₂ uptake.

Interactions with Other Plants

As noted by During and van Tooren (1990) as a general principle, bryophyte habitats can be defined by not only the physical environment, but also the tracheophyte vegetation associated with it. Nevertheless, at that time few studies had analyzed the functionality of these interactions.

Tracheophytes on boulders and inselbergs collect soil, provide shade, and retain moisture for longer times than unvegetated areas. Protection by the monocot *Cyanotis lanata* (Figure 31) permits *Archidium* (see Figure 32) to survive on savannah rock outcrops in southwestern Nigeria (Egunyomi 1984; Oluwole & Adetunji 2010). [The naming of this *Archidium* has been problematic, with Egunyomi naming it *Archidium ohioense*, then Frahm and Porembski (1994) determining it to be *Archidium globiferum* in West Africa. However, currently it seems to be considered to be *Archidium acanthophyllum*.] During the rainy season, the annual mosses *Bryum argenteum* (Figure 20) and *Pelekium gratum* (Figure 33) may also appear in this association (Egunyomi 1984).

Figure 33. *Pelekium cf. gratum*, a species that often accompanies *Archidium acanthophyllum* on rock outcrops in southwest Nigeria. Photo by Shyamma L., through Creative Commons.

On these southwestern Nigerian inselbergs, there is a three-member association that illustrates relationships among the moss *Archidium acanthophyllum* (see Figure 32), tracheophyte *Cyanotis lanata* (Figure 31), and lichen *Diploicia canescens* (Figure 34) (Oyesiku & Amusa 2010). Oyesiku and Egunyomi (2004) found a frequency of 50% of occurrences of *Archidium acanthophyllum* with *Cyanotis lanata*, whereas only 20% grew alone and 30% grew with other plants, suggesting some benefit from its association with *C. lanata*. But these two species grow best in somewhat different optima. For *C. lanata*, the optimum pH is 6.7, whereas it is 7.7 for *A. acanthophyllum*. *Cyanotis lanata* density increases and *Archidium acanthophyllum* decreases from March to September, whereas both the *A. acanthophyllum* and *C. lanata* decrease from September to December (Figure 35). This is likely due to the strong increase in temperature of the substrate to 39.6°C in December. Both plants are harmed at temperatures above 50°C. In June and September, the relative humidity above the vegetation increases significantly, with a mean of 79% during the study. Data indicate that *C. lanata* and *A. acanthophyllum* facilitate each other. As noted in other ecosystems (e.g. Richardson 1958; Edward & Miller 1977), thick bryophyte growths can serve as insulation to buffer the temperature of the underlying substrate. Richardson (1958) also noted that bryophytes could reduce evaporation. Both of these properties provide a more favorable environment for the roots of tracheophytes. Oyesiku and Egunyomi (2004) verified that these relationships are true for bryophytes on inselbergs.

Figure 34. *Diploicia canescens*, a lichen that occurs on rock outcrops in southwestern Nigeria. Photo by Jymm, through public domain.

On these inselbergs in southwestern Nigeria, the lichen *Diploicia canescens* (Figure 34) maintains a consistent density throughout the year (Oyesiku & Amusa 2010). On the other hand, the monocot *Cyanotis lanata* (Figure 31) and the moss *Archidium acanthophyllum* (see Figure 32) coexist, but in this relationship, the density of *A. acanthophyllum* decreases as that of *Cyanotis lanata* increases from March to September (Figure 35). From September to December, both species decrease (Figure 35). Whereas the moss and monocot seem to facilitate each

other, the lichen is inhibited by growth of these two species.

Figure 35. Quarterly density dominance of three interacting plants and lichens on the Baasi Inselberg, Nigeria. Modified from Oyesiku and Egunyomi 2004.

The bryophytes and tracheophytes can also have nutrient cooperation. Bryophytes collect dust and runoff that contain nutrients. These can later be transferred to the tracheophytes. Oyesiku (2018 in press) investigated these relationships between *Archidium acanthophyllum* (see Figure 32) and *Cyanotis lanata* (Figure 31).

Lava Flows

Tropical lava flows provide unique rock habitats. Ah-Peng *et al.* (2007) investigated the altitudinal differences on a recent lava flow (19 years old) on Réunion Island. Because of the uniformity of the lava flow, it is easier than in most habitats to isolate variables such as altitudinal effects. They surveyed bryophyte communities from 250 to 850 m asl using the three substrates of ground and rachises of two fern species. As in many other altitudinal studies, bryophyte diversity increased with altitude. They identified 70 species of bryophytes in the study, with diversity related to microhabitats. The lava flows support a high number of pioneer organisms that are able to colonize remnant lowland rainforest.

Richness and Diversity

Rocky outcrops and inselbergs form islands amid the surrounding soil vegetation (Silva *et al.* 2014a, b), although Silva and coworkers did not compare the flora of the inselbergs with the surrounding vegetation. If they are correct, the species that arrive there must often come from a distance and must rely on **stochasticity** (unpredictable events). Silva and coworkers demonstrated that such processes are the major factors determining species clustering at a regional scale. Such a relationship was not clear at the local level.

Later, Sarthou *et al.* (2017) provided us with evidence that the surrounding forest, regional climate, and inselberg features including altitude, shape, habitats, summit vegetation, epiphytism, and fire events contribute to shifts in the distribution of species and functional traits. These factors determine the floristic patterns on inselbergs in French Guiana and demonstrate that the surrounding forest

can contribute to the inselberg vegetation. This is probably even more likely for bryophytes.

Ribeiro *et al.* (2007) often found xerophytes and hydrophytes (of the tracheophytes) side-by-side on the boulders due to the small scale environmental heterogeneity. Such conditions also support the great variety of bryophytes on these rocks.

Africa

The inselbergs of West Africa are geologically old and typically dome-shaped monoliths (Porembski & Barthlott 1996). The vegetation differs starkly from that of the surrounding vegetation. The inselbergs provide a severe climate with extreme temperatures and light intensity. Nevertheless, ~600 tracheophyte species occur among these inselbergs, predominately in the grasses (Poaceae), sedges (Cyperaceae), and legumes (Fabaceae). The rocks provide such habitats as cryptogamic crusts, rock pools, monocotyledonous mats, and ephemeral flush vegetation that can be distinguished based on physiognomy (Porembski *et al.* 1997). The ephemeral flush vegetation is the richest in species (Porembski & Barthlott 1996). Moss cushions, particularly those of *Bryum arachnoideum* (Figure 10), can establish where seepage water is sufficient (Frahm & Porembski 1994).

The tracheophytes on Ivory Coast inselbergs exhibit low **beta diversity** – that is, the flora is relatively uniform across the country (Porembski & Barthlott 1996). Higher beta diversity occurs in the small habitats like rock pools, presumably due to stochasticity. Diversity decreases from savannahs toward the rainforest zone. In the drier areas in the northern part of the Ivory Coast, the growing conditions are less favorable, permitting weak competitors to have a better chance.

On the tropical inselbergs of the Ivory Coast (Côte d'Ivoire) (Figure 36) and Zimbabwe, Frahm and coworkers found that the number of bryophyte species does not correlate with either size of inselberg or elevation (Frahm 1996; Frahm *et al.* 1996). In the Ivory Coast, species richness is greater when the inselberg is in the savannah compared to those in rainforest regions. In the Ivory Coast, they found total species richness of inselbergs to be 31, whereas in Zimbabwe it was only 25. Only 3 families are represented. These researchers found that inselberg bryophytes have larger distribution areas and no endemic species compared to tracheophytes on them. Eight species are common to both. One interesting feature is that these bryophytes typically lack sexual reproduction, but have "conspicuous" vegetative reproduction.

Figure 36. Inselberg (kopje) in Marada Hills, Zimbabwe. Photo by Kevin Walsh, through Creative Commons.

The highest number of bryophyte species from African inselbergs was in the Côte d'Ivoire with 31 species, contrasting with the lowest number of 16 in the Seychelles. This can probably be explained by the location of Côte d'Ivoire in the rainforest as well as in the savanna belt, widening the surrounding vegetation types. Most of the species of bryophytes are acrocarpous mosses, with only *Sematophyllum fulvifolium* and *Erythrodontium squarrosus* representing the pleurocarpous mosses.

Frahm and Porembski (1997) visited the small tropical African country of Benin. They identified 8 liverworts and 10 mosses from inselbergs. Of these, 5 liverworts [*Acrolejeunea emergens* (Figure 37), *Riccia atropurpurea* (Figure 38), *R. congoana* (Figure 39), *R. discolor*, *R. moenkemeyeri*] and all of the mosses [*Archidium ohioense* (possibly *A. acanthophyllum*; Figure 32), *Brachymenium acuminatum* (Figure 40), *B. exile* (Figure 41), *Bryum arachnoideum* (Figure 10), *B. argenteum* (Figure 20), *Bryum depressum*, *Garckea moenkemeyeri* (see Figure 42), *Hyophila involuta* (Figure 43-Figure 44), *Philonotis mniobryoides* (see Figure 58) and *Weissia cf. edentula* (Figure 45)] proved to be new records for the country. This may relate more to lack of studies than to uniqueness of the inselbergs.

Burke (2002b) found that in Namibia, soil properties do not seem to have an important role in the arid environments. Furthermore, parameters such as slope aspect and angle play a minor role. The grassland and shrubland plant communities relate primarily to general habitat, elevation, size of inselberg, and geology. The inselbergs are able to harbor plant species from neighboring higher rainfall areas, thus providing a propagule source for recolonization.

Burke (2003) found that granite inselbergs in Namibia are more closely related to mountain habitats than are the dolerite ridges. And as expected, higher inselbergs are more closely related to mountain habitats than are lower inselbergs. Many species, especially those with broad habitat requirements, are common to both inselbergs and mountain habitats. On the other hand, the short-lived transient species are more similar between the dolerite ridges and the "mainland." Thus, the granite inselbergs can be important sources of remnant populations from a wetter past, whereas the dolerite ridges can form species pools for the rangeland.

Kürschner (2003) extended our knowledge of rock outcrops in the Jabal Arays area of Yemen. Here they found communities of *Riccia jovet-astiae* (see Figure 38-Figure 39) and *Riccia argenteolimbatae* on the thin soils overlying volcanic rock outcrops in monsoon areas where woodlands are characterized by *Sterculia africana* (Figure 46). These are typically accompanied by *Mannia androgyna* (Figure 47) and *Barbula unguiculata* (Figure 48-Figure 49). The shallow soils generally have large numbers of riccioid and marchantioid liverworts, with *Riccia atromarginata*, *R. albolimbata* (Figure 50-Figure 51), and *R. argenteolimbata* characterizing the association.

In the Drakensberg area of South Africa, Hodgetts *et al.* (1999) found that lowland sandstones support common and widespread species that can survive long drought periods. More species are present where there is more moisture, as in ravines, rock crevices, and on stream banks. A different suite of species occur on shaded sandstone cliffs and rocks. A third type of community occurs in flushes. Exposed rocks generally have few species, with *Grimmia pulvinata* (Figure 52) and *Ptychomitrium cucullatifolium* (Figure 53) being common here. On the basalt rocks, at about 3,000 m asl, most species are restricted to crevices, on boulders, and in the turf below the cliffs. *Quathlamba debilicostata* (in narrow cracks) and *Orthotrichum oreophilum* (in cushions on inner vertical and overhanging surfaces of wider cracks; Figure 54) seem to occur only in vertical cracks in the basalt cliffs.

Neotropics

Porembski *et al.* (1998; Porembski 2007) defined **inselbergs** as "mostly" dome-shaped rock outcrops in all climatic and vegetational zones of the tropics." In Brazil, these consist of Precambrian granites and gneiss that form ancient and stable landscape elements. Because of their exposure, they create harsh conditions of microclimate. These strikingly different conditions result in strikingly different vegetation. One of the most characteristic communities is one of monocotyledonous mats. These can provide cover and retain moisture that permits some bryophytes to survive there. Porembski and coworkers, studying tracheophytes, found that the alpha diversity (community diversity) of the mats differed little among the six outcrops studied. However, beta diversity (regional) differed greatly between sites. The Brazilian rock outcrops demonstrate a higher diversity compared to those of West African inselbergs, with the appearance of more endemics in the Brazilian communities. However, some species considered endemics at that time may have proved to be synonyms of more widespread species since then. Nevertheless, the diversity is high, perhaps due to the large species pool.

Silva (2012) studied the rock communities in the state of Pernambuco, Brazil. She divided the microhabitats on the outcrops into exposed rock, fissure, soil island, and **cacimba** (rock pool pit in wet or marshy ground, collecting water present in soil that accumulates in it by condensation). Substrates also differed: rock, live trunk,

dead trunk, and soil. She identified 49 species in 36 genera and 20 families. Of these, 34 were mosses, 15 were liverworts. The most species-rich families were the leafy liverworts **Lejeuneaceae** (Figure 37) (7 spp) and **Frullaniaceae** (Figure 55) (4 spp), and the moss families **Bryaceae** (Figure 20) (6 spp), **Dicranaceae** (Figure 27-Figure 28, Figure 56) (4 spp), and **Pottiaceae** (Figure 14) (4 spp), comprising 53% of the species. The liverwort genus *Frullania* (Figure 55) and moss genus *Campylopus* (Figure 56) had the highest species richness. The most common species were the mosses *Brachymerium exile* (Figure 57), *Bryum argenteum* (Figure 20), *Campylopus pilifer* (Figure 56), *C. savannarum* (Figure 27-Figure 28), *Philonotis hastata* (Figure 58), and *Syrrhopodon gaudichaudii* (Figure 59-Figure 60), and the liverworts *Frullania kunzei* (Figure 55) and *Riccia vitalii* (Figure 61); frequencies are in Table 1. Two of the less common species, *Atractylocarpus brasiliensis* (see Figure 62) and *Riccia taeniiformis* (Figure 63), are endemic to Brazil. **Turf** comprised 74% of the life forms. The most species richness (37 spp., 89%) occurred on soil islands that were 1.0 and 4.9 cm deep, whereas only 12 species occurred on rock. Approximately half the species had a wide distribution pattern. Similarity among sites was less than 50%.

Like Silva (2012), when studying Brazilian ironstone outcrops Peñaloza-Bojacá *et al.* (2018a) found the greatest bryophyte diversity on soil, but also on the rocks. They identified 108 species of bryophytes (42 liverworts and 66 mosses). In Cangas sites, Peñaloza-Bojacá *et al.* (2018b) reported 96 bryophyte species from Brazilian ironstone outcrops. These were comprised of 56 mosses and 40 liverworts, with 68 of the species associated with tree microhabitats and 67 species with bark substrates. The ironstone sites seem to harbor more species than other types of rock outcrops in the country.

Silva and Germano (2013) studied rock outcrops in the caatinga biome in the state of Paraíba, Brazil, from February 2010 to May 2011 and identified 21 bryophyte species, 6 liverworts and 15 mosses. They were able to identify three species clusters. These were **generalist** species that required high light. Their leaf structures generally permitted them to withstand drying environmental conditions.

In their study of the campos rupestres of Chapada Diamantina, Bahia, Brazil, Bastos *et al.* (2000) identified 65 taxa (41 moss species, 24 liverwort species) comprising a total of 20 families. Most of these taxa seem to be restricted to the Chapada Diamantina and are not known from other parts of the state.

Sarthou *et al.* (2009) examined the factors that have a role in the seral stages on the inselbergs in French Guiana. The environment is harsh, with violent storms, intense runoff, and lightning strikes, destroying vegetation cover and organic matter. They considered the vegetational changes to be truly successional, not conditioned by slope. The vegetation experienced cyclic changes that were reinitiated by fire (lightning), wood-destroying fungi, and termites that destroyed the vegetation.

In her inselberg succession studies, Sarthou and coworkers (2009, 2017) found that where the aerial parts of *Clusia minor* (Figure 67) have been destroyed, the ground frequently is covered with mosses and lichens. Their rhizoids capture and retain soil particles, preventing them from being flushed away by water.

Figure 67. *Clusia minor*, an inselberg species that is replaced by mosses and lichens when it is destroyed by fire or other disturbance. Photo by David J. Stang, through Creative Commons.

Sarthou *et al.* (2017) compared 22 inselbergs in French Guiana. They found that the spatially dictated environmental gradient was a primary driver in the floristic composition on these inselbergs. Southward communities have more drought-adapted plants. The northern group has high endemism. The north-south gradient is driven by regional climate (annual rainfall), forest matrix (canopy openness), and inselberg features (altitude, shape, habitats, summit forest, degree of epiphytism, fire events).

Breen (1953) studied bryophytes in subtropical Florida, USA. She found that a number of tropical species occurred exclusively on limestone in subtropical Florida (and in many cases other southern states). Tropical *Jaegerinopsis* (Pterobryaceae), *Vesicularia* (Hypnaceae; Figure 68), *Meteoriopsis* (Figure 69), *Papillaria* (Figure 70), and *Syrrophodon* (Figure 59-Figure 60) are restricted mostly to hammocks, usually on bark of 1-2 species of hardwoods. In swamps, *Cyclodictyon* (Figure 71) and some tropical *Fissidens* (Figure 72) occur. But the limestone regions hold the most bryologically interesting species. Most of the coastal land in the Caribbean and in the West Indies is of limestone origin. She found 11 Neotropical species that in Florida are restricted to limestone. *Luisierella barbula* is a tiny species easily overlooked, but is relatively widespread in Central America and Brazil. *Hyophiladelphus agraria* (see Figure 73) is widespread in both the Neotropics and subtropics. *Weissia*

jamaicensis (Figure 74) occurs in some Central American countries as well as Florida; it is sterile in Florida. This species typically occurs there with *Marchantia paleacea* (Figure 75). *Hypopterygium tamarisci* (Figure 76) is a tropical relic in Florida, also known from both Central and South American tropics. *Leptodictyum riparium* (Figure 77), also a Floridian limestone dweller, is more widespread in aquatic habitats, but is known from Mexican tropics. *Gymnostomiella vernicosa* (Figure 78-Figure 79) is also in Jamaica, Haiti, and Mexico. *Plaubelia sprengelii* (Figure 80) also occurs in the West Indies, Mexico, and Central America, whereas *Syrrophodon prolifer* (Figure 81) occurs in these locations plus South America, typically on thin layers of soil over limestone in protected pockets. *Taxiphyllum cuspidatum* (see Figure 82) occurs on boulders. *Hyophila involuta* (Figure 43-Figure 44) is a common tropical rock dweller, but is again restricted to limestone in Florida. *Fissidens hallianus* (see Figure 72) is restricted in the USA to Florida. The other species Breen found on the Floridian limestone are not tropical.

Conceição and Pirani (2005) noted the lack of quantitative studies in tropical cave habitats. They compared outcropping, intertidal, and trench habitats, and found that when different types of habitats are contiguous, there is greater heterogeneity of both strata and life forms in a restricted area, supporting more species. Their study was not based on bryophytes, but it would be interesting to test this hypothesis on the bryophytes.

Summary

Inselbergs (abrupt rock outcrops) and other rock formations are typically xeric and have unique vegetation surrounded by vegetation of a different type, often isolating them like an island. Temperatures and water availability can vary widely, and exposure to high light intensity is common. The bryophytes, and even the tracheophytes, are typically **poikilochlorophyllous mats**). Differing niches are created by fissures and crevices, pockets where water collects, tracheophyte shade, and vertical faces that are shaded or exposed.

Limited competition permits **stochastic** processes to determine communities. Surprisingly, inselberg vegetation units of South America and Africa are similar.

Moss **cushions** are common. Adaptations such as hyaline tips and awns protect against UV light during dry periods. Leaves often twist when dry, have infolded leaf margins, thickened cell walls, small cells, and papillae to protect against UV damage and to retain water longer. Lobules help to store water in some leafy liverworts. Mosses such as *Leucobryum* have hyaline cells that store water and protect the chlorophyll. Sexual reproduction is infrequent. Photo-oxidative protection protects chlorophyll from UV light when dry. *Riccia* species on thin soil produce large spores with short-range dispersal and storage in diaspore banks, permitting them to be **shuttle** species. Other bryophytes are drought-tolerant **cushions**, **short turf-forming perennial shuttle species**, **perennial stayers**, and **pauciennial colonists**. Mosses are more likely to have asexual reproduction, whereas liverworts mostly exhibit sexual reproduction. *Bryum argenteum* is a common rock resident that frequently has sporophytes, perhaps due to sperm dispersal by springtails and mites. It is important to conserve groups of inselbergs to facilitate stepping stone dispersal. For others (e.g. **Meteoriaceae**, **Neckeraceae**, **Pterobryaceae**, *Plagiochila*, and *Lejeuneaceae*), having other suitable substrates increases dispersal potential.

In some cases the bryophytes retain moisture and collected nutrients that provide for the tracheophyte roots, whereas the tracheophyte provides shade that cools the bryophytes and protects from UV damage, as seen in the moss *Archidium globiferum* and the shrub *Cyanotis lanata*.

In Africa, inselbergs surrounded by savannah have a higher species richness than when forests surround them. Inselbergs can harbor recolonization sources for surrounding disturbed dry habitats. Asexual reproduction predominates. Leafy liverworts seem to be more common on the Neotropical rock outcrops than on the African inselbergs. *Riccia* species are common on thin soils in both areas. Having trees and shrubs to provide shade can greatly increase the diversity. Limestone areas in subtropical Florida, USA, provide similar habitats and harbor a number of tropical species.

CHAPTER 8-13

TROPICS: INTERACTIONS AND ROLES

Figure 1. *Craugastor bransfordii* on mosses in the tropics. Note the moss stuck to its skin (arrow). Photo by Jason Folt, with permission.

Role

Although we have discussed the role of bryophytes in retaining water earlier, its role in water relations in the tropics cannot be overemphasized. Romero (1999) suggested that bryophyte sensitivity to moisture could be an indicator of the health of the forests where the bryophytes abound. In one submontane forest in Tanzania, epiphytes (including bryophytes, lichens, and tracheophytes) comprised $2,130 \text{ kg ha}^{-1}$, intercepting about 15,000 L of rainfall water per hectare (Pócs 1980). In the elfin (cloud) forest, at only 2,120 m, a biomass of $14,000 \text{ kg ha}^{-1}$ intercepts nearly $50,000 \text{ L ha}^{-1}$. Thus, the impact of bryophytes on the water and nutrient regime of the cloud forest is surely significant.

In montane forests, bryophytes make considerable contribution to both biomass and litter. Growth of epiphytic bryophytes in Monteverde, Costa Rica, was approximately 39-49.9% per year, providing a net productivity of $122\text{-}203 \text{ g m}^{-2} \text{ yr}^{-1}$ (Clark *et al.* 1998). Nitrogen accumulation in these bryophytes was also

significant at $1.8\text{-}3.0 \text{ g N m}^{-2} \text{ yr}^{-1}$. Most of the decomposition seems to occur the first year, with loss from litterbags in the canopy of $17\pm 2\%$ and $19\pm 2\%$ by the end of the second year. On the ground, losses were quite different, with $29\pm 2\%$ the first year and $45\pm 3\%$ after two years. One advantage to the ecosystem was that approximately 30% of the initial N mass was released rapidly both on the ground and from canopy litter. Furthermore, green shoots on the ground lost about 47% of their initial N content within the first three months. Although these were significant rapid releases from these sources, providing a steady supply of N to the soil, the remaining N content was recalcitrant, creating an N sink within the bryophytes. What may be more important is their role in transforming N from mobile forms reaching the canopy as atmospheric deposits to highly immobile forms. This maintenance of low N levels despite atmospheric deposition may help to maintain these low-nutrient bryophyte habitats and prevent the conversion to graminoids more typical of fertilized soil conditions.

Even in lowland floodplain forests, bryophyte biomass can be significant in the accumulation of nutrient elements. With an accumulation of only 210-1,400 kg ha⁻¹ ash-free dry weight biomass on 10-year-old stakes in a floodplain, Frangi and Lugo (1992) still considered that the bryophytes in these floodplains served as biotic filters of flood waters that could retain nutrients in the terrestrial system.

In Guadeloupe and other tropical locations, nutrients in the canopy, particularly in the upper canopy of the montane rainforest, are released from bryophytes in pulses (Coxson 1991). These pulses result from rewetted bryophytes that have suffered membrane damage during desiccation. The ions are normally those of intracellular pools that were not otherwise available to the throughfall. During rewetting experiments, concentrations reached 11.8 kg ha⁻¹ yr⁻¹ for N, 1.4 kg ha⁻¹ yr⁻¹ for P, and 80.1 kg ha⁻¹ yr⁻¹ for K.

Bryophytes provide a substrate for tracheophyte epiphytes to become established. In a study of the palm *Socratea exorrhiza* (Figure 2), Zotz and Vollrath (2003) found that tracheophytic epiphytes on these trunks are associated with bryophyte patches to a much greater extent than dictated by chance, suggesting a higher success rate, but none seem to require bryophytes for establishment. In the lowland rainforest of Guyana the bryophyte mats and their accumulated debris support different tracheophyte epiphytes in the lower canopy than can be found in the middle and upper canopy branches (ter Steege & Cornelissen 1988).

Figure 2. *Socratea exorrhiza*, a palm on which tracheophytic epiphytes are more frequently associated with bryophytes. Photo by A. Araujo, through Creative Commons.

Bryophytes also moderate the microclimate. Stuntz *et al.* (2002) reported the importance of epiphytes in moderating the climate of the crowns in the rainforest, creating a natural air conditioning. In this case, they were discussing members of the pineapple family, finding that water loss through evaporative drying at microsites adjacent to them is nearly 20% lower than at exposed microsites. They create a habitat that is significantly lower in temperature than sites with no epiphytes in the same tree crown. Hence, these tracheophytic epiphytes create a habitat more hospitable to bryophytes, but it is likely that the bryophytes also contribute to evaporative cooling, thus helping to lower the temperature. These cooler microsites with greater moisture provide suitable habitats for small arthropods.

Tropical ferns are often associated with bryophyte-covered substrates. Carvalho *et al.* (2012) noted that *Cochlidium connellii* (see Figure 4), a fern in the **Polypodiaceae**, grows among mosses in rocky crevices. *Trichomanes robustum* (**Hymenophyllaceae**; Figure 3) and *Terpsichore taxifolia* (**Polypodiaceae**; Figure 5) occur on moss-covered trunks in the upper montane forest in Brazil and other locations in the tropics.

Effect on Tree Seedlings

One might think that bryophytes would benefit tree seedlings by maintaining moisture, but often they are a detriment. The shade tents in the experiments at the alpine treeline in northern Ecuador did indeed have a greater growth of mosses, indicating greater moisture (Bader *et al.* 2007). But thick mats of mosses can be detrimental. Bader and coworkers found that seedlings of forest trees in the tropics often appeared to have negative growth because the bryophytes, especially mosses, grew up around them. This growth often deprived the seedling leaves of light. Bader and coworkers concluded that the seedlings grew in the mosses because no other substrate was available in the forest and did not appear to be benefitted by them.

Bryophyte and Fauna Relationships

In an Ecuadorian cloud forest (Figure 7), Zitani *et al.* (2018) found annelids, molluscs, crustaceans, millipedes, centipedes, arachnids, and hexapods (and others) among the bryophytes. And of course many birds use bryophytes for making nests, especially the pendent and mat-forming species (Cao & Caihua 1991) (see also Chapter 16). And some rodents occur only in mossy forests (see Chapter 17).

When the new species *Herbertus sendtneri* (Figure 6) was discovered, it displayed swollen tips resembling gynoecea (Gradstein *et al.* 2018). These proved instead to be small, whitish colonies of protozoans that resemble gnathifers, but remain to be identified. These infected

shoot tips failed to develop normally and instead produced branch innovations (1-2) below the swollen tips.

Figure 6. *Herbertus sendtneri*. Photo by Paulo Henrique Silva <siaram.azores.gov.pt>, with online permission.

Zitani *et al.* discovered an arboreal **Onychophoran** (velvet worm; Figure 8), along with a **Lepidopteran** (butterfly or moth) mimic, among the epiphytic bryophyte mats that are up to 10 cm deep in an Ecuadorian cloud forest (Figure 7). **Onychophorans** are highly susceptible to desiccation, so the bryosphere most likely maintains their moisture at a safe level.

Figure 8. **Onychophoran**, a moss inhabitant in the tropics. Photo through Creative Commons.

Insects abound in tropical forests, including those in bryophyte mats (Nadkarni & Longino 1990). Epiphytes can contribute antifeedants that help protect the host. Frahm and Kirchhoff (2002) tested alcoholic extracts from the moss *Neckera crispa* (Figure 9) and the liverwort *Porella obtusata* (Figure 10) on feeding by the slug *Arion lusitanicus* (Figure 11). *Neckera crispa* had only low antifeedant properties at 0.5% or more dry weight. *Porella obtusata*, on the other hand, was moderately effective at concentrations of 0.05%, with total effectiveness at 0.25% of dry weight.

Most of the animal interactions are discussed in the chapters on interactions in volume 2, but some deserve repetition here for those who want a quick view of their roles in the tropics. In addition to the many bryophytes in the tropics and the many more waiting to be discovered, there are likely many unusual or intimate relationships with insects to be discovered.

Arthropods

Many arthropods live among the epiphytic bryophytes. Yanoviak *et al.* (2004) compared the arthropod assemblages in the vegetative portions vs the humic portions of Neotropical cloud forest epiphyte mats. Many types of arthropods occur among the bryophytes of the Neotropical cloud forests. Bryophytes at different elevations and tree levels provide different conditions for these arthropods and thus increase their diversity in the tropics. Furthermore, the green and brown portions of the bryophytes support different communities, with the green portion containing twice as many individuals and species per gram dry mass compared to the brown portion.

Some species of invertebrates seem to be associated exclusively with bryophytic epiphytes. *Bryospilus repens* (Branchiopoda) has been considered a strictly epiphytic moss inhabitant (Cammaerts & Mertens 1999).

The rainforest brings new meaning to letting moss grow on your feet – or head or back. In the cloud forests of Papua New Guinea, at 2,000-3,000 m asl, one can find mosses (*Daltonia angustifolia*; Figure 12) and liverworts [*Cololejeunea* (Figure 13), *Microlejeunea* (Figure 14), and *Metzgeria* (Figure 15)] on the back of a beetle, a small weevil (*Curculionidae*) in the genus *Gymnopholus* (Figure 12) (Gressitt *et al.* 1965; Gradstein *et al.* 1984; Gradstein & Equihua 1995). *Daltonia* is not restricted to this weevil, but rather grows on bark and small branches of the montane rainforest where it is able to subsist when it is not being transported around the canopy. Gradstein and coworkers (1984) attribute the ability of *Daltonia* to inhabit the beetle to the ability of this moss to mature quickly and grow where the beetle lives. It is likely that the moss affords camouflage to the beetle. Could it also make the beetle distasteful?

Epizoic bryophytes occur on a variety of insects in the tropics. Epiphyllous liverworts sometimes extend their substrate to the forewings and pronotum of the Costa Rican

shield mantids [*Choeradodis rhombicollis* (Figure 16) and *C. rhomboidea* (Figure 17)] (Lücking *et al.* 2010). These insects can become home to five species of liverworts. In their collection of 84 individuals, the researchers found 60 with epiphylls. They colonized more females than males and more of *C. rhombicollis* than *C. rhomboidea*. This is likely due to the longer lifespan of females and suggests that the same should be true for host leaves. The bryophytes may provide camouflage for the insects.

Figure 16. *Choeradodis rhombicollis*, a mantid whose wings can be colonized by epiphyllous liverworts. Photo by Benjamins444, through GNU free documentation license.

Figure 17. *Choeradodis rhomboidea*, a mantid whose wings can be colonized by epiphyllous liverworts. Photo by Andreas Kay, through Creative Commons.

Several mantids and walking sticks are mimics of mosses or liverworts. In other cases, insect larvae may use epiphyllous bryophytes as host plants in the tropics (DeVries 1988).

Callaghan (1992) described the behavior of 16 **Lycaenidae** butterflies in Nigeria. The larvae of all these species grazed on epiphylls "such as lichens and fungi." Mimicry is much more common in the tropics than elsewhere. Occasionally epiphyllous bryophytes, especially liverworts, are able to contribute to this mimicry.

Insects and other animals associated with your bryophyte collections can cause immigration control to quarantine your specimens for months and may result in your never seeing them again. Heating/drying methods beforehand can drive these inhabitants out or kill them, increasing your chances of getting your samples through customs.

Vertebrates

Reptiles and Amphibians

Many tropical amphibians (see, for example, Allison & Kraus 2000) and some snakes and lizards are associated with bryophytes. Many tropical epiphytes provide nesting sites and cover for animals such as salamanders (Bruce 1999). Some amphibians use them as calling sites, with the bryophytes modifying the types of sounds they make. Others use them for egg-laying sites. See Chapters 14 (Amphibians) and 15 (Reptiles) in Volume 2 (Bryological Interaction) for details.

In a study in the montane cloud forest of Cameroon, Böhme and Fischer (2000) found lizards with a greenish coloration. This ground chameleon, *Rhampholeon spectrum* (Figure 18), was sporting an overgrowth of four species of typically epiphyllous liverworts from the family Lejeuneaceae. The species included *Cololejeunea jovetastiana* (see Figure 19) and *Colura digitalis* (Figure 20) as the most abundant; only a few plants of *Cololejeunea* sp. were present; *Lejeunea* (Figure 21) was present in only two samples.

Figure 21. *Lejeunea anisophylla*; *Lejeunea* is one of the genera of leafy liverworts known to live on the lizard *Rhampholeon spectrum*. Photo by Lionel Courmont, through Creative Commons.

But a stranger vision might be that of a lizard with a head dress! In the Mexican rainforest, *Corythophanes cristatus* (Figure 22-Figure 23), a lizard of the lowland rainforest of the Chiapas, sports a crown of filamentous algae including *Cladophora* (dominant; Figure 24), and Chaetophorales (Figure 25), with the tiny leafy liverwort *Taxilejeunea obtusangula* (Figure 26) living among them (Gradstein & Equihua 1995). This liverwort species is normally a common bark inhabitant, but also occurs on rocks (Evans 1911).

Rodents

Even mice (moss mice) live among bryophytes in the tropics. In Sulawesi, Indonesia, moss mice live and nest among the bryophytes (Helgen & Helgen 2009).

Bryophytes on Fungi

A surprising number of bryophytes are able to grow on the sporocarps of **Basidiomycota** fungi. Vital *et al.* (2000) identified 26 moss and 35 liverwort species growing on these substrates. None was exclusive to the fungi, all occurring on dead trunks where fungi occurred as well. Could it be that the fungus provides some chemical that is needed for the bryophyte life cycle to be completed?

Summary

Bryophytes can play major roles in water and nutrient cycling in tropical forests. In particular, they provide suitable habitat for nitrogen-fixing Cyanobacteria, as well as trapping nutrients from rainwater and the atmosphere. These nutrients can be

released in pulses, often at important times for forest growth.

Bryophytes in trees provide suitable substrate for many species of flowering and fern epiphytes, but their exact role is poorly known. On the other hand, many organisms use the mosses as homes or for nesting materials. Inhabitants include insects and other arthropods, velvet worms, annelids, molluscs, frogs, snakes, and rodents. On the other hand, bryophytes can inhibit the growth of bacteria and fungi and discourage herbivory by insects and other herbivores. Some of these organisms are known exclusively from bryophytes. Rodents and birds use bryophytes as nesting materials. Some bryophytes grow on insects or lizards and may provide camouflage. And a surprisingly large number of bryophytes are able to grow on fruiting parts of fungi.

Acknowledgments

My appreciation goes to Sean Edwards, who frequently has sent me interesting publications on interactions of animals and bryophytes.

CHAPTER 8-14

TROPICS: DISTURBANCE AND CONSERVATION

Figure 1. Deforestation in Indonesia, a common scene throughout the tropics. Photo from Rainforest Action Network, through Creative Commons.

From a northern perspective, most of what we hear about the tropics is about massive disturbance. Hence, it would be irresponsible to discuss this region without at least a glimpse of the impact of disturbance on the bryophyte flora. Unfortunately, we have no before-and-after data for the vast areas that have been converted from tropical rainforest into short-lived agricultural land and that are now experiencing the jungle of plants tolerant of low nutrients, shallow soil, and exposure. However, some recent comparative studies may help us understand what we have lost.

Natural Disturbance

Nature has her own form of devastating disturbances. These include events such as hurricanes, tornadoes, and other high winds, animal activities, volcanoes, fire, and extreme drought.

El Niño and Hurricanes

Despite the frequency of hurricanes in some tropical areas, it appears that few studies have addressed the effects

on bryophyte communities. Weber (1985) seems to be one of the earliest. He assessed the effects on both bryophytes and lichens resulting from the El Niño in the Galápagos Islands.

Hurricanes can have severe impacts on the epiphytic bryophytes in the tropics (Loope *et al.* 1994). Hurricanes can be very powerful forces that destroy nearly everything in their paths. In Puerto Rico, Hurricane Hugo created mass destruction in 1989. Recovery in the cool cloud forest has been slow compared to that of the lowland. Bryophytes were stripped from the trees by the high-powered winds and rain. Fortunately, the return frequency of hurricanes to any given area is low, usually occurring after years or decades (Lodge & McDowell 1991). But at the same time, the life span of a canopy tree or a forest ecosystem is longer than that interval.

Considering the number of hurricanes in the tropics, and the considerable damage I have witnessed to epiphytic bryophyte communities following Hurricane Hugo (see Weaver 1999) in Puerto Rico, I am surprised at how few

studies have addressed the damaging effects of hurricanes on these communities.

Nutrient Relationships

Nutrient levels can affect the damage to trees and their adhering bryophytes. Herbert *et al.* (1999) found that large trees sustained damage at twice the frequency of smaller trees. Thus, trees that had a richer phosphorus environment were more susceptible to damage due to greater growth.

Hurricanes alter the nutrient cycling in tropical forests (Lodge *et al.* 1991). Hurricane Hugo (Figure 2), in September 1989, struck Puerto Rico, severely damaging wet forest sites. This, and other hurricanes since, have caused a massive increase in fine litter as leaves (Figure 3), small twigs, and other miscellaneous debris were ripped from the trees and deposited on the forest floor. Concentrations of N and P increased as much as 1.5 times for N and 3.3 for P compared to normal litter fall. This raises the question of effects on competition and the success of bryophytes under these conditions.

Figure 2. Hurricane Hugo forest damage in Puerto Rico. Photo by Matthew C. Larsen and Angel J. Torres Sánchez, USGS, through public domain.

Figure 3. El Yunque forest after Hurricane Irma, showing extensive leaf litter and branches brought down by the hurricane. Photo by Joel S. Olivencia, USDA, through public domain.

Walker *et al.* (1996) mentioned bryophytes in their study comparing altitudinal responses by hurricane-damaged forests in Puerto Rico. Nutrient treatments initiated 1-6 months after the hurricane decreased the bryophytes threefold while causing graminoids to increase 10-fold in the cloud forest.

The cloud forest understory is dominated by bryophytes; epiphytes are common. Walker *et al.* (1996) tested the effects of fertilization on the vegetation following hurricane damage. Fertilization increased biomass of the graminoids (grasses, sedges) in the elfin cloud forest by a factor of 10, whereas bryophytes decreased 3-fold. The same differences were absent in the lowland forest. Cover of ferns did not respond to differences in treatment or time. At the high elevations, bryophyte biomass is most likely sustained by the constant high humidity. It is likely that the bryophytes were negatively affected by the fertilizer salts. They could also have been out-competed by the graminoids. Recovery of the bryophytes was most likely facilitated by their ability to spread. As I have observed in Puerto Rico after Hurricane Hugo (Figure 2), the bryophytes are removed from the trees in patches, leaving behind the source for new growth. This removal is due to high winds and driving rain.

Recovery

Some bryophytes escape damage by living in protected locations. The rare liverwort species *Lejeunea paucidentata* (Lejeuneaceae; Figure 4) occurs in the rainforests of Dominica (Figure 5) (Schäfer-Verwimp 1999). Fortunately, it escapes hurricane damage because it lives on small fern fronds in the undergrowth and benefits from similar conditions in humid secondary vegetation or in heavily damaged old growth rainforest. On the other hand, Schäfer-Verwimp considers that the disappearance of *Phycolepidozia exigua* (Figure 6) is possibly due to hurricane damage to bark. This species most commonly grows on the bark of old trees, but old trees tend to be more susceptible to hurricane damage than the more pliable young trees.

Figure 6. *Phycolepidozia indica*, a species that seems to have disappeared due to hurricanes. Photo by Uwe Schwarz, courtesy of Robbert Gradstein.

Many have tried to determine what limits the species that become established on a given tree. Yeaton and Gladstone (1982) tried to determine what determines the structure of the epiphytic tracheophyte community on the calabash tree (*Crescentia alata*; Figure 7-Figure 8). As a result of their data analysis, they hypothesized that the colonization pattern is the result of the quantity of propagules produced by each species. It is possible that this is an important factor for bryophytes as well.

Figure 7. *Crescentia alata* with epiphytes in the Guanacaste dry forest. Photo by Daniel H. Janzen, through Creative Commons.

Figure 8. *Crescentia alata* in the Guanacaste dry forest. Photo by Daniel H. Janzen, through Creative Commons.

Nadkarni (2000) found a 30% reduction in bryophyte cover at severely impacted sites. She demonstrated, by experimental branch stripping, that epiphyte colonization occurs upwards from the **abaxial** (in this case, lower) branch surface. She considered that the shading by the branch permitted these abaxial sites to retain more water, increasing the time that the surface provided a suitable microclimate.

Bryophyte Loss Effect on Tracheophytes

Batke and Kelly (2015) documented the effects of a hurricane on the epiphytic bryophytes in the Cusuco National Park, northwest Honduras (Figure 9). They considered the epiphytes to be mechanically dependent plants and examined how hurricanes affected these dependents (Figure 10). Although the effect on bryophytes was not discussed directly, the researchers found that differences in life forms and families of tracheophytes among the tree branches resulted from branch surface area and bryophyte cover. Hence, the destruction of bryophyte mats led to reduced communities of tracheophytic epiphytes. They found that branches on trees that were more severely impacted had significantly lower cover. They considered that branches that were stripped of bryophytes and their dependent (Figure 10) plants during the severe gusts are less likely to experience early recolonization.

Damage to the bryophyte communities can affect other epiphytes as well. Tremblay (2008) assessed the relationships of a rare epiphytic orchid after Hurricane Georges. At first he could find no correlation with the percent cover of mosses on standing trees. But a non-parametric density contour map revealed that the moss density does seem to affect the population size of the orchids. Using this technique, Tremblay demonstrated that the orchids are present more frequently when there is a 40-90% moss cover.

Fire

Many forests around the world are subject to fire. In the tropical cloud forests, the bryophytes may actually reduce fire damage. They not only reduce the likelihood of fire because of the moisture they hold, they also facilitate growth of additional epiphytes through their moisture-absorbing and moisture-holding capacity (Proctor 1982; Frahm & Gradstein 1991). This moisture-holding capacity reduces the flammability of the forest (Brujinzeel & Proctor 1995).

Nepstad *et al.* (2008) noted that forest degradation and dieback and subsequent drought increase the susceptibility to forest fires. And fires increase drought, further increasing the susceptibility to bryophyte loss. Furthermore, deforestation and smoke can inhibit rainfall, further increasing fire risk. These researchers predicted

that in the next 20 years following 2008 approximately 55% of the Amazon forests will be cleared, logged, damaged by drought, or burned.

Diaspore banks can facilitate recovery of bryophytes after a fire. In a diaspore bank, Zander and During (1999) found the moss *Neophoenix matoposensis* (Pottiaceae) in Zimbabwe as a new species. They recommended the "forced diaspore bank analysis" as a means to find small species with short life cycles, giving them only limited above-ground exposure. In this case the method was used to uncover species in experimental fire plots. Two additional species were uncovered as new to Zimbabwe and new to Africa. One of these was previously known only from Brazil and Australia.

Volcanoes

Air pollution is not always of human origin. Volcanic activity (Figure 11, Figure 15) can be a major contributor. Baudoin (1985) reported that epiphyllous bryophytes can be used satisfactorily as indicators of volcanic air pollution.

Figure 11. Pāhoehoe lava flows, Hawaii. Picture from Brocken Inaglory, through Creative Commons.

Volcanoes offer opportunities for observing effects of elevation with fewer environmental variables than most substrates. However, when they erupt, they create severe disturbances. These severe habitats, following cooling, create bare rock substrate that differs drastically from the surrounding area. Smith (1981) compared the bryophyte and lichen communities of these severe substrates with those of the surrounding ecosystems at the Puhima Geothermal Area in the Hawaii Volcanoes National park. He found very few of the species from surrounding areas to be present on the volcano ground in geothermal areas. The center of the geothermal area is nearly lacking in any vegetation. Only small communities of vegetation, dominated by the endemic moss *Campylopus praemorsus* (see Figure 12) are scattered here. The mosses seem to provide a safe haven for the lichen *Cladonia oceanica* (see Figure 13), where it grows epiphytically on the mosses in areas lacking the high temperatures. Outside that central zone, where temperatures are lower, the grass *Andropogon* (Figure 14) dominates. Here, both *Campylopus praemorsus* and *Cladonia oceanica* commonly produce reproductive structures.

Figure 14. *Andropogon leucostachyus*; the genus *Andropogon* dominates outside that central zone of a geothermal vent, where root temperatures are lower. Photo by João Medeiros, through Creative Commons.

In Costa Rica, Griffin (1974) suggested that sulfur gasses downwind from a volcano might account for the paucity of mosses there. Both species composition and cover of mosses are diminished on the downwind side of the Poas Volcano (Figure 15).

Figure 15. Poas Volcano, Costa Rica, showing downwind plume of steam. Photo by Franz Xaver, through Creative Commons.

Ah-Peng *et al.* (2007) found 70 species of bryophytes on a 19-year-old lava flow. They suggested that the high diversity is promoted by the host substrate and the bryophyte adaptations to colonize this new substrate. Hence, the disturbance by the volcano brought new space there to house a wide diversity of pioneer organisms.

Animal Activity

Forest animals can likewise be very destructive to bryophytes (Nadkarni 2000). Howler monkeys (*Alouatta* spp.; Figure 16) and tayras (*Eira barbara*; Figure 17) knock clumps of moss and other epiphytes from the branches as they climb and jump about. White-faced capuchins (*Cebus capucinus*; Figure 18) remove them to look for invertebrates in the bromeliads. Most literature indicates that such disturbances are easily and quickly healed with recolonization coming primarily through encroachment from the sides of the plots, thus having the same species. But in the detailed study at Monteverde, Costa Rica, mimicking effects of animal activity, Nadkarni found something quite different when she removed 75 cm strips of epiphytes from canopy branches. Despite the presence of neighboring plants, recolonization was extremely slow, with no colonization during the first five years after stripping. When it did occur, the communities were quite different. Crustose and foliose lichens began the colonization, two groups that were totally absent originally. And rather than encroaching from the sides, colonization extended from the bottoms of the branches. By the sixth year, there were some algae and bryophytes on the undersides of branches. It was not until the eighth year that some of the bryophytes from the underside had joined on the top side. Small seedlings began to appear in the tenth year.

Rare and Threatened Species

By their very nature, severe habitats often have rare and endangered species. That is because bryophytes must have special adaptations to survive in these extreme habitats. Perhaps they sacrifice competitive ability to achieve this physiological adaptation.

Gradstein (1992a) noted that loss of tropical species may vary considerably in deforested areas, depending on the size of the area affected and degree of habitat change. This damage is greatest for shade epiphytes, with an estimated 10% of rainforest species under threat by 1992. Gradstein listed 19 endangered species and 27 rare ones that are disappearing from the rainforests. Costa Rica and Panama have been particularly vulnerable, along with the Greater Antilles, the Chocó, southeastern Brazil, and parts of Amazonia.

Koponen (1992) considered the bryophytes in the tropical (and temperate) regions to have much more danger of becoming rare or extinct than those of the boreal and Arctic regions. The richest tropical floras are in the rainforests and montane forests, and deforestation creates disjunct patterns. Deforestation is particularly problematic in China, where nearly all the forests have been cut for agriculture. Very few bryophyte species from virgin tropical forests are able to survive in manmade habitats.

On the other hand, some disturbed habitats, created by agroforestry, can provide the conditions needed for some of the rare species. For example, Gradstein (1999) rediscovered the endangered leafy liverwort *Spruceanthus theobromae* (Lejeuneaceae; Figure 19) on cacao trees (*Theobroma cacao*; Figure 20) in western Ecuador.

Figure 19. *Spruceanthus theobromae*, a species endemic to cacao plantations. Photo by Robbert Gradstein, with permission.

Figure 20. *Theobroma cacao* with bryophytes; this species supports some forest bryophytes in plantations in the tropics. Photo by Fpalli, through Creative Commons.

The real loss of tropical rare and endangered species is difficult to assess. Many areas were destroyed before any bryophyte assessment occurred. And many species considered rare or endemic have proven to be synonyms of species in a neighboring country or mountain.

Pollution and Disturbance

Managing for bryophytes often does not coincide with the best management plan for the forest. Andersson and Gradstein (2005) studied the biodiversity of bryophyte and

lichen epiphytes in cacao plantations (Figure 21) in western Ecuador. They found 51 bryophyte and 61 lichen species. The managed cacao plantation epiphyte assemblages resembled those of natural tropical rainforests, but with lower species richness. Species also were typically found lower on the trunks. The species on cacao were typically widespread Neotropical or pantropical species. But *Spruceanthus theobromae* (Figure 19) is endemic to cacao plantations in western Ecuador. Management involving manual removal of epiphytes in the plantations significantly impacted the epiphyte species diversity. High management intensity particularly affected diversity of liverworts and lichens, but not mosses. As one might expect, plantations with low management had the highest percent cover of bryophytes. Plantations with low and moderate management serve as reserves for some ecological specialists, making these plantations important in the conservation of epiphytes.

Figure 21. *Theobroma cacao* plantation in Dominican Republic, home for a number of bryophytes, some of which would normally be in local forests. Photo by C. T. Cooper, through public domain.

Working in tropical rainforests of the Pacific, Pócs and Tóthmérész (1997) found that the average species richness in the most diverse epiphyll communities was 8-9 per leaf. Degraded habitats exhibited as few as 3-4 species. At the habitat level, the number of species could reach 24-25 species. The number of species per habitat does not typically decrease as a result of habitat degradation because **beta diversity** (differences in species composition among sites; regional diversity) tends to increase while the number of species per leaf decreases. The study emphasizes the importance of the scale of the study in order to assess the impacts of disturbance.

Some of our understanding of microhabitat differences can be derived from studies on the effects of disturbance. For example, Werner and Gradstein (2009) compared various degrees of disturbance in closed-canopy mixed acacia forest (old secondary), pure acacia forest (old secondary), forest edge, young semi-closed secondary woodland, and isolated trees in grassland. They found that density of bryophytic epiphytes on 100 trees of *Acacia macracantha* (Figure 22) in northern Ecuador at 2,300 m asl is significantly lower in edge habitat and on isolated trees than in closed forest. Forest edge is more

impoverished than semi-closed woodland and has similar floristic affinity to isolated trees and to closed forest types. The microhabitats among these habitat types vary, contributing to the diversity. As they point out, "Assemblages were significantly nested; habitat types with major disturbance held only subsets of the closed forest assemblages, indicating a gradual reduction in niche availability." They found no diversity effect from distance to the forest for epiphytes on isolated trees. Species density is closely correlated with crown closure. They concluded that microclimate, not dispersal constraints, determine most of the epiphyte assemblages. The researchers also concluded that the bryophytic epiphytes are sensitive indicators of changes in microclimate and human disturbance in the montane dry forests. A major treatise on the canopy community is that of Lowman *et al.* (2013).

Figure 22. *Acacia macracantha*, a species where density of bryophytic epiphytes in northern Ecuador at 2300 m asl is significantly lower in edge habitat and on isolated trees than in closed forest. Photo by Vladeq, through Creative Commons.

Deforestation

Deforestation has become a major factor impacting diversity and biomass in the tropics (Figure 23). "Between 1990 and 1997, 5.8 ± 1.4 million hectares of humid tropical forest were lost each year, with a further 2.3 ± 0.7 million hectares of forest visibly degraded." (Achard *et al.* 2002) although the rate has slowed in recent years, deforestation continues, increasing the total impact.

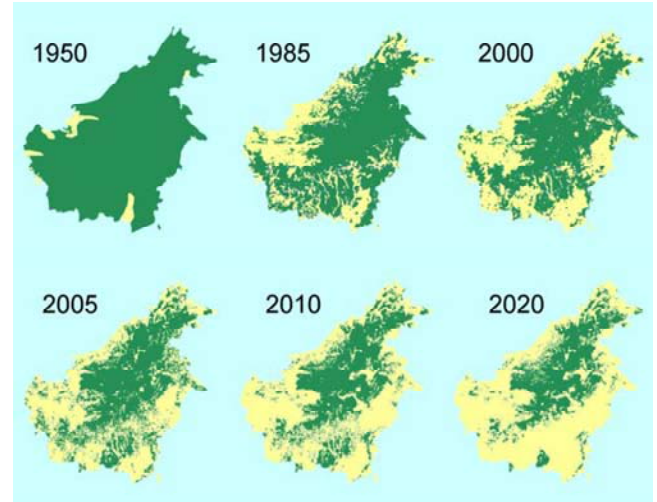

Figure 23. 70 years of Borneo deforestation. Photo courtesy of Robbert Gradstein.

Scatena *et al.* (2010) noted that the cloudy, wet, difficult terrain of the tropical montane cloud forests had afforded the bryophytes some protection from deforestation. However, in the late 1970's and early 1980's, even these forests were being torn down or fragmented. By the 1990's they became one of the most threatened ecosystems in the world, with a loss rate exceeding that of the lowland tropical forests ($1.1\% \text{ y}^{-1}$ vs. $0.8\% \text{ y}^{-1}$).

Deforestation (Figure 1, Figure 24) has greatly reduced diversity of bryophytes, as one might expect. The loss of high canopy has forced species that typically occupy the canopy to appear as low as the base of the tree (Gradstein 2002). This change in position correlates with the microclimate of the canopy in the mature forest, with the microclimate in the fallows matching closely the humidity and air temperature of the mature canopy. Such is not the case with the microclimate of the tree bases under the mature canopy.

Figure 24. Deforestation in the Amazon forest. Photo by Matt Zimmerman, through Creative Commons.

Pócs (1989) reported that epiphytes are much rarer in disturbed forests than they are in undisturbed forests in submontane rainforests in the East Usambara Mountains of East Africa. Rather, the species in the disturbed forests are sun species and occur on the lower parts of trunks of *Maesopsis* (umbrella tree; Figure 25). In the undisturbed

forests, these same species occur in the canopy. Pócs has also found a decline in epiphytes in the "undisturbed forest." He attributed this to the drying climate.

Henderson *et al.* (1991) reported that approximately 90% of the South American tropical mountain forests had been converted into pastureland or other non-forest use. Bryophyte losses are greater among mosses than among liverworts (Jácome *et al.* 2011). Shade species are more affected than drought-tolerant canopy species. The latter species are able to grow in lower positions on the remaining trees. A dense canopy is important in maintaining high diversity (Steffan-Dewenter *et al.* 2007; Sporn *et al.* 2009). Despite the negative impact, in Costa Rica the secondary forests may have up to 40% of their epiphytic species exclusively in the secondary forest.

Alvarenga *et al.* (2009, 2010) likewise reported a highly significant loss of richness as a result of habitat loss in a Brazilian Atlantic forest. The most conserved fragments have more than 10 times the species richness of the least conserved fragment. In non-conserved fragments, the epiphytes do not colonize the lower trunks (2.1-10 m) or higher zones. Instead, they are restricted to the lowest 2 m at the tree base and clearly exhibit an altered floristic composition. Specialists of sun or shade are impacted more than generalists. The generalists decrease in richness in non-conserved habitats, but their proportion increases due to the loss of specialists. The habitats that retain their rich epiphyte flora are greater than 300 ha in size – an uncommonly large size in the Brazilian Atlantic rainforest.

Figure 25. *Maesopsis eminii* (umbrella tree) providing shade for a coffee plantation. Photo by Aniruddha Dhamorikar, through Creative Commons.

In upper montane *Quercus copeyensis* forests (Figure 26) of Costa Rica, Holz and Gradstein (2005) found that total species richness of bryophytes and lichens differs little between primary and early or late secondary forests. The high richness in the secondary forest is most likely due to the high humidity under the closed canopy. Nevertheless, species composition differs markedly. After 40 years of recovery, 46 (one-third) of the species still had not become re-established. Of all recorded species, 40% (68 species) occur exclusively in the secondary forests.

Figure 26. *Quercus copeyensis* forest wherein species richness differs little between primary and secondary forest, but the kinds of species differ. Photo through Creative Commons.

When epiphytes were transplanted to lower elevations in the Bolivian Andes, the cover became more even and dominance of individual species decreased (Jácome *et al.* 2011). The researchers concluded that as climate changes, individual species responses will differ, resulting in new community relationships. They warn that short-term responses might not be indicative of long-term responses.

Costa (1999) compared epiphytic bryophyte diversity in primary and secondary lowland rainforests of southeastern Brazil. The highest species richness occurs in mature secondary hillside rainforest (43 species). The lowest is in a highly degraded hillside rainforest (6 species) and a hillside secondary rainforest (5 species). As seen elsewhere, the important families are *Lejeuneaceae* (Figure 4; 23 species, 30%) and *Sematophyllaceae* (Figure 27; 7 species, 10%). And as in other studies, the canopy

has the highest number of exclusive species (45% of canopy species). The shade epiphytes are the most affected by deforestation and many do not return 20-45 years after the destruction. However, after 80 years the species composition is similar to that of the primary forest.

Figure 27. *Sematophyllum* (Sematophyllaceae); Sematophyllaceae is among the important moss families from the lowland rainforests of southwestern Brazil. Photo by Michael Lüth, with permission.

In a different location in southeastern Brazil, Costa (1998) found the highest species richness in the mature secondary hillside rainforest (43 species). The lowest is again the highly degraded hillside rainforest (6 species).

Nöske *et al.* (2008) compared the epiphyte diversity of mature and recovering forest and that in open vegetation in the montane zone of Ecuador. They were unable to discern any pattern of change in species richness among different taxonomic groups (lichens, bryophytes, tracheophytes, and moths) with increasing disturbance. However, richness of epiphytic bryophytes decreased significantly from mature forest through the cline to open vegetation. For some of the taxa, the modified habitats serve to increase overall biodiversity in the Andes.

Hyvönen *et al.* (1987), however, found that many mosses can find suitable niches even in disturbed areas, unless destruction of the habitat is complete. Nevertheless, some are eliminated by current practices of land use. In their study on the Huon Peninsula of Papua New Guinea, they used 18,000 specimens to determine effects of disturbance on the bryophytes. Of 43 species, 14 were restricted to undisturbed habitats, 16 occurred about equally in both, and 23 were preferentially in disturbed areas. Primeval habitats were dominated by terrestrial and epiphytic mosses; weedy species occurred in disturbed habitats. The sensitive epiphytic species that decreased with disturbance include *Meteorium buchananii* (Figure 28), *Trachypus bicolor* (Figure 29), *T. humilis* (Figure 30), *Pseudotrachypus wallichii*, *Cryptopapillaria fuscescens*, and *Pelekium contortulum* (Figure 31). In addition, *Campylopus clemensiae* (see Figure 42) and *Leptocladia flagellaris* grow on living trees as well as rotten wood. Soil species that are sensitive include *Dawsonia grandis*, *D. papuana* (see Figure 32), *Rhodobryum giganteum* (Figure 33), with less substrate-discriminating *Macrothamnium hylocomioides* (see Figure 34), *Thuidium cymbifolium* (Figure 35), and *T. glaucinum* (Figure 36). Persistent species include *Bryum apiculatum*

(Figure 37) and *Plagiomnium integrum* (see Figure 38), although they decrease in altered habitats. On the other hand, the outer crown epiphyte *Leptostomum intermedium* (see Figure 39) seems to increase with human influence, but that could be an artifact due to the difficulty of sampling it. The species that clearly increase with disturbance include *Brachymenium nepalense* (Figure 40), *Bryum billardieri* (Figure 41), *Campylopus exasperatus*, *C. umbellatus* (Figure 42), *Elmeribryum philippinense*, and *Orthomnion elimbatum* (Figure 43). Species that were clearly present only following disturbance include *Bryum argenteum* (Figure 44) and *Gemmabryum subapiculatum* (syn.= *Bryum microerythrocarpum*; Figure 45).

Evidence shows that logging does not have to be totally destructive. The main effect of such disturbance in tropical forests is increased desiccation due to greater wind movement and insolation, causing a reduction in biomass of epiphytic bryophytes (Norris 1990). This, in turn, decreases the water and mineral retention of the remaining bryophytes and interferes with their ability to trap and release water and mineral nutrients. In Papua New Guinea, Norris found that logging and agricultural practices may alter bryophyte species frequency, but with careful attention to logging management, there is no evidence of a significant loss of species.

When Romero (1999) compared bryophytes in logged and non-logged plots in a tropical montane forest in Costa Rica, he found that pendent epiphytes were more abundant on branches less than 1 cm in diameter. The highest biomass was that of branches supporting shade-tolerant species, *i.e.*, non-logged plots.

A comparison of fallow land (4-15 years) vs submontane rainforest in Bolivia reveals considerably less diversity of both bryophyte families and species in the fallows (Acebey *et al.* 2003). Surprisingly, there is little difference in liverwort diversity between them except in the

very young (4-year-old) fallows. Life forms differ, with significantly more smooth mats (72%) in the fallows. Nevertheless, in just 10-15 years, approximately half of the bryophyte taxa of the rainforest are re-established among the trees of the fallows. Most of these arrivals are ecological generalists and sun-loving epiphytes, with ecological specialists and shade species arriving and establishing more slowly. The highest diversity of the fallows is in the understory, contrasting with the highest richness in the canopy of the uncut rainforest. The shift to lower parts of the trees in the fallows corresponds with the greater air humidity there and most likely also with lower temperatures and reduced light intensity.

The Neotropics are not the only tropical area experiencing serious species loss. Turner *et al.* (1994) reported extinction of 594 of the 2,277 tracheophyte species in the Republic of Singapore. Epiphytic species have suffered 62% loss. These losses are due to deforestation (99.8% of primary forest) and disturbance, with the mangrove epiphytic flora disappearing completely. These losses will necessarily impact the losses of bryophytes through loss of substrate, shade, and sufficient humidity.

Much of the land in the tropics has been lost to agriculture before we have even assessed what bryophyte species live there. Sulawesi, Indonesia (Figure 46), is characterized by steep slopes that are often difficult for bryologists to navigate, but logging has nevertheless altered the environment. Ariyanti *et al.* (2008) investigated the bryophytes on tree trunk bases in the natural forest, selectively logged forest, and cacao plantation (Figure 21) shaded by remnants of the natural forest there. They found that species richness differs little among these forest types. But on close inspection, one finds that the moss richness is lowest in the cacao plantations, but the liverwort richness differs little among the forests. By contrast, the moss cover differs little among the forests, but liverwort cover is significantly less in the disturbed forest. Species composition likewise differs markedly in the cacao plantations compared to the natural forests and selectively logged forests. Drought-sensitive species are notably rare or absent in the cacao plantation, with drought-tolerant species replacing them. Large vs small trees have little effect on bryophyte species composition except in the cacao plantation; the latter phenomenon the researchers attribute to changes in stemflow of precipitation water.

Figure 46. Tangkoko National Park, North Sulawesi, Indonesia. Photo by Lip Kee Yap, through Creative Commons.

Gradstein and Sporn (2010) compared epiphytic bryophytes from different land use types in several countries of the Neotropics and Indonesia (Sulawesi), including natural rainforests, secondary rainforests, fallows, isolated pasture trees (Figure 20), and cacao agroforests (Figure 21). They found changes in species richness between these disturbed habitats and the various disturbances to vary by 0-10% species loss in the old secondary forest and up to 65-80% loss in young fallows and cacao agroforests. The cacao agroforests lost 75% of their species. In contrast, the remnant forest trees in pastures provide a rich habitat where bryophytes can be conserved. In submontane forests, there were considerable changes in life forms, but these changed little in the montane zones. Sun epiphytes replace shade epiphytes in the deforested areas. The study demonstrates the importance of canopy cover in preserving the rainforest bryophyte vegetation.

Benítez *et al.* (2015) likewise noted the decline of bryophyte and lichen epiphytes in moist tropical montane forests, due to deforestation and habitat loss. Benítez and coworkers investigated 240 trees in primary and secondary forests of southern Ecuador and found that diversity is higher in primary forests and lower in monospecific secondary forest stands. Habitat loss and reduction of canopy cover negatively affect total diversity. This, in turn, modifies the water balance and nutrient cycling of these forests, further complicating the loss of bryophytes and lichens. Shade epiphytes are replaced by sun epiphytes, and species richness diminishes.

In the fragmented Afrotropical forests, Malombe *et al.* (2016) found the diversity of epiphyllous bryophytes exhibits no direct correlation with the distance from forest edge. However, they are affected by microenvironmental variables. These variables include tree species composition, sunlight exposure, and canopy structure, all factors that are typically affected by deforestation, even just thinning.

Cloud forests (Figure 47) are unique ecosystems with high bryological diversity and cover in the northern Andes (Benavides & Gutierrez 2011). But this ecosystem is also one of the most endangered ecosystems in the tropics. Agricultural techniques using slash and burn leave behind isolated individual palms in the middle of newly created grasslands or agricultural fields. This isolates the rare canopy bryophyte species. In Colombia, 72 liverwort species and 21 moss species comprised these epiphytic communities. The researchers found a decrease in the number of species from the forest to the grassland. The diversity likewise decreases from base to canopy of palms, with the more common species appearing an average of 4 m lower on the palms in the grassland when compared to those in the forest. The species remaining tend to be drought-tolerant forest species and species that commonly occur in disturbed sites. Hence, these isolated palms do not serve as suitable refugia for the rarer cloud forest species.

Cordova and del Castillo (2001) conducted a chronosequence study exclusively on tree bases in a tropical montane cloud forest in Mexico (Figure 48). The trees examined were in stands of 15, 45, 75, >90 years old, and a primary forest, and had originally been tropical montane cloud forests. They sampled the trees at 1 dm intervals using a sampling grid, up to 160 cm. Total

epiphyte cover increases with forest age, following an S-shaped curve. The highest rate of increase is between 15 and 45 years. Whereas moss and liverwort cover increases with stand age, macro- and microlichen cover appear to be independent of age. Cover of microlichens decreases as cover of mosses and tracheophytes increases. Total epiphyte cover per unit area shows some decrease as the diameter of the tree increases.

In an assessment of bryophytic epiphytic diversity in Columbian (Figure 49) forest patches, Orrego (2005) suggested that there is a direct relationship between bryophyte species diversity and the structural heterogeneity of forest fragments. He cautioned that a single index is not adequate to assess the epiphytic bryophyte diversity.

Figure 49. Mangrove forest and lowland forest, Ensenada de Utria, Chocó, Colombia. Photo by Philipp Weigell, through Creative Commons.

Gradstein (2008) noted that drought-intolerant species suffer more than drought-tolerant ones under the loss of cover due to deforestation. In the South American tropics, disturbance causes high species turnover and the return to the original epiphytic bryophyte flora is slow. Even after 50 years of forest recovery, the bryophyte flora is still very different from the undisturbed flora. Gradstein and Sporn (2010) documented the tropical diversity of epiphytic bryophytes with land use gradients.

Gradstein and Sporn (2010) summarize the effects of deforestation on the bryophyte communities of the tropics:

1. Deforestation has a significant impact on the bryophyte diversity in what was once forested land. Old secondary forests still experience 0-10% loss, whereas young fallows and cacao agroforest can have 65-80% loss. Epiphytic bryophytes are more strongly affected than are lichens (Gradstein 1992b), with a 4X turnover of bryophytes compared to lichens (Nöske *et al.* 2008). In the arid regions, bryophytes are more sensitive to land use changes than are the tracheophytes (Werner & Gradstein 2009).
2. Life form proportions change in the submontane forests, but not in the montane forests. **Mats** increase in submontane fallows and **tufts** increase in cacao agroforests; this change is accompanied by a loss of **fans**, **pendants**, and **tails**.
3. Shade epiphytes disappear as more exposure is created, and these are replaced by sun epiphytes. Epiphyte heights on the trees experience a shift to lower locations. The canopies become almost devoid of epiphytes.
4. Canopy closure, microclimate, and host tree characteristics serve as drivers of the epiphytic bryophyte diversity under different land-use types, indicating that canopy cover is necessary to maintain the rainforest diversity (Steffan-Dewenter *et al.* 2007). As a result, it may take more than 100 years for the bryophyte diversity to fully recover in second-growth forests.

5. Remnant trees in the pastures can provide a rich habitat where bryophyte species can be conserved. However, some agroforests, such as the cacao agroforest, are unable to provide this role (Andersson & Gradstein 2005).
6. Some bryophyte species can serve as indicators of land-use change at the local and regional scales, but not at larger scales. Qualitative and quantitative study of life forms and ecological groups of epiphytic bryophytes promise to provide bioindication of land-use change and rainforest disturbance in the tropics.

Fragmentation Effects

Deforestation is creating forest fragments in many areas of the tropics (Figure 1). Zartman (2003) discussed the effects of this habitat fragmentation on epiphyllous bryophyte communities in central Amazonia. He found that regionally common taxa are often reduced in epiphyll diversity in small fragments. On the other hand, rare taxa are often more abundant in fragments than in continuous forest habitat. Larger fragments (100 ha) exhibit higher species richness, abundance, and among site variation than do the smaller fragments (1 & 10 ha).

Silva and Pôrto (2009) assessed effects of fragmentation on bryophytes of decaying logs in the Atlantic Forest remnants in northeastern Brazil. They identified 99 bryophyte species (52 liverworts, 47 mosses). They determined that fragment size is important in determining the community structure on decaying logs. They did not find a correlation between distance from forest edge and bryophyte richness or cover, suggesting that the relationship is non-linear.

Zartman and Shaw (2006) consider the demographic mechanisms causing species loss in the tropics to be greatly under-explored. To contribute to the understanding of the impact of fragmentation, they chose the epiphyllous leafy liverworts *Radula flaccida* (Figure 50) and *Cololejeunea surinamensis* (see Figure 51). They transplanted these two species to study sites with areas ranging 1, 10, 100, up to 110,000 ha. All the transplants exhibited significantly positive local growth with a nearly constant per-generation extinction probability of 15%. In reserves of 100 ha or greater, the colonization rate nearly doubled (to 48%) compared to small reserves (27%). They considered this an indication that epiphyll loss in small fragments was due to reduced colonization.

Figure 51. *Cololejeunea calcarea*; *Cololejeunea surinamensis* reproduces more frequently by fragments in larger forest fragments. Photo by Hermann Schachner, through Creative Commons.

Bryophytes have relatively fast colonization and extinction rates, making them ideal study organisms for the effects of forest fragmentation (Pharo & Zartman 2007). Nevertheless, they are limited by dispersal, and this somewhat random process helps to explain their observed recolonization patterns.

Nevertheless, edge effects have an impact on community structure, especially where these create abrupt differences in microclimate. Establishment experiments repeatedly indicate dispersal limitation to explain the absence of typical forest species in fragmented habitats (Zartman & Nascimento 2006; Gunnarsson & Söderström 2007).

Younger fragments (<25 yrs), in particular, have lower richness and different species composition than adjacent mature forests (Pharo *et al.* 2004). Similarly, Snäll *et al.* (2003) found that age of the trees is more important than size for the moss *Orthotrichum* (Figure 52) on aspen (*Populus*; Figure 53) trees. Older trees support larger colonies.

Figure 53. *Populus* bark showing old and young parts of the tree. Photo through public domain.

In southern Veracruz, Mexico, the number of epiphytic tracheophyte species per tree and total estimated biomass correlate most with tree size, measured as diameter at breast height (Hietz-Seifert *et al.* (1996). When considering this relationship, the number of epiphytes on remnant trees is similar to that in the forest plots. However, the forest plots still differ significantly from each other, a response Heitz-Seifert and coworkers considered might be due to differences in humidity. The number of epiphytes on isolated forest tree species exhibit a negative correlation with distance from the forest border. The researchers also considered that some of the differences exhibited by the remnant trees, which included many figs, may have been due to the attraction of birds and bats that could contribute to seed dispersal. Although the importance of various environmental variables differ between bryophytes and tracheophytes, some of these same variables may affect both, and destruction of bryophytic epiphytes can affect the success of tracheophytic epiphytes and *vice versa*.

In open, disturbed areas in the Amazonian Andes of northern Peru, contrasting with the larger life forms of the forests, the disturbed and exposed areas comprising secondary forests are characterized by **short turf**-forming acrocarpous mosses that have a **colonist life strategy**, a life form not typically found within the developed forests (Kürschner & Parolly 1998; Kürschner *et al.* 1999).

Visnadi (2018) examined fragmented vegetation in Brazil by assessing the bryophytes in seven urban parks in São Paulo. As we might expect, those parks with different types of environments had greater species richness. More

densely wooded neighborhoods with colder temperatures supported the richest bryoflora. Even one vulnerable species, *Metzgeria hegewaldii*, and two endemic species (*Fissidens pseudoplurisetus* - Figure 54 and *Pterogoniopsis paulista*) occurred in some of these fragments.

Figure 54. *Fissidens pseudoplurisetus*, a species endemic to Brazil and found in environmental fragments such as parks. Photo by Juçara Bordin, with permission.

Harvesting

Deforestation isn't the only human danger. Harvesting of bryophytes for commercial use likewise can endanger the bryophytes (Peralta & Wolf 2001). In addition to many Neotropical areas, in India, Japan, and China mats of mosses are peeled from their substrates for use in the horticulture industry (Wuethrich 1993; Peck 2006; Peck & Moyle Studlar 2008). These can greatly reduce cover on the reachable branches and logs.

In the monarch butterfly biosphere reserve, Sierra Chincua, Michoacan, Mexico, mats of bryophytes are harvested, packed, and sold in Mexico City for ornamental use. One family alone (about 10 members) harvested 50 tons (fresh weight) of bryophytes in one collecting season. This created a mosaic of gaps of bare soil in the mossy layer, with an average gap size of 0.48 m². This moss removal consequently caused the removal of 11,000 *Abies* (fir) seedlings that were growing with the mosses.

In the montane tropical oak-bamboo forests in Costa Rica, pendent bryophytes are a locally valuable resource subject to commercial harvesting (Romero 1999). Thus, logging that destroys the habitat of these taxa is of local concern. These harvestable bryophytes include the mosses *Pilotrichella flexilis* (Figure 55-Figure 56), *Phyllogonium viscosum* (Figure 57), *Zelometeorium* sp. (Figure 58), and *Squamidium leucotrichum* (Figure 59) and the leafy liverworts *Frullania convoluta* (Figure 60) and other *Frullania* species. These pendent life forms are important in water interception and thus might be expected to have an important effect on the hydrological balance in these forests. However, nine years after careful selective logging in a montane oak-bamboo forest, there were no detectable negative impacts on the biomass of these bryophytes at commercially available heights (1-3 m). Unfortunately, there is no comparable study in Costa Rica to show the

impact of bryophyte harvesting on their successful return. In Africa, Jacobsen (1978) found that epiphytes require a minimum of 7-10 years to regenerate after harvesting from the forest.

Industrialization and Air Pollution

In addition to habitat loss, pollutants can destroy canopy bryophytes. Bryophytes are scavengers of atmospheric nitrogen as they collect the dust from the atmosphere. In this way, they are able to serve as bio-indicators of nitrogen pollution. Shi *et al.* (2017) examined epiphytic bryophytes from a subtropical montane cloud forest in southwest China. The critical load of nitrogen deposition there was estimated at $18 \text{ kg N ha}^{-1} \text{ yr}^{-1}$. The bryophytes become nutrient pools in these circumstances. These high levels are detrimental to the bryophytes, with a significant decrease in cover when the nitrogen input is only $7.4 \text{ kg ha}^{-1} \text{ yr}^{-1}$. The study site had a nitrogen deposition rate of $10.5 \text{ kg ha}^{-1} \text{ yr}^{-1}$. The researchers suggested that the high N levels not only did direct damage, but caused the leakage of magnesium and potassium, both essential nutrients for cellular metabolism.

Escocia Ariza (1998) reported losses of epiphyllous and epiphytic bryophyte species in the 20th century. The industrial district in particular has lower coverage, sexual reproduction, diversity, and a lower index of community vigor. **Chlorosis** (loss of green color of chlorophyll) indicates stress. *Lejeunea trinitensis* (Figure 61) emerged as a stress-tolerant species, whereas *Leptolejeunea exocellata* (Figure 62) is a sensitive species that disappears from the industrialized area. The species present in the polluted area are **colonists**, particularly on rocks. The colonization is a slow process. Species with both sexual and asexual reproduction are more successful at establishment.

Figure 62. *Leptolejeunea elliptica*; *L. exocellata* is a stress-intolerant species. Photo by Yang Jia-dong through Creative Commons.

Vareschi (1953) was one of the earliest researchers on tropical air pollution in Venezuela. These studies were actually the reverse of most, looking at the influence of the forests and parks on the air quality of the city of Caracas. Rebelo *et al.* (1995) reported on the epiphytic bryophyte communities under the effects of air pollution in Brazil.

In 1992, Durán *et al.* used the Index of Air Purity (IAP) to evaluate the responses of epiphytic mosses to air pollution in Mexico City, Mexico. They were able to demonstrate a significant negative correlation ($p < 0.5$) between these IAP values and SO_2 , NO_2 , NO_x , and Pb (lead). On the other hand, there were significant positive correlations with ozone. This relationship is manifest in the gradual decrease in frequency and cover of epiphytic mosses in Mexico City.

Bryophytes in temperate zones are well known for their ability to accumulate heavy metals (*e.g.* Faus-Kessler *et al.* 2001). But the behaviors of tropical bryophytes are less well known. Based on many temperate studies showing that bryophytes were good accumulators of heavy metals, Lisboa and Borges (1995) examined the potential use of bryophyte diversity as an indicator of pollution in Belém, in the lower Amazon region of Brazil.

Jayasekera and Rossbach (1996) conducted one of the few tropical species to address this issue. They examined background levels of heavy metals and their differences in plants of different taxonomic groups, including bryophytes, in a montane rainforest in Sri Lanka. They found that when a lichen (*Usnea barbata*; Figure 63-Figure 64), an epiphytic club moss (*Huperzia selago*; Figure 65), an epiphytic fern (*Pleopeltis lanceolata*; Figure 66), an epiphytic orchid (*Bulbophyllum elliae* (see Figure 67), a large dicotyledonous tree (*Actinodaphne ambigua*; see Figure 68), and a moss [*Pogonatum* sp. (Figure 69)] were compared for their heavy metal content, the levels were essentially homogeneous for Cd, Cu, Pb, and Zn. The moss *Pogonatum* had the highest degree of homogeneity for lead. The primitive taxa, the lichen *Usnea* and moss *Pogonatum*, seem to have higher accumulation levels of As, Cd, Co, and Pb than do the tracheophytes.

On the other hand, bryophytes have been used to help clean the air and remove pollutants (Vareschi 1953). Bryophytes greatly expand the available surface area for trapping and immobilizing both water and ions from the atmosphere (Coxson 1991).

Radiation

Although the studies on radiation effects on tropical bryophytes are limited, the extensive study at El Verde, Puerto Rico (Figure 71), did include bryophytes (Odum *et al.* 1970). High levels of radiation fallout retention were present in the epiphytic mosses in the mossy forest (Figure 72) of the Luquillo Mountains in 1962. The algae-moss-liverwort encrustations had the highest levels of radiation, with massive moss colonies being second. Bromeliads and rooted plants had less. Radioactivity in tree leaves was in proportion to the epiphyllous growths on them, and that growth was related to leaf age.

Figure 72. Elfin forest at the Luquillo Mountains, Puerto Rico. Photo by Janice Glime.

Man-made Habitats

Many forested areas have been replaced by man-made habitats. These provide greater variety in available habitats. In the tropics, one can find *Diplophyllum obtusatum* (Figure 73), *Solenostoma sphaerocarpum* (Figure 74), and *Schistochilopsis incisa* (Figure 75) in

man-made habitats (Gradstein & Vána 1987). It appears that these Laurasian species have spread relatively recently through human activities.

Figure 73. *Diplophyllum obtusatum*, a species that thrives in man-made habitats. Photo by Paul Davison, with permission.

In Alto Beni, Bolivia, corticolous bryophytes on trees in the primary rainforest decreased significantly in the

fallows as measured after 4-15 years (Cabby *et al.* 2003). But liverwort diversity barely changed except in the 4-year-old forest. **Smooth mats** had a significantly higher percentage (72%) in the fallows, perhaps due to the warmer, drier microclimate. But even in the 10-15-year-old fallows, only about half the species had returned, mostly generalists and sun epiphytes. Whereas species richness is highest in the undisturbed canopy, in the fallows it is highest in the understory, with **rough mats, fans, and tails** shifting to lower heights on the trees, most likely due to changes in air temperature and air humidity.

If sufficient natural forest is retained, artificial forests can increase the diversity by providing new niches. Petit and Symons (1974) reported 28 bryophyte species from 17 artificial woodlands planted with *Cupressus* (Figure 76-Figure 77) and *Acacia* (Figure 22) in Burundi, Africa. In these woods, the litter layer is covered with bryophytes and the flowering plants are almost absent.

Figure 77. *Cupressus lusitanica* (= *Hesperocyparis lusitanica*) being harvested in Uganda. Photo by J. D. Ward, USDA Forest Service, <Bugwood.org>, through Creative Commons.

Sillett *et al.* (1995) compared bryophyte diversity in *Ficus* tree crowns from the cloud forest and a pasture in Costa Rica. In the lower montane wet forest, they found

127 bryophyte species (50 mosses, 76 liverworts, 1 hornwort) in the inner crowns of only six *Ficus tuerckheimii* trees. Of these, 52 were found only in the intact forest, whereas only 18 species occurred exclusively in the isolated trees of the pasture. One of the factors contributing to the differences was a moisture gradient that diminished away from the intact forest.

In the northern Andes, roadside habitats in humid locations can be invaded by canopy liverworts from the montane forest (Gradstein 1992b). These include such liverwort species as *Dicranolejeunea axillaris*, *Frullania brasiliensis* (Figure 78), *Frullania convoluta* (Figure 60), *Frullanoides densifolia* (Figure 79), *Herbertus acanthelium* (see Figure 80), *Jamesoniella rubricaulis* (Figure 81), *Omphalanthus filiformis* (Figure 82), and *Taxilejeunea pterigonia* (see Figure 83). In such locations these liverworts behave as pioneers.

Climate Change

Benzing, in 1998, stressed the vulnerabilities of tropical forests to climate change, and even more so to that of their bryophytic inhabitants. Noting the complexity of these systems, he pointed to the narrow set of circumstances that define the habitats for these bryophytes. This raises the concern of their often underestimated role in both hydrology and mineral cycling, added to their ability to support a wide diversity of smaller organisms such as salamanders, arthropods, fungi, and micro-organisms, making them major contributors to the ecosystem. Yet their vulnerability in tropical forests under climate change is great.

Many bryophytes in the tropics are approaching their limits of tolerance to the high temperatures that increase their rate of respiration (see Microclimate above). Hence, as considered by Zotz and Bader (2009), "rising temperatures could have disastrous effects." Moving farther away from the equator may provide a refuge for some species, but the authors suggest that epiphytes may be "particularly threatened" because the cloud forest habitats are likely to be the most seriously affected. And these are species-rich habitats where "exceptional" species occur. They furthermore are often isolated, requiring long-distance dispersal to reach a suitable climate.

Durán *et al.* (1992) used the IAP values to demonstrate that higher rainfall and relative humidity helped to account for higher bryophyte diversity values. Climate changes can affect these parameters, making some areas drier. Furthermore, bryophyte IAP values exhibit a negative correlation with temperature.

Climate change studies in the tropics are of utmost importance in a region where many species are already limited by temperature. Jácome *et al.* (2011) summarized what we know about the effects on the epiphytic bryophyte communities of simulated climate change in the tropics. Based on a translocation experiment in the upper montane forest in Bolivia they showed that exposure to air temperature increases of 1.5-2.5°C had a measurable effect on the structure of epiphytic bryophyte communities of the tropical montane forest within two years. The results confirm the sensitivity of non-tracheophytic epiphytes to

atmospheric changes and predict that changes in the climatic regimes of tropical montane forests will rapidly affect the rich non-tracheophytic epiphyte communities.

Epiphytes seem to be particularly vulnerable to climate change because they must survive "at the interface of vegetation and atmosphere" (Zotz & Bader 2009). Furthermore, land use exacerbates the problem by decreasing the suitability of the environment. On the other hand, some drought-resistant species may benefit. They projected that new assemblages would form among bryophytes and lichens. But rising temperatures can be very destructive for both bryophytes and lichens. This will most likely be most detrimental to the habitats in the tropics with exceptional species richness, in particular, the cloud forests.

Sometimes human interference resulting in local climate change actually helps bryophytes. Kautz and Gradstein (2001) found that the critically endangered *Spruceanthus theobromae* (Lejeuneaceae; Figure 19) grows on the trunk bases of *Theobroma cacao* (Figure 20-Figure 21) in 12 plantations that had minimal management. In fact, the researchers felt that it should instead be considered as a near-threatened species and removed from the World Red List.

Recovery

Hallingbäck and Tan (1996) bemoaned the loss of species worldwide, citing reduction, fragmentation, and isolation of their habitats, in addition to damaging pollution. They noted the value of designating certain bryophytes as key species to protect because of the associated plants and animals that would also be protected. But if areas already impacted are allowed to recover, what can we expect?

Return of bryophytes to remnant forests after logging is slow. In subtropical rainforests of Australia, few bryophytes had returned even 25 years after the disturbance (Chapman & King 1983). The same was true in southeastern Brazil (Costa 1999). In Costa Rica, isolated remnant trees (e.g. Figure 84), lacking the dense canopy of the undisturbed forest, had bryophyte diversity reduced by 50% compared to the remaining intact forest.

Figure 84. Tropical montane meadow with remnant tree; undisturbed forest is on the far side of the river in back, San Francisco Reserve, Ecuador, 2000 m asl. Photo courtesy of Robert Gradstein.

Gradstein and Sporn (2010) found that canopy closure, microclimate, and host tree characteristics are important in determining epiphytic bryophyte diversity. Preservation of the canopy, therefore, is important in maintaining this diversity. Recovery of bryophyte communities after clear-cutting is very slow and may take more than 100 years.

Recovery following deforestation requires the presence of viable plant parts or reproductive units. Olarinmoye (1986), working in Nigeria, examined survival strategies in three species during re-establishment after a period of drought. *Hyophila involuta* (Figure 85-Figure 86) is able to re-establish through spores, with its sporophyte production appearing to give it a competitive advantage compared to *Barbula indica* (Figure 87) and *Fissidens asplenioides* (Figure 88). The latter two species were similarly wide-spread, using vegetative regrowth from rhizoids, shoot bases, apices, or the main stem, with rhizoids contributing the most regrowth.

Liu *et al.* (2007) elaborated the species on the forest floor and on the tree trunks in the forest of Heishiding Nature Reserve, Guandong, China. They found that species composition of the mature forest was similar to that of the mixed pine and broad-leaved forest, and to young secondary forest, but community structure of the mature forest was quite different from that of the secondary forest. Most of the bryophytes occurred on the tree trunks (40 species), with only 24 species on the forest floor. Bryophyte cover was low on both substrata. Species richness of forest floor bryophytes in 2,500 m² quadrats ranged 8 to 13 with 0.59% to 1.12% cover. Slope and microenvironment were the primary determinants of species distribution and richness on the forest floor. Epiphytes, on the other hand, exhibited 12 to 20 species with a mean cover of 0.63 to 1.63% in these plots. The

researchers concluded that bryophytes in 30-year-old secondary broad-leaved forest had returned to the level of the mature broad-leaved forest.

Corrales *et al.* (2010) recorded 151 terrestrial bryophyte species in secondary and planted montane forests in the northern portion of the Central Cordillera of Colombia. Secondary montane forests have a higher weighted species richness than do the pine plantations. Weighted species richness is higher in secondary montane forests and cypress plantations than in pine plantations. Cypress plantations have the highest bryophyte abundances, although Detrended Correspondence Analysis indicates a high floristic similarity among the various forest types. Differences seem to relate to soil pH, slope, and light availability. Regional patterns depend on continuous dispersal of propagules.

Serrano (1996) found 37 species of mosses in 25 genera in disturbed areas in the municipality of Bayamon, Puerto Rico. *Fissidens* is the most species-rich genus. The most frequent of all species is *Fissidens zollingeri* (see Figure 88), occurring at all study sites. It is an indicator of disturbed areas. Urbanization further reduces the number of species present. One mechanism accounting for the spread of the species is spore production. Of the 37 species, 18 were observed with capsules and these species tended to occur more frequently when their sporophytes were more frequent. Only 7 species exhibited special vegetative reproductive structures. Among the pleurocarpous species, those with the greatest frequency in collections were those colonizing the greatest number of substrates.

Conservation Issues

Gradstein (1992a, b) and Pócs (1996) emphasized that conservation of epiphytes "can only be achieved through the rigorous protection of the forests."

Hallingbäck and Hodgetts (2000) contend that the negative impact of habitat loss has already gone too far in the tropical lowlands. Forested land has been cleared continuously for the expansion of the human population and the agriculture to support it (Hyvönen *et al.* 1987).

Hodgetts *et al.* (2016) raised concern about the very diverse tropical Atewa Forest in the Eastern Region of Ghana. This area is highly threatened by human activities, including illegal mining, farming, and hunting, as well as threat from industrial bauxite mining. Little is known of its bryophyte flora, and it could be lost before it can be explored adequately. A single survey in March 2014 revealed 164 species, with 58 new to Ghana and 1 new to science.

Costa and Faria (2008) noted conservation priorities for bryophytes in the state of Rio de Janeiro, Brazil. Recognizing the high degree of biological diversity, with an estimated 1,040 species of bryophytes, they cautioned that most of the inventories have focussed on the montane rainforest and coastal region. Among those bryophytes that have been recorded, 14% are considered vulnerable or threatened in the region. They considered the old-growth Atlantic forests (Figure 89) to be among most important habitats needing conservation, citing reduction, fragmentation, and isolation as causes for concern. Although 13% of the land area of the state is protected,

these protected areas are mostly montane and upper montane Atlantic rainforests.

Figure 89. Atlantic Forest, Antonina Bay, Brazil. Photo by Deyvid Setti and Eloy Olindo Setti, through Creative Commons.

As already noted, Jacobsen (1978) found that epiphytes require a minimum of 7-10 years to regenerate after harvesting of the forest. In any case, deforestation leads to local extinction of species (Gradstein 1992b). Shade epiphytes are the most easily affected by disturbance.

The International Association of Bryologists has representation on the IUCN (International Union for Conservation of Nature). To quote Söderström *et al.* (1992), "The conservation process involves recognizing and listing rare and decreasing species, recording their distribution, biology and specific threats, proposing conservation programmes, and executing these programmes." But they point out that the large gaps remaining in our knowledge about bryophytes complicate conservation practices. They list areas needing further study, including taxonomy, bryogeography, habitat demands, natural dynamics, dispersal ability, population structure, and genetics. They stress the importance of focussing on conservation of habitats and sites where species can survive on their own.

In this regard, Villaseñor *et al.* (2006) gathered data on the rich moss and *Senecio* (Figure 90) flora in the Trans-Mexican volcanic belt. They were able to identify 11 hotspots that are beneficial to the rich species composition of both groups. They conclude that 18 "cells" in this range would conserve the total diversity of both mosses and *Senecio* species in these species-rich hotspots. It is important that we identify such hotspots and find ways to conserve them.

Figure 90. *Senecio toluccanus*, a common species of the Trans-Mexican volcanic belt. Photo by Juan Carlos Pérez Magaña, through Creative Commons.

Twenty years ago, our knowledge of tropical bryology was quite meager, making conservation efforts problematic. Sastre de Jesus and Tan (1995) noted the problems in Puerto Rico and the Philippines. As noted by Streimann (1994) for Australia, conservation programs must be preceded by a good knowledge of the bryophytes. In absence of those data, he recommended that at least for those areas that are poorly known for bryophytes, those areas conserved for vascular plants, including national parks and forest reserves, would in most cases be adequate to conserve bryophytes as well.

The bryophyte flora of Mexico was somewhat better known, with more than 900 species, including 98 endemic taxa (Delgadillo 1996). Even so, many areas still need to be explored. Meanwhile, habitat destruction may be destroying some taxa forever. Delgadillo bemoaned the fact that there still was no legislation to protect the habitats of any Mexican mosses.

As in Mexico, moss diversity in the tropical Andes is extensive, with 2,058 species known in 1995. Although this number is probably inflated due to the same species being named multiple times in different locations, the presence of 343 genera and 75 families is still an indicator of the high diversity. Churchill *et al.* (1995a) estimate the

actual number to be 1,500-1,700 species. They contended that the tropical Andes are eight times as rich in moss species as the Amazon basin. Churchill (1996) summarized the status of our knowledge of moss diversity and conservation in the Andes, noting the needs to prepare for the future. But one of the problems with conserving bryophytes in Neotropical cloud forests (Figure 47) is that they are typically surrounded by xeric habitats unsuitable for their survival (Churchill *et al.* 1995b).

Holz and Gradstein (2005) considered that genera and species of bryophytes and macrolichens that are exclusive to the primary (uncut) forests could be used as indicator taxa and that these species and their forests should be conserved.

In French Guiana, water availability affects the bryophyte life forms. When Pardow *et al.* (2012) compared the life forms of the lowland cloud forests with those of the other lowland forests, they concluded that life forms could indicate lowland cloud forests that are appropriate for conservation. This would permit conservation of a rich bryophyte flora with higher biomass and cover.

With 1,000 epiphyllous liverworts worldwide, these tiny plants represent a group that is also endangered worldwide (Pócs 1996). Of these, 504 are in Asia and 375 in the Americas. They are by far the most species rich in the tropical and subtropical rainforests, but as these forests disappear, so do the epiphylls.

Climate change studies in the tropics are of utmost importance in a region where many species are already limited by temperature. Jácome *et al.* (2011) summarized what we know about the effects on the epiphytic bryophyte communities to simulated climate change in the tropics.

Newer tools may help us to process the data in meaningful ways to understand environmental impacts. In summarizing the symposium and priorities for future research, presented at the first IAB and IAL Symposium on Foliicolous Cryptogams, Gradstein and Lücking (1997) noted that multivariate statistical methods were useful in analyzing the foliicolous community data.

With the inevitability of global climate change, bryophytes living in tropical mountain habitats are clearly in danger. Zhang (2001) found a linear increase in number of species per forest plot with an increase in altitude. As those areas become warmer, those species may not have the time needed for significant dispersal to distant areas with a similar cool climate.

Gradstein and Pócs (1992a) advised that protection of as much as possible of the remaining natural tropical rainforest area seems the best approach to the conservation of the tropical bryophyte flora. This seems to be working in the Wet Tropics of northern Queensland, Australia.

Current Status

In 1982, Schultze-Motel referred to the crisis in tropical bryology. Part of this crisis is the loss of habitats and species before we have even explored to determine what is there to be lost. Even worse, we know little of their role in these sensitive, disappearing ecosystems, even today.

In 1992, Motito *et al.* recognized the need for bryological study in Cuba (Figure 91). At that time 383 infrageneric bryophyte taxa were known, and studies had begun on phytochemistry and antibiosis. However, it seems that little progress has been made since then on protection of species or of understanding their ecology.

Figure 91. Montane moist forest, Pico Turquino, Cuba. Photo by Male Gringo, through Creative Commons.

In Brazil, biological diversity is high, particularly in the state of Rio de Janeiro (Figure 92). In this area, there are many bryophyte endemics with a total species number estimated at ~1,040 species. Of these, 150 species are classified as vulnerable or threatened. Unfortunately, many of the 1,040 species are in the "data deficient" category, so their abundance is not known, nor do we know what conditions are needed to maintain them. Fortunately, almost 13% of Rio de Janeiro is protected land, but it is mostly in the montane and upper montane Atlantic rainforests. The remaining old-growth Atlantic rainforests are in need of greater conservation.

It appears that the Wet Tropics of Australia may be among the best protected areas with rare and endemic species (Streimann 2000). Most of these areas are in national parks, national estates, world heritage sites, and flora reserves. Evenso, they are impacted by tourism.

Summary

Natural disturbances such as El Niño, hurricanes, fire, volcanoes, and animal activity can dislodge bryophytes or provide conditions unsuitable to their continued growth. Some rare and threatened species thrive in these altered conditions, but in general these are potential sources of species losses.

Disturbance is a major cause of loss of species and populations in the tropics. Approximately half of the bryophyte taxa lost on fallow land can become re-established in 10-15 years; most of these are ecological generalists and sun-loving epiphytes. For others it can take 100 years. Sufficient fragment size is important in maintenance and re-establishment of species.

The highest diversity of the fallows is in the understory, contrasting with the highest richness in the canopy of the uncut rainforest. This difference is the result of light penetration, and in some cases moisture.

Human harvesting of bryophytes for horticulture and other human uses not only reduces the bryophyte cover, but also removes habitat for numerous invertebrates and many amphibians.

Industrialization can raise nitrogen levels beyond the limits of tolerance. Heavy metals accumulate in the bryophytes and can reach lethal levels. On the other hand, the bryophytes can serve as filters to remove these pollutants from the air, in some cases after the bryophytes die.

Man-made habitats displace natural habitats, but they do increase the number of niches. Some species thrive in these new niches. For example, the leafy liverwort *Spruceanthus theobromae* is currently known from the bark of cacao on plantations.

Many bryophytes have narrow temperature, light, and moisture requirements. Changing climate can not only destroy the forests where they live, but change the microclimate so that it is no longer suitable for them.

Bryophyte recovery can take a long time. In particular, those species living on mountain tops may not have any suitable propagule source without intervening unsuitable habitats. Even in restored lowland rainforests, recovery of bryophyte diversity can require more than 100 years.

The most pressing issues seem to be massive losses of habitat due to agriculture and forestry management for trees only. But climate change is likely to be a close second in the loss of tropical bryophytes in the tropics.

Current practices are beginning to recognize that some species can be conserved by maintaining larger fragments, keeping more trees where trees are cut, and designating more land to conservation.

sent several papers and a marked up copy of this chapter text where I had repeated myself, which led to my discovery that I must not have finished organizing this subchapter.

CHAPTER 18-1

CAVES – THE ENVIRONMENT

Figure 1. Stalactite, stalagmite, and column formations in Avshalom Cave, Israel. Photo by Sir Joseph, through Creative Commons.

Caves

Traditional definitions of caves note such characteristics as perpetual darkness, environmental stability, and oligotrophy, characters that apply to large cavities (**macrocaverns**) in rocks (Moseley 2009a). Moseley attempted to provide an ecological definition of a cave. But he did this from an animal perspective, and thus light mattered less than for bryophytes. By definition, macrocaverns, mesocaverns, and microcaverns differ from each other only in magnitude (*i.e.* scale). Because these caves differ in more characteristics than size, particularly in view of the habitat needs of the inhabitants, we should more properly refer to subterranean habitats.

Schuster (1958) noted that bryophytes are able to survive in small niches or "pockets" because of their small size, causing them to be limited by their microenvironment

rather than the macroenvironment. Thus, we can find unique communities in caves, no matter how small the cave may be (see Schade 1917; Clausen 1952).

Terminology

Caves bring with them a set of terminology that is unfamiliar in other contexts. Some are necessary to understand the relevant literature.

Caves themselves, typically known as underground or subterranean habitats, have a number of other names, including **alcove**, **antre**, **cavern**, **cavity**, **chamber**, **den**, **dugout**, **gallery**, **grotto**, **hollow**, **pothole**, **recess**, **rock shelter**, **subterrane**, and **tunnel**. As a synonym of sinkhole (Figure 2), **doline** (Figure 3) or **dolina** refers to shallow, usually funnel-shaped depression of ground surface formed by solution in limestone regions.

Figure 2. Sinkhole with bryophytes in Wilson County, Tennessee, USA. Photo by Brian Stansberry, through Creative Commons.

Figure 3. Doline diagram by B.Z. Saylor, MIT, <oeit.mit.edu>.

Terms Used to Describe Caves

algific: cold producing

algific cave: subterranean cave that vents cold air; Figure 4

Figure 4. Algific talus slope with vent northeastern Iowa. Photo courtesy of Beth Lynch.

column: formed by union of stalagmite and stalactite; Figure 5, Figure 6

Figure 5. Travertine dripstone columns, San Salvador Island, Bahamas. Photo by James St. John, through Creative Commons.

Figure 6. Labelled speleothems. Photo by Dave Bunnell, through Creative Commons.

flowstone: rock deposited as thin sheet by precipitation from flowing water; Figure 6, Figure 7

Figure 7. Travertine flowstone and draperies, Diamond Caverns, Kentucky. Photo by James St. John, through Creative Commons.

helictite: distorted form of stalactite, typically resembling twig; usually made of needle-form calcite and aragonite; Figure 8-Figure 9

Figure 8. Helictites at Treak Cavern, Derbyshire, UK. Photo by Bill Lion, through Creative Commons.

Figure 9. **Helictites** at Jenolan Caves, Australia. Photo by Jason 7825, through Creative Commons.

soda straws: speleothem in form of hollow mineral cylindrical tube; tubular stalactites; Figure 6, Figure 10

Figure 10. Travertine soda straw stalactites in dolostone, Crystal Cave, Wisconsin, USA. Photo by James St. John, through Creative Commons.

speleothem: structure formed in cave by deposition of minerals from water, *e.g.* stalactite or stalagmite; Figure 6

stalactite: type of cave structure, hanging from cave ceiling, formed by deposition of minerals from water (stalactites have to hang on tight; they form on the ceiling); Figure 1, Figure 6

stalagmite: type of cave structure, projecting from cave floor, formed by deposition of minerals from water dripping from ceiling (**stalagmites** are little mites; they form on the **ground**); Figure 1, Figure 6

talus: broken rock; Figure 11

Figure 11. **Talus slope** at Ruby Mountains. Photo from USGS, through public domain.

Moseley (2009a) defined cave dwellers, based on animals that live in caves. Various authors have used the same terms to describe bryophyte cave dwellers.

1. **Troglobites:** Obligate cavernicoles: species that can survive only in caves.
2. **Troglophiles:** Facultative cavernicoles: species which survive and are able to complete their life-cycle in caves, but also survive and complete their life-cycle in other habitats.

3. **Trogloxenes:** Species found in caves which cannot complete their life-cycles there:
 - a. **Habitual troglloxenes** – Species which habitually frequent caves and thus, whilst not completing their life-cycle there, form a part of the cave community (also called ‘regular troglloxenes’).
 - b. **Accidentals** – Surface (**epigean**) species introduced accidentally, *e.g.* by floods, or by straying in.

Moseley (2009a, b) contended that this grouping "lends support to the proposal, recently made elsewhere, that caves can be seen as transitional environments (ecotones) between adjacent hypogean, epigean and/or endogean communities. It also appears to eliminate a number of longstanding conceptual and terminological difficulties, and might offer a rich framework for new understanding of subterranean ecology."

Ecotones

I have seen an analogy that **ecotones** are like a membrane, occupying relatively little space between two constituents. Cave openings have been compared to these ecotones, providing a rapid transition between environmental conditions, *i.e.* between hypogean, epigean, and endogean communities (Moseley 2009a).

Moseley (2009b) considers all caves to be ecotones because they have a "steep environmental gradient between adjacent ecological communities or ecosystems." Within the cave, the ecotonal changes include light levels (Figure 12), temperature (Figure 12), relative humidity (Figure 12), CO₂ concentration, and physical scale. These parameters apply well to large caves and caverns, but would not seem to apply as well to the very small caves between boulders or under ledges. Nevertheless, even these small spaces can have light and moisture gradients. Moseley argues that considering caves as ecotones can change the way we understand the communities we find there. He raises the question of what role "these transitional habitats play in the initial colonization of the subterranean milieu; and in persistence, adaptation and speciation of hypogean organisms." Although Prous *et al.* (2004) and Moseley examine the notion of caves as ecotones using an animal perspective, the ecotone perspective should apply to plant communities as well, particularly the bryophyte communities that respond to varying levels of light (*e.g.* Pentecost & Zhang 2001).

Prous *et al.* (2004) suggested a methodology using a similarity matrix. Prous *et al.* (2015) further elaborated on cave entrances as ecotones, noting that bryophytes were present as far as 30 m into the cave. The depth of light penetration is very much dependent on the size of the opening, the inclination, and the surrounding vegetation and rock formations that can block light entrance to the cave. Prous and coworkers reported "considerable light penetration even at 30 m."

Cave Conditions

Caves typically serve as islands, providing habitats that are isolated from similar conditions outside the cave (Culver 1970). Hence, they can maintain isolated populations of bryophytes that continue to reproduce, mostly asexually. Under this isolation, bryophytes can

develop unique genotypes and even cryptic species, as noted already for animals (Moseley 2009a). In fact, Culver (1971) even considered caves to be like archipelagoes. But Culver (1970) pointed out that caves differ from islands by a lack of area effect. Nevertheless, both are subject to effects of time and stochastic processes.

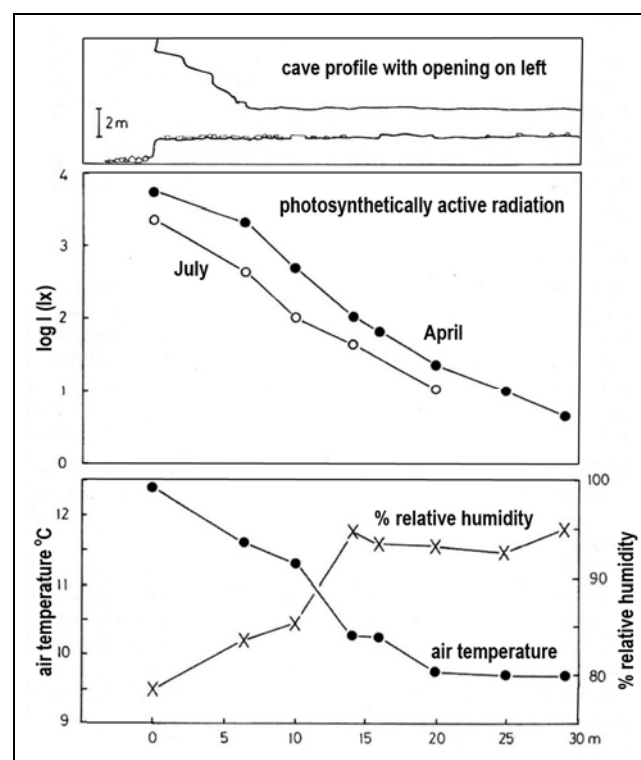

Figure 12. Cave parameters. Modified from Pentecost & Zhang 2001.

Caves provide natural laboratories for assessing the effects of gradients on species compositions (Poulson & White 1969). As islands, they can also help us to understand the effect of isolation on rate of genetic change and natural selection. And caves are simple systems with few tracheophytes to affect either competition or microclimate.

Tuttle and Stevenson (1978) have summarized the variation to be found in one cave environment and its impact on biological populations. They point out that many researchers have assumed a constancy in the cave environment, particularly that of temperature, assuming that it approximates the mean annual surface temperature. Researchers also often assume that humidity is near saturation and essentially unvarying. It is true that the cave environment varies less than that of the surrounding area, but it can indeed vary, at least in some caves, and this can impact the cave fauna (Jegla & Poulson 1970; Juberthie & Delay 1973; Delay 1974; Juberthie 1975; Poulson 1975; Tuttle 1975, 1976; Wilson 1975; Peck 1976), and presumably also the flora.

Substrate

Working in Eastern Australia, Downing (1992) noted that bryophytes were more abundant, exhibiting greater percent cover and a greater number of species, on limestone substrates than on nonlimestone substrates. Such preference may contribute to the diversity found in caves.

Fraser *et al.* (2014) suggested that in glacial regions organisms could have survived in geothermal areas in sub-ice caves. Such refugia could have permitted bryophytes to survive in these glacial areas until the ice receded. However, the ice itself is not a very good substrate.

Light

Like most studies, Mason-Williams and Benson-Evans (1967) identified two important ecological factors in Welsh caves: substrate and penetration of light. But they noted that aspect was also important, with north-facing walls having abundant growth and the south-facing walls having scanty, often atypical, growth. Bryophytes in higher light intensities had relatively typical life forms, but as light diminished the dendroid forms and smooth mats became less frequent and rough mats, thalloid mats, and wefts predominated. Spores of bryophytes were common throughout the sampled areas of the cave.

Similarly, Jedrejko and Ziober (1992) investigated bryophytes in caves on the Kracków-Wieluń Upland. They identified 10 liverworts, 59 mosses, and 3 unidentified mosses. Of these, 50% occur only where they get at least some time in full light. As expected, the number of species decreased with distance from light sources of cave inlets. Only 25% of the species occurred in continuously dry places.

Our constant attempts to classify things, even when they represent a continuum, have resulted in identification of the cave as the twilight zone **near** the entrance, a **middle** zone of complete darkness, and a zone of complete darkness and constant temperature **deep** in the cave (Poulson & White 1969). Among the fauna, the middle zone has several very common species which may go in and out of the cave.

Temperature and Humidity

Light, moisture, and temperature are variables in the cave environment and are not as constant as once thought. Buecher (1999), in a study of Kartchner Caverns in Arizona, USA, found that the cave could become drier due to increased airflow. This was caused by air entering from a second entrance and also by climate change. The relative humidity in the cave was 99.4% (pretty damp!) but had the potential of dropping to only 98.7%. At this only slightly lower humidity, the moisture loss from the cave surfaces would double! This would initiate the drying of the cave interior. Outside moisture is always less than that in the cave except during rain events. But since movement of air into the cave in summer is reduced, this does little to replenish lost humidity.

De Freitas and Littlejohn (1987) illustrate the seasonal changes in Glowworm Cave in New Zealand. They found that the external air temperature and humidity can be determinants of the spatial and temporal distribution of air temperature and humidity within the cave. The external conditions are also important in determining direction of airflow. In winter, these forces result in strong drying and cooling of the cave interior. External air enters the cave and is warmed. In summer the humidity levels of the cave rise substantially, resulting in condensation throughout the cave as it warms.

Gamble *et al.* (2000) demonstrated that tropical flank margin caves in the Bahamas and Puerto Rico presented different temperature regimes from those in temperate

regions. These caves tend to be warmer than outside the cave in winter and cooler in summer. They also lacked diurnal temperature fluctuations. One cause for these differences is that these marginal caves tend to have a width greater than the length. Tidal water can also serve as a buffer to temperature conditions. These differences could be reflected in the bryophyte flora.

Cao and Yuan (1999) examined the water-holding capacity of the various groups of photosynthetic organisms and their effects on the carbon cycle on the rock surface. They found that the loss vs of absorption of water for algae was 18.8 and 1.6 times respectively, for lichens 2.9 and 19.1 times, and for mosses 81.2 and 8.1 times, compared to rocks with none of these growths. The organisms permit the rocks to hold onto water longer, increasing the rates of carbonate rock corrosion beneath them. Nutrients accumulate in these colonized areas and the biological cycle is accelerated.

CO₂

Asencio and Aboal (2011) noted that cave CO₂ concentrations were high (0.8% in cave compared to 0.45% in atmosphere). Oxygen was slightly lower (18.5%) than that of the atmosphere (~21%). The temperature ranged 27-43°C – much more variation than many people seem to expect in caves. The humidity (100%) is quite favorable for algal species.

Some caves have changing airflow patterns between summer and winter (Spotl *et al.* 2005). This results in changes in CO₂ levels within the cave. Spotl and coworkers document the predictable changes from high *p*CO₂ (partial pressure of dissolved CO₂; gas phase pressure of carbon dioxide in air above waterway which would be in equilibrium with dissolved carbon dioxide) in summer and low *p*CO₂ in winter in the Obir Cave in Austria. Winter flushing by relatively CO₂-poor air enhances degassing of CO₂ in the cave and leads to a high degree of supersaturation of calcite in dripwater (see also Whitaker *et al.* 2009).

Frisia *et al.* (2011) recorded a similar phenomenon in Grotta di Ernesto cave (NE Italy). Air advection causes the winter *p*CO₂ to drop in the cave air to ~500 ppm from a summer peak of ~1500 ppm, with a rate of air exchange between cave and free atmosphere of approximately 0.4 days. The process of cave ventilation forces degassing of CO₂ from dripwater before calcite precipitation onto stalagmites.

When investigating the Scoska Cave in the UK, Whitaker *et al.* (2009) suggested that bryophytes could act as CO₂ sinks, but that decomposition of bryophytes would release CO₂. They concluded that most of the CO₂ in the photic zone of the cave came from advection and diffusion of air from deeper in the cave.

Mazina and Popkova (2020a) examined the effects of high CO₂ levels on the photosynthetic organisms in the photic zone of the Anyashka Cave in the Caucasus. The dominant photosynthesizers were **Cyanobacteria**. Nevertheless, the highest gross primary productivity (GPP) occurred in communities dominated by pteridophyte and bryophyte species on water-splashed clay. Such communities on limestone or clay on limestone exhibited lower GPP. The GPP of these various communities varied from -0.1503 g C m⁻² h⁻¹ to -0.0109 g C m⁻² h⁻¹. They also

found that some of these communities served as CO₂ sinks, but others were actually CO₂ sources.

In the seven caves studied in Montenegro, Mazina *et al.* (2020) found that all communities on various substrates were carbon sinks, in both summer and winter. Maximal dry mass production occurred when acrocarpous mosses and case-forming **Cyanobacteria** dominated, both being maximal for both phototrophic respiration and gross primary production.

In the Balcarka Cave and adjacent soils in the Czech Republic, Faimon *et al.* (2012) determined that human visitors and **epikarstic** (uppermost weathered zone of carbonate rocks with substantially enhanced and more homogeneously distributed porosity and permeability) sources contribute to the CO₂ levels in the caves. The epikarstic source seems to control the dripwater chemistry and maximum CO₂ in the cave. In show caves such as this one, breathing by visitors and door openings create fluctuations in the levels.

In the Císařská Cave (Moravian Karst, Czech Republic), Faimon *et al.* (2006) compared the chamber CO₂ levels with that of the drip chemistry. They found that the peak levels of CO₂ during visitor presence did not reach the theoretical values at which the dripwater carbonates and air CO₂ would be at equilibrium. However, visitation only resulted in 2.85 hours of human contribution. Increasing that to 4 hours could exceed the dripwater contribution. Nevertheless, achieving the threshold values at which water would damage the calcite would require extreme conditions, *e.g.*, simultaneous presence of 100 persons in the cave chamber for 14 h.

Howarth and Stone (1990) found that in May and June the CO₂ levels in the deeper passages in Bayliss Cave, Australia, reached up to 200X the ambient CO₂ in the atmosphere. This environment supported the largest diversity of obligate cave fauna known in its bad air zone. Such levels should be beneficial for photosynthetic organisms, provided there is sufficient light, and can permit growth even in low light (Lovalo *et al.* 2010). Artificial illumination in such conditions should create an interesting environment for bryophytes and algae. Photosynthetic studies are needed across the CO₂ and light gradients, coupled with laboratory experiments to sort out the individual effects.

Liu *et al.* (2017) examined the **carbonic anhydrase** activity of six epilithic mosses on soil in the Puding karst area, Guizhou Province, China. Carbonic anhydrase **catalyzes** the bidirectional conversion of carbon dioxide (CO₂) and water (H₂O) into bicarbonate (HCO₃⁻) and protons (H⁺). These reactions are important in the photosynthetic pathway but are also important in the CO₂ equilibrium of the habitat.

Huang *et al.* (2015) found that external carbonic anhydrase activity differed among the bacteria, fungi, and **Actinomycota**. This activity in bacteria and fungi was promoted by Zn and Co, whereas it was promoted most by Ca in **Actinomycota**. See also Li *et al.* 2005 for more cation and anion effects. The role of these reactions in facilitating bryophyte photosynthesis remains unknown.

Suitability for Flora and Fauna

Culver and Pipan (2009) note that the more superficial subterranean habitats such as small drainages that emerge

as seeps, small cavities in the uppermost part of karstified rock, talus slopes, and cracks and shallow tubes in lava share only two important characters with caves. They are **aphotic** (having too little light for photosynthesis) and they harbor fauna suited for subterranean life. For bryophytes, only the often very limited photic portion is of relevance. They consider that these aphotic habitats may have given rise to species of animals adapted for the deepest parts of caves. For bryophytes, the openings of such small "caves" could serve the same role, providing stepping stones between caves or serving as refugia where suitable cave habitats may have been destroyed by human activity.

Radiation

Damaging radiation in caves can be much greater than outside. Buecher (1999) concluded that in Kartchner Caverns this was not enough to be of concern for cave visitors, but they could be for long-term employees. Measurements at the cave entrance are not representative of the deeper parts of the cave.

Algific Caves

The **algific caves** (Figure 13-Figure 18) result from cold air drainage in places like the driftless area of northeastern Iowa and southwestern Wisconsin, USA. These serve as refugia for boreal bryophyte species (Andrews 2003; Dale Vitt, pers. comm. 4 August 2021).

Figure 18. Algific talus slope with mossy vent, northeastern Iowa. Photo courtesy of Beth Lynch.

Andrews (2003) described the windhole caves at Ice Mountain, West Virginia, USA (Figure 19). He concluded that bedrock benches in the subsurface of the slope provides surfaces where cooler air and water become trapped. This results in frost and ice accumulation. Surface benches at the bottom of the slope are continuously cooled by the heavier down-slope winds. Although the airflow cycles and structural makeup of the algific caves differs among North American locations, they typically sustain an unusually cold environment. These environments are able to support species that otherwise occur in more northern or higher altitude sites.

Figure 19. Algific slope cave formation, Ice Mountain, West Virginia, USA. The three colors are three different types of bedrock. Modified from Andrews 2003.

Non-Bryophyte Flora

The changes in the flora of caves are very dependent on light intensity. Whereas the entrance of the cave may have tracheophytes, including seed plants, further in the cave the **Cyanobacteria**, algae, bryophytes, and ferns are the only photosynthetic organisms able to grow in the limited light (Gurnee 1994; Lamprinou *et al.* 2014; Turchinskaia *et al.* 2019). Less commonly they may have liverworts or lichens; fungi and bacteria comprise non-photosynthetic organisms (Czerwik-Marcinkowska *et al.* 2019).

Roldán and Hernández-Mariné (2009) summarized some of the important factors determining phototrophic biofilm communities in three caves in Spain. They found that these films consisted of **Cyanobacteria**, green microalgae, diatoms, mosses, and lichens, and that these communities differed among sampling sites. Light-related stress and low humidity both result in thinner biofilms and lower species diversity. Similarly, the duration of light exposure reduces both thickness and diversity.

Microbes

In addition to photosynthetic organisms, caves provide suitable habitat for microbes and fungi (Laiz *et al.* 1999). Water communities are mainly composed of gram-negative rods and cocci (**Enterobacteriaceae** and **Vibrionaceae**), while those of ceiling rocks are mainly *Streptomyces* spp. (Figure 20). The conditions include high humidity, relatively low and stable temperature, water pH close to neutrality, and varying mixes of organic matter. These conditions seem to favor colonization and long-term growth of **Actinomycota** over other heterotrophic bacteria on ceiling rocks in the Altamira cave, Spain.

Figure 20. *Streptomyces* sp. Photo by Doc Warhol, through Creative Commons.

Cyanobacteria and Algae

Algal and cyanobacterial communities have been described in a number of caves around the world. These communities typically form a zone dependent on the light intensity. For example, Selvi and Altuner (2007) have described the algal flora in Ballica Cave in Turkey. Buczkó and Rajczy (1989) reported 49 algal taxa, but only 17 bryophyte taxa in three caves in Hungary.

In caves of Bashkirskiy Ural Biosphere Reserve (southern Urals, Bashkortostan Republic, Russia), Gainutdinov *et al.* (2017) found 42 taxa of **Cyanobacteria** (42.9%), 31 taxa of **Bacillariophyta** (31.6%), 20 taxa of **Chlorophyta** (20.4%), 3 taxa of **Charophyta** (3.06%), and 2 taxa of **Ochrophyta** (2.04). *Leptolyngbya boryana* (**Cyanobacteria**; Figure 21-Figure 22), *Mychonastes homosphaera* (**Chlorophyta**; Figure 23), and *Eolimna minutissima* (**Bacillariophyta**; Figure 24) were present in all caves examined. The authors found that the diatoms *Humidophila contenta* (Figure 25), *Hantzschia amphioxys* (Figure 26), and *Orthoseira roeseana* (Figure 27), present in these caves, were those most commonly mentioned in other publications on caves. Others mentioned from other caves were *Pinnularia borealis* (**Bacillariophyta**; Figure 28), *Stichococcus bacillaris* (**Chlorophyta**; Figure 29), and *Klebsormidium flaccidum* (**Charophyta**; Figure 30-Figure 31). These species occurred in the highly illuminated areas on cave walls and on mosses at the cave entrance. Dominant algae in well-illuminated zones include the diatoms *Orthoseira roeseana*, *Humidophila contenta*, and *Hantzschia amphioxys*, and *Oscillatoria rupicola* (**Cyanobacteria**; Figure 32), using substrates of damp walls and mosses. They concluded that the similarity of algae on the wall surfaces and on mosses was because the moss samples were usually collected from the walls. The mosses at the cave entrances usually exist in moist conditions with adequate lighting, favoring the growth of algae.

Lowe *et al.* (2013) discovered two new species of diatoms in the genus *Orthoseira* (see Figure 27) from lava tubes in Hawai'i and Île Amsterdam (subAntarctic). The bottoms of these caves have a cover of mosses and liverworts surrounding a puddle.

Mulec and Kosi (2009) note the invasion of algae and **Cyanobacteria** deep into the caves where artificial illumination has been added so that visitors can see the cave interior. The caves are usually naturally humid, and the illumination makes them suitable for these growths. The authors consider the invading phototrophic organisms to be inappropriate aesthetically, but they note that the organisms also cause degradation of the cave substrata they colonize. These are especially problematic in caves with prehistoric art (Figure 33). It is advisable, for the preservation of the cave walls and art, to eliminate these **Cyanobacteria** and algae early because they play the most important role in early stages. Mosses and ferns typically colonize later. These photosynthetic organisms have acquired the name of **lampenflora**.

Distribution and species of **Cyanobacteria** and algae in caves are typically limited by the same parameters that influence bryophytes in cave habitats – reduced light intensity, low nutrients, and absence of seasonality (Dayner & Johansen 1991; Pedersen 2000; Popović *et al.* 2015). To these defining habitat characters, Mulec *et al.* (2008) added temperature, humidity, and flowing water as important in delimiting the aerial habitats.

Popović *et al.* (2015) noted that the biofilm on cave walls in Božana Cave (Serbia) included **Cyanobacteria**, algae, and microfungi. Popović *et al.* (2016) found a new coccoid member of the **Cyanobacteria**, *Nephrococcus serbicus*, from the Božana Cave, Serbia. Popović *et al.* (2015) found that chlorophyll content of the biofilm was not proportional to the light intensity, but was instead proportional to the biomass of the film. Coccoid **Cyanobacteria** were the most abundant at the lowest light intensities, whereas **Nostocales** occurred in the highest light. *Desmococcus olivaceus* (Figure 35-Figure 36) and *Trentepohlia aurea* (Figure 37-Figure 38) were the only green algae on the walls, whereas *Gloeocapsa* (Figure 39), *Scytonema* (Figure 40), *Aphanocapsa* (Figure 41), and *Chroococcus* (Figure 42) were the most common **Cyanobacteria**, with 21 taxa of *Chroococcus* alone.

Mulec *et al.* (2008) reported on the **aerophytic** (designates living in air in terrestrial habitats, on rocks, stones, sediments, trees, needing water only from atmosphere) algal community from a cave entrance in contrast to the lampenflora. They found the entrance community to be almost entirely **Cyanobacteria**, whereas at the lights green algae (**Chlorophyta**) became more dominant. They concluded, based on lack of correlation of chlorophyll *a* concentration per surface unit with photon flux density, that microhabitat substrate characteristics were important in influencing algal growth. The chlorophyll *a* concentration is lower in algae at the cave entrance than it is among the lampenflora. The low temperatures of the cave result in a low light saturation point. At 9°C, the production of accessory photosynthetic pigments is elevated considerably in the **Cyanobacterium** *Chroococcus minutus* (Figure 43) and green alga *Chlorella* sp. (Figure 44).

Figure 44. *Chlorella vulgaris*. A cave member of *Chlorella* increases its accessory photosynthetic pigments when the temperature is lowered to 9°C. Photo by Neon, through Creative Commons.

Popović *et al.* (2017) found that the greatest number of phototrophic microorganisms in three Siberian caves were **Cyanobacteria**, with *Gloeocapsa* (Figure 39, Figure 50, Figure 55, Figure 56) being the most diverse genus. They found that relative humidity is important in accounting for differences among the three microbial communities in the three caves. **Cyanobacteria** mostly occurred in locations with lower relative humidity, whereas **Chlorophyta** (green algae) and **Bacillariophyta** (diatoms) occurred where there was higher humidity.

Some of the biofilm taxa can be recognized by their colors (Popović *et al.* 2020). Coccoid cyanobacterial forms create gelatinous, olive to dark-green biofilms. *Gloeobacter* (Figure 45) appears purple; *Gloeocapsa* (Figure 46) is yellow, and *Chroococcidiopsis* (Figure 47) forms a black film. The heterocystic biofilms are primarily *Nostoc* (Figure 48-Figure 49) and are brown to dark in color.

Czerwik-Marcinkowska (2013) studied the **Cyanobacteria** and algae in ten caves in the Ojców National Park, Poland. The author identified 35 **Cyanobacteria**, 30 **Chlorophyta**, and 20 from other groups of algae. These were dominated by aerophytic **Cyanobacteria** (see also Komáromy *et al.* 1985). The **Cyanobacteria**/algae *Gloeocapsa alpina* (Figure 50), *Nostoc commune* (Figure 48-Figure 49), *Chlorella vulgaris* (Figure 44), *Dilabifilum arthropyreniae*, *Klebsormidium flaccidum* (Figure 51), *Muriella decolor*, *Neocystis subglobosa*, and *Orthoseira roseana* (Figure 27) were the most abundant taxa in all ten caves. The **Cyanobacteria** are typically the only phototrophs in the deepest parts of the caves, but around the entrance and electric lights they must compete for light with the other algae, bryophytes, and even ferns (Round 1981). Czerwik-Marcinkowska (2013) suggested that it was the nearly constant conditions that were so favorable to these algae.

In Seneca Cavern, Ohio, USA, Dayner and Johansen (1991) found 25 algal taxa in subaerial habitats. These were mostly aerophilic species, with the most abundant being *Chlorella miniata*, *Pleurochloris commutata* (**Ochrophyta**; see Figure 52), *Navicula tantula* (Figure 53), and *Navicula contenta* f. *biceps*. They considered the dim light in this earth crack cave and lack of running water to be the reason for the smaller than typical number of species.

Mazina and Popkova (2020b) found *Chroococcus minutus* (Figure 43) and *Chlorella vulgaris* (Figure 44) to be the most frequent phototrophs in all the studied caves in Ukraine, Italy, and Hungary.

When lights are present in caves, the phototrophs can penetrate to a much greater distance. Komáromy *et al.* (1985) used cluster analysis to clarify relationships of the photosynthetic organisms in the cave. These researchers found 42 algal taxa in a single Hungarian show cave. (This number apparently included the **Cyanobacteria** as they were considered by the authors to be blue-green algae). They noted that the **Cyanobacteria** were species with

small cell sizes and that both lichens and liverworts are extremely rare in the habitats surrounding lamps. They delineated the algae by using scrapings that were then cultured on liquid Bold medium.

Figure 53. *Navicula tantula*, a species that is among the most abundant algae in Seneca Cavern, Ohio, USA. Photo from UTEX, through Creative Commons.

Czerwik-Marcinkowska *et al.* (2019) similarly cultured scrapings of the algae and *Cyanobacteria* from walls of a cave in the Tatra Mountains of Poland. Ten of the species were *Cyanobacteria*; *Gloeocapsa* (Figure 39) was the most diverse genus. Four were diatom taxa. Diversity did not relate to temperature or humidity.

Czerwik-Marcinkowska *et al.* (2019) explored the relationship between brown bears (*Ursus arctos*; Figure 54) in caves and the diversity of airborne algae and *Cyanobacteria* in the Glowoniowa Nyża Cave, Tatra Mountains, Poland. Like Popović *et al.* (2017), they found the cyanobacterial genus *Gloeocapsa* (Figure 39, Figure 50, Figure 55, Figure 56) to be the most diverse. The highest number of species were in *Cyanobacteria* (10), but they also found 10 algae and four diatom species. The algal diversity did not correlate with temperature or humidity. The aerophytic organisms in the wall flora were apparently brought by wind, whereas the ones on twigs may have been brought by wind and bears. The bears in the cave use mosses, among other materials, to line their dens, creating another means of dispersal into the cave.

Figure 54. *Ursus arctos* (brown bear), a potential disperser of *Cyanobacteria* and algae into some caves. Photo by Magnus Johansson, through Creative Commons.

Nostoc commune (Figure 48-Figure 49) forms thick mats along with other airborne algae in the Glowoniowa Nyża Cave, Tatra Mountains, Poland (Czerwik-Marcinkowska *et al.* 2019). *Gloeocapsa atrata* (Figure 55) occurs in the cave and among mosses, especially on wet rocks (John *et al.* 2011). *Gloeotheca palea* (Figure 56) occasionally grows among mosses (Czerwik-Marcinkowska *et al.* 2019).

Like many other researchers, Czerwik-Marcinkowska *et al.* (2015) found that aerophytic **Cyanobacteria** were the most important members of the cave photosynthetic microflora. The most frequent were *Aphanocapsa* (Figure 41), *Chroococcus* (Figure 42, Figure 43), *Gloeocapsa* (Figure 50, Figure 55-Figure 56), *Leptolyngbya* (Figure 21-Figure 22), and *Synechocystis* (Figure 57). The predominant green algae were *Apatococcus* (Figure 58), *Klebsormidium* (Figure 31), *Chlorella* (Figure 44), *Muriella*, and *Neocystis*. Diatoms were dominated by *Orthoseira* (Figure 27) and *Pinnularia* (Figure 28). The algae were mostly cosmopolitan and ubiquitous, with simple nutrient requirements and wide ecological tolerance.

Figure 57. *Synechocystis* sp., a member of **Cyanobacteria**, one of the most important members of the cave photosynthetic microflora. Photo by Yuuji Tsukii, with permission.

Figure 58. *Apatococcus* sp., a member of **Chlorophyta**, one of the most important members of the cave photosynthetic microflora. Photo by Yuuji Tsukii, with permission.

Popović *et al.* (2017) likewise found that most of the taxa in cave biofilms in Serbia belonged to the **Cyanobacteria**. **Chroococcales** were dominant, and *Gloeocapsa* (Figure 50, Figure 55-Figure 56) was the most diverse genus. They found that **Cyanobacteria** were able to dominate where humidity was lower; **Chlorophyta** and **Bacillariophyta** occurred in locations with higher humidity. The chlorophyll *a* content was highest on horizontal surfaces, corresponding with the highest content of organic and inorganic matter as well. The highest water content was maintained in biofilms that contained many **Cyanobacteria**.

Pouličková and Hašler (2007) reported aerophytic diatoms from caves in central Moravia in the Czech Republic. Rushforth *et al.* (1984) explored the subaerial diatom flora in the Thurston lava tube in Hawaii, USA. These occurred on wet mucilage and bryophytes on the walls. Falasco *et al.* (2015) described a new species of diatom (*Nupela troglaphila*) from the Bossea Cave in Italy. They also noted that Rushforth *et al.* (1984) had found *Nupela thurstonensis* on the wet walls and bryophytes of the Thurston lava tube in Hawai'i. Both species occurred near the entrance and the artificial lighting.

Falasco *et al.* (2014) reported that the cave flora produces polysaccharides, proteins, lipids, and nucleic acids. This matrix is anionic, and facilitates the adsorption of cations and dissolved organic molecules from the cave formations. These exchanges can contribute to the corrosion of the cave walls. Diatoms, in particular, typically colonize these areas when there is sufficient light. Falasco and coworkers reported 363 species of diatoms listed in the literature as occupying subterranean habitats. The most frequent cave diatom species, in order from most frequent, are *Hantzschia amphioxys* (Figure 26), *Humidophila contenta* (Figure 25), *Orthoseira roseana* (Figure 27), *Luticola nivalis* (see Figure 59), *Pinnularia borealis* (Figure 28), *Diademsis contenta* var. *biceps* (see Figure 60), and *Luticola mutica* (Figure 61). They also noted that it is not uncommon to find new species in these habitats.

Figure 59. *Luticola* sp.; *Luticola nivalis* is one of the most frequent diatoms in caves. Photo by A. E. Drahos, through Creative Commons.

Figure 61. *Luticola mutica*, one of most common species of diatoms in caves. Photo by Lane Allen, through Creative Commons.

Hantzschia amphioxys (Figure 26) is aerophilous (Germain 1981) and one of the most frequently recorded taxa on submerged bryophytes (Reichardt 1985; van de Vijver & Beyens 1997). *Humidophila contenta* (Figure 25) occurs on both wet walls and on bryophytes (Rushforth *et al.* 1984; Roldán & Hernández-Maríné 2009). *Diadmesmis contenta* var. *biceps* (see Figure 60) occurs on wet walls and bryophytes (Dayner & Johansen 1991; Falasco *et al.* 2014). *Luticola mutica* (Figure 61) is one of the most frequent taxa on submerged bryophytes (Reichardt 1985; van de Vijver & Beyens 1997); it is resistant to moderately high conductivity levels (Pouličková & Hašler 2007). This tolerance seems to account for its common occurrence also in lowland rivers (van Dam *et al.* 1994; Czerwik-Marcinkowska & Mrozińska 2011).

Pinnularia borealis (Figure 28) is one of the most frequent diatoms on submerged bryophytes (Reichardt 1985; Van de Vijver & Beyens 1997; Falasco *et al.* 2014). Nevertheless, Vande Vijver and Beyens (1997) found it to be in an assemblage on very dry mosses in South Georgia. *Pinnularia borealis* (Figure 28), common in the Glowoniowa Nyża Cave, is aerophilous, but frequently occurs on submerged bryophytes and in wild caves near the main entrance on very wet walls (Garbacki *et al.* 1999). Van de Vijver and Beyens (1997) found that *Pinnularia borealis* size drops with the increasing dryness of the moss habitat.

Borrego-Ramos *et al.* (2018) reported on the diatoms from the Valporquero Cave in Spain. They found that moss-dwelling diatom associations differed from those in other parts of the cave. They found *Mayamaea cavernicola* (incorrectly identified as *Navicula seminulum* var. *hustedtii*; Figure 62), a species already known from a lava tube cave on the Hawai'ian Islands (Rushforth *et al.* 1984). A different sample from the Spanish cave was almost entirely made up of *Humidophila gallica* (see Figure 25).

Figure 62. *Mayamaea atomus*; *M. cavernicola* is a species known from lava tubes and caves. From Sarah Spaulding and Mark Edlund, <diatoms.org>, with permission.

Lauriol *et al.* (2006) found that 80% of the diatoms in ice caves (Figure 63) of the Yukon Territory were of local origin from subaerial habitats near the cave entrances. These include the sub-aerial diatoms *Orthoseira dendroteres* (a common bryophyte dweller; Figure 64) and *O. roseana* (Figure 27). Larger caves tended to have more species, presumably due to the greater air circulation in these caves. The **grus** (accumulation of angular, coarse-grained fragments resulting from granular disintegration of crystalline rocks), ice plugs, and ice stalagmites have the greatest relative abundance of diatoms, but the lowest diversity. Can these principles serve as models for bryophytes? It appears that they do.

When light enters the cave, particularly at the entrances, **Cyanobacteria** contribute to the growth of **stalactites** (tapering structures hanging like icicles from roof of cave, formed of calcium salts deposited by dripping water; "stalactites must hang on tight;" think **c** for ceiling; Figure 1, Figure 6) and **stalagmites** (mound or tapering columns rising from floor of cave, formed of calcium salts deposited by dripping water and often uniting with stalactite to form column; "stalagmites are little mites;" think **g** for ground; Figure 1, Figure 6) (Mulec *et al.* 2007).

The **Cyanobacteria** contribute to making the layers of stromatolitic stalagmites. Mulec *et al.* (2007) found 35 taxa associated with them at the cave entrance of Škocjanske jame, Slovenia. These had a low portion of coccoid **Cyanobacteria** and other **Cyanobacteria** such as *Calothrix* sp. (Figure 65), *Homeothrix* sp. (Figure 66), and *Schizothrix* sp. (Figure 67).

One bryophyte that seems to occur in multiple caves is *Eucladium verticillatum* (Figure 68-Figure 69) (Dalby 1966a). It actually helps to build the stalactites by

collecting the dripping lime water. The stalactite surrounds the moss, and green leaves are visible only at the tips. It is notable that this species does not become etiolated even in the lowest illumination where it grows. Dalby found that it did not even become etiolated when kept in a polyethylene bag in total darkness for two months, but with no light I wouldn't have expected it to grow at all.

Figure 68. *Eucladium verticillatum* with mineral deposits on leaf tips. Photo by Armand Turpel, through Creative Commons.

Figure 69. *Eucladium verticillatum* forming stalactite (eucladiolite) in mine in Dorset, UK. Note the nearly horizontal development of the eucladiolith. Photo from Dalby 1966b.

In the carbonate depositions on the lighted side of the stalactites, there were 14 species of **Cyanobacteria**, mainly coccoid forms (Mulec *et al.* 2007). Their growth and biolithogenic activity are especially associated with the moss *Eucladium verticillatum* (Figure 68-Figure 69). This results in formations known as **eucladioliths** (Figure 69) (Dalby 1966b).

Czerwik-Marcinkowska and Mrozińska (2011) reported 82 species of aerophytic **Cyanobacteria** and algae from 25 caves in the Polish Jura. Of these, 33 species were **Cyanobacteria** with the **Chlorophyta** represented by 30 species. There were even 2 species of **Dinophyta**. They found a number of rare species, some of them specific to these caves. **Cyanobacteria** at the entrance and around lights included predominantly *Calothrix parietina* (Figure 65), *Gloeocapsopsis magma* (Figure 70-Figure 71), *Nostoc commune* (Figure 48-Figure 49), *Oscillatoria brevis*

(Figure 72), and *Tolypothrix tenuis* (Figure 73). These **Cyanobacteria** competed with algae, especially the **Chlorophyta** *Chlamydomonas* sp. (Figure 74), *Muriella decolor*, and *Klebsormidium flaccidum* (Figure 31), as well as with mosses and pteridophytes. The moss *Cratoneuron* (Figure 75) was accompanied by aerophilic diatoms [*Humidophila contenta* (Figure 25), *Gomphonema italicum* (Figure 76-Figure 77)] and **Chlorophyta** [*Chlorella vulgaris* (Figure 44), *Trentepohlia aurea* (Figure 37-Figure 38), *Stichococcus bacillaris* (Figure 29)].

Sciuto *et al.* (2017) described the new genus *Timaviella* (Leptolyngbyaceae in Cyanobacteria) from the Giant Cave lampenflora in Italy. There were actually two species described for it in that cave (*Timaviella circinata* and *Timaviella karstica*).

Koch (1976) suggested that bryophytes create runoff that might affect the other organisms living with them. One such possibility is indicated between bryophytes and the green alga *Protococcus vestitus* (Figure 78). Data also suggested that bryophytes might be important in colonization by *Trochiscia ohioensis* (see Figure 79). It was closely associated with bryophytes at Ash Cave Cliff in Ohio, USA. But whereas *Trochiscia ohioensis* occurred in 51 collections, bryophytes occurred in only 6 of these. Nevertheless, both *Protococcus vestitus* and *Trochiscia ohioensis* had high correlations with bryophytes. They were present in 18 of the 20 stands in which *Trochiscia ohioensis* occurred. (Unfortunately, I was unable to match either of these algal species names to any in AlgaeBase; all records of the rare *Protococcus vestitus* other than this one are 19th century.) Koch suggested that the bryophytes, especially thallose liverworts, could retain enough moisture to make the habitat suitable for the algae. The frequently abundant chroococcalean Cyanobacteria are only present with the bryophytes when there is abundant moisture present.

Cyanobacteria with **heterocysts** (Figure 80) can fix atmospheric N_2 into usable forms (Lamprinou *et al.* 2012) that prepare the environment for colonization of other **Cyanobacteria**, algae, and mosses (Ortega-Calvo *et al.* 1995). **Cyanobacteria** are important in many ecosystems for their ability to transform atmospheric nitrogen into usable forms. Asencio and Aboal (2011) found that *Scytonema julianum* (see Figure 40) contributed to this activity in Vapor Cave in Spain.

Fungi

Vanderwolf *et al.* (2013) documented 1029 species of fungi, slime molds, and yeasts, based on 225 publications on caves and mines. They found the **Ascomycota** to be the dominant group among these. The cave fungi communities are typically those requiring few nutrients (**oligotrophic**) and tolerating year-round low temperatures (**psychrotolerant**).

Fungi in three Serbian caves were primarily **Ascomycota** or **Zygomycota** (Popović *et al.* 2017). Popović *et al.* (2015, 2017) found that **Ascomycota** were common [e.g. *Alternaria* (Figure 81-Figure 82), *Aspergillus* (Figure 83), *Cladosporium* (Figure 84), *Epicoccum* (Figure 85-Figure 86), *Penicillium* (Figure 87-Figure 88), and *Trichoderma* (Figure 89-Figure 90)], while **Zygomycota** and **Oomycota** were less frequent in Božana Cave, Serbia. The only member of **Basidiomycota** was one of *Rhizoctonia s.l.* (Figure 91-Figure 92) (Popović *et al.* 2017).

Figure 93. *Penicillium glandicola*, a frequent species in the Domica Cave system in Slovakia. Photo by Y. V. Sagar, through Creative Commons.

Air currents in the cave are likely to contribute to dispersal of fungal spores, but Jurado *et al.* (2009) suggested that insects within the cave might play a role in spore dispersal as well. This possibility is further supported by the fact that most of the fungi proved to be **entomopathogens** (micro-organisms capable of infecting insects). In European caves with rock-art paintings (Figure 33), a test area was sterilized and after two months the rock tablets placed there were heavily colonized by fungi.

Nováková (2009) reported on the microscopic fungi isolated from the Domica Cave system in Slovakia. The frequent species included *Penicillium glandicola* (Figure 93), *Trichoderma polysporum* (see Figure 89-Figure 90), *Oidiodendron cerealis*, *Mucor* spp. (Figure 94-Figure 95), *Talaromyces flavus* (Figure 96-Figure 97), and species of the genus *Doratomyces* (Figure 98).

Summary

Caves are interesting ecotones of light and temperature gradients. They are further differentiated on type of substrate, pH, aspect, and air exchange. CO₂ levels can be higher than outside the cave, promoting greater photosynthesis in the limited light. Although conditions do fluctuate, they are more constant than outside the cave, being cooler in summer and warmer in winter. Because of these conditions, caves are often refugia, permitting the growth of species that do not grow elsewhere in the area.

A wide variety of caves exist, both large and small. Some are created in crevices, some among the rocks of talus slopes, and some in volcanic tubes, with a variety of other cave-like conditions as well. These can harbor rare species.

In addition to an array of bryophytes in the photic zone at the entrance of caves, others penetrate into the twilight zone. **Cyanobacteria**, algae, and fungi join the bryophytes, but usually penetrate farther into the darkness. *Streptomyces* (**Eubacteria**) species dominate the rock microbes. Among the **Cyanobacteria** *Gloeocapsa* often has the most species in a cave, but in others it is *Chroococcus* that has the most species.

Species like *Scytonema julianum* with heterocysts are able to fix atmospheric nitrogen gas into ammonia and ultimately amino acids.

Humidophila contenta, *Hantzschia amphioxys*, and *Orthoseira roeseana* are among the most frequent diatoms in caves, although *Pinnularia borealis* is common in some areas. Frequent **Chlorophyta** include *Stichococcus bacillaris* and *Klebsormidium flaccidum*. Fungi are most likely to be **Ascomycota** or **Zygomycota**, with **Basidiomycota** being relatively rare.

Rare and new species often occur in caves in the unusual conditions. Competition from tracheophytes is limited, further encouraging the growth algae and bryophytes.

Acknowledgments

Many Bryonettors responded to my call for images for this chapter. Wolfgang Hofbauer provided me with a paper that gave me a good list of current references on wind holes. Thank you to our Chinese colleagues (Wen Ye, Xinlei Guo, Yang Liu, Xiaoming Shao, and Wang Zhe) who responded to my request for the English translation of the abstract of a Chinese study.

CHAPTER 18-2

CAVES – OVERALL BRYOPHYTE FLORA

Figure 1. Mammoth Cave entrance showing ferns and other plants at entrance and the rapid entrance into darkness. Photo through Creative Commons.

Bryophyte Flora

Overall

Lämmermayer (1912) described the bryophyte flora in 48 caves in Austria. He reported 72 bryophyte species. *Eurhynchium* s.l. was the most frequent genus and was represented by 6 species. *Eurhynchium praelongum* (Figure 2-Figure 3) occurred at only 200 lux. Thompson (1945) was among the early explorers of cave mosses. Rajczy (1978) explored the cave environment and its effect on mosses. Barr (1964) noted that the occurrence of numerous species of animal troglobites in any major limestone region is common and highly probable. But is that true of bryophytes?

Figure 2. *Eurhynchium praelongum* in England, member of the most common bryophyte genus in Austrian caves. Photo by Janice Glime.

Figure 3. *Eurhynchium praelongum*, a species that occurred at 200 lux light intensity in an Austrian cave. Photo by Michael Lüth, with permission.

Hajdu (1977) opined that there are no true troglobites among the bryophytes because of their light limitations. Mosses (**Bryophyta**) form the bulk of the plant biomass in the caves studied in Hungary, and this seems to be the most likely case for most caves. Tracheophytes are more limited by light, and the algae and **Cyanobacteria** (Figure 4) form only thin crusts, thus contributing less to biomass.

Figure 4. **Cyanobacteria** and algae on rock formations in Lost River Caverns, Pennsylvania, USA. Photo by Janice Glime.

Studied Caves

I was surprised when I began this chapter to find how many studies there have been on cave bryophytes. Studies included the Azores (Figure 5) and Canary Islands (González-Mancebo *et al.* 1989, 1991, 1992); Jennings (2009) wrote a Master's thesis on bryophyte diversity in Azorean caves. Other studies include Isle of May (Watson 1953), Jura Souabe, Swabian Alps, Germany (Dobat (1970), Saarland, Germany (Weber 1989), grottos in Italy, karst caves in the Ercole cave area, and Carso Triestino of Italy (Lo Giudice & Privitera 1984; Polli & Sguazzin 2002; Castello 2011), Polish caves (Ziober 1980, 1981), sea caves on the Isle of Capri in Italy (Sguazzin 2005), Cave Baradla (Figure 6) in Hungary (Hajdu & Orban 1981), other caves

in Hungary (Rajczy 1982, 1989, 1990), Cave Perama in Greece (Rajczy 1979), caves in Romania (Stefureac 1985), moss and algal development in an urbanized cave in Bulgaria (Stoyneva *et al.* 2002), and karst caves in England (Zhang & Pentecost 2002).

Cros and Rosselló (1984) relocated the mosses *Palustriella commutata* (Figure 7-Figure 8) and *Eucladium verticillatum* (Figure 9-Figure 10) reported by Maheu (1912) in caves of the Pityusic Islands in the Mediterranean Sea, but no bryophytes were mentioned in the early studies by Maheu (1912) in the coastal caves.

Figure 9. *Eucladium verticillatum* in lime seep, a bryophyte that prefers limestone substrate. Photo by Resso Taelspeus, through Creative Commons.

Downing (1992) compared substrate preferences of bryophytes at three locations in southeastern Australia, including the Jenolan Caves (Figure 11). Limestone substrates had more abundant bryophytes, exhibiting more species and greater percent ground cover, than did nonlimestone substrates. Many of the species from limestone sites were typical of arid and semiarid habitats in Australia. Downing *et al.* (1995) listed the bryophytes of Wombeyan Caves (Figure 12) in New South Wales. Downing *et al.* (1997) revisited the Yarrangobilly Caves (Figure 13) in New South Wales, Australia, and reported that most of the mosses collected by Watts in 1906 were still present. Martin (2003) reported on the flora of a volcanic collapse pit on the lower slopes of Onehunga, Auckland.

In China, Zhang (1993) described moss communities of the Maolan karst caves. Zhang and Wang (2002) studied them at the Flying-Dragon Cave. Wang and Zhang (2002) explored the bryophytes in karst caves in Guangxi Province, China. Zhang *et al.* (2005) studied karst caves in the Guilin area (Figure 14). Li *et al.* (2015, 2019) studied the karstification processes and bryophyte diversity in

various locations in China. Cong *et al.* (2017) studied epilithic mosses on rock in the Puding karst area.

Figure 14. Cave in Guilin area, China. Photo by Michael Gunther, through Creative Commons.

Shiomi (1991) described the ecological distribution of bryophytes and other plants based on cave effects on the Akiyoshi-dai Plateau in Japan.

Ren *et al.* (2021) characterized the cave bryophyte flora as having a poor but unique diversity. They found that it was related to the vegetation and microhabitat. When comparing six karst caves with varying degrees and types of disturbance in southern China (Figure 15), they found a total of 43 angiosperm species, 20 lycophyte and fern species, and 20 species of bryophytes. The highest disturbance coincided with the lowest species richness, number of individuals, and Shannon-Wiener diversity index, but had the highest Simpson's dominance index. Less disturbance was the opposite, corresponding with the highest species numbers, numbers of individuals, and Shannon-Wiener diversity index, and lowest Simpson's dominance index. Diversity also was affected by habitat heterogeneity, light intensity, water status, and nutrient availability. Liverworts were more common in low-light conditions; mosses were more common in strong light and were more drought tolerant. Diversity of bryophytes and tracheophytes diminished from the entrance to the intermediate plots to the distant plots (Figure 16). The bryophytes form crusts around the lights, facilitating colonization by other plants.

Figure 15. Furong Cave, a karst cave in southern China. Photo by Brookchi, through Creative Commons.

Figure 16. Cave species vs distance from entrance. Modified from Ren *et al.* 2021.

Pentecost (2010) found a total of 59 species, including 4 algae, 3 lichens, 47 bryophytes, 4 ferns, and only 1 angiosperm in Scoska Cave, UK (Figure 17). This is the most bryologically rich cave in Britain. Most (all but 9) of the species were recorded from other caves in Europe. Species richness declines rather irregularly from the entrance to 34 m depth, with relative irradiance decreasing from 12% of that in open sky to 0.004% at 34 m into the cave. Bryophytes occurred from 0-16 m into the cave, with relative irradiance decreasing to 0.2%. Only algae were able to grow at 34 m from the entrance. Whereas light decline represented a continuum, substratum characteristics and surface moisture were more irregular and accounted for various differences in the bryophyte flora.

Figure 17. Scoska Cave, UK. Photo by Bob Jenkins, through Creative Commons.

Moisture can also play a major role in determining the bryophyte flora. In one relatively dry cave on the Juan Fernandez Islands (Figure 18), Skottsberg (1935) found only the liverwort *Balantiopsis purpurata* (see Figure 19), although it was fairly well developed there. In another, *Symphyogyna hochstetteri* (see Figure 20) occurred in the illuminated edges of shallow pits, whereas *Fissidens maschalanthus* (see Figure 41-Figure 42) formed a closed carpet. In another cave Skottsberg found *Balantiopsis purpurata*, *Lepidozia* sp. (Figure 21), *Riccardia brevirarnosa* (see Figure 98), *Riccardia insularis* (see Figure 98), and *Symphyogyna hochstetteri*, and the mosses *Distichophyllum subelimbatum* (see Figure 22), *Fissidens maschalanthus*, and several small areas of *Philonotis krausei* (see Figure 23). It is somewhat unusual

to find more liverworts than mosses in a cave. On the Juan Fernandez Islands *Riccardia insularis* is not known outside the caves.

Figure 23. *Philonotis fontana*; *Philonotis krausei* occurs in a cave on the Juan Fernandez Islands. Photo by Malcolm Storey, DiscoverLife.com, with online permission.

Bryophytes seem to be less diverse than algae in caves. Buczkó and Rajczy (1989) found 17 bryophyte taxa, compared to 49 algal taxa, in three caves in Hungary. The most characteristic moss was *Amblystegium serpens* (Figure 24-Figure 25).

Figure 25. *Amblystegium serpens* leafy stem. Photo by Hermann Schachner, through Creative Commons.

Refugia

Caves often serve as refugia for rare species of more northern bryophytes, as observed in the Red River Gorge (Figure 26) of Kentucky, USA (Studlar & Snider 1989). Likewise, Christy and Meyer (1991) found that the **algific** (cold-producing) talus slopes in Wisconsin, USA, provided suitable microclimates for disjunct or relict plant and invertebrate populations. One third of the 39 species of bryophytes were restricted to the cold air vents there.

Figure 26. Red River Gorge, Kentucky, USA, showing caves in cliff. Photo by Jarek Tuszyński, through Creative Commons.

Puglisi *et al.* (2019) found boreo-arctic-montane species in some of the high mountain caves in Sicily; Fiol (1995) found that cavities in Mallorca (Figure 27) served as refugia. Alegro *et al.* (2015) found the circumpolar boreo-arctic montane *Isopterygiopsis pulchella* (Figure 28-Figure 29) and *Platydictya jungermannioides* (Figure 30-Figure 31) in rock crevices and caves as well as scattered in higher mountain areas of Croatia.

Figure 28. *Isopterygiopsis pulchella*, a species known from the low-light habitats of rock crevices and caves in Croatia. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Gabriel *et al.* (2006, 2011) considered the caves in the Azores (Figure 5) to serve as a refuge for bryophytes. Mulec (2018) likewise considered the dimly lit cave conditions to be refugia for some plants.

Figure 29. *Isopterygiopsis pulchella*, a species of low-light locations. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

On the Socompa Volcano, Andes, Halloy (1991) found that at 6000 m asl communities of bryophytes, algae, fungi, lichens and animals formed at cave entrances where warm vapor (9-37°C) was emitted. These warmer conditions at such high elevations permitted the development of communities, including bryophytes, up to 200 m².

Distance

In an artificial cave in the Iwato-jinja area of Japan, Nakanishi (2002) found that bryophyte communities only extended 13 m into the cave, stopping 6 m short of the end of the cave (Table 1). The composition of the epigeous bryophyte communities changed more rapidly ($ATR=5.97$) (ATR = average turnover rate of species; Itow 1991) than did those of the other communities along the environmental gradients.

Table 1. Bryophytes on soil of Iwato-jinja, Minamitakaki, Nagasaki, Japan, showing position in the cave, up to 15 m. From Nakanishi 2002, with updated nomenclature.

Figure 32. Lava tube, Maui, Hawai'i. Photo by Dronepicr, through Creative Commons.

Lowe *et al.* (2013) found that the bottom of a lava tube cave (Figure 32) in Hawai'i was covered by bryophytes surrounding a puddle.

Prior (1961) provided a short review of cave bryophyte studies. He noted that the bryophytes from the Luray Caverns (Figure 33) in Virginia, USA, were all known from nearby areas in Virginia. Furthermore, the same genera were known from caves in Europe. These Luray Cavern species included *Amblystegium serpens* (Figure 24-Figure 25) (only 1 location, but with capsules), *Anomodon rostratus* (Figure 34), *Ptychostomum pseudotriquetrum* var. *bimum* (= *Bryum pseudotriquetrum* var. *bimum*; dense mats on moist limestone; see Figure 35-Figure 36), *Campylium hispidulum* (with sporophytes at 3 of 8 locations; on moist limestone and silt; Figure 37), *Tortula obtusifolia* (1 large mat on wet limestone with 2 capsules; Figure 38-Figure 39), *Eurhynchium hians* (on wet limestone, abundant, 3 of 19 collections with abundant sporophytes; Figure 40), *Fissidens bryoides* (moist limestone at cave entrance; Figure 41-Figure 42), *Funaria hygrometrica* (with numerous capsules; Figure 43), *Leptobryum pyriforme* (with numerous capsules at 10 of its 18 sites; Figure 44-Figure 45), *Leskea polycarpa* (on wet limestone, at edge of underground lake; Figure 46-Figure 47).

Numbers of Species

Sguazzin and Polli (2011) reported 7 liverworts and 25 mosses from a cave on Mount Saint Michael off the coast of Cornwall. Zhang and Pentecost (2002) found 65 bryophyte taxa in 41 genera and 20 families in various karst caves in England (from 1998 to 2000) and Pentecost and Zhang (2001) found 4 algae, 3 lichens, 47 bryophytes, 4 ferns, and 1 angiosperm in just the Scoska Cave (Figure 17), North Yorkshire, UK, the most species-rich cave known in Britain to date. All but nine of these species were known from other European caves. Castello and Strazzaboschi (2013) reported 9 liverworts and 33 mosses from Della Grotta Dell'orso (Figure 48) in Italy. In Sicily, Puglisi *et al.* (2019) identified 20 liverworts, 3 hornworts, and 113 mosses in 28 caves. Rajczy (1979) found only 2 liverworts and 14 mosses at the upper entrance of Cave Perama (Figure 49) in Greece, but only 7 mosses were found within the cave. Rajczy *et al.* (1986) reported 11 algae and 7 bryophyte taxa in one cave and 38 algae, 12 moss, 1 fern, and 1 angiosperm in another in the Bükk Mountains of Hungary (Figure 50).

Figure 50. Cave entrance, Balla-barlang Cave, Bükk Mountains, Hungary. Photo by Czina Tivadar, through Creative Commons.

Jedrejko and Ziober (1992) found 72 bryophyte species, including 10 liverworts, 59 mosses, and 3 mosses that remained unidentified in the Kracków-Wieluń Upland caves of Poland. Of these, 50% developed only in full access of light, with numbers of species diminishing with distance from the entrance.

In China, Zhang *et al.* (1996a, b) reported 59 bryophyte species in 43 genera from the karst caves of Huangguoshu. Zhang *et al.* (2005) found 28 species in only 18 genera in karst caves of the Guilin area, China (Figure 14).

Ammons (1933) found 46 moss and 44 liverwort species at the entrance of McKinney's Cave, West Virginia, USA. She noted the absence of *Reboulia* (Figure 51) and *Eucladium* (Figure 9-Figure 10). Within the cave she reported 31 liverwort species and 34 moss species, including 3 *Sphagnum* (Figure 69) species.

Species

Mason-Williams and Benson-Evans (1967) described some of the ecological requirements of cave bryophytes in South Wales. Most of the caves visited had mesophilous forms with a pH tolerance of 4.8-7.0. These included *Amblystegium serpens* (Figure 24-Figure 25), *Bryoerythrophyllum recurvirostrum* (Figure 52-Figure 53), *Thamnobryum alopecurum* (Figure 54-Figure 55), *Fissidens bryoides* (Figure 41-Figure 42), *F. taxifolius* (Figure 56-Figure 57), *Ctenidium molluscum* (Figure 58), *Rhizomnium punctatum* (Figure 59). Few acid-tolerant forms occurred: *Polytrichum juniperinum* (Figure 60-Figure 61), *Pseudotaxiphyllum elegans* (Figure 62-Figure 64), *Hypnum cupressiforme* (Figure 65-Figure 66), *Blindia acuta* (Figure 67-Figure 68), *Sphagnum subnitens* (Figure 69). The mesophilic liverworts *Pellia epiphylla* (Figure 70-Figure 71) and *Plagiochila asplenoides* (Figure 72) were also present at most sites. Surprisingly, to me at least, *Pellia endiviifolia* (Figure 73) and *Conocepalum conicum* (Figure 74-Figure 75) were found less frequently. Mason-Williams and Benson-Evans (1958) considered *Pseudotaxiphyllum elegans* to be one of the most shade-tolerant mosses in acid sites.

In North America, Maheu (1926) explored Mammoth Cave (Figure 76) and two others in Kentucky, USA. The bryophytes in all three caves were identical: the mosses *Anomodon attenuatus* (Figure 77-Figure 78), *A. rostratus*

(Figure 34), *Brachythecium rivulare* (Figure 79), *Eurhynchium praelongum* (Figure 2-Figure 3), *Gymnostomum calcareum* (Figure 80-Figure 81), and *Plagiomnium rostratum* (Figure 82), and the thallose liverwort *Marchantia polymorpha* (Figure 83). Maheu described the plants as etiolated, and lacking sporophytes. *Marchantia polymorpha* occurred in the least light but did not exhibit the morphological changes seen in the other species.

Among the 17 bryophyte species in three Hungarian caves (e.g. Figure 6), the most common included *Pellia endiviifolia* (Figure 73), *Amblystegium serpens* (Figure 24-Figure 25), *Bryum* sp. (see Figure 88), *Encalypta vulgaris* (Figure 89), *Eucladium verticillatum* (Figure 9-Figure 10), *Eurhynchium schleicheri* (Figure 90), *Fissidens taxifolius* (Figure 56-Figure 57), *Plagiomnium cuspidatum* (Figure 91), *Rhynchostegiella tenella* (Figure 86-Figure 87), and *Rhynchostegium murale* (Figure 92) (Buczkó & Rajczy 1989).

The flora of a very wet rock cave in Corsica, France, however, had a different array of species (Sotiaux *et al.* 2007). These included *Aneura maxima* (Figure 93-Figure 95), *Lophocolea fragrans* (Figure 96-Figure 97), and *Riccardia multifida* (Figure 98) near a stream in the cave; *Plagiothecium cavifolium* (Figure 99) occurred in a rock cave along a stream. *Neckera menziesii* (Figure 100) occurred in microcaves in schist rocks. *Gymnostomum aeruginosum* (Figure 101-Figure 102) was more typical of caves, occurring in a rock cave.

Rajczy *et al.* (1986) were unable to relocate four cave species in a Hungarian cave. One of these was a typical cave dweller, *Eucladium verticillatum* (Figure 9-Figure 10), which may have been destroyed by excavations. *Rhynchostegiella tenella* (Figure 86-Figure 87), a typical cave moss, was found as new.

Tanaka *et al.* (2001) discussed the mosses of a limestone cave in Kyushi, Japan.

Zonation

The steepest and most evident zonation pattern in caves is related to light intensity. Pentecost and Zhang (2001) found that species richness exhibited an irregular decline from the entrance (12% relative irradiance compared to open sky) to 0.004% relative irradiance at 34 m depth. Bryophytes occurred at 0-16 m in light that declined to 0.2% relative irradiance. Differences in substrate characters and surface moisture caused the irregularities in bryophyte decline with distance.

Zhang *et al.* (1996b) identified 68 communities of bryophytes in 7 karst caves in the Huangguoshu area of China. They classified the ecological distribution of the bryophytes as limestone and dolomite, limestone soil, and cave tufa.

Hajdu (1977) considered the zones to be cave entrances, area around lights, and darkness. Hajdu considered the cave-dwelling plants to have extremely low ecological requirements. Nevertheless, there seems to be no species that is restricted to cave environments.

More commonly, caves are divided into three major zones based on light intensity. These are **entrance** (Figure 1), **twilight**, and **dark** zone (World Atlas 2021). But perhaps this is not the most appropriate classification for photosynthetic organisms since they are unable to occupy the third zone.

Hajdu (1977) described the vegetation changes within the cave from the most harsh habitat to the most favorable. In that order, they progressed from blue-green bacteria to green algae and diatoms to mosses and finally in the best conditions to ferns. But he noted that the larger plants will eventually outgrow the smaller ones, thus causing mosses to replace the algae. Fiol (1995) examined bryophytes at cavity entrances in Mallorca (Figure 27) and described different regions, especially in shafts.

Uniyal *et al.* (2007) described the zonation seen in an array of caves as a result of decreasing light. They found that the liverworts *Plagiochasma appendiculatum* (Figure 103-Figure 104), *Plagiochasma pterospermum*, *Plagiochila chinensis* (Figure 105), *Porella densifolia* (see Figure 106), and *Targionia hypophylla* (Figure 107-Figure 108), and mosses *Anomodon rugelii* (Figure 109-Figure 110), *Plagiothecium neckeroideum* (Figure 111-Figure 112), and *Pelekium versicolor* (Figure 113) occur at the twilight zone near the cave entrance. *Funaria* (Figure 43) and *Cyathodium* (Figure 115) invade the bare substrate further into the cave. *Cryptomitrium himalayense* (see Figure 114), *Cyathodium tuberosum* (Figure 115), *Lejeunea* (Figure 116), *Fissidens* (Figure 56-Figure 57), *Isopterygium albescens* (see Figure 117), and *Plagiothecium neckeroideum* occur on rock ledges in the cave interior. Even further from the entrance light one might find *Cryptomitrium*. *Stephensoniella brevipedunculata* (Figure 118) and *Hymenostylium recurvirostrum* (Figure 119-Figure 120) may grow together in deep-shaded caves (Tewari *et al.* 1994).

Figure 126. *Conocephalum japonicum*, a species that occurs at the bottom of caves of Guizhou Province, China. Photo by David Long, with permission.

Li *et al.* (2019) identified three zones for liverworts in four caves in the Guizhou Province, China: middle-depth cave, mainly of *Cyathodium smaragdinum* (Figure 124) + *Pellia endiviifolia* (Figure 73) + *Riccia fluitans* (Figure 125); lower-middle-depth cave, mainly of *Cyathodium smaragdinum* + *Riccia fluitans*; bottom cave, mainly including *Pellia endiviifolia* + *Conocephalum japonicum* (Figure 126) + *Dumortiera hirsuta* (Figure 127). These caves tended to have 1-2 dominant liverwort species. The diversity in both vertical and horizontal distances from the entrance were affected by the gradient variation of temperature, humidity, and illumination.

Summary

Among the cave bryophyte flora, *Eurhynchium* often is represented by the most species, often occurring in very low light (200 lux). But light limitation limits the number of bryophyte species able to grow at any distance into the cave, creating zones known as **entrance**, **twilight**, and **dark**. Algae and **Cyanobacteria** typically comprise more species than do bryophytes; liverworts are usually few in species number. Light conditions create a zonation pattern of ferns in the best conditions, to moss, to algae, and in the most distant photic zone, the **Cyanobacteria**. Disturbance further limits the species richness. And as one might expect, richness decreases with distance from the cave entrance. Nevertheless, the cave bryophyte flora tends to be unique, with some species known only from caves in some regions. Caves serve as refugia in many geographic regions.

There are many studies on the cave flora in Europe and Asia, but studies occur on all the continents. *Eucladium verticillatum* occurs frequently on both sides of the Atlantic and may contribute to the formation of stalactites in limestone caves. Likewise, *Amblystegium serpens* is common in a wide range of caves and locations. The Australian cave species tend to be species from arid and semiarid habitats.

Acknowledgments

Bryonettors Wolfgang Hofbauer, Jerry Jenkins, Jan Kucera, Gordon Rothero, Christian Schröck, and Dale Vitt responded to my Bryonet call for interpretation of the image used in Figure 8.

CHAPTER 18-3

CAVES – ZONES OF BRYOPHYTE FLORA

Figure 1. View of the twilight zone and entrance light at Son Doong Cave, Vietnam. Photo by Doug Knuth, through Creative Commons.

Habitat Differences

Cave Mouth Area

The area near the opening of the cave (Figure 1) can often have its own flora, different from the surrounding area and different from the cave entrance. These floral differences result from exposed rock of the cave, cool air emitted from the cave, and differing moisture conditions. Depending on the site, it might be drier due to exposure, but it can also be moister from air emitted by the cave. This is particularly true of caves with additional openings elsewhere among the rocks.

Conard (1938) found *Pohlia elongata* (Figure 2) with capsules and *Pohlia prolifera* (Figure 3) with propagules around a cave mouth near Au Train, Michigan, USA. Capsules are typically uncommon within caves, but conditions of light and moisture, coupled with seasonal changes, can support the production of sporophytes near the entrance.

Figure 2. *Pohlia elongata* capsules, a species found with capsules around a cave mouth in Michigan, USA. Photo by David T. Holyoak, with permission.

Figure 3. *Pohlia prolifera* with numerous propagules among the leaves, a species that occurs around a cave mouth in Michigan, USA. Photo by Hermann Schachner, through Creative Commons.

Areas near entrances can even support species unique in the area. For example, Aziz (2011) reported *Tortula truncata* (Figure 4) in rock fissures and at the mouth of Baston cave, a new species for Iraq.

Figure 4. *Tortula truncata* with numerous capsules, a species found for the first time in Iraq around a cave entrance. Photo from Botany Website, UBC, with permission.

Salamah *et al.* (2019) found six bryophyte species in the area near the Selarong Cave, Indonesia. These were *Hyophila involuta* (Figure 5-Figure 6), *Barbula consanguinea* (see Figure 7), *Bryum erythropus* (see Figure 123), *Weissia controversa* (Figure 8-Figure 9), *Preissia* sp. (Figure 10-Figure 11), and *Vesicularia dubyana* (Figure 12).

Figure 14. *Conocephalum conicum* males, a species that forms large colonies in the area near the entrance of Grotta dell'orso, Italy. Photo by Janice Glime.

Castello and Strazzaboschi (2013) described the exterior of the Della Grotta Dell'orso Cave (Figure 13). The exterior near the entrance had a northern exposure with intense dripping. They found that these conditions permitted growth of numerous bryophytes that are typical of the cave interiors, particularly from the shady, damp walls at the entrance. However, in the darker interior, few species are present, and only develop to about 10 m into the cave.

Puglisi *et al.* (2018) recognized a number of communities in the entrance and twilight area of Sicilian caves. In the lava caves, these included the liverwort species of *Plagiochasma rupestre* (Figure 15-Figure 16), *Riccia glauca* (Figure 17-Figure 18), and *Targionia hypophylla* (Figure 19); hornwort *Anthoceros crispatus* (see Figure 20); and moss species of *Amphidium mougeotii* (Figure 21-Figure 22), *Bartramia ithyphylla* (Figure 23), *Brachythecium velutinum* (Figure 24-Figure 25), *Pohlia annotina* (Figure 26-Figure 27), *Pohlia cruda* (Figure 28), *Rhabdoweisia fugax* (Figure 29), *Rhynchostegiella tenella* (Figure 30), and *Timmia bavarica* (Figure 31). In the karst caves they found *Eucladium verticillatum* (Figure 32-Figure 33), *Thamnobryum alopecurum* (Figure 34), *Timmiella barbuloidea* (see Figure 35), and *Weissia controversa* (Figure 8-Figure 9).

Figure 34. *Thamnobryum alopecurum*, a species that occurs in the karst caves of Sicily. Photo by Michael Lüth, with permission.

Figure 35. *Timmiella* sp.; *Timmiella barbuloidea* occurs in the karst caves of Sicily. Photo by Ken-Ichi Ueda, through Creative Commons.

The cave mouth can influence the vegetation near the entrance due to moist and cool air drafts emanating from the cave. Dalton (1995) found *Seligeria cardotii* (see Figure 36) as a new record for Tasmania on a moist calcareous rock face that was overhanging the entrance to a small cave. The moist conditions of the habitat were attributed to the limestone cave entrance and supported a lush bryophyte and fern flora there.

Figure 36. *Seligeria* sp.; *Seligeria cardotii* occurs in Tasmania on a moist calcareous rock face overhanging the entrance to a small cave. Photo by Bob Klips, with permission.

Gabriel *et al.* (2011) reported a number of bryophyte species that occurred both in the cave entrances and in the native forest in the Azores (Figure 37): *Cyclodietyon laetevirens* (Figure 38), *Plagiochila longispina* (Figure 39), *Plagiothecium nemorale* (Figure 40), *Tetrastichium virens* (Figure 41), and others.

Figure 37. Cave entrance in the Azores. Photo by Diego Delso, through Creative Commons.

Figure 41. *Tetrastrichium virens* with capsule, a species that occurs in both cave entrances and in the native forest in the Azores. Photo by Michael Lüth, with permission.

What seems to be lacking is a widespread comparison of abundance and frequency of each species of bryophyte within vs around the caves, particularly on similar substrata. Some studies imply that bryophyte cover is richer inside the cave due to the more constant conditions and available moisture. In other cases, the exterior is more favorable due to greater light intensity.

Entrance

"The entrance zone refers to the entry point of a cave, which usually receives adequate sunlight. This part of the cave opens to the outside environment and experiences varied temperatures, as it adjusts to the external environment and climate. The entrance zone can be either naturally formed or created by humans. Green plants grow in this zone because it has sunlight, which is needed for photosynthesis. The entrance zone of a cave can be inhabited by various forms of life, including beetles, small rodents, spiders, snakes, salamanders, earthworms, millipedes, owls, and snails. Additionally, certain terrestrial animals, such as raccoons and bears, may take refuge in the entrance zone to sleep, eat, and nest." (World Atlas 2021). These animals may influence the kinds of plants that arrive and survive there.

The cave entrance often provides protection not available further away. This can be shade and greater

moisture, thus protecting it from bright sun, high temperatures, and drought. For example, Aziz (2011) reported *Tortula viridifolia* (Figure 42) at the entrance of a cave as new for Iraq.

Figure 42. *Tortula viridifolia* with capsules, on rock, was reported as a new species for Iraq from a cave entrance. Photo by George G., through Creative Commons.

Grebe (1918) observed bryophytes from 5-10 meters from the mouths of several caves in Germany. The light was very dim and was reflected in from the cave surface. He reported thick mats of *Amblystegium serpens* (Figure 43-Figure 44) around electric lights in Dunkel der Deckenhöhle at Iserlohn. Fiol (1995) explored the flora of cavity entrances of more than 40 cavities in Mallorca (Figure 45). He was able to report relict species and frequent species in the shafts. The moss *Homalia lusitanica* (Figure 46) occurs between 40 and 200 lux, whereas *Cyanobacteria* can survive 1/2000 of the surface light. The access region of the caves tend to support xerophytes, including the liverworts *Plagiochila asplenioides* (Figure 47) and *Porella arboris-vitae* (Figure 48), and mosses *Anomodon viticulosus* (Figure 49), *Ctenidium molluscum* (Figure 50-Figure 51), and *Scorpiurium circinatum* (Figure 52-Figure 53). In the entrance he found the liverworts *Conocephalum conicum* (Figure 14), *Mesoptychia turbinata* (Figure 54), and *Pellia endiviifolia* (Figure 55), and the mosses *Neckera crispa* (Figure 56) and *Rhynchostegiella tenella* (Figure 30), as well as a few of the access region species.

Rushin (1973) reported that mostly bryophytes grow on the upper ledges near the cave entrance and where light reaches the floor of the Natural Trap Cave (Figure 57) in the Bighorn Mountains of Wyoming, USA. The cool, moist environment is ideal for the bryophytes. But farther into the cave where it is dark, only bacteria and fungi survive.

Figure 57. Natural Trap Cave, Wyoming. Photo from Bureau of Land Management, through public domain.

Borges *et al.* (2008) indicated a twofold importance of cave entrances for both bryophytes and arthropods in the Azores (Figure 37). They are sheltered and humid, supporting good diversity of bryophytes representing 25% of the Azorean bryophyte flora; many of the species found there are rare or endemic. They argued that these serve as hotspots for species that permit us to answer ecological questions.

In Montenegro, Kozlova *et al.* (2019) found 64 species of algae and Cyanobacteria and 21 species of bryophytes in the entrance zone of 7 caves (Figure 58). They found that the morphology of the cave entrance was more important than the proximity to the opening in determining the composition of the phototrophic community.

Figure 58. Cave entrance in Montenegro. Photo through Creative Commons.

Buczko and Rajczy (1989) reported the troglophile *Eucladium verticillatum* (Figure 32-Figure 33) "in great mass" on rock at the entrance of a Hungarian cave.

Natcheva (2008) reported *Conocephalum conicum* (Figure 14, Figure 59-Figure 61) from the Zandana (Biserna) cave in Bulgaria. My own experience supports this as a suitable habitat for the species. I have seen it on canyon walls at Hocking Hills, Ohio, USA (Figure 59-Figure 60), behind Hungarian Falls (Figure 61) in Houghton County, Michigan, USA, and near the entrance in a cave in Wales.

Figure 59. *Conocephalum conicum* on canyon walls, Hocking Hills, Ohio, USA. Photo by Janice Glime.

Figure 60. Ash Cave at Hocking Hills, Ohio, USA. Photo courtesy of Kim Barton.

Figure 61. Crest of Hungarian Falls, Tamarack City, Michigan, USA. *Conocephalum conicum* grows behind the waterfall on the rock. Photo by Janice Glime.

Pentecost and Zhang (2006) found *Eucladium verticillatum* (Figure 32-Figure 33), *Gymnostomum aeruginosum* (Figure 62-Figure 63), and *Palustriella commutata* (Figure 64-Figure 65) at cave entrances in European travertines, but these species failed to penetrate into the twilight zone. Pentecost and Zhang (2001) found that these three species were common at 0-4 m from the entrance with 10% relative irradiation (RI) in Scoska Cave (Figure 66) in the UK.

Zhang *et al.* (2004a) studied the bryophytes in the entrance zone of a karst cave in Kunming, China. Ren *et al.* (2021) found a similar restriction to that in the UK found by Pentecost and Zhang (2001, 2006) for the mosses *Ectropothecium zollingeri* (Figure 67), *Hypopterygium tamarisci* (Figure 68), *Plagiomnium vesicatum* (Figure 69), and *Racopilum cuspidigerum* (Figure 70-Figure 71), and the liverwort *Lejeunea sordida* (see Figure 75-Figure 76) to the entrance area of karst caves in southern China.

Gabriel *et al.* (2008) noted that cave entrances in the Azores (Figure 37) were particularly humid. Gabriel (2006) found that ~25% of the Azorean bryoflora can be found in this habitat. He noted that 19 vulnerable and 13 rare bryophytes on the European Red List can be found there. Gabriel *et al.* (2008) used both published records and their own field sampling to evaluate the species diversity and rarity of bryophytes at the entrances of all known Azorean lava tubes and volcanic pits (Gabriel *et al.* 2008). They found the frequent liverworts to include *Calypogeia arguta* (Figure 72), *Jubula hutchinsiae* (Figure 73-Figure 74), and *Lejeunea lamacerina* (Figure 75-Figure 76). Frequent mosses included *Epipterygium tozeri* (Figure 77-Figure 78), *Eurhynchium praelongum* (Figure 79), *Fissidens serrulatus* (Figure 80), *Pseudotaxiphyllum elegans* (Figure 81), *Tetrastichium virens* (Figure 41), and *Tetrastichium fontanum* (Figure 82). Even some rare Azorean species appeared at the entrances: *Archidium alternifolium* (Figure 83-Figure 84), *Asterella africana* (Figure 85), and *Plagiochila longispina* (Figure 39). Gabriel *et al.* (2018) found *Radula holtii* (Figure 86) at cave entrances in the Azores (Figure 37) and expressed concern that climate change and other factors of anthropogenic origin could threaten it. Gabriel *et al.* (2011) consider *Asterella africana* to be a specialist of cave entrances.

Ros *et al.* (2000) found *Schistidium cinclidodonteum* (Figure 87) on rocks with soil in a protected and dark cave in Morocco (Figure 88). Its more typical habitat is on acid rocks that are periodically flooded or in stream beds.

Figure 87. *Schistidium cinclidodonteum*, a species that occurs on rocks with soil in a dark cave in Morocco. Photo by Scot Loring, through Creative Commons.

Pilkington (2003) found the flora of the cave entrance of a cave in Ireland (Figure 89) to contrast sharply with that of the nearby surface vegetation. The entrance had 23 species of tracheophytes and 17 species of bryophytes in 20 quadrats: *Ctenidium molluscum* (Figure 50-Figure 51), *Eurhynchium praelongum* (freq=14; Figure 79), *Fissidens taxifolius* (Figure 90), *Thuidium tamariscinum* (Figure 91-Figure 92), *Palustriella commutata* (wet places; Figure 64-Figure 65), *Rhizomnium punctatum* (Figure 93), *Pellia endiviifolia* (Figure 55), *Thamnobryum alopecurum* (freq=20; Figure 34), *Plagiochila asplenioides* (Figure 47), *Plagiomnium undulatum* (freq=15; Figure 94-Figure 95), *Plagiomnium affine* (Figure 96), *Calliergonella cuspidata* (Figure 97), *Plagiochila spinulosa* (Figure 98-Figure 99), *Brachythecium rutabulum* (Figure 100), *Hookeria lucens* (wet places; Figure 101), *Isoetecium myosuroides* (Figure 102), and *Dichodontium pellucidum* (Figure 103). Note that only *Pellia endiviifolia*, *Plagiochila asplenioides*, and *Plagiochila spinulosa* are liverworts.

Gabriel *et al.* (2006) found relatively rare species at cave entrances in the Azores (Figure 37), including the non-threatened *Frullania azorica* (Figure 104-Figure 105), *Frullania microphylla* (Figure 106), *Homalia webbiana* (Figure 107), *Marchesinia mackaii* (Figure 108-Figure 109), *Myurium hochstetteri* (Figure 110), *Fissidens luisei* (name of unknown status; Figure 111), and the rare *Tetrastichium fontanum* (Figure 82), *Fissidens coacervatus* (Figure 112), and *Tetrastichium virens* (Figure 41). *Radula wichurae* (see Figure 86) is vulnerable. Other more common species were also present at cave entrances: the hornwort *Anthoceros punctatus* (Figure 113); liverworts *Calypogeia arguta* (Figure 114), *Lophocolea coadunata* (Figure 115), *Conocephalum conicum* (Figure 14, Figure 59-Figure 61), *Fossombronia casepitiiformis* (Figure 116), *Frullania tamarisci* (Figure 117), *Lejeunea lamacerina* (Figure 76), *Lunularia cruciata* (Figure 118), *Plagiochila bifaria* (Figure 119), *Porella obtusata* (Figure 120), *Radula lindenbergiana* (Figure 121), *Riccardia latifrons* (Figure 122); mosses *Bryum canariense* (Figure 123), *Campylopus pilifer* (Figure 124-Figure 125), *Epipterygium tozeri* (Figure 77-Figure 78), *Heterocladium wulfsbergii* (Figure 126-Figure 127), *Hypnum cupressiforme* (Figure 128-Figure 129), *Leucobryum juniperoideum* (Figure 130), *Plagiothecium nemorale* (Figure 40), *Perigonium gracile* (Figure 131), *Scorpiurium circinatum* (Figure 132-Figure 133), *Thamnobryum maderense* (Figure 134). This is an unusually large number of liverworts for cave habitats.

Even small caves can provide unique local habitats. In the Flume (Figure 135) at Franconia Notch, New Hampshire, USA, *Campylium chrysophyllum* (Figure 136)

was only found on the floor of a small cave above the falls (Glime 1982).

Figure 135. Flume, Franconia Notch, New Hampshire, USA, where small caves can have *Campylium chrysophyllum*. Photo by Janice Glime.

Twilight Zone

The **twilight zone** (Figure 137) is the part of a cave that receives a small amount of sunlight since it is not too far from the entrance. This seems to coincide with the **threshold** part of the cave, where light penetrates to some degree. This zone is cool and damp, and its temperature is usually relatively constant. The twilight zone is shared by both outside organisms and cave dwellers.

Figure 137. Twilight zone of Rawhiti Cave, South Island, New Zealand. Photo by Pseudopanax, through public domain.

Pleurocarpous mosses such as *Amblystegium serpens* var. *juratzkanum* (Figure 138) predominate among bryophytes in areas with less light (down to 232 lux) in the three Hungarian caves studied by Buczkó and Rajczy (1989), although the acrocarpous moss *Bryoerythrophyllum recurvirostrum* (Figure 139) also occurs in deeper parts.

Figure 138. *Amblystegium serpens* var. *juratzkanum* with capsules, on rock. Pleurocarpous mosses such as this one predominate in areas with less light. Photo by Štěpán Koval, with permission.

Figure 139. *Bryoerythrophyllum recurvirostrum* showing red base, an acrocarpous moss that grows in deep parts of caves. Photo by Janice Glime.

In Mallorcan caves (Figure 45), Fiol (1995) described the "transition zone," which presumably corresponds with the **twilight zone**. The bryophytes in this zone seem to include the most cavernicolous of the entrance species, including *Eucladium verticillatum* (Figure 32-Figure 33), *Fissidens dubius* (Figure 140), *Homalia lusitanica* (Figure 46), *Mnium* sp. (Figure 152-Figure 153), and *Thamnobryum alopecurum* (Figure 34). *Thamnobryum alopecurum* and *Homalia lusitanica* mark the light extinction limit of bryophytes into the next zone. Relicts include the liverwort *Jungermannia atrovirens* (Figure 141), and the mosses *Taxiphyllum wissgrillii* (Figure 142), *Orthothecium intricatum* (Figure 143), and *Rhizomnium punctatum* (Figure 62), all of which were known in Mallorca only from these caves.

In the Azores (Figure 37), Frahm (2005) found bryophytes in a small crater with a cave at the bottom.

Ferns are common where there is enough light, but bryophytes extend farther into the dark interior. These are primarily *Riccardia chamedryfolia* (Figure 144-Figure 145) and *Thamnobryum* sp. (Figure 34), with smaller quantities of *Cyclodictyon laetevirens* (Figure 38) and *Fissidens serrulatus* (Figure 80). He describes the *Thamnobryum* as conspicuous because of its large, lax plants with long, flagelliform branches.

Figure 144. *Riccardia chamedryfolia*, a species that occurs in a cave at the bottom of a crater in the Azores. Photo by Bernd Haynard, through Creative Commons.

Figure 145. *Riccardia chamedryfolia*. Photo by Hugues Tinguy, with permission.

In the Della Grotta Dell'orso, Italy (Figure 146-Figure 147), Castello and Strazzaboschi (2013) found *Oxyrrhynchium speciosum* (Figure 148) and *Taxiphyllum wissgrillii* (Figure 142) on a large boulder 10 m from the entrance, marking the deepest position of bryophytes in the cave. Bryophyte growth in the twilight zone was more reduced than at the entrance, with species exhibiting stunted growth in small patches. Other species in the twilight zone included *Fissidens crispus* (Figure 149), *Isopterygiopsis pulchella* (Figure 150-Figure 151), *Mnium stellare* (Figure 152-Figure 153), *Neckera complanata* (Figure 154-Figure 155), and *Rhynchostegiella tenella* (Figure 30).

Pentecost and Zhang (2001, 2006) found that *Eurhynchium pumilum* (Figure 156), *Fissidens adianthoides* (Figure 157-Figure 158), and *Pseudotaxiphyllum elegans* (Figure 81) were frequent bryophytes in the region 6-10 m with relative illumination (RI) 1-2% in Scoska Cave (Figure 66), North Yorkshire, UK. *Amblystegium serpens* (Figure 44), *Fissidens dubius* (Figure 140), and *Thamnobryum alopecurum* (Figure 34) penetrated the furthest. *Thamnobryum alopecurum* was the most frequently encountered bryophyte in the cave. Further into the cave they found *Orthothecium intricatum* (Figure 143), *Pseudotaxiphyllum elegans*, *Rhynchostegiella teneriffae* (Figure 159), and *Platydictya confervoides* (Figure 160-Figure 161) (15.9 m, RI 0.23%). *Dichodontium pellucidum* (Figure 103) was restricted by substrate to clay soil.

Ren *et al.* (2021) found that some species were restricted to the twilight zone of six karst caves in southern China. *Fissidens taxifolius* (Figure 90) and *Hyophila javanica* (see Figure 162) occurred only in intermediate light. *Radula kojana* (Figure 163-Figure 164) was found only in deep plots. This led them to conclude that liverworts were better adapted to low light conditions, but this needs a much wider sampling effort in a wide range of caves. Furthermore, they found that the mosses were in locations that indicate they are more drought tolerant, which could account for the absence of liverworts in areas closer to the opening.

Pentecost and Zhang (2001) found that in Scoska Cave (Figure 66), UK, *Hypnum resupinatum* (Figure 165), *Orthothecium intricatum* (Figure 143), and *Weissia* cf. *perssonii* (Figure 166) penetrated the farthest, to regions where the RI fell to about 0.4%. Liverworts were unable to penetrate very far, an absence that the researchers attributed to the dry conditions of the cave. Only *Conocephalum conicum* (Figure 14, Figure 59-Figure 61) and *Metzgeria conjugata* (Figure 167) were able to penetrate to 12 m.

Wang *et al.* (1998) examined the biokarst formations in the twilight zone of Chinese caves.

In a study of 17 Guilin caves (*e.g.* Figure 168), Zhang *et al.* (2005) found *Gymnostomum calcareum* (Figure 169-Figure 170), *Hymenostylium recurvirostrum* (Figure 171-Figure 172), and *Philonotis turneriana* (Figure 173) associated with travertine deposits in the twilight zone of karst caves in the Guilin area of China. Guo *et al.* (2018) examined the communities of dolomite cave twilight zones in Shuidong Cave in Guizhou Province, China.

Stalactites and Stalagmites

In addition to growing on cave walls, some bryophytes are able to grow in the stalactite or stalagmites where there is enough moisture dripping down. In Yunnan Province, P. R. China, Zhang *et al.* (2004b) found *Gymnostomum aurantiacum* (see Figure 169-Figure 170) and *Hymenostylium recurvirostrum* (Figure 171-Figure 172). These can contribute to the formation of the stalactites. *Eucladium verticillatum* (Figure 32-Figure 33) and *Didymodon* (Figure 174) are also important in forming stalactites. For a description of this process, see Chapter 18-1 of this volume. Bryophytes seem to be rare on the surfaces of these formations, perhaps in part due to the changing nature of the formations.

Figure 174. *Didymodon brachyphyllus* on rock; *Didymodon* is an important genus for forming stalactites. Photo by Michael Lüth, with permission.

Vertical Shafts

Not all cave inclines progress slowly away from the entrance. Moseley *et al.* (2013) describe a cave in Nova Scotia, Canada, that has vertical shafts as entrances (Figure 175). The fern zone is missing, and three pleurocarpous mosses are dominant: *Loeskeobryum brevirostre* (Figure 176), *Isopterygiopsis muellerianum* (Figure 177-Figure 178) (1st dominant), and *Heterocladium dimorphum* (Figure 179), along with two liverwort species: *Calypogeia* (Figure 72; Figure 114) and *Lophocolea* (Figure 115). The crustose lichen *Lepraria* sp. also occurs on the shaft walls. *Isopterygiopsis muellerianum* is the most prominent bryophyte and extends to the deepest location of photosynthetic organisms. *Loeskeobryum brevirostre* is present only in the uppermost part of the shaft where it is able to receive sufficient light.

Summary

The cave bryophyte flora is generally divided into that of the **entrance**, **twilight zone**, and **dark zone**. A further zone of note is the cave mouth area on the outside of the cave. The penetration of light suitable for photosynthesis is the limiting factor for these bryophyte distributions.

Because of the influence of cave temperatures on the **mouth** area, this area can have species that are unique within the region. There tend to be more liverworts there, and mosses such as propaguliferous *Pohlia* spp. and *Tortula truncata* may be present.

The **entrance** provides only a short distance with sufficient light for a number of species, with morphology of the opening being more important than distance in determining light penetration. One of the most common bryophytes here is *Amblystegium serpens*. The cave moss *Eucladium verticillatum* is often in this zone, especially on the eastern side of the Atlantic. This area can harbor rare species, and species composition often contrasts sharply with that outside the cave.

The **twilight zone** has a more buffered climate than the entrance, but due to low light it has fewer species. Both *Amblystegium serpens* and *Eucladium verticillatum* extend into this zone, often being abundant. Its often moist conditions and suitable substrate can create refugia for bryophytes not occurring elsewhere in the region. Several species of *Fissidens* are among those surviving in this low light.

Stalactites and stalagmites are seldom colonized by bryophytes, but *Eucladium verticillatum* and several other bryophytes can contribute to their formation. **Vertical shafts** differ in flora and light intensity from horizontal cave entrances.

Acknowledgments

As always, I am indebted to the many people who have given me permission to use their images. And I thank those foray leaders who have included caves and cave-like environments in the field trips.

CHAPTER 18-4

CAVES – BRYOPHYTE STRATEGIES

Rare Species and New Finds

I have tried throughout the book not to reveal the exact location of rare species. Bryologists and other collectors have been known to contribute to the disappearance of species from some locations through their collections.

Unique habitats always draw our attention in anticipation of finding something new, as already reported in Chapters 18-1 for the **Cyanobacteria** and algae in caves. Some of the rare bryophytes have been mentioned in Chapters 18-2 to 18-3. Likewise, the various caves and cave-like habitats often don't disappoint us for new bryophytes, particularly if they have not previously been explored by a bryologist. For example, Aziz (2011) reported 17 new species records for Iraq, and four of these were associated with caves. These included *Tortula viridifolia* (Figure 2) cited as *Pottia wilsonii* var. *crinata* and *Tortula truncata* (Figure 3-Figure 4).

Figure 2. *Tortula viridifolia* with capsules, a species Aziz found in caves as new to Iraq. Photo by Michael Lüth, with permission.

Vitt and Belland (1997) found that 25% of the mosses in Alberta, Canada, are rare. This study allows us to assess the characteristics of rare species. In their study, they found that pleurocarpous species, long-lived perennials, and competitive strategists were less likely to be among the rare species. Members of **Bryales**, **Dicranales**, and **Funariales** are more likely to be represented, whereas **Hypnales**, **Orthotrichales**, and **Sphagnales** are underrepresented. Of interest in cave bryology is that 42% of the rare species have boreal distributions, 57% occur on soil, and 34% occur on rock. These attributes make caves suitable places for finding disjunct and rare species.

Since caves create unique conditions within an ecosystem or region, it is not surprising to find that they harbor species that are rare for that area. In the Red River Gorge of Kentucky, USA, Studler and Snider (1989) found rare mosses and liverworts were "favored by the numerous caves and ravines." In the caves they found such rare species as *Bryoxiphium norvegicum* (Figure 5), *Hookeria acutifolia* (Figure 6), *Brothera leana* (Figure 7), *Diphyscium mucronifolium* (Figure 8), *Rhabdoweisia crispata* (Figure 9), *Syrhropodon texanus* (Figure 10), *Trichostomum tenuirostre* (Figure 11-Figure 13), and *Plagiochila sullivantii* (Figure 14) representing relict or disjunctive taxa.

Evans and Nichols (1935) reported that the original specimens of *Mesoptychia gillmanii* (as *Jungermannia gillmanii*; Figure 15) came from a cave in a cliff of Potsdam sandstone on an island in Lake Superior. This was collected in 1867 by Henry Gillman and seems to be the first liverwort collected in Michigan. However, Stephani concluded that it was in fact *Lophozia inflata*. Observations of the paroicous inflorescences later placed it in the genus *Leiocolea*, but its current status in Söderström *et al.* (2016) places it back in *Mesoptychia gillmanii*.

Figure 15. *Mesoptychia gillmanii*, a species first reported in Michigan, USA, from a cave in a cliff of Potsdam sandstone on an island in Lake Superior. Photo by David Wagner, with permission.

Hermann (1964) added *Aneura pinguis* (Figure 16) to the known flora of Mt. Katahdin, Maine, USA, from a collection on the peaty floor of a cave between huge boulders.

Sguazzin and Polli (2011) found *Ptychostomum moravicum* (= *B. laevipilum*; Figure 17-Figure 18) from a cave on Mount Saint Michael off the coast of Cornwall. Puglisi *et al.* (2019) found species that are rare in Sicily: *Brachytheciastrum collinum* (Figure 19), *Grimmia torquata* (Figure 20), *Ptychostomum cernuum* (Figure 21-Figure 22), *Rhabdoweisia fugax* (Figure 23), and *Tortula*

bolanderi (Figure 24) in Italian caves. Castello and Strazzaboschi (2013) reported the liverwort *Cololejeunea rossettiana* (Figure 25) from Della Grotta Dell'orso karst cave as new to the Friuli Venezia Giulia region of Italy.

Figure 25. *Cololejeunea rossettiana*, a rare species found in caves in Italy. Photo by George G., through Creative Commons.

In the Azores, Gabriel *et al.* (2006) found 119 bryophyte species in lava tubes and volcanic pits from Graciosa Island. However, there were no endemic plants from the Azores present. On the other hand, six European and four Macaronesian endemic species occurred in the entrances of these cave formations. One of these was a Vulnerable species and three were Rare. These cave entrances are important sites for harboring rare and endemic species.

Singh and Singh (2007) reported new records for Doon Valley, India, citing *Mesoptychia gillmanii* (Figure 15) in or near caves, *Asterella wallichiana* (Figure 26), *Plagiochasma appendiculatum* (Figure 27), *Marchantia paleacea* (Figure 28), and *Riccia cruciata* (see Figure 29) from a cave.

Figure 26. *Asterella wallichiana* on ledge, a species that was collected in or near a cave in India, adding to the known Indian bryophyte flora. Photo by Forest Owlet, through Creative Commons.

Figure 29. *Riccia huebeneriana*; *Riccia cruciata* occurs in or near a cave in India, adding to the known Indian bryophyte flora. Photo by Show Ryu, through Creative Commons.

Puglisi and Privetera (2018) reported *Tortula bolanderi* (Figure 24) at the entrance of a grotto on Mt.

Etna in Sicily, a species that is rare in the Mediterranean area. Ursavaş and Çetin (2014) described the new species *Cinclidotus asumaniae* (see Figure 30) from a cave in southern Turkey, where it was on submerged and emergent rocks.

Figure 30. *Cinclidotus riparius*; *Cinclidotus asumaniae* was described as a new species from a cave in southern Turkey. Photo by Hermann Schachner, through Creative Commons.

In the Azores, Gabriel *et al.* (2006) reported interesting species in the lava tubes and volcanic pits. They were able to find six European and four Macaronesian endemic species in the entrances of these volcanic formations, including one vulnerable species and three rare species. Rare species at these entrances include *Fissidens coacervatus* (Figure 31), *Tetrastichium fontanum* (Figure 32), and *Tetrastichium virens* (Figure 33); the liverwort *Radula wichurae* (Figure 34) is considered vulnerable.

Figure 34. *Radula kojana* branch; *Radula wichurae* is a vulnerable species that occurs at cave entrances. Photo by Kochibi, through Creative Commons.

In the Neotropics of Fernando de Noronha, Brazil, Vital *et al.* (1991) found *Fissidens cf. elegans* (Figure 35) to be common at the entrance of a small cave.

Figure 35. *Fissidens elegans* on rock, a species common at the entrance of a small cave in Brazil. Photo by Wayne Lampa, through Creative Commons.

On Isle Royale, in Lake Superior, Thorpe and Povah (1935) reported *Atrichum tenellum* (Figure 36) from a cave in Rock Harbor, but the misidentification of *Mnium thomsonii* (Figure 37) as *M. orthorrhynchum* in the USA (Crum 1983) means this could be in error, and now *M. orthorrhynchum* is considered a synonym of *Atrichum tenellum*.

Figure 36. *Atrichum tenellum*, a species known from a cave on Isle Royale, Michigan, USA. Photo by Hermann Schachner, through Creative Commons.

Figure 37. *Mnium thomsonii*, possibly the species found in a cave on Isle Royale. Photo by Hermann Schachner, through Creative Commons.

I cite several examples here, but there certainly must be more that were not immediately obvious to me.

Liverworts

Cyathodium cavernarum (Figure 1, Figure 38-Figure 39)

Cyathodium cavernarum (Figure 1, Figure 38-Figure 39) earned its name as a cave liverwort, but it is not restricted to caves. It has been described as **iridescent** (showing luminous colors that seem to change when seen from different angles; Figure 39) (Reeb *et al.* 2018) and **luminous** (Zhang *et al.* 2004b). Zhang *et al.* 2004b) attributed this to a "peculiar light-reflecting power which produces a kind of starry effect, so that the plants seem to flood the dark caves where they grow with a luminous, golden-green light."

Figure 38. *Cyathodium cavernarum* on rock. Photo by Hermann Schachner, through Creative Commons.

Figure 39. *Cyathodium cavernarum* on rock where it is dark enough for its iridescence to show. Photo by Jan-Peter Frahm, with permission.

Cyathodium cavernarum (Figure 1, Figure 38-Figure 39) is frequently found within 1-12 m into the karst caves of Guangxi province, P. R. China, whereas *C. smaragdinum* (Figure 40) occurs within 0.5-22 m (Zhang *et al.* 2004a). The latter species lacks luminescence. Zhang *et al.* (2004b) similarly reported *Cyathodium cavernarum* from karst caves in Yunnan Province, P. R. China, but there it was found at 6~24 m into the cave.

Differences in depth permissible for growth can result from greater light penetration into the cave, influenced by the size of the opening and shading outside the cave.

Figure 40. *Cyathodium smaragdinum* on rock. Photo through Creative Commons.

On Réunion Island, Ah-Peng *et al.* (2010) found *Cyathodium cavernarum* (Figure 1, Figure 38-Figure 39) on the walls of a lava cave. In Birds'-Nest Cave in Sarawak, Holttum (1938) found it with the fern *Tectaria dissecta* (Figure 41) in low light, forming an association at the furthest photosynthetic location from the mouth of the cave.

Figure 41. *Tectaria dissecta* on cave wall, one of the ferns living in low light in caves. Photo by Gildas Gâteblé, through Creative Commons.

Cyathodium cavernarum (Figure 1, Figure 38-Figure 39) is a widely distributed pantropical species (Duckett & Ligrone 2006), primarily of low altitudes (Nair *et al.* 2005). Duckett and Ligrone (2006) expanded its distribution with a find in southern Italy. Surprisingly, Glenny (2002) reported it from Australia. It is found in both urban areas and shaded disturbed areas. For example, Pócs and Arnstein Lye (1999) found it on overhanging, dripping or sprayed rocks as well as on temporarily inundated, muddy riverine forest floors. In Gujarat, India, it is one of the most widely distributed species of liverworts (Shah & Gujar 2016).

Scott *et al.* (1997) described *Cyathodium cavernarum* (Figure 1, Figure 38-Figure 39) from a collection in Australia: "The glistening golden-green plates of this very pretty thallose species, ~c. .5-1 cm across have an almost iridescent lustre accentuated by the darkness of the habitat. It seems to be confined to the floor of a single small cleft in south-facing cliffs of the Napier Range in the Kimberley

region of Western Australia." Glenny (2002) notes that the plants die off in late spring, regrowing from spores at the end of each wet season. This assumes that it is an annual with a very precarious survival in any location. One might expect this strategy to eventually be lost in cave populations that lack the usual seasonal fluctuations.

Mosses

Bartramia ithyphylla (Figure 42-Figure 43)

De Leeuw *et al.* (1998) describe the Antarctic *Bartramia ithyphylla* (Figure 42-Figure 43) from Cuverville Island, Antarctica. It grows in cushions in shallow caves and crevices, sometimes upright and sometimes upside down on the ceiling of the cave. It produced sporophytes in the crevices, but not elsewhere. Could it be that the caves and crevices, in this case, permit them to live in the otherwise hostile environment of Antarctica? Nevertheless, it is not restricted to these habitats elsewhere in the Antarctic region (Bergstrom *et al.* 2002; Matteri & Schiavone 2004). But on the South Sandwich Islands, this species occurs only on the heated soil of geothermal areas (Convey & Lewis Smith 2006).

Figure 43. *Bartramia ithyphylla* leaf cs showing papillae and internal layering of leaf. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

***Cyclodictyon laetevirens* (Figure 44)**

Porley (2013) tells the story of the discovery of the moss *Cyclodictyon laetevirens* (Figure 44) in a Cornish sea cave. This resulted in its eradication by "a well-meaning but seriously misguided vicar keen to stop anyone else finding it." Porley was pleased to report that it was subsequently found in another cave nearby.

Figure 44. *Cyclodictyon laetevirens*, a moss that can live in sea caves. Sean Edwards, with permission.

Cyclodictyon laetevirens (Figure 44) is a rare moss in Britain and Ireland. It tolerates both acid and mildly basic substrata on deeply-shaded wet rocks in ravines, caves, and crevices near waterfalls (Smith 1978; Hill *et al.* 1994). *Cyclodictyon laetevirens* is unable to survive either dehydration or freezing (Burch 2003), perhaps explaining its existence in caves where the conditions are less variable.

***Didymodon glaucus* (Figure 45-Figure 46)**

Porley (2007) reported another threatened bryophyte, *Didymodon glaucus* (Figure 45-Figure 46), from caves in Europe. The species occurs deep in caves, near the entrance or surrounding artificial lights. Such localities are known in Hungary and Germany. In Luxembourg it occurs under rocky overhangs of calcareous sandstone, with similar habitats in Norway. Despite its somewhat wide occurrence in caves and shaded rock overhangs, it must reproduce completely by vegetative means; only female plants are known. Apparently *Didymodon verbanus*, a species with only males known, is actually the male of this species (Kučera 2002; TROPICOS 2021).

Figure 45. *Didymodon glaucus*, a threatened species that succeeds in caves in Europe. Photo by Tomas Hallingbäck, with permission.

Figure 46. *Didymodon glaucus* leaf cells showing strong costa. Photo by Hugues Tinguy, with permission.

Didymodon glaucus (Figure 45-Figure 46) produces protonemal gemmae (Figure 47), both chains and single gemmae from modified axillary rhizoids (Porley 2004). In some locations, protonemal gemmae of *Eucladium verticillatum* (Figure 52-Figure 53) occur mixed with this species in the deep shade of clefts. On the other hand, *D. glaucus* does not tolerate excessive shading and the leafy plant disappears; however, the protonema often persists. *Amblystegium serpens* (Figure 48), when growing intermixed with *D. glaucus* (Figure 45-Figure 46), is able to increase as *D. glaucus* declines. Within 5 years, only a few moribund gemmae-bearing leafy shoots remain. Nevertheless, *D. glaucus* is able to penetrate deep into the cave, where it is able to grow in the light of the artificial cave lights.

Figure 47. *Didymodon glaucus* spores and tuber (protonemal gemmae). Photo by Hugues Tinguy and F. Bick, with permission.

Figure 48. *Amblystegium serpens* on rock ledge, a species that can outcompete *Didymodon glaucus* in low light. Photo by Claire Halpin, with permission.

Didymodon glaucus (Figure 45-Figure 46) is also known from calcareous walls of caves in the French Alps (Skrzypczak 2004) and inside cave entrances in Germany (Frahm 2005). In Sussex it grows in crevices and hollows.

The life strategy (During 1979, 1992) of *Didymodon glaucus* (Figure 45-Figure 46) has been considered a short-lived shuttle colonist by Hodgetts (1996) and a stress-tolerant perennial by Hallingbäck (1998). Despite its lack of spores, it is able to colonize quickly. Porley (2005) observed that it colonized a freshly exposed section of chalk between February 2003 and May 2004 at a location several meters from the nearest location. Dispersal outside of caves can be by rabbits that run along the cliff face ledges. In locations unsuitable for rabbits, it may benefit from snails such as *Trochulus striolatus* (Figure 49) and *Cochlodina laminata* (Figure 50) that have been observed crossing the moss.

***Epipterygium koelzii* (see Figure 51)**

Robinson (1968) found *Epipterygium koelzii* (see Figure 51) in a damp cave in the Himalayas. It remains an endemic there with apparently no further reports outside that area (Hanusch *et al.* 2020).

Figure 51. *Epipterygium tozeri*; *Epipterygium koelzii* occurs in a damp cave in the Himalayas. Photo by Ken-Ichi Ueda, through Creative Commons

***Eucladium verticillatum* (Figure 52-Figure 53)**

As I read the many studies on caves, I got the impression that *Eucladium verticillatum* (Figure 52-Figure 53) was perhaps the most likely bryophyte to find in a cave.

Figure 52. *Eucladium verticillatum*, a limestone species that builds tufa and statoliths in streams and caves, respectively. Photo by Christian Berg, through Creative Commons.

Figure 53. *Eucladium verticillatum*. Photo by Hermann Schachner, through Creative Commons.

Eucladium verticillatum (Figure 52-Figure 53) was found for the first time in Indiana, USA, in a wet, cave-like depression (Miller & Thomson 1959). Shirzadian and Gholami (2001) treated it as the first moss report from the Alisadr Cave in Iran. Aboutabl *et al.* (1999) widened the types of caves with their report of the species on exposed rocks or fragments in protected habitats, including "small" caves and wet crevices. Its growth formed carpets that covered wide areas on the vertical rock of a cave. It became inundated by rainwater and its surface exhibited a dense cover of the *Nostoc* (Cyanobacteria; Figure 54) balls. They found a higher concentration of metals in plants from a wadi-bed than from those in the cave.

Figure 54. *Nostoc commune* on soil with mosses. Photo by Yamamaya, through Creative Commons.

Popkova *et al.* (2019) found that *Eucladium verticillatum* (Figure 52-Figure 53) and several algae and Cyanobacteria (Figure 54) dominate the photosynthetic communities near the entrance and around lights in the Ahshtyrskaya Cave in Russia.

Osada (1958) described the habitats (Figure 55-Figure 63) of *Eucladium verticillatum* (Figure 52-Figure 53). It is

rare, despite being widespread geographically. Gradstein (1972) reported *Eucladium verticillatum* (Figure 52-Figure 53) from the entrance of a cave on the Maltese Islands, growing on moist limestone. It also had non-cave habitats on a moist perpendicular wall below an irrigation gully where it was whitish and lime-encrusted. A similar form is found in the Mediterranean area on constantly moist limestone rocks near springs and rivulets.

Figure 62. *Eucladium verticillatum* with mineral deposits. Photo by Martina Peoltl, through Creative Commons.

Figure 63. *Eucladium verticillatum* with mineral deposits on leaf tips. Photo by Armand Turpel, through Creative Commons.

Wigginton (2001) notes that *Eucladium verticillatum* (Figure 52-Figure 53) growing under an overhang in a deep gully was encrusted with tufa (Figure 61-Figure 63). The leaves were atypical, lacking the recurved, basal marginal teeth (Figure 64) and having sparse papillae, sometimes lacking the papillae entirely (Figure 65).

Figure 64. *Eucladium verticillatum* leaf. Photo by Armand Turpel, through Creative Commons.

Figure 65. *Eucladium verticillatum* leaf margin showing sparse papillae, as one might find in a cave. Photo by Armand Turpel, through Creative Commons

Little is known of the reproduction of *Eucladium verticillatum* (Figure 52-Figure 53). It is **dioicous** and sporophytes seem to be rare in caves, although Dalby (1966a) reported seeing shrivelled archegonia. Instead, it appears that gemmae are the primary means of reproduction. These structures are attached to rhizoid branches among the lowermost leaves.

Dalby (1966a) provided a detailed description of the plants and the cave conditions where they occurred in a cave in Dorset, UK. The plants occurred in a mine cave of a sea cliff, where they occupied the floor, walls, and ceiling, penetrating to 14.6 m from the opening. Their light limit seemed to be at about 100 lux. Prior (1961) reported that growth stopped at about 400-500 lux in Luray Cavern. Mulec and Kubešová (2010), in Slovenian show caves, found that *Eucladium verticillatum* had the widest range of

acceptable light levels (1.4 to 530.0 $\mu\text{mol photons m}^{-2} \text{s}^{-2}$) for photosynthesis.

Dalby (1966a) reported that the plants remained alive in a polyethylene bag in total darkness for two months. It did not become etiolated, but Dalby did not indicate if it grew. Etiolation would require growth. It is possible that such long periods of darkness in the cave could be compensated by periods when the sun is low in the sky and light penetrates farther into the cave. These plants developed wider leaf laminae in poor light. *Eucladium verticillatum* (Figure 52-Figure 53) forms **eucladioliths** (Figure 66) by accretions around several stems. They ultimately leave the eucladiolith hollow. These structures are affected by growth of the moss toward light and downward pull of gravity. They are prone to breaking away from the ceiling, and when that happens, more *Eucladium verticillatum* will often colonize the bare spot.

Figure 66. *Eucladium verticillatum* forming stalactite (eucladiotite; eucladiolith) in mine in Dorset, UK. Photo modified from Dalby 1966b.

Pentecost (1996) further described the formation of eucladioliths. The formation involves deposition of calcium carbonate through photosynthesis, evaporation, and CO_2 escape. Pentecost estimated that 6-12% of the carbonate was deposited through photosynthesis, 10-20% through evaporation, and the remaining 70-80% through gas escape.

Despite its rarity, El-Saadawi *et al.* (1997) were able to assess the variation in the chemical constituents of *Eucladium verticillatum* (Figure 52-Figure 53).

***Eurhynchium hians* (Figure 67-Figure 69)**

Reports on *Eurhynchium hians* (Figure 67-Figure 69) seem to be few. Papp *et al.* (2008) reported that it occurs on limestone rock in a cave in Montenegro. Prior (1961) reported it from the Luray Cavern in Virginia, USA. Achoual *et al.* (2021) found it associated with *Oxyrrhynchium speciosum* (Figure 70-Figure 71) stream under the waterfall of Pigeon Cave in Morocco. Wareham (1941) reported *Eurhynchium hians* from Hocking County, Ohio, USA, where many caves and canyons exist, but he did not mention its habitat there. It is also able to grow around lamps in show caves (Kubešová 2001), where it was frequent in the Moravian Karst of the Czech Republic.

***Homalia webbiana* (see Figure 72-Figure 74)**

In the Azores, Gabriel *et al.* (2006) reported *Homalia webbiana* (see Figure 72-Figure 74) in the lava tubes and volcanic pits. *Homalia webbiana* is endemic to Europe and is known from only 10 localities in the Azorean archipelago. Sjögren (2003) found that it prefers pH above 5.5, permitting it to occur on lava boulders of stone fences and on cement. It can occur in strongly exposed habitats and is highly drought tolerant and is highly dominant on tree trunks, but it also occurs on cement and on coastal lava boulders in stone fences where it is greatly exposed.

Figure 72. *Homalia trichomanoides*; *Homalia webbiana* occurs in lava tubes and volcanic pits in the Azores. Photo by Janice Glime.

Figure 73. *Homalia trichomanoides*. Photo by Andrew Spink, with permission.

Figure 74. *Homalia trichomanoides*, on a canyon wall, Jacob's Creek, Keweenaw Co., Michigan, USA. Photo by Janice Glime.

There have been numerous taxonomic and systematic publications on *Homalia webbiana*, but ecological information is not very frequent. In part because of the confusion in the identity of the species, Ros *et al.* (2013) consider *Homalia webbiana* (see Figure 72-Figure 74) to be restricted to Macaronesia.

Mittenia plumula (Figure 75-Figure 77)

Mittenia plumula (Figure 75-Figure 77) has lots of similarities to *Schistostega pennata* (Figure 75-Figure 77), including persistent, highly refractive protonemata, protonemal gemmae, and pennate leaves (Stone 1961a, b, 1986; Frahm 2012). It also seems to prefer similar habitats. Stone (1961a) describes the protonema (Figure 78-Figure 79) as highly refractive and lenticular.

Figure 79. *Mittenia plumula* protonema from New Zealand. Photo courtesy of David Glenn.

Figure 82. *Mittenia plumula* growing on soil at wombat hole entrance, Mt. Wilson, NSW, Australia. Photo by Janice Glime.

Fife (1984) reported *Mittenia plumula* (Figure 75-Figure 77) from New Zealand. Its habitats include silt soil beneath a sandstone overhang in a roadcut, clay soil in a crevice beneath roots, and mesic humus beneath a granite boulder. It seems to prefer soil (Figure 83) to rock and occurs mostly in small cavities. Similarly, Beever and Brownsey (1993) found it under soil overhangs in New Zealand. But its habitats there also include rock walls of caves (Figure 84).

***Schistostega pennata* (Figure 85-Figure 118)**

I first saw *Schistostega pennata* (Figure 85-Figure 118) on a field trip in New York, USA. It was in a small cave in a bank (Figure 87) where one had to look carefully to avoid shading it completely. It has earned its names of cave moss, goblin gold, or Dragon's gold (Berqvist 1991). In a cave in Alger County, Michigan (Figure 88-Figure 90), *Schistostega pennata* occurs on the ceiling of the cave, visible in the dim light due to its unique way of rotating its protonemal chloroplasts (Figure 91-Figure 102) to reflect (and absorb) maximum light intensity (Crum 1983). Conard (1938) refers to its presence in a tiny cave near Au Train, perhaps referring to the same location as that of Crum. He noted that *Schistostega pennata* "disappears" when you block the light so that it is unable to reflect (as in Figure 87).

In Japan, there is a national monument (Figure 103-Figure 104) to the cave where *Schistostega pennata* (Figure 85-Figure 118) grows (Glime & Iwatsuki 1987). It inspired an opera that told the lore of a group of stranded sailors who spent the winter in the cave. They had no source of food and no way to travel in the dead of winter, so they resorted to cannibalism. When the last two men remained, one of these sailors was saved from death because his would-be killer saw the glow of the moss behind the poor sailor's head and changed his mind about murdering his companion for food. Kanda (1988) reviewed the status of the colony in the cave.

Figure 103. *Schistostega pennata* Monument in Japan. Photo by Janice Glime.

Figure 104. *Schistostega pennata* monument, Japan, with view into cave where the moss grows. Photo by Janice Glime.

Schistostega pennata (Figure 85-Figure 118) grows in a variety of low-light habitats (Figure 105-Figure 110). I have seen *Schistostega pennata* in Germany at the base of a boulder on soil that was protected by the overhang of the boulder. The most prolific growth I have seen was on the roof of a cave behind a waterfall in the Upper Peninsula of Michigan, USA (Figure 88). In Iraq, Aziz (2011) reported it from a Shanadar cave (also spelled Shanidar; Figure 111), noting its rarity in Iraq.

Figure 111. Shanadar cave, Iraqi Kurdistan, a cave where one can find *Schistostega pennata*, a rare species in Iraq. Photo by Osama Shukir Muhammed Amin, through Creative Commons.

Kanda (1971) described cave localities for *Schistostega pennata* (Figure 85-Figure 118) in Hokkaido, Japan. Its substrate rocks included granite, andesite, and the base of a fallen tree. The mean pH of its substrates was 4.7, but it was found once at 6.8. Matsuda (1963) noted that it also occurs in artificial caves.

Reinoso Franco *et al.* (1994) reported on its ecology in the Iberian Peninsula. The cave was very humid, only 50 m above the sea, and the substrate had a pH of 5.7. Werner (2011) reported it as occurring in caves in Luxembourg.

Schistostega pennata (Figure 85-Figure 118) is listed as rare in Latvia, with only 21 published records from 1924 until 2010 (Mežaka *et al.* 2011). Of these, 18 records were from protected areas. Its most common habitat there is on *Picea abies* (Figure 112) root mass rather than on sandstone. This demonstrates that even small "caves" such as those created by roots provide suitable habitat. It also occurs in the minicaves made by roots in calcareous areas (Crum 1983).

Figure 112. *Picea abies* that can form a habitat for *Schistostega pennata* among exposed roots. Photo from European Environment Agency, through Creative Commons.

Schistostega pennata (Figure 85-Figure 118) has sticky spores (Figure 113-Figure 116) much like those of the *Splachnaceae* (Ignatov & Ignatova 2001). This suggests that it may be dispersed by animals, perhaps insects. Its rapid expansion upon arrival at a new location in Russia supports this, and Ignatov and Ignatova suggest it could be dispersed by birds, mammals, insects, or spiders.

Figure 113. *Schistostega pennata* leafy plants with sporophytes. Photo courtesy of Martine Lapointe.

Figure 115. *Schistostega pennata* capsule with sticky spores. Photo by Misha Ignatov.

Figure 116. *Schistostega pennata* SEM of spore surface. Photo by Misha Ignatov.

Edwards (1978) described protonemal gemmae (Figure 117-Figure 118) from a British *Schistostega pennata* (Figure 85-Figure 118). In particular, he noted the similarity to those of *Mittenia plumula* (Figure 75-Figure 77). This is a common means of propagation in cave bryophytes.

Figure 117. *Schistostega pennata* protonemata with gemmae branches. Photo courtesy of Misha Ignatov.

Takakia lepidozoides (Figure 119-Figure 122)

Takakia (Figure 119-Figure 122) has been reported from distant places around the world. It is so unusual that for a long time bryologists were unable to put it into a phylum with certainty. Phycologists wouldn't claim it as an alga. In the absence of sporangia or antheridia, it was originally classified as a liverwort, but Mizutani (1967) considered the stalked archegonia to be a moss character. Finally, sporophytes were found in *Takakia ceratophylloides* (Figure 123) and it has capsules with spiral sutures that split much like those of *Andreaebryum* (Figure 124). It is now classified as a moss (Murray 1988; Smith & Davison 1993).

Figure 119. *Takakia lepidozoides*, a species sometimes found in caves or cave-like situations. Photo by Quentin Cronk, through Creative Commons.

Figure 123. *Takakia ceratophylla* with dehiscent capsules. Photo by Karen Renzaglia, with permission.

Figure 124. *Andreaebryum macrosporum* with capsules. Photo by Botany Website, UBC, with permission.

In the Kinabalu National Park, Sabah, Malaysia, Akiyama *et al.* (2001) found *Takakia lepidozoides* (Figure 119-Figure 122) at Paca Cave. Unfortunately, it is unclear if it is inside or near the cave. Caves are certainly not its typical habitat. Persson (1958) found it on soil partly covering non-calcareous rocks. Higuchi and Lin (2005) reported it from Taiwan. Other records from the Himalayas likewise are in cool locations, but not caves. It seems to prefer places that are constantly moist.

***Tetrodontium brownianum* (Figure 125-Figure 130)**

In Michigan, USA, *Tetrodontium brownianum* (Figure 125-Figure 130) occurs under over-hanging ledges of calcareous sandstone near Munising (Steere 1942). These ledges are associated with waterfalls. Sporophytes were present only on plants attached to the ceiling of an open cave, but not on plants adhering to vertical rock walls.

A number of the rare bryophytes that are known from caves seem to have unusual protonemata. *Tetrodontium brownianum* (Figure 125-Figure 130) instead has a rather unusual stem (Hodgetts 1915). It is nearly stemless with the vegetative part consisting of a tuft of narrowly clavate frondiform leaves (Figure 125). These may even be somewhat palmately branched at the apex where the capsule (Figure 126) is produced.

Figure 125. *Tetrodontium brownianum* plant showing the short stem and branching. Photo by Hugues Tinguy, with permission.

Figure 126. *Tetrodontium brownianum* with capsules. Photo by Andy Hodgson, with permission.

Figure 127. *Tetrodontium brownianum* with capsules. Photo by Hugues Tinguy, with permission.

Slack and Horton (2010) explored the bryophytes of the Bering Glacier Region. There one can find small caves formed by the rocks of the tundra. They found the rare *Tetrodontium brownianum* (Figure 125-Figure 130) in such a small cave there. Other records indicate that it lives on the underside of overhanging rock. Müller (2004) found it inverted on a sandstone overhang in Saxony. Grout (1899) reported it from stones in Devil's Den in New Hampshire, USA, where it grew upright on moist stones near the top of the cave.

Figure 128. *Tetrodontium brownianum* upside down on boulder, showing setae and capsules. Photo by Stefan Gey, through Creative Commons.

Figure 129. *Tetrodontium brownianum* upside down on boulder. Photo by Stefan Gey, through Creative Commons.

Gauthier (2011) described the genus *Tetradontium* from Québec, Canada, to grow exclusively in the shade on both acidic and limestone rocks. It occurs suspended from the ceiling of rock shelters (caves?), in rock wall crevices (Figure 130), and even at the bottom of caves in constant high humidity but not oozing rocks. Williams (1968) reported it as new to Ontario, Canada, occurring in moist crevices of shaded granite cliffs.

Figure 130. *Tetrodontium brownianum* habitat in rock wall crevices. Photo by Stefan Gey, through Creative Commons.

Pentecost and Rose (1985) reported *Tetrodontium brownianum* (Figure 125-Figure 130) as common under rock overhangs at the Wealden sandrocks in the UK. Pursell (2006) found it in a similar Saxon habitat on the underside of a sandstone overhang.

In North America, Lawton and Ireland (1963) reported it from under a rock ledge in Washington state. Taylor (1967) found it British Columbia on a boulder face in the forest, presumably receiving enough shade from the forest. Snider and He (1992) referred to *Tetrodontium brownianum* (Figure 125-Figure 130) as a rare cave moss in Ohio, USA.

***Timmia norvegica*/*Timmia sibirica* (Figure 131-Figure 132)**

Vitt and Horton (1979) found what they considered might be *Timmia norvegica* (Figure 131-Figure 132) on rock in the spray zone in a small limestone cave in Banff National Park in Alberta, Canada. Although the species is somewhat common in more northern locations, it is critically imperiled in Alberta and represented a new record for the province at the time. The authors suggested that it

might actually be a previously undescribed species. However, later investigations caused Horton (1981) to place it in *T. sibirica*, a species that is also critically endangered in Alberta, having a predominantly High Arctic distribution. The typical habitat of *T. sibirica* is on strongly calcareous substrates adjacent to waterfalls, along streams, or in low-lying tundra (Horton 1981). Based on nuclear and chloroplast sequence data, Budke and Goffinet (2006) considered this to be a morphotype of *T. norvegica* with the presence of multipapillose cells in *T. sibirica* being a homoplastic trait. Hedenäs (2011) further evaluated the *norvegica* group and concluded, based on the 26S differences and morphological evidence, that *T. sibirica* is a valid separate species.

Figure 131. *Timmia norvegica*, a species that sometimes grows in small caves in limestone areas. Photo by Hermann Schachner, through Creative Commons.

Figure 132. *Timmia norvegica*, a species that sometimes grows in small caves in limestone areas. Photo by Hermann Schachner, through Creative Commons.

Timmia sibirica is a relatively rare species, occurring mostly on wet or moist calcareous sites (FNA 2021). It is often near small streams or on seepage slopes, near snowmelt areas, or in open tundra depressions. Its distribution is throughout the Arctic tundra, but at low elevations. Fedosov *et al.* (2018) reported *T. sibirica* on a gentle foothill slope and moist hollow on gravelly ground on the Russian Arctic Severny Island, demonstrating its lack of necessity for a cave-like environment.

Brassard (1979) noted the rarity of sporophytes in the genus *Timmia*, with only three populations known with sporophytes for *T. norvegica* (Figure 131-Figure 132) and only immature spores known from *T. sibirica*.

Bryophyte Adaptations

Zhang *et al.* (1996a, b) reported that of eight bryophyte life forms found in the karst caves of Huangguoshu, Guizhou, China, the predominate forms were **mats**, **short turfs**, **tall turfs**, and **wefts**. In the karst caves in England, Zhang and Pentecost (2002) found **fans** (4.08%), **mats** (4.08%), **short turfs** (20%), **tall turfs** (9.22%), and **wefts** (61.5%)

The pH seems to matter. Mason-Williams and Benson-Evans (1958) found that there is a richer bryophyte flora on limestone than on acid rocks. In water, high pH prevents most bryophytes from getting enough CO₂ for photosynthesis. So what is the value of the high pH to bryophytes in many caves?

Many of the cave bryophytes grow on the ceiling of the cave. This means adherence is important, particularly where the ceiling is dripping. Hughes (1982) found that the rhizoids of *Tortula muralis* (Figure 133) become well cemented in the oolitic limestone. We might expect similar attachment in cave bryophytes.

Figure 133. *Tortula muralis* on rock, a species that produces protonemal gemmae in caves. Photo by Bjorn S., through Creative Commons.

Rajczyk (1978; 1978-1979) found that *Atrichum undulatum* (Figure 134) could live more than two years in cave conditions. The humidity ranged 95-100%.

Responses to Low Light

Puglisi *et al.* (2018) demonstrated a relationship between lighting conditions and bryophyte life form in Sicilian caves. Davison *et al.* (1995) reported "interesting" morphotypes in two liverworts from Cave Spring, Mississippi, USA.

Marschall and Proctor (2004) reported that bryophytes, especially liverworts, typically grow in light conditions at <10% relative illumination. But in a single limestone cave, Pentecost and Zhang (2001) reported that 14 species of mosses and liverworts grew at light levels below 0.5% relative illumination. *Fissidens dubius* and *Thamnobryum alopecurum* occurred at levels as low as 0.2% relative illumination. For the cave moss *Schistostegia pennata*, survival at even lower levels (0.005-0.2% relative illumination) is possible (Toda 1918).

Lang (1905) described the morphology of *Cyathodium* (Figure 1, Figure 38-Figure 39). It has retained the layer of air chambers with pores (Figure 135), but the basal portion of the thallus is mostly only a single layer of cells. It lacks assimilation filaments in the air chambers and instead assimilation occurs in the epidermis (Figure 135). This could be a photosynthetic advantage by reducing light blockage by the plant itself.

Figure 135. *Cyathodium cavarnarum* thallus pore and photosynthetic epidermis. Photo courtesy of Noris Salazar Allen.

Dunham and Lowe (1927) described the unusual growth of bryophytes in such habitats as caves. He discovered early in his career that bryophytes, like tracheophytes, "reach out" to the light, at times exceeding their normal height in low light conditions. He describes the leaves of *Leptobryum pyriforme* (Figure 136) from a specimen that had grown in the basement of an old iron foundry – the stems were 5 cm long compared to 1 cm in the light. A similar elongated growth occurred in *Ceratodon purpureus* (Figure 137) from the dark pocket of a ledge. I have experienced the same etiolated appearance of mosses growing in my terrarium, making the habitus unrecognizable.

Figure 137. *Ceratodon purpureus* with capsules, a species that responds to low light by stem elongation. Photo by Štěpán Koval, with permission.

Etiolation is a common response of mosses to low light (Mulec 2018). Dalby (1966b) reported that *Pohlia nutans* (Figure 138) becomes etiolated when buried under leaves. In a cave, *Eurhynchium* sp. (see Figure 67-Figure 69) has elongated branches with small, widely spaced leaves. I have found that mosses in plastic bags continue to grow in the lower light of the lab, becoming very etiolated.

Figure 138. *Pohlia nutans* with capsules, on rock, a species that elongates when buried by leaves. Photo by J. C. Schou, with permission.

In caves of South Wales, Mason-Williams and Benson-Evans (1967) found that dominant bryophyte growth forms changed with light intensity. As the light decreased, **dendroids** and **smooth mats** decreased in abundance, whereas **rough** or **thalloid mats** and **wefts** increased.

Dalby (1966b) reported on various responses to reduced light in caves. In *Rhizomnium punctatum* (Figure 139) and *Cyrtomnium* (Figure 140), the leaves grew perpendicular to the light, which in a cave comes from a low position that would normally strike the side of any plant growing away from gravity. In *Eurhynchium hians* (Figure 67-Figure 69), it is the flattened branches that grow perpendicular to light. *Eucladium verticillatum* (Figure 52-Figure 53) leaves become broader in shade (Figure 141) and Dalby noted that this response is uncommon in mosses. The liverwort *Conocephalum conicum* (Figure 142-Figure 143), on the other hand, is smaller in the shade; even the areolae are 1/3 as wide. By contrast, *Eucladium verticillatum* growing near a lamp died when the lamp was replaced with a brighter bulb. I have seen the same thing happen to house plants that are placed outside when the weather gets warm. But in this case, Dalby considered the heat and resulting desiccation to be the cause of the *E. verticillatum* death.

Richards (1932) found that *Isopterygiopsis muellerianum* (Figure 144) in complete darkness in a cave had numerous small chloroplasts. Richards assumed it was growing saprophytically, but it is also possible that in some seasons, probably winter, it received enough light to grow. At other times it could be dormant. Even protonemata can remain dormant for an inordinate period of time. Bristol (1916) found that protonemata that had remained sealed for 50 years began to grow when given water and light, demonstrating the incredible dormancy capability of some bryophytes.

Uniyal *et al.* (2007) noted that bryophytes are able to acclimate to low light. Watkins (2002) examined the adaptations of *Megaceros pellucidus* (Figure 145) to extremely low light conditions. The light conditions of $0.5\text{--}7\ \mu\text{mol photons m}^{-2}\ \text{s}^{-1}$ where it grows in the wet, cool temperate rainforest are similar. Unlike cave bryophytes, this species has the opportunity to use the burst of light in sunflecks. But its ability to use reflected light from water (or rocks in caves) could be similar to opportunities for cave bryophytes. The chloroplast position of this hornwort in its rainforest habitat is an expanded form that is situated on the periclinal cell wall closest to the light source. Thallus sections revealed that when the thallus is irradiated with blue light of more than $3\ \mu\text{mol photons m}^{-2}\ \text{s}^{-1}$ the

chloroplasts shrank "dramatically" and moved to a position on anticlinal walls. Red (662 nm) light of $<130 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ or darkness did not elicit any response in the chloroplast position except in those cells that had been exposed to blue light. In the latter case, the chloroplast expanded and resumed the position closest to the light source. Specimens were obtained from the Apiti Glow Worm Caves where sunlight is reflected off the river surface, reaching considerable distance into the cave. As seen in Figure 146, the light penetration changes as the sun arches across the sky during the day.

Gabriel and Bates (2003) studied the photosynthetic responses of bryophytes and the effects of light intensity on these responses of bryophytes from the Azores. They found photosynthetic saturation at $30 \mu\text{mol m}^{-2} \text{s}^{-1}$. The lowest rate was in *Andoa berthelotiana* (Figure 147) ($20 \mu\text{mol m}^{-2} \text{s}^{-1}$) and the highest in *Myurium hochstetteri* (Figure 148) ($68 \mu\text{mol m}^{-2} \text{s}^{-1}$). The dark respiration rate is critical for tolerating shade; it was highest in the species with the highest P_{max} . The extremely low light compensation point of $7 \mu\text{mol photons m}^{-2} \text{s}^{-1}$ in *Fissidens serrulatus* (Figure 149) is adaptive in its deep shade and cave habitats. *Myurium hochstetteri*, on the other hand, is restricted to habitats with good illumination; it has the highest light compensation point.

One adaptation that may be helpful to cave bryophytes is the ability to synthesize chlorophyll in the dark. The data on this topic is scant indeed, and it seems to be

assumed to be a bryophyte character even though it appears that it has only been demonstrated in *Marchantia* (Figure 150-Figure 151) (Takio *et al.* 1988; Ueda *et al.* 2014). Takio and coworkers demonstrated that cultured cells of *Marchantia paleacea* subsp. *diptera* (Figure 150) had a doubling time of 1.2 days when grown in the light and 1.5 days when grown in the dark. Chlorophyll concentrations were high ($6-15 \mu\text{g mg}^{-1}$ dry weight) in both types of cultures. But this is not conclusive evidence that whole plants growing deep in caves are able to sustain such ability. The cultures were maintained at least 16 days before these measurements, but they had glucose in the medium, so we need evidence that the glucose did not provide the energy needed for the dark production of chlorophyll.

Figure 150. *Marchantia paleacea* subsp. *diptera* females with capsules, a subspecies whose cultured cells produce chlorophyll in the dark. Photo by Janice Glimme.

Another study on *Marchantia polymorpha* (Figure 151) indicates that it has the genes for light-independent Pchl_{ide} reductase (Ueda *et al.* 2014). But in flowering plants, these genes (for DPOR) that occur in the chloroplast seem to be lost. This means that *M. polymorpha* has the enzyme needed to produce chlorophyll in the dark.

Figure 151. *Marchantia polymorpha* gemmae cups, growing among rocks. This species has genes for producing chlorophyll in the dark. Photo by Rudolf Macek, with permission.

But what about other bryophytes? Ueda and coworkers noted that we do not understand why the DPOR genes have been lost from the chloroplast in some land plants, while persisting in others. Nor do we understand what environmental factors might have played a role in this loss in some and not in others. I cannot accept one record of these genes in a single liverwort as proof of their general presence in bryophytes. Nevertheless, their presence in *Marchantia polymorpha* (Figure 151), and their implied presence in *Marchantia paleacea* var. *diptera* (Figure 150), suggest that at least some cave bryophytes might be able to produce chlorophyll in the dark. This would make living in the limited light of caves, and particularly near the artificial lighting, an opportunity to take advantage of these genes for DPOR.

Jack Brunkard (Bryonet 17 August 2021) explained the two enzymes (LPOR and DPOR) that can catalyze the same reaction of reducing protochlorophyllide to chlorophyllide *a* (the immediate precursor of chlorophyll). LPOR is light dependent and DPOR is not. DPOR is strongly and irreversibly inhibited by oxygen. Brunkard suggested that many bryophytes that live in low light and moist environments that become hypoxic could gain an advantage from having DPOR in these environments. On the other hand, for plants that live in well-oxygenated habitats, DPOR would be inhibited by the oxygen. Furthermore, red light is most effective in production of LPOR, but many bryophytes live in forests that transmit predominantly green light through the canopy. This means that bryophytes with DPOR (that does not need red light) would have an advantage in these conditions. In some caves green light transmission predominates through the surrounding canopy and into the cave. But for the lampenflora, in most cases the light source emits predominantly red waves. Clearly we need further studies on the presence of DPOR throughout bryophytes and how it relates to their habitats.

Reproduction

Komáromy *et al.* (1985) found that the mosses occupying lamp-lit areas in the Anna-Barlang cave of Hungary were mostly **colonists** and **perennials**, each represented by five species. Colonists were the most frequent, most likely as a function of good dispersal ability. The cave bryophytes must be able to establish quickly or remain for a long time. Mason-Williams and Benson-Evans (1967) reported that spores were common and widespread in caves in South Wales, were commonly found around the threshold areas, and were widespread in soil samples throughout the caves. Nevertheless, protonemal gemmae seem to be important in the reproduction of cave mosses. Whitehouse (1980) found these on *Didymodon luridus* (Figure 47, Figure 152), *Gyroweisia tenuis* (Figure 153-Figure 154), *Eucladium verticillatum* (Figure 52-Figure 53), and *Schistostega pennata* (Figure 85-Figure 118). He considered them to be an adaptation for survival and propagation at low light intensities.

Figure 154. *Gyroweisia tenuis*. Photo by Tomas Hallingbäck, with permission.

Allen and Korpelainen (2006) found *Cyathodium* (Figure 1, Figure 38-Figure 39) species to be **r-selected** (have high reproductive capacity). The **dioicous** species

that produce abundant sporophytes also produce tubers. As already noted, *Cyathodium cavernarum* (Figure 1, Figure 38-Figure 39) dies off in late spring and regrows from spores at the end of the wet season (Glenny 2002).

Summary

Caves are among those environments that often have rare, relict, or even unique species. Some of these are specialized cave or low light species, not to be found outside such habitats. Others are widespread species with a broad ecological range.

Cyclodictyon cavernarum is the only liverwort that is primarily a cave dweller, exhibiting a "luminescence" similar to that seen in *Schistostega pennata*. A number of mosses are either rare or occur predominantly in low light.

Rhizoids are important for "cementing" bryophytes to the cave ceilings. pH can be important in creating a favorable CO₂ environment.

Thallose liverworts such as *Cyathodium* compensate for low light by reducing plant interference, in this case by having photosynthesis in the epidermis. **Etiolation** is common in mosses in low light. Dominant growth forms change from **dendroids** and **smooth mats** to **rough** or **thalloid mats** and **wefts** as light decreases. Growth tends to form perpendicular to light. Chloroplasts can be more numerous in low light. *Marchantia* can synthesize chlorophyll in the dark, but this has not been explored in other taxa; DPOR may facilitate this when oxygen levels are low, *i.e.*, light is too low for photosynthesis. Both protonemata and gametophores can remain dormant for long periods of time.

Colonists and **perennials** seem to be most successful. Spores can be common throughout the caves, but protonemal gemmae are more common than in species assemblages in most other habitats. The **r-selected** species may have an advantage, but this needs to be explored for cave species.

Acknowledgments

Many Bryonettors responded to my call for images for this chapter. Wolfgang Hofbauer provided me with a paper that gave me a good list of current references on wind holes. Thank you to our Chinese colleagues (Wen Ye, Xinlei Guo, Yang Liu, Xiaoming Shao, and Wang Zhe) who responded to my request for the English translation of the abstract of a Chinese study. Thank you to Jake Brunkard and Benjamin Gutman for helping me to understand the state of knowledge of dark production of chlorophyll in bryophytes.

CHAPTER 18-5

CAVES – CAVERNS

Figure 1. Luray Cavern, Virginia, USA – a popular tourist cavern shown here illuminated with electric lights. Alejocrux, through public domain.

Caverns

Caverns are both natural and artificial. They are made by natural processes, but those places we typically call caverns are extensive networks of tunnels with interesting rock formations that attract the attention of tourists. To this end, enterprising companies installed lights that extend the distance into the cavern where the bryophytes, algae, and ferns are able to live.

Prior (1961) described the mosses in the well-known Luray Caverns, Virginia, USA (Figure 1). He found *Amblystegium serpens* (Figure 2) forming a loose mat with sporophytes in only one location on wet limestone.

Amblystegium serpens is also common in European caves (e.g. Mulec & Kubešová 2010), but it is widespread and common outside caves, frequently presenting sporophytes. *Anomodon rostratus* (Figure 3) likewise occurred on moist limestone, along with *Leptobryum pyriforme* (Figure 4), but also occurred on silt of the cavern (Prior 1961). *Bryum pseudotriquetrum* (Figure 5) formed fairly "dense mats" on moist limestone, along with *Leptobryum pyriforme*. *Campylium hispidulum* (Figure 6), sometimes with capsules, was scattered among 8 locations on moist limestone, either alone or with *Leptobryum pyriforme* and/or *Eurhynchium hians* (Figure 7). The latter species was abundant, occurring at 19 of the 33 study plots, either

in pure stands or mixed with other bryophytes. Only 3 populations of this species had sporophytes, but these were abundant. *Tortula obtusifolia* (Figure 8-Figure 9) formed a large, dense mat on wet limestone with just 2 sporophytes. *Fissidens bryoides* (Figure 10-Figure 11), a tiny rock-dwelling species, occurred only once, near the entrance. *Funaria hygrometrica* (Figure 12-Figure 13), a widespread species typically in exposed locations, occurred only once, with abundant sporophytes, contrasting sharply with *Leptobryum pyriforme*, a species lacking sporophytes in the cavern despite being present at 18 locations. *Leskea polycarpa* (Figure 14) occurred only once, on wet limestone at the edge of an underground lake.

Figure 14. *Leskea polycarpa*, a species that occurred at the edge of an underground lake in the Luray Caverns. Photo by Hugues Tinguy, with permission.

Contrasting to the Northern Hemisphere Luray Caverns, de Lange and Stockley (1987) found only one of the same genera in the Lost World Cavern at Waitomo, New Zealand, where the light levels are low and the humidity is high. Documented species there include the liverworts *Lobatiriccardia alterniloba* (Figure 15), *Heteroscyphus triacanthus* (Figure 16), *Frullania nicholsonii* (Figure 17-Figure 18), *Monoclea forsteri* (Figure 19-Figure 20), *Radula buccinifera* (Figure 21-Figure 22), and *Symphyogyna tenuinervis* (Figure 23), and mosses *Achrophyllum dentatum* (Figure 24), *Beeveria distichophylloides* (Figure 25), *Camptochaete arbuscula* (Figure 26-Figure 27), *Cyathophorum bulbosum* (Figure 28), *Distichophyllum microcarpon* (see Figure 29), *Echinodium hispidum* (Figure 30), *Fissidens leptocladus* (Figure 31), *Gymnostomum calcareum* (Figure 32-Figure 33), *Hypnodendron arcuatum* (Figure 34-Figure 35) (Smart 1978), *Hypopterygium filiculaeforme* (Figure 36), *Leucobryum candidum* (Figure 37) (Smart 1978), *Lopidium concinnum* (Figure 38) (Smart 1978), *Papillaria crocea* (Figure 39-Figure 40), *Pseudotaxiphyllum falcifolium* (Figure 41), *Racopilum convolutaceum* (Figure 42), *Thamnobryum pandum* (Figure 43), *Thuidium laeviusculum* (Figure 44-Figure 45) (Smart 1978), and *Weymouthia mollis* (Figure 46), with *Achrophyllum dentatum*, *Echinodium hispidum*, and *Thamnobryum pandum* being the most important and common around the cave entrance. These species also occur in the low-light flora near the cave.

Visitors increase the exposure of the caverns to fluctuating temperatures, moisture fluctuations, drafts, propagules, light, exhaled CO₂, trampling, and other factors

that alter the ability of bryophytes to reach and succeed in the interior of the caverns. Rakovec (2020) modelled the effect of visitor number and cave size on visitor impact. He found that the direct human sources of heat and CO₂ cause linear responses. But the exchange between the walls and the exterior have exponential consequences dependent on time. Thus, visitors have both direct and indirect effects on the flora in the display caverns.

Cave Lamp Communities (Lampenflora)

The flora associated with lights in caverns (**lampenflora**) has fascinated many researchers (e.g. Lundegårdh 1931; Maheu & Guérin 1935; Shiomi 1973; Rajczy 1979, 1989; Rajczy *et al.* 1985; Padiśák *et al.* 1985; Végh 1985; Rajczy *et al.* 1986; Rajczy & Buczkó 1989; Olson 2002; Zhang & Wang 2002; Mazina & Maximov 2011; Cigna 2012; Mazina 2016a, b). Mulec (2012) noted that permanent electric lights are used in show caves to highlight cave formations for visitors. But these also create new ecological conditions that permit the colonization by lampenflora. Although the community is relatively complex, it is also limited in diversity, comprised usually of **Cyanobacteria** outermost from the light, to algae, bryophytes, and ferns (closest to the light) (Boros 1964; Castello 2014; D'Agostino *et al.* 2015; Mazina 2015; Kurniawan *et al.* 2018; Mulec 2018; Kozlova & Mazina 2020; Pfendler *et al.* 2021). Flowering plants are usually unable to live in these sites, although Mazina (2015) found two species of flowering plants near lamps in the Nomoafonskaya Cave, Abkhazia, in the South Caucasus.

Naturally illuminated caves provide sufficient light at the entrance and a short distance into the twilight zone (Figure 47) for some bryophytes to reach extensive development (Mulec 2018). Beyond that, in the dark zone, plants, including bryophytes, are only able to live near artificial lighting. Mazina (2016a) noted that the bryophyte diversity is higher in caves with artificial lighting. Popkova *et al.* (2019) noted that the lampenflora tends to be similar to that of the entrance zone. Thatcher (1949) found that the lampenflora extended 8-61 cm from the lamps, with light intensities ranging 250-800 lux. Verdoorn (1932) offers the opinion that the very dim light conditions may be offset by the higher carbon dioxide content of the limestone.

In New York, USA, Haring (1930) described the flora of the Howe Caverns. The lights were turned on and the caverns opened to the public in 1929. Within 2.5 months plant life began to appear. After 8 months, she identified 7 species of bryophytes from the two clumps given to her, although nearly 50 lights had bryophyte colonies. She listed the liverwort *Marchantia polymorpha* (Figure 48) and the mosses *Amblystegium serpens* (Figure 2), *Amphidium mougeotii* (Figure 49-Figure 50), *Brachythecium rutabulum* (Figure 51), *Bryoerythrophyllum recurvirostrum* (Figure 52), *Bryum caespiticium* (Figure 53-Figure 54), *Leptobryum pyriforme* (Figure 4), and *Rosulabryum capillare* (Figure 55).

Kozlova and Mazina (2020) concluded that macrogroups dominated by bryophytes had well-defined boundaries, whereas the microgroups dominated by green algae were often located between these macrogroups, thus forming distinct but small communities and transitions.

Succession

Algae and *Cyanobacteria* typically are the first of the lampenflora to arrive (Hajdu 1977; Mulec & Kosi 2009; Cigna 2012). Following that are the bryophytes, ferns, and less frequently, seed plants. But Hajdu (1977) contends that the mosses will eventually outgrow and suppress the algae (presumably including the *Cyanobacteria*).

Hazslinsky (2002) noted that the lampenflora can spread "rather quickly." In Baradla Cave, Hungary, it doubled in seven years. Thomas (1897) reported that *Rhynchostegiella tenella* var. *cavernarum* (Figure 56) appeared around cave lights in about one year after their installation. The species *Rhynchostegiella tenella* has been found in underground rooms of the Roman Coliseum, suggesting that it is also a long-time stayer. Pfendler *et al.* (2021) conducted a quantitative study on bryophyte colonization on illuminated limestone blocks in caves. Some of the blocks similarly had dense colonization within a year.

Figure 56. *Rhynchostegiella tenella*, a species that has appeared around cave lights within a year of their installation. Photo by Michael Lüth, with permission.

Popkova *et al.* (2019) found that the greatest similarity between the lampenflora and the entrance occurred under the greatest light intensity, supporting the role of light in determining the community structure. *Eucladium verticillatum* (Figure 57-Figure 58) was the predominant bryophyte in these photic zones, accompanied by the *Cyanobacteria Microcystis pulverea* (Figure 59) and *Scytonema drilosiphon* (see Figure 60) and the airborne and widespread green alga *Chlorella vulgaris* (Figure 61).

Species Numbers

As an example of the distribution among photosynthetic groups near lamps, in addition to 2 flowering plants, Mazina (2015) found 34 species of **Cyanobacteria**, 5 **Chlorophyta**, 2 **Ochrophyta** (planktonic and benthic algae), 9 **Bacillariophyta** (diatoms), 22 **Bryophyta**, and 6 **Polypodiophyta** (ferns etc.) in Vorontsovskaya Cave, Russia. Komáromy *et al.* (1985) found 42 alga taxa (including **Cyanobacteria**), 10 moss taxa, and 1 fern taxon in the lamp-lit areas of the cave Anna-Barlang near Lillafüred, Hungary. In Italy, Castello (2012, 2014) found 16 moss species and 2 ferns (algae were not assessed) in the lampenflora. Castello found that some of the mosses were typical of cave entrances in the Italian Karst, but others were typical of disturbed and open habitats. Lundegårdh (1931) described the zonation as ferns nearest to the lamp, mosses farther away, and algae at the farthest locations from the light.

Mazina and Maximov (2011) reported 14 **Cyanobacteria**, 4 **Chlorophyta**, 4 **Bacillariophyta**, 11 **Bryophyta**, and 5 **Polypodiophyta** among the lampenflora of an excursion cave in Russia. The ferns were juveniles and the only moss with sporophytes was *Isopterygiopsis pulchella* (Figure 62). Moss protonemata (Figure 63) were subdominants on the limestone and argillaceous veneers (coverings containing clay).

Figure 62. *Isopterygiopsis pulchella* with capsule, the only species with a capsule in a Russian excursion cave. Photo by Michael Lüth, with permission.

Figure 63. Protonemata of the moss *Physcomitrium pyriforme*, a typical sight in cave lampenflora. Photo by Bob Klips, with permission.

In an exhibition cave in the Czech Republic, Faimon *et al.* (2003) found 12 taxa of algae and **Cyanobacteria** (Figure 59-Figure 60) and 19 moss taxa.

Dominant Species

Pentecost (2011) described the lampenflora of tourist caves in northern England. The **Cyanobacteria** (Figure 59-Figure 60) numbered 18 species, supporting the conclusion that it is the most species-rich group in the lamp communities. He also found 6 diatoms, 4 bryophytes, 1 coccoid green alga, and 1 fern species. The **Cyanobacteria** were the predominant organisms and grew at light levels of $0.06\text{--}2.08\ \mu\text{mol m}^{-2}\ \text{s}^{-1}$. *Eucladium verticillatum* (Figure 57-Figure 58) was the most common moss, surviving in light levels of $0.55\text{--}2.08\ \mu\text{mol m}^{-2}\ \text{s}^{-1}$.

Mulec and Kubešová (2010) reported species from 8 Slovenian show caves. Once again, *Eucladium verticillatum* (Figure 57-Figure 58) was among the most frequent mosses, along with *Amblystegium serpens* (Figure 2), *Brachythecium* sp. (Figure 66), and *Fissidens taxifolius* (Figure 64). Bryophytes and ferns together comprised 37 taxa. Not surprisingly, *Eucladium verticillatum* had the widest range of photosynthetic photon flux density ($1.4\text{--}530.0\ \mu\text{mol photons m}^{-2}\ \text{s}^{-1}$). *Cratoneuron filicinum* (Figure 65) even developed sporophytes at 2.1 and $2.4\ \mu\text{mol photons m}^{-2}\ \text{s}^{-1}$. *Brachythecium salebrosum* (Figure 66) developed sporophytes at $4.7\ \mu\text{mol photons m}^{-2}\ \text{s}^{-1}$.

Figure 66. *Brachythecium salebrosum*, a species that can develop sporophytes at $4.7 \mu\text{mol photons m}^{-2} \text{s}^{-1}$. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Maheu (1926) recorded 6 moss species [*Anomodon attenuatus* (Figure 67), *A. rostratus* (Figure 3), *Brachythecium rivulare* (Figure 68), *Eurhynchium praelongum* (Figure 69), *Gymnostomum calcareum* (Figure 32-Figure 33), and *Plagiomnium rostratum* (Figure 70)], and the liverwort *Marchantia polymorpha* (Figure 48) from the twilight zone, including lamp areas, of Mammoth Cave, Kentucky, USA. These bryophytes were etiolated and lacked sporophytes. Barr (1968) later reported 200 species of animals, 67 species of algae, 27 species of fungi, and 7 species of twilight-zone bryophytes in the Mammoth Cave system.

Like many other studies, D'Agostino *et al.* (2015) found that the bryophytes in the Zinzulusa Show Cave (South Italy) mainly consisted of unidentified protonemata (Figure 63) and the mosses *Rhynchostegiella tenella*

(Figure 56) and *Eucladium verticillatum* (Figure 57-Figure 58). The latter species is instrumental in the formation of concretions that grow from water that drips from the ceilings, but are oriented toward the outside of the cave due to the phototropic growth of the moss (Figure 117).

In a cave in Hungary, Komáromy *et al.* (1985) found the mosses *Brachythecium velutinum* (Figure 71), *Campylium chrysophyllum* (Figure 72), *Eucladium verticillatum* (Figure 57-Figure 58), *Fissidens dubius* (Figure 73), *F. pusillus* (Figure 74), *Gymnostomum calcareum* (Figure 32-Figure 33), *Hypnum cupressiforme* (Figure 75), *Pseudoscleropodium purum* (Figure 76), *Rhynchostegium megapolitanum* (Figure 77), and *Tortella tortuosa* (Figure 78) near lights. These were all common species outside the caves. Note the absence of liverworts.

Verdoorn (1927) reported *Brachythecium velutinum* (Figure 71), *Rhynchosstegium murale* (Figure 79), and *Rosulabryum capillare* (Figure 80) around the dim lights of 2 German caves. These exhibited small, etiolated, and crumpled leaves.

Kubešová (2001) reported 46 species of bryophytes in the lampenflora in public caves in the Moravian Karst (Czech Republic) in the 1960s to 1970s, but only 34 were located in 1999-2000. Of these, 2 liverworts and 10 moss species could not be relocated, but 2 new moss species were found. The bryophytes present all occur on the soil and rocks outside the caves (Rajczy 1989; Šmarda 1970). The mosses *Amblystegium serpens* (Figure 2), *Eurhynchium hians* (Figure 7), *Leptobryum pyriforme* (Figure 4), and *Rhynchosstegium murale* (Figure 79) were frequent in the 1970s and in the later study (Kubešová 2001). The liverworts *Fossombronina wondraczekii* (Figure 81) and *Pellia epiphylla* (Figure 82) and the mosses *Aulacomnium androgynum* (Figure 83), *Dichodontium pellucidum* (Figure 84), *Eurhynchium angustirete* (Figure 85), *Mnium marginatum* (Figure 86), *Plagiomnium affine* (Figure 87), *Plagiomnium rostratum* (Figure 88), *Rhizomnium punctatum* (Figure 89), *Timmia bavarica*

(Figure 90), *Tortella tortuosa* (Figure 78), and *Trichostomum tenuirostre* (Figure 91-Figure 92), were not relocated. The mosses *Ditrichum flexicaule* (Figure 93-Figure 94), *Rhodobryum ontariense* (Figure 95), and *Thamnobryum alopecurum* (Figure 96) were new in the present study. The mosses *Brachythecium velutinum* (Figure 71), *Ceratodon purpureus* (Figure 97-Figure 98), *Dichodontium pellucidum* (Figure 84), *Funaria hygrometrica* (Figure 12-Figure 13), *Leptobryum pyriforme* (Figure 4), *Physcomitrium pyriforme* (Figure 63, Figure 99), *Rhynchostegium murale* (Figure 79), and *Tortula subulata* (Figure 100-Figure 101) had at least some fertile populations in the 1970s, but only *Funaria hygrometrica* (Figure 12-Figure 13) was fertile in the later study. Hajdu (1977) noted that sporophytes were rare in cave bryophyte populations. Were these changes due to competition by later arrivals, or to changing conditions due to human presence?

Figure 101. *Tortula subulata* with immature capsules, on rock. Photo by Hugues Tinguy, with permission.

Kubešová (2013) reported *Amblystegium serpens* (Figure 2), *Brachytheciastrum velutinum* (Figure 102), *Cratoneuron* spp. (Figure 65), and *Fissidens taxifolius* (Figure 64) as frequent species around lights in 14 caves in the Czech Republic, all common outside caves as well. In total, he found 62 moss species, but no liverworts, with 0-24 species in a single cave. Overall, 45% of the bryophyte flora remains the same as in the past (1960s-70s). In the 1988-1990 period, 26% of the species were newly recorded. Only nine of the 1960-70's species of mosses were relocated in 1988-1990.

Figure 102. *Brachytheciastrum velutinum*, a frequent species around lights in 14 caves in the Czech Republic. Photo by Claire Halpin, with permission.

When Kubešová (2005, 2006) reviewed the bryophytes in public caves in the Czech Republic, he found that the mosses *Amblystegium serpens* (Figure 2), *Brachythecium velutinum* (Figure 71), *Fissidens taxifolius* (Figure 64) and *Leptobryum pyriforme* (Figure 4) were the ones most frequently present in both early studies in the 1960s-70s and in 2004.

But in North America, the composition differs. Thatcher (1949) noted the absence of both *Reboulia* (Figure 103) and *Eucladium* (Figure 57-Figure 58) in Crystal Cave in Wisconsin, USA, a tourist cavern. Only *Ceratodon purpureus* (Figure 97-Figure 98), *Fissidens*

taxifolius (Figure 64), *Leptobryum pyriforme* (Figure 4), and *Rosulabryum capillare* (Figure 80) were found in both the Crystal Cave, Wisconsin, and the Czech caverns. Instead, Thatcher reported the thallose liverwort *Marchantia polymorpha* (Figure 48) and the mosses *Barbula unguiculata* (Figure 104), *Brachythecium populeum* (Figure 105-Figure 106), *Brachythecium salebrosum* (Figure 66), *Bryoerythrophyllum recurvirostrum* (Figure 52), *Bryum caespitium* (Figure 53-Figure 54), *Leptodictyum riparium* (Figure 107-Figure 108), *Plagiomnium cuspidatum* (Figure 109), and *Warnstorfia fluitans* (Figure 110) from Crystal Cave. A small amount of the fern *Cryptogramma stelleri* (Figure 111) was the only fern present, and in only a small amount, but with prothalli, growing among moss protonemata (Figure 63). *Bryum caespitium* was the only moss to display a sporophyte – a single sporophyte for the entire study.

Figure 103. *Reboulia hemispherica* with archegoniophores; *Reboulia* is found in some European caverns, but was absent in Crystal Cave, Wisconsin, USA. Photo by Bob Klips, with permission.

Figure 112. *Oxyrrhynchium schleicheri*, one of the most common mosses near cavern lights at the Trieste Karst in NE Italy. Photo by Hugues Tinguy, with permission.

Castello (2014) found 16 moss species and 2 ferns in 26 sites near artificial lights of various kinds in the Trieste Karst in NE Italy. The most common of these were the mosses *Eucladium verticillatum* (Figure 57-Figure 58), *Fissidens bryoides* (Figure 10-Figure 11), *Oxyrrhynchium schleicheri* (Figure 112-Figure 113), and *Rhynchostegiella tenella* (Figure 56) and the fern *Asplenium trichomanes* (Figure 114-Figure 115). Of these, *Eucladium verticillatum* was the most common, exhibiting a wide amplitude for light intensity and substrate type (see also Dalby 1966a; Popkova *et al.* 2019). The most important factors determining the species present were light intensity, water availability, type of substrate, morphological features of surfaces, and presence of clay. To these factors, Mazina (2016a) added the connection of the location with the surface.

Figure 113. *Oxyrrhynchium schleicheri* branch. Photo by Hermann Schachner, through Creative Commons.

Modifications of Cave Dwellers

Piano *et al.* (2015) found that increased illumination was the primary factor influencing both increased presence and increased productivity of **Cyanobacteria** (Figure 59-Figure 60), **diatoms** (Figure 116), and **green algae** (Figure 61). The presence of seeping water on the substrate and the distance from the cave entrance are important in determining patterns of colonization. Differences in light likewise influences the bryophyte flora, its appearance, its physiological acclimation, and its productivity.

The lampenflora organisms are usually ubiquitous in nature, having the ability to survive in new conditions through a wide ecological tolerance (Mulec 2012; Mazina 2016a). Nevertheless, lampenflora bryophytes are often etiolated (Mulec 2018). Conard (1932) remarked on the *Fissidens taxifolius* (Figure 64) that he found within 20 cm of a light in Crystal Cave, Virginia, USA. The leaves were more widely spaced than in typical specimens outside caves. Prior (1961) found that the leaves of cave-dwelling mosses are often much more crisp than those outside the cave. Prior also found that the number of chloroplasts seems to be unaffected by the light intensities; nevertheless, the mosses are typically pale, resulting from a reduction in chlorophyll content.

Maheu (1926) summarized the reported modifications of cave and sink hole bryophytes. These included sterility, elongation of leaves, increased spacing of leaves along the stem, elongation of cells, and disappearance or attenuation of the costa or rib. The liverworts present the least

modification, despite penetrating the greatest distance into the cave.

The phototropic response is quite evident among acrocarpous mosses, with some inclined as much as 75° from vertical at the deepest location of mosses in the cave (Prior 1961). When the nearest lamp is on the ground, this response is evident throughout the growth; such responses cause some statoliths to develop horizontally (Figure 117). For example, sporophytes on *Leptobryum pyriforme* (Figure 4) are inclined in the same way as the stem of the gametophyte.

Figure 117. *Eucladium verticillatum* forming stalactite (eucladiotite) in mine in Dorset, showing horizontal growth of the statolith (eucladiolith in this case). Photo from Dalby 1966b.

Life Strategies

In a Hungarian cave, Komáromy *et al.* (1985) found that moss species in lamp-lit areas were **colonists** and **perennials** (5 species each). Similarly, in the Czech Republic Kubešová (2006, 2013) found the most frequent life strategies to be **colonists** and **perennials**, but also included fugitives, with the most common growth forms being **short turf** and **rough mat**.

Sporophytes are generally scarce among bryophytes in caves. Prior (1961) seems to have found more than most bryologists, with 50% of the moss species in Luray Cavern Kentucky, USA, having sporophytes. As noted earlier, he found *Amblystegium serpens* (Figure 2), *Campylium hispidulum* (Figure 6), *Tortula obtusifolia* (Figure 8-Figure 9), *Eurhynchium hians* (Figure 7), *Funaria hygrometrica* (numerous; Figure 12-Figure 13), and *Leptobryum pyriforme* (Figure 4) with sporophytes in at least some locations. He noted that plants farthest from the lights often did not have capsules, but conceded that these could simply be too young.

Propagation and Survival

Mazina and Kozlova (2018) attempted to determine dominant propagation means occurring in the Lipska Cave in Montenegro. They used soil and water samples from the unlighted zone and cultured them to understand the propagules that were able to enter through airflows. Among these, they identified 17 species of algae and **Cyanobacteria**, and 12 bryophyte species. The mosses *Fissidens taxifolius* (Figure 64) and *Brachythecium tommasinii* (Figure 118-Figure 119) dominated the

lampenflora communities, while *Entodon schleicheri* (Figure 120) and *Tortella* sp. (Figure 78) had the highest abundance in the natural entrance zone.

In Russia and the Crimea, Mazina (2016a) found the highest species diversity of bryophytes and ferns in caves where the lampenflora had not been removed. In seeming

contrast, Burgoyne *et al.* (2021), using DNA identification, found that bacterial communities of unlit nearby caves had a greater diversity than did the excursion caves with lights (Lehman Caves, Great Basin National Park, Nevada, USA). There was little overlap among the communities of the Lehman Caves. Could it be that the lampenflora out-competed the bacteria? But this would not be true away from the lights.

In Virginia, USA, caves, Lang (1941) found the colors of the lampenflora to add a "pleasing variation" to the natural colors of the rock formations. These same organisms are absent within the caves where there are no lights. Lang noted that during the tourist season, the organisms may experience a lighted period as long as that in nature outside the cave. However, in winter they are seldom illuminated and usually turn yellowish or brown and die. On the other hand, many such caves around the world continue to serve the public throughout the year, permitting the continued growth of the lampenflora.

Lang (1943) collected mosses from the Luray Caverns, Virginia, USA, and kept them between blotters, dry and dark for one year. Under these conditions, the mosses remained as green as when first collected. This is consistent with their ability to dry in nature and remain alive, whereas those that were kept moist by the cave, but without light, most likely used up their energy through respiration and were therefore unable to manufacture new chlorophyll while remaining physiologically active.

Conservation and Control Measures

Although the lampenflora is considered by some to be unsightly, the greater concern is its ability to deteriorate the substratum. **Cyanobacteria** (Figure 59-Figure 60), in particular, are common in these dimly lit conditions (Mulec 2012).

Conservation in the caves can have conflicting goals. On the one hand, to maintain the original conditions of the natural cave, it is desirable to prevent or remove the growth around cave lights needed to provide safety to tourists (Kim 2008). On the other hand, these can be points of interest to both scientists and tourists, illustrating the differences in light requirements among the algae, bryophytes, and ferns. Furthermore, lights are necessary for safety in show caves.

In Pacitan, Indonesia, the extensive karst topography creates a large number of caves, several of which serve as show caves (Kurniawan *et al.* 2017). The show caves provide many jobs in the area, both in the caves and in the community through tourism, and they are of essential economic importance to the local area. This use is more sustainable of the caves than is mining, but the tourism creates problems that are often in conflict with management for profit.

Many impacts of cave visitation are more subtle, noticed only by those conducting intensive study on the cave. This is particularly true for the non-photosynthetic cave dwellers. Elliott (2006) noted that typical cave dwellers such as some insects, salamanders, bats, and other animals have long life spans, slow rates of reproduction, and ability to survive in low food conditions. Some of the cave dwellers (*e.g.* moths, raccoons, bears) are seasonal, surviving there in winter and other unfavorable weather conditions. These organisms often avoid humans and can disappear without the average visitor ever noticing.

Human Impacts

Kurniawan and coworkers (2017) cited various dangers to the natural beauty of the caves: cement walkways, lights of various colors, big fans, added perfumes, weak regulation of visitor numbers, breakage and other damage of the rock formations, and application of dangerous substances to lessen the odor of guano and repel the cave fauna. Not only do the lights permit growth of lampenflora, but visitors introduce dust that covers the formations and alters their colors, leave garbage, vandalize, alter the microclimate, and cause decline in the numbers of biota. Similar impacts have been documented in other studies (Gillieson 2011; Mulec 2019).

Most cave formations of interest for tourists occur in limestone formations. The presence of lampenflora introduces organic acids that can corrode the limestone substrate (Aley 2004; Cigna 2012).

Russell and MacLean (2008) also noted the addition of concrete and steel structures, change in the air movement regime, and alteration of temperature through the movement of warm bodies through the cave. Human presence in the cave can also alter the available CO₂ (Russell & MacLean 2008; Lamprinou *et al.* 2014). This becomes more apparent when ventilation is limited (Russell & MacLean 2008; Lang *et al.* 2015). And the addition of entrances or blockage of entrances changes airflow patterns within the cave, with the entrance of visitors disturbing the relatively limited variation in temperature and humidity.

Visitors to caves can be a major source of propagules, especially on shoes and boots (Mulec 2014). Mulec estimated that more than 10,000 colony-forming units arrive per 100 cm² in such caves.

Many researchers have pointed out the destructive nature of cave lamps and human presence to the natural formations (Rajczy *et al.* 1997; Kubešová 2001; Cigna 2011; Gillieson 2011; Parise 2011; Mulec 2012; Šebela & Turk 2014; Mazina 2015; Piano *et al.* 2015; Meyer *et al.* 2017; Mulec 2019; Pfendler *et al.* 2021). Mulec (2012) considered the lampenflora to be unsightly, as well as having detrimental effects on the underlying substrata. But, unfortunately, the chemicals available to remove the lampenflora are not specifically targeted to these organisms, but can also be detrimental to the cave fauna. Furthermore, they can corrode the very substrate that is in need of protection. New lighting technology and better practices seem to be a better means of control.

In public caves in the Czech Republic, Kubešová (2006) found that the species richness was highest in the caves where the visitors' tour was long and the caves experienced the highest number of visitors. Hence, it is likely that humans are strong dispersal agents.

Treatments - Chemical

In Crystal Cave, Sequoia National Park, California, USA, Meyer *et al.* (2017) found that 1.0 and 0.5% sodium hypochlorite (Clorox) effectively eliminate lampenflora in 11 and 21 days, respectively, greatly outperforming 15.0% hydrogen peroxide. The springtail *Tomocerus celsus* (see Figure 121) had a similar diet both when living among the lampenflora and away from it. Nevertheless, *T. celsus* experiences a negative response to 1.0% sodium hypochlorite, and its presence was inversely related to the effectiveness of each treatment.

Figure 121. *Tomocerus vulgaris*; *Tomocerus celsus* lives among the lampenflora in Crystal Cave, Sequoia National Park, California, USA. Photo by Andy Murray, through Creative Commons.

Because chlorine and other compounds used to remove lampenflora are deleterious to the cave substrate, Faimon *et al.* (2003) tested hydrogen peroxide as an alternative in a cave in the Moravian Karst, Czech Republic. They found that a 15% by volume solution was an adequate strength to destroy the lampenflora. But limestone and speleothem dissolution rates were 1 order of magnitude higher than that by the karst water. To alleviate this problem, they found that there was little damage if a few limestone fragments were added to the solution at least 10 hours prior to application.

Mulec (2018) elaborated on the types of changes that lampenflora can make in caves. Plant thalli can calcify, and tuffaceous stalactites and stromatolitic stalagmites add variety to the cave formations. But these are natural processes, at times increased by access of the phototrophs deeper into the cave by the presence of artificial light.

In prehistoric caves, serious damage may occur to wall paintings, as observed in the Lascaux cave in France (Ruspoli 1986). In historic caves where cave art is of interest, alteration of the artwork is of concern (Mulec 2018). The hygroscopic nature of the **Cyanobacteria** (Figure 59-Figure 60) and algae (Figure 61) and can make them especially harmful to artwork (Roldán *et al.* 2006). The lampenflora creates a greenish cast to the artwork and the photosynthetic organisms promote the growth of bacteria and fungi that "weather" the underlying art. Mulec (2018) contended that altering the spectra of the lights did not help in preventing lampenflora. Instead, he recommended removing the lampenflora and restricting the use of the lamps.

Kim (2008) noted that even though the lights may be shut down for periods of time, these **Chlorophyta** (Figure 61) and **Bryophyta** that have disappeared grow again "immediately" when suitable growth conditions return. Kim (2008) recommended the "necessity" of keeping the illumination distance over 2 m and using indirect light. This researcher warned against unintentional dispersal by moist pieces of cloth or sponge when removing the lampenflora and noted the importance of removing them at an early stage of development. Heat created by the lighting can also be a problem.

Sea caves (Figure 122) require special management (Gurnee 1994) that involves innovative techniques to

protect them from the intrusion of visitors and exposure to the destructive sea air. These are sometimes protected by glass enclosures, use of boats and vehicles that keep visitors from especially sensitive areas, and lighting and cleaning techniques that minimize lampenflora.

Figure 122. View from inside of sea cave at Cape Greco National Park, Cyprus. Photo by Kallerno, through Creative Commons.

De Freitas (2010) emphasized the importance of managing the microclimate in the caves. These are easily altered by changes in entrance conditions, changing both spatial and temporal patterns of the climates within the cave. And changing air patterns will necessarily change patterns of dispersal of propagules. This means that management techniques must be appropriate to a particular cave condition or needed environmental condition.

Treatments – Alternative Lighting Regimes

Kim (2008) reported that the cave green algae and bryophytes disappeared by shutting down the lights and maintaining the natural low temperatures in caves. But this is not an option in show caves.

Whereas daylight spectrum lighting and red-enriched tungsten lighting promote the growth of **Cyanobacteria**, algae, and plants, UV light has antibiotic properties and is even used in hospitals and microbiology labs to control pathogens and contaminants. UV lights have been used to control the lampenflora in some caves (Mulec & Kosi 2009). In Grotta Gigante, Trieste, Italy, new germicidal lamps earned the cave the 2008 Green certificate (Fabbriatore 2009). These were considered environmentally friendly and kept the lampenflora under control. For safety purposes, these are on timers that turn them on when no other lights are on in the cave. They can be detrimental to human eyes and skin, so their use should be avoided when humans are in the cave. But what about the fauna of the cave?

Pfendler *et al.* (2021) experimented with the growth of bryophytes on block samples with several pigments such as one might find in the prehistoric art. Several blocks in the study sustained dense bryophyte propagation. Nevertheless, the success of growth rate correlated with the chemical composition of the pigments. Such elements as As, Cr, Ti, and Co reduced bryophyte growth. UV-C light proved to be highly efficient *in situ*, although in the laboratory such treatments experienced fast recolonization. The researchers suggested that the recolonization was due

to the high density of the bryophyte growth that protected the lower parts from the UV-C light penetration.

Perhaps a better solution is the use of green light (Roldán *et al.* 2006). Changes in the light spectrum can include pigment changes in the **Cyanobacteria** and algae. In fact, green light affects pigment composition (Tandeau de Marsac *et al.* 1988; Albertano 1991). But it also retards growth (Hauschild *et al.* 1991) and causes vacuolation in the chlorophyll thylakoid system (Albertano 1991). An added bonus is that it provides the maximum absorbance in human vision.

Using the cyanobacterian *Gloeotheca membranacea* (Figure 123) and chlorophyten *Chlorella sorokiniana* (Figure 124), Roldán *et al.* were able to demonstrate that green light could prevent the growth of photosynthetic organisms, except for those capable of modifying accessory pigments. Even so, the very light-adaptable *Gloeotheca membranacea* exhibited lower photosynthetic pigment biovolume, smaller thylakoid regions, and a weaker mean fluorescence intensity.

Pollution and Role of Bryophytes

In the Zhijin Cave in China, heavy metal pollution was introduced by the development of the karst caves for show

purposes. Liu *et al.* (2018) sought to determine the effect of the bryophytes on the cave pollution. The cave had 12 liverwort and 37 moss taxa, dominated by **Pottiaceae**, **Fissidentaceae**, and **Mniaceae**. Mercury levels were especially elevated and represented the most serious pollutant in the cave. The bryophyte community diminished as the heavy metal levels increased. Furthermore, the bryophytes served as accumulators that could be used to indicate the level of pollution in the cave. The liverwort *Conocephalum conicum* (Figure 125), in particular, is affected by substrate Hg content and can be used as a biomonitor in caves.

Figure 125. *Conocephalum conicum*, a species that can be used to monitor mercury in caves. Photo by Claire Halpin, with permission.

One consequence of the lampenflora is the production of **aragonite** (mineral consisting of calcium carbonate, typically occurring in white seashells, including pearls, and as colorless prisms in deposits in hot springs) instead of **calcite** (more common form of calcium carbonate in limestone caves) (Forti 1980). This is accomplished by the different arrangement of atoms. Such modifications can be minimized by use of special lamps that do not support the range of maximum absorption for photosynthesis (Gurnee 1994; Olson 2002; Roldán *et al.* 2006; Mulec & Kosi 2009; Lamprinou *et al.* 2014).

Summary

Succession of **lampenflora** usually begins with **Cyanobacteria**, then algae, then bryophytes, and finally ferns (and possibly flowering plants). The **Cyanobacteria** and algae are forced farther and farther from the light by the increasingly larger bryophytes and ferns. The caves with lamps typically have greater species diversity of bryophytes and other cave flora.

Dominant bryophyte species, and those with widespread occurrence, include *Amblystegium serpens*, *Eucladium verticillatum*, *Fissidens bryoides*, and *Fissidens taxifolius*, but dominant species differ regionally. Liverworts are few or absent. *Rhynchostegiella tenella* can arrive and establish within one year.

Bryophytes in the low light of caves, whether in the twilight zone or around lights, frequently have diminished chlorophyll content (pale), leaves more widely spaced, leaves elongated, cell elongation, reduction of costa, and reduction or lack of sexual structures. They are often positively phototropic.

The lampenflora are typically **colonists** and **perennials** with a **rough mat** or **short turf** life form. The sporophyte generation is poorly represented, and the plants seem to rely on asexual propagules and fragmentation for spreading within the cave. Those with sporophytes typically produce them frequently outside the caves, but the converse is less likely.

The lampenflora is typically considered a nuisance in caverns. It changes the colors, increases the decomposition of the cave, and can damage prehistoric artwork. Efforts to remove or prevent the lampenflora include peroxide, scraping, and reducing the time lights are on. But new treatments with green light or use of UV light when humans are not present offer promise.

Although bryophytes are susceptible to damage by pollutants, they can also be accumulators that help to remove heavy metals and other pollutants introduced by human activity.

Acknowledgments

Many Bryonettors responded to my call for images for this chapter. Wolfgang Hofbauer provided me with a paper that gave me a good list of current references on wind holes. Thank you to our Chinese colleagues (Wen Ye, Xinlei Guo, Yang Liu, Xiaoming Shao, and Wang Zhe) who responded to my request for the English translation of the abstract of a Chinese study. Once again I thank Lars Söderström for his help in tracking down the correct name for *Leiocolea muelleri* and Rod Seppelt for helping me catch the misspelling of *Achrophyllum dentatum*. Ryszard Ochrya helped me in clarifying nomenclature that couldn't be linked in TROPICOS or World Flora Online.

CHAPTER 18-6

CAVES – SIMILAR SECLUDED HABITATS

Figure 1. Zen Iwatsuki photographing fissure in lava, with bryophytes, Grjotagja, Myvatn, Iceland, 1985. Photo by Janice Glime.

Artificial "Caves"

Mine Shafts

Mines and mine shafts, in many ways, act like caves. Their cold air typically comes from lower levels rather than through channels above. They are dark, and they are usually damp. These habitats can have their own unique bryophyte flora, often influenced by the types of minerals being mined. Strip mines can in some cases resemble sink holes, but often have a much shorter history and much less moisture. But I have to wonder why I was unable to find many studies on these human-made habitats.

In Ireland, Holyoak and Lockhart (2009) found *Cephaloziella massalongi* (Figure 2) at the top of a copper

mine shaft on rock where it was lightly shaded (Figure 3). Although it seems to always be associated with copper in Britain, *Cephaloziella massalongi* only occurs on acidic sites (Figure 4), and is not known from limestone sites. Cornish sites typically have pH levels of 5.1-5.4 and are often associated with moderate levels of both lead and zinc as well as copper. Callaghan (2011) studied the ecology of this species and found that it typically grows in shaded conditions (Figure 4) with less than 10% relative light, a level that characterizes many of the liverworts (Marschall & Proctor 2004). In an old mine adit of Wales, it grew at 2.5 lux (0.2% relative light). Callaghan suggested that *Cephaloziella massalongi* may be confined to such shaded conditions because of its need for moisture and inability to successfully compete elsewhere.

Figure 2. *Cephaloziella massalongi*, a copper-tolerant liverwort. Photo by Des Callaghan, with permission.

Figure 4. *Cephaloziella massalongi* in Hermon Copper Bog under overhanging sod that provides it with shade. Photo by Des Callaghan, with permission.

The number of taxa in the Tongshankou Copper Mine in China is much greater than in many caves (Pen & Zhang 2005). So far 29 moss taxa, representing 7 families and 20 genera, have been identified. Pan *et al.* (2011) found a similar number of species (30 taxa) in four abandoned mercury mines in China. Bryophytes occurred within the first 10 m into the mine. The life forms were 60% short turfs, 33% wefts, and 7% mats. Among these was the luminous thallose liverwort *Cyathodium smaragdinum* (Figure 5).

Figure 5. *Cyathodium smaragdinum*, a luminous thallose liverwort that is known from a copper mine in China. Photo by 楊玉鳳, through Creative Commons.

Koponen (1977) reported the mosses *Pohlia nutans* (Figure 6) and *Ceratodon purpureus* (Figure 7-Figure 10) at a depth of 176 m in a mine in Finland. But this mine was continuously illuminated by electric lights. The mosses covered an area of ~0.5 m² in this mine under a constant ~8°C and high humidity. The mine was rich in zinc, lead, and copper. *Ceratodon purpureus* is a moss of a wide range of habitats, from dry roadsides to submerged in Antarctic ditches and resplendent on its boulders (Figure 9). It is not unusual to see it growing on stone ledges (Figure 10).

Figure 10. *Ceratodon purpureus* on a shaded ledge in Dollar Bay, Michigan, USA. Photo by Janice Glime.

Mine entrances seem to be overlooked habitats where one might find unusual species in areas where similar cave habitats are absent. On the other hand, the surface around mines is typically rich in ore and often has rare species (*e.g.* Callaghan 2018), but these areas are not similar to caves and will be discussed elsewhere.

Subways

Subways are manmade caves, but are typically illuminated and are open at both ends. They are likely to suffer from the pollution created by trains.

The granitic subway in Stockholm has lighting throughout. Established in 1970, the tunnel has a flora including *Cyanobacteria*, fungi, bacteria, diatoms, and the moss *Eucladium verticillatum* (Figure 11), a species not known elsewhere in Stockholm. Its occurrence on granite is unusual – it usually occurs on limestone. The subway also is home to a spider that is unknown elsewhere in Sweden.

Small Caves and Fissures

Various fissures and cracks in rocks (Figure 1, Figure 12-Figure 13), including lava, make tiny caves and cave-like habitats that are suitable refuges for bryophytes. While

in Iceland, Yojiro Iwatsuki uncovered *Saelania glaucescens* (Figure 14) growing completely hidden under cracked rocks in a lava field (Figure 15-Figure 17).

Figure 12. Fissures in hard lava rock, Myvatn, Iceland, making cave-like environments. Photo by Janice Glime.

Figure 17. *Saelania glaucescens* with capsules revealed from under lava crack N of Reykjavik, Iceland. Photo by Janice Glime.

Krukowski and Świerkosz (2005) found the fern *Vandenboschia radicans* (Figure 18) in its easternmost locality in Europe. Its gametophytes grew in horizontal rock fissures with sparse growths of the mosses *Schistostega pennata* (Figure 19) and *Distichium inclinatum* (Figure 20). I observed the same phenomenon with *Asplenium scolopendrium* gametophytes growing among mosses on the vertical sides of boulders in the Upper Peninsula of Michigan, USA.

Scree

Scree (slopes covered with small loose stones; **talus**; Figure 21-Figure 22) create numerous minicaves that can act as refugia for more northern boreal and Arctic

bryophyte, pteridophyte, and arthropod species (Růžička *et al.* 2012). These can even have year-round ice.

Figure 21. Scree in Switzerland, creating tiny darkened caves where bryophytes enjoy protection. Photo by Urs Kormann, through Creative Commons.

Figure 22. Talus slope at Ruby Mountains, Nevada, USA. Photo from USGS, through public domain.

In the Czech Republic, 92 bryophyte and 10 pteridophyte species were encountered among the scree. The liverworts *Sphenolobus saxicola* (Figure 23), *Diplophyllum taxifolium* (Figure 24), *Gymnomitrium*

concinnum (Figure 25), *Gymnomitrium corallioides* (Figure 26-Figure 27), and *Barbilophozia sudetica* (Figure 28), and mosses *Andreaea rupestris* (Figure 29), *Polytrichastrum alpinum* (Figure 30), *Racomitrium fasciculare* (Figure 31) and *Racomitrium lanuginosum* (Figure 32) have isolated populations in the Kamenec Hill of the Czech Republic, and the populations of the fern *Cryptogramma crista* (Figure 33) and liverworts *Gymnomitrium* spp. (Figure 25-Figure 27) represent the lowest known elevational limits for the Czech Republic and Central Europe. Some species occur only near ice plots, including the liverworts *Diplophyllum taxifolium*, *Gymnomitrium corallioides*, and *Lophozia sudetica* and the mosses *Andreaea rupestris* and *Polytrichastrum alpinum*. On the other hand, the liverworts *Sphenolobus saxicola* and *Gymnomitrium concinnum* and mosses *Racomitrium fasciculare* and *Racomitrium lanuginosum* never occurred near ice.

These scree habits likewise provide a deep labyrinth where arthropods and other organisms find refuge (Růžicka *et al.* 2010). In NE Bohemia, Czech Republic, deep vertical spaces among the scree provide microhabitats for montane bryophyte species such as the liverwort *Diplophyllum taxifolium* (Figure 24), and the mosses *Dicranum elongatum* (Figure 34) and *Pohlia drummondii* (Figure 35) occur. Living among these are numerous arthropods, with spiders and beetles being the most numerous. A total of 304 species of arthropods were identified in the study.

Figure 34. *Dicranum elongatum* with capsules, a species that lives in deep cavities among the scree in NE Bohemia, Czech Republic. Photo by Jean Faubert, with permission.

Figure 35. *Pohlia drummondii*, a species that lives in deep cavities among the scree in NE Bohemia, Czech Republic. Photo by David T. Holyoak, with permission.

In Iceland, the mosses *Distichium capillaceum* (Figure 36-Figure 37), *Mnium marginatum* (Figure 38), and *Pohlia cruda* (Figure 39), and the fern *Cystopteris fragilis* (Figure 40), grow over the **loess** (silt-sized sediment formed by accumulation of wind-blown dust) deposits inside the scree cavities, surviving with reduced light but buffered microclimate (Blažková 1973). Similar associations also occur in crevices on loess in the Czech Republic (Hesselbo 1918; Šmarda 1947).

Similar cavities occur in lava fields (Figure 41). Blažková (1973) described these from northern Iceland. Aeolian sediments accumulate on the bottom of these cavities. Light intensity is greatly reduced and the microclimate is buffered from the extremes at the surface. Blažková reported 12 bryophyte species from these. In very dark parts of the cavities mainly liverworts occur, including *Blepharostoma trichophyllum* (Figure 42), *Mesoptychia collaris* (Figure 43-Figure 44), and *Sauteria alpina* (Figure 45-Figure 46). Close to the openings where it is well illuminated, one can find *Polytrichum juniperinum* (Figure 47-Figure 48) and especially *Timmia austriaca* (Figure 49).

Bjarnason (1991) considered every cavity around a boulder at Hekla (Figure 50), southern Iceland, to be

different, thus making all the holes different in ecological character. The moss *Racomitrium lanuginosum* (Figure 32) frequently grows on these rocks and covers the cavity (Figure 51-Figure 52), making the area somewhat dangerous for walking. The very deep, narrow lava clefts (Figure 53-Figure 54) support vegetation similar to that of the holes, with *Conostomum tetragonum* (Figure 55), *Pohlia drummondii* (Figure 35), *Pohlia wahlenbergii* (Figure 56), and *Polytrichastrum sexangulare* (Figure 57-Figure 58). The vegetation in these narrow lava cavities at Hekla has a very different flora from those in northern Iceland (Figure 41). Some species prefer the holes in the Hekla area, but are not restricted to them: the liverworts *Blepharostoma trichophyllum* (Figure 42) and *Nardia geoscyphus* (Figure 59) and the mosses *Isopterygiopsis pulchella* (Figure 60), *Mnium stellare* (Figure 61), *Oligotrichum hercynicum* (Figure 62), and *Pohlia cruda* (Figure 39). Many species also occupy the crags, including the liverworts *Diplophyllum albicans* (Figure 63) and *Mesoptrychia gillmanii* (Figure 64) and the mosses *Encalypta ciliata* (Figure 65) and *Plagiothecium cavifolium* (Figure 66-Figure 67). Others occur in small ruptures in the main surface (Figure 54), including the liverwort *Cephaloziella divaricata* (Figure 68-Figure 69) and mosses *Dicranoweisia crispula* (Figure 70), *Diphyscium foliosum* (Figure 71), and *Pohlia drummondii*. As in northern Iceland, *Racomitrium lanuginosum* (Figure 32, Figure 51-Figure 52) is common near the openings of the holes, infrequently accompanied by *Andreaea rupestris* (Figure 29) and *Schistidium apocarpum* (Figure 72) (Bjarnason 1991). As in northern Iceland, the moist, sandy bottom (40-60 cm) supports small patches of liverworts; mixed with larger bryophytes such as the moss *Bartramia ithyphylla* (Figure 73) and liverwort *Plagiochila porelloides* (Figure 74). In wide, shallow holes the number of species is greater at this sandy bottom, including *Brachythecium albicans* (Figure 75), *Polytrichum juniperinum* (Figure 47-Figure 48), *Rhytidiadelphus squarrosus* (Figure 76), and *Timmia austriaca* (Figure 49).

Ice Caves

Bryophytes in ice caves (Figure 77) are much more uncommon. Jakab (2000) found *Heterocladium heteropterum* (Figure 78-Figure 79) and *Cyrtomnium hymenophylloides* (Figure 80) in ice caves in Romania. But outside, the caves can cause a **temperature inversion** (reversal of normal decrease of air temperature with altitude). Other bryophytes seem to benefit from the conditions emanating from these caves, permitting more Arctic species to survive here.

Windholes

Windholes (Figure 81-Figure 83, Figure 88) are also known as **Kaltluftlöcher**, **Kondenswassermoore**, and **ventaroles** (Wolfgang Karl Hofbauer, pers. comm. 26 July 2021). Natural windholes are made by the wind in sandstone formations as a result of centuries of wind and weather, making the rock formations pock-marked with windholes and caves. In summer, these cool the surrounding area with cool air that blows out, but during winter the air from the windholes is milder than that of the surrounding area (Kong *et al* 2011). These can be categorized as talus (Figure 84), cave (Figure 81-Figure 83), and sink types of windholes. Like caves, these can provide refugia for plants that normally occur at higher elevations or closer to the poles (Kong *et al*. 2012).

Figure 85. *Protochilopsis grandiretis*, an Arctic species that grows in windholes in Austria. Photo by Vadim Bakalin, with permission.

Harald Zechmeister (pers. comm. 26 July 2021) described the windholes in Austria. These have channels that are over 100 m long. This permits them to reach interior temperatures that are just slightly above 0°C, often creating ice cores at the openings that persist through the summer. This favors the growth of Arctic-alpine liverworts like *Protochilopsis* (= *Schistochilopsis*) *grandiretis* (Figure 85), *Odontoschisma macounii* (Figure 86), or *Tritomaria scitula* (Figure 87) at low altitudes. He reports more than 100 bryophyte species associated with the surroundings of approximately 20 windholes.

Figure 86. *Odontoschisma macounii*, an Arctic species that grows in windholes in Austria. Photo from Earth.com, with permission.

Figure 87. *Tritomaria scitula*, an Arctic species that grows in windholes in Austria. Photo by Tomas Hallingbäck, with permission.

Bakalin *et al.* (2017) describe these as formations in East Manchuria of Russia as places where the wind enters large holes tens of meters above, then goes underground, where it passes among wet stones and cliffs in areas with much lower temperatures due to evaporation of water from the stones. Therefore, at the exit hole, the air temperature may be about 10°C below that of the surrounding environment.

In the Wisconsin Driftless Area, USA, Christy and Meyer (1991) similarly reported disjunct species that are restricted to the "refrigerated" windholes (Figure 88). Among these, the tiny moss *Seligeria donniana* (Figure 89) was new to Wisconsin. Among the 39 species of bryophytes identified from four of the largest algific slopes, one third were restricted to these cold air vents. These included the liverworts *Marchantia polymorpha* (Figure 90), *Porella platyphylla* (Figure 91), and *Preissia quadrata* (Figure 92), and the mosses *Abietinella abietinum* (Figure 93), *Anomodon attenuatus* (Figure 94), *Anomodon rostratus* (Figure 95), *Bartramia pomiformis* (Figure 96), *Brachythecium oxycladon* (Figure 97), *Koponeniella*

graminicolor (Figure 98), *Bryoerythrophyllum recurvirostrum* (Figure 99), *Campylium chrysophyllum* (Figure 100), *Ceratodon purpureus* (Figure 7-Figure 10), *Climacium americanum* (Figure 101), *Didymodon fallax* (Figure 102), *Entodon seductrix* (Figure 103), *Eurhynchium hians* (Figure 104), *Hylocomiadelphus triquetrus* (Figure 105), *Mnium marginatum* (Figure 38), *Mnium stellare* (Figure 61), *Plagiomnium cuspidatum* (Figure 106), *Plagiomnium medium* (Figure 107), *Pohlia wahlenbergii* (Figure 56), *Rhodobryum ontariense* (as *Rhodobryum roseum*; Figure 108), *Seligeria campylopoda* (Figure 109), *Seligeria donniana*, *Thuidium delicatulum* (Figure 110), and *Thuidium recognitum* (Figure 111).

Figure 112. *Hylocomium splendens*, a northern species that can be found around windhole vents in Iowa, USA. Photo by Hugues Tinguy, with permission.

Beth Lynch (pers. comm. 29 July 2021) finds a few bryophyte species that are common around the windhole vents of northeastern Iowa, USA (Figure 81-Figure 82), but are very infrequent or absent in the surrounding areas. Presumably due to these microclimatic conditions, *Hylocomium splendens* (Figure 112) and *Hylocomiadelphus triquetrus* (Figure 105) can be relatively common on the algific slopes, but are absent in other cool, moist microsites in the area. It is interesting that, like most caverns, these areas seem to be devoid of leafy liverworts.

Higuchi (1991) reported that the montane mosses *Dicranum elongatum* (Figure 34) and *Pohlia drummondii* (Figure 35) and liverwort *Diplophyllum taxifolium* (Figure 24) occur in windhole areas of the Senpoku-gun in Japan.

The unusual microclimate near the windholes can bring surprises for curious bryologists (Choi *et al.* 2020). Choi *et al.* (2020) found *Mannia fragrans* (Figure 113) and *Mannia androgyna* (Figure 114) in windholes near the Donggang River, the first find of these species in Korea. Borovichev and Bakalin (2016) similarly reported *Mannia triandra* (Figure 115) from the windhole area of Magadan Province and the Korean Peninsula.

Shirasaki (1990) investigated the ecological distribution of bryophytes in the windhole areas of Mt. Naeba, Niigata and Nagano Prefectures, Japan. Shirasaki (1998) found that the moss *Trachycystis flagellaris* (Figure 116) sometimes grows on the ground under shrubs where there are cool sites maintained by windholes that provide a temperature below 10°C and a high air humidity in warmer seasons.

Figure 116. *Trachycystis flagellaris*, a species that grows on the ground under shrubs where there are cool sites maintained by windholes in Japan. Photo by Misha Ignatov, with permission.

Hitoshi and Masaji (2003) found that in the windhole area of Niigata Prefecture, Japan, one could find *Pogonatum urnigerum* (Figure 117) and *Polytrichastrum formosum* (Figure 118) growing together. Elsewhere, *Pogonatum urnigerum* is able to grow at higher elevations than those of *Polytrichastrum formosum*, whereas their distribution on a flat map is similar. *Pogonatum urnigerum* often has caducous leaves, as known in the Arctic (Long 1988) and in northern New York, USA (McDaniel & Miller 2000).

At the Bixby State Park and Preserve in Iowa, USA, Kleinman and Blisard (2018) reported 68 bryophyte species from the algific talus slopes near cold air vents. Of these, 16 moss species and 1 liverwort species are uncommon elsewhere in the Bixby park.

Sinkholes

Sinkholes (cenote, sink, sink-hole, sink hole, swallow, swallow hole, or doline; Figure 119-Figure 121) are large depressions in the ground due to collapse of the underlying substrate. This collapse is often caused by karstic processes that dissolve underlying carbonate rocks.

Figure 119. Sinkhole along Rio Camuy, Puerto Rico, aerial view. Photo from US Geological Survey, through Creative Commons.

Figure 120. Looking out of deep sinkhole at Gouffre-v-hdr in France, showing vegetation at the bottom. Photo through Creative Commons.

Figure 121. Sinkhole with bryophytes in Wilson County, Tennessee, USA. Photo by Brian Stansberry, through Creative Commons.

Linares *et al.* (2017) demonstrated the correlation between drought and the formation of sinkholes. This has occurred repeatedly in the karst of the fluvial valley of northeastern Spain (Figure 122), and it has been widely visible in Florida, USA (Figure 123), due to the emptying of aquifers by water usage and periods of drought.

Sinkholes encompass some of the same characteristics as caves, especially high humidity and reduced light intensity (Maheu 1926). Because they are sunken, they tend to be more moist than the surrounding forest, with humidity increasing toward the base (Maheu 1926; Li *et al.* 2020b). The additional moisture is at least a contributor to lower temperatures. Maheu noted that the same dominant genera of mosses occurred in the sinkholes as in caves: *Anomodon* (Figure 94-Figure 95), *Eurhynchium* (Figure 104), *Mnium* (Figure 38, Figure 61). Perhaps this is in part due to their ease of starting protonemata from stems and leaves of these mosses. Maheu also considered that the protonemata of the mosses could enter in symbiosis with fungi. The modifications in these conditions are likewise similar to those of cave bryophytes: sterility, leaf elongation, longer internodes, elongation of cells, and disappearance or attenuation of the rib or costa.

The sinkhole often has greater bryophyte diversity than does the surrounding surface forest, but it also can increase the diversity of the adjoining forest. Li *et al.* (2020a) reported 71 taxa of bryophytes from a sinkhole forest in southeastern China, whereas the forest at the surface had only 29, and farther from the sinkhole only 22 taxa were present (Figure 124). Furthermore, the sinkholes were more favorable to liverworts, with 22 taxa compared to only 2 in the adjoining surface forest. In this study, 93% of the sinkhole bryophytes were absent from the surface forest. Li and coworkers found that in the sinkholes the dominant families were **Brachytheciaceae** (Figure 75, Figure 104), **Fissidentaceae** (Figure 128), **Plagiochilaceae** (Figure 74), and **Hypopterygiaceae** (Figure 125). The sinkhole bryophytes, by importance, were *Conocephalum conicum* (Figure 126), *Homaliodendron montagneanum* (see Figure 127), *Fissidens cristatus* (Figure 128), *Leucobryum glaucum* (Figure 129-Figure 130), *Makinoa crispata* (Figure 131), *Plagiomnium rhynchophorum* (Figure 132), *Claopodium aciculium* (see Figure 133), *Eurhynchium laxirete* (see Figure 104), *Claopodium gracillimum* (see Figure 133), and *Fissidens hyalinus* (Figure 134). The surface families were completely different, with the exception of **Brachytheciaceae**.

Figure 134. *Fissidens hyalinus* (whitish green), one of the most important bryophytes associated with sinkholes in a sinkhole forest in southeastern China. Photo by Ivanov, with permission.

In the Guda Sinkhole in China, Li *et al.* (2020b) found 75 species of bryophytes. They recorded the highest bryophyte diversity and abundance in the middle and upper sections, with the lowest in the top section and in the base. Furthermore, the most rapid turnover of species occurred in the two middle sections, presumably in response to a rapidly changing gradient of conditions of light and moisture. On the other hand, Vána *et al.* (2014) found the liverworts *Riccardia insularis* (see Figure 135) and *Calypogeia fissa* (Figure 136) on both the floor and wall of a sink-hole cave on Ile Amsterdam in the South Indian Ocean.

Figure 135. *Riccardia multifida*; *Riccardia insularis* occurs in a sink-hole cave on Ile Amsterdam in the South Indian Ocean. Photo by Hermann Schachner, through Creative Commons.

Figure 136. *Calypogeia fissa*, a liverwort that occurs on both the floor and walls of a sink-hole cave on Ile Amsterdam in the South Indian Ocean. Photo by Claire Halpin, with permission.

In the large (280 m deep, 300 m diameter) Monkey-Ear sinkhole in China, Li *et al.* (2018) found 71 species of bryophytes. The greatest diversity was on tree trunks (41 species), followed by forest land > stone surfaces > carrion > leaf surfaces. There are 10 different life forms, 88% of which are typical of dark, humid habitats, whereas only 12% are adapted to bright light and dry conditions. The dissimilarity with surface bryophyte communities is high. Light, humidity, and temperature all influence the distribution of species, but light had the most influence.

In their study of Karst Mountain Sinkhole of Southeastern China, Li *et al.* (2020a) found that the number of life forms diminished from the sink hole to the first forest site and diminished more to the second (farthest) forest site (Figure 137).

Figure 137. Sinkhole vs forest life forms in Karst Mountain Sinkhole of Southeastern China. Modified from Li *et al.* 2020a.

Thus, like caves, sinkholes provide refugia for species that are unable to live in that geographic region outside the sinkhole (Li *et al.* 2020a). Enclosing cliffs reduce the rate of water loss, thus increasing the humidity within the sinkhole. And these same cliffs can contribute to shading that reduces the temperature as well as the light levels. Furthermore, at least in the sinkhole studies in southeastern

China, the nutrients are in greater supply in the sinks (Figure 138), although one would think this would be more beneficial to tracheophytes than to bryophytes.

Figure 138. Soil nutrients in sinkhole forest and two surface forests. Bottom and top sections of the box plots indicate the inner quartile ranges. Horizontal bar within the box represents median. Whiskers indicate spread. Modified from Li *et al.* 2020a.

Rosseló and Ginés (1980), referring to them as potholes, reported 36 species of bryophytes in 23 sinkholes of Mallorca. They considered *Eucladium verticillatum* (Figure 11), *Fissidens cristatus* (Figure 128), *Homalia lusitanica* (Figure 139), *Mnium* sp. (Figure 38, Figure 61), and *Thamnobryum alopecurum* (Figure 140) to be "regular inhabitants." These species are likewise known from caves.

Figure 139. *Homalia lusitanica*, a common species in sinkholes of Mallorca. Photo by Hugues Tinguy, with permission.

Figure 140. *Thamnobryum alopecurum* with capsules, a common species of sinkholes of Mallorca. Photo by David T. Holyoak, with permission.

Ferguson and Knobloch (1998) likewise found a high plant diversity in the Pliocene sinkhole of Willerhausen, Germany. Herrero-Borgonon and Puche (1987) found 26 moss species in the sinkholes of the Valencia region, Spain. In the Apuseni Mountains of Romania, Sass-Gyarmati *et al.* (2009) identified 21 liverwort and 59 moss species in sinkholes, compared to 43 species of *Cyanobacteria* and 50 of lichens.

Sinkholes can often present interesting species that are not found in other habitats of the area and, like caves, may provide conditions suitable for species of more polar or higher elevation habitats (Luo & Zhang 2017). Li *et al.* (2020c) explored the third largest sinkhole in the world – Haolong sinkhole in China. They identified 183 species, of which 26 are endemic to China.

Reyes-Colón and Sastre-D.J. (2000) reported 50 bryophyte species two sinkholes in the north-central karst region of Puerto Rico. They found that the bryophyte flora of the sinkholes was very different from that of the Puerto Rican forests and considered them to be centers for diversity in the area. Pérez and Jesús (2009) reported new bryophyte species from sinkholes in old-growth forest fragments in Puerto Rico. Allred (1998) rediscovered the tiny moss *Fissidens littlei* (Figure 141) in a sinkhole in New Mexico, USA.

Figure 141. *Fissidens littlei*, a rare, tiny moss found in a sinkhole in New Mexico, USA. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Other rare surprises may delight the explorer. In the Alpena, Michigan, USA, limestone sinks, Robinson and Wells (1956) found *Mannia sibirica* (see Figure 113-Figure 115), *Seligeria calcarea* (Figure 142-Figure 143), and *Tritomaria scitula* (Figure 87), all new for Michigan. In all, there were 110 species of bryophytes in six sinks. Later Miller and Vitt (1970) found *Orthotrichum pallens* (Figure 144) in sinkholes in Alpena County – a new species for the eastern part of North America. Priwer (1979) reported that bryophytes were dominant in number of species in these sinks, and that she did not find rare species of tracheophytes.

Figure 142. *Seligeria calcarea* with capsules, a species that occurs in the Alpena limestone sinks, Michigan, USA. Photo by Michael Lüth, with permission.

In New Zealand, *Timmia norvegica* (Figure 145) occupies sinkholes on rock where there is seepage and calcareous detritus over marble (Horton & Bartlett 1983). This species is one of the bipolar species whose distributions are hard to explain.

Figure 145. *Timmia norvegica*, a species that occurs on seepage rocks in calcareous sinkholes in New Zealand. Photo by Hermann Schachner, through Creative Commons.

Cao *et al.* (2020) described the relationship of the bryophytes to the microbial communities of sinks in the Guizhou Province, China. They found 145 species of bryophytes in the sinks, five of which were highly drought tolerant, including *Eurohypnum leptothallum*, *Hyophila involuta* (Figure 146-Figure 147), and *Racopilum cuspidigerum* (Figure 148). They found that both moss species and the karst rocky desertification types affect the microbial communities, but that the moss species had the much stronger effect on the microbial diversity. Bacteria species composition changed strongly between mosses and drought resistance factors. Hence, bryophytes play a strong role in these communities.

Figure 146. *Hyophila involuta* wet, a highly drought-tolerant moss found in karst sinks in Guizhou Province, China. Photo by Bob Klips, with permission.

Figure 147. *Hyophila involuta* dry, a drought-tolerant species that survives on dry vertical rock surfaces. Photo by Bob Klips, with permission.

Figure 148. *Racopilum cuspidigerum*, a highly drought-tolerant moss found in karst sinks in Guizhou Province, China. Photo by Andrew Thornhill, through Creative Commons.

Like so many of the richest bryophyte sites, sinkholes are subject to human disturbance (Liu *et al.* 2019). As refugia, the sinkholes play a crucial role in retaining many rare species, at least at the local level. As you might expect, the number of species in undisturbed sinkholes was considerably higher than in those affected by tourism or farming. Others, sadly, are used as garbage dumps.

Karstification

Karst (type of topography formed from dissolution of soluble rocks such as limestone, dolomite, and gypsum; characterized by underground drainage systems with sinkholes and caves) topography provides a variety of cave-like small and large spaces where bryophyte can live.

Šmarda (1947) recorded the presence of *Distichium capillaceum* (Figure 36-Figure 37) and *Timmia bavarica* (Figure 149) at the bottom of the deep karstic Macocha Chasm in the Czech Republic, thriving in little light but a moist environment with basic soil.

Figure 149. *Timmia bavarica*, a species that grows at the bottom of the deep karstic Macocha Chasm in the Czech Republic. Photo by Hugues Tinguy, through Creative Commons.

Jia *et al.* (2014) explored the role of karst bryophytes and their local occupancy. They found 33 bryophytes in their study area in a Guizhou mountain area of China. In

particular, they found that bryophytes were important in storing water, becoming saturated at 849-1474% of dry weight. Soil absorption ranged 464-1025%. Furthermore, they absorbed the heavy metals Pb, Zn, and Cd, with concentrations 2.25, 3.98, and 2.49 times that in their substrates, respectively. The concentrations in the bryophytes were not significantly correlated with that in their substrate. The researchers concluded that bryophytes had an important role both in providing a water reserve and in absorbing heavy metals from automotive exhaust. The water absorption helps to stabilize the road slopes in the karst area. Wu *et al.* (2019) described the vertical distribution of the **Hypopterygiaceae** and the environmental factors influencing that distribution in a karst sinkhole in China.

Bryokarst

That's right. Bryophytes contribute to karstification (Meng *et al.* 2019). Meng and coworkers explained that bryophytes can act as physical forces, including expansion, curling, freezing, and thawing (Figure 150-Figure 151). These are most evident under alternating wet and dry conditions and can destroy rock. They also can destroy rocks through metabolic secretions and the H_2CO_3 formed using the CO_2 expelled in respiration.

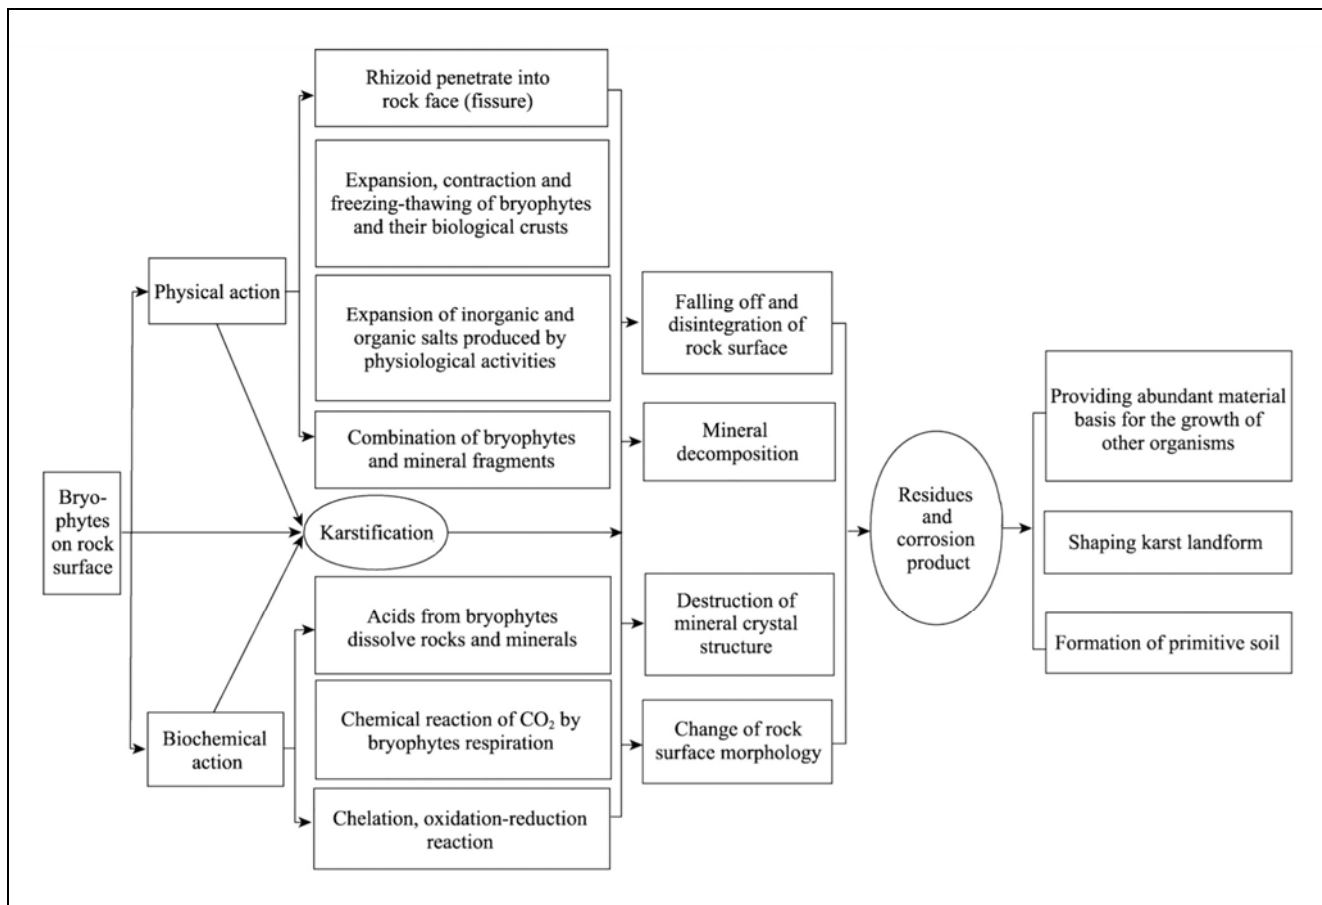

Figure 150. Flowchart showing bryophyte role in karstification. Mosses on the rock surface use physical and biochemical action to destroy and corrode the rock, change the rock surface morphology, and form the karst microtopography. The dissolved products are deposited to form the original soil. Modified from Meng *et al.* 2019.

Figure 151. Three-way circulation interaction modified from Meng *et al.* (2019). The bryophytes, environmental factors, and rock promote and restrain each other in the karstification process. The environmental factors and rock affect the karstification process and its efficiency by controlling the community characteristics, morphology, physiological processes, genes, and other bryophyte factors. The resulting lithology, composition, occurrence of rock, and the improvement of the bryophytes on the rock surface microhabitat (temperature, humidity, light, soil fertility, microbes) are closely related to the rate of karstification.

Zhang *et al.* (1996) described four types of **bryokarst** deposition from caves (drop bryophytes-tufa, waterfall bryophyte-tufa, seasonal river bryophyte-tufa, and phototropism bryophytes-scale) in the Huangguoshu area of China, based on light, water availability, and bryophyte growth. They also identified four forms of bryophyte corruptions: corrosional hole, corrosional spot, corrosional block, and corrosional filament. These caves had 59 species of bryophytes in 43 genera.

Pentecost (1987) enumerated the annual growth rates of some mosses associated with tufa formation: *Palustriella commutata* (Figure 152), 1-4 mm; *Eucladium verticillatum* (Figure 11), 2-3 mm; *Hymenostylium recurvirostrum* (Figure 153-Figure 155), 1-3 mm; *Platyhypnidium riparioides* (Figure 156), *ca.* 30 mm. Pentecost (1996) followed this study with one on the role of photosynthesis vs other factors in the karstification process. *Palustriella commutata* and *Eucladium verticillatum* both deposited 6-12% of the carbonate through photosynthesis. In addition, 10-20% was deposited through evaporation and 70-80% through gas evasion.

Lyons and Kelly (2020) pointed out the paucity of knowledge regarding deposition rate of tufa or the growth rates of involved bryophytes living in petrifying springs. Using fixed bar markers, they measured the heights of bryophytes at six petrifying springs in Ireland. They found that tufa deposits increased $20.5 \pm 1.1 \text{ mm yr}^{-1}$. The moss *Palustriella commutata* (Figure 152) worked together with the surface water to increase the annual deposition of tufa by $5.7 \pm 1.9 \text{ mm}$. Unvegetated tufa achieved a growth of only $16.5 \pm 3.0 \text{ mm yr}^{-1}$. Thus, with an annual growth of $27.6 \pm 1.9 \text{ mm}$, *Palustriella commutata* outgrows the unvegetated tufa growth. The smaller mosses *Didymodon tophaceus* (Figure 157-Figure 158) and *Eucladium verticillatum* (Figure 11) grew only $9.1 \pm 1.6 \text{ mm yr}^{-1}$ and $9.5 \pm 1.3 \text{ mm yr}^{-1}$, respectively, thus being less important in tufa formation; they were typically displaced by *Palustriella commutata* through competition.

Figure 158. *Didymodon tophaceus*, a tufa moss that grows at a mean of $9.1 \pm 1.6 \text{ mm yr}^{-1}$. Photo by David T. Holyoak, with permission.

Waterfall Caves

Waterfalls often fall over ledges, creating a curtain in front of shallow caves. These caves are typically shaded and moist, with rock surfaces (Figure 159).

Figure 159. Waterfall in West Virginia, USA, with bryophytes and ferns growing on the ledges behind the water. Photo by Eileen Dumire, with permission.

I have seen *Conocephalum* (Figure 126, Figure 160-Figure 161) species several times in the shallow caves behind waterfalls (Figure 162). Although these were usually named as *Conocephalum conicum* (Figure 126) in North America, we have recently realized that these are really *Conocephalum salebrosum* (Figure 160-Figure 161), a species with much larger thalli than those of the former. This habitat occurs in the Keweenaw Peninsula of Michigan, USA, and at Hocking Hills, Ohio, USA. The latter also has a number of small caves where the species is abundant.

Figure 162. Scot Falls, Michigan, USA, with cave behind waterfalls. Bryophytes occur on the ceiling of the cave. Photo by Janice Glime.

Higuchi *et al.* (2020) reported *Fissidens geminiflorus*, *F. nobilis* (Figure 163), and *Timmiella anomala* (Figure 164) on wet stones in a cave behind a waterfall in Cambodia.

Figure 163. *Fissidens nobilis*, a moss that lives on wet stones behind a waterfall in Cambodia. Photo by Janice Glime.

Figure 164. *Timmiella anomala*, a moss that lives on wet stones behind a waterfall in Cambodia. Photo from Earth.com, with permission.

Natalie Cleavitt found *Haplodontium macrocarpum* (Figure 165) in Mountain Park, Alberta, Canada, where it occurs on the underside of overhangs associated with ephemeral waterfalls (Dale Vitt, pers. comm. 4 August 2021).

Figure 165. *Haplodontium macrocarpum* on cave wall, a species that also occurs under overhangs of ephemeral waterfalls. Photo by René J. Belland, with permission.

Townsend (2006) reported *Epipterygium tozeri* (Figure 166) from Kenya in a cave behind a waterfall.

Figure 166. *Epipterygium tozeri*, a species that grows in a cave behind a waterfall in Kenya. Photo by Hugues Tinguy, with permission.

Other Bryophyte Roles

Building and destroying cave formations are not the only roles of bryophytes in caves. They increase the diversity of stalactites and stalagmites (Mulec 2018). They can be diversity hotspots. Bryophytes increase the loss of water by 81.2 times and absorption by 8.1 times, the highest compared to the algae (18.8 and 1.6) and lichens 2.9 and 19.1) (Cao & Yuan 1999). Bryophytes also prolong the period of water loss by 610%, but do not extend the period of absorption. This improves the water holding by 57.2 times! This increases the activity of the carbon cycle on the rock surface, affection rates of corrosion under the growths.

Pentecost (1999) notes the importance of bryophytes, along with algae, in stabilizing ephemeral sand ripples on steep rock surfaces in the UK. Fu and Zhang (2010) identified four types of bryophyte erosions on limestone: erosional fusion, erosional plaques, erosional bands, and erosional blocks.

Ren *et al.* (2010) found that the rare and endangered flowering plant *Primulina tabacum* (Figure 167) is found

only at cave entrances of a small number of karst caves in southern China. The researchers transplanted small plants of this species to several new cave entrances. The only seedlings that survived were associated with the moss *Gymnostomiella longinervis* (Figure 168), performing well under the cover of the moss. It appears that the moss nurse plant is necessary for the success of *P. tabacum*.

Figure 167. *Primulina linearifolia* × *Primulina tabacum*; *Primula tabacum* seems to require the moss *Gymnostomiella longinervis* to be successful in karst cave entrances. Photo by Kenpei, through Creative Commons.

Submerged cave bryophytes can serve as substrate for the diatom *Pinnularia borealis* (Figure 169) (Czerwik-Marcinkowska *et al.* 2019). The cyanobacterial *Gloeocapsa atrata* (Figure 170) occurs frequently on

mosses on wet cave wall rocks in the Glowoniowa Nyża Cave. The latter species can contribute to nitrogen fixation, thus increasing the levels of usable nitrogen in the cave.

Cave Fauna Interactions with Bryophytes

Galas *et al.* (1996) found that the decay rates of two seed plants and of moss were all slow in a mountain cave in the Tatra Mts., Poland. They attributed this slowness to the absence of large shredders in the cave. The energy released through respiration by microorganisms on the moss was higher than that released from microorganisms on sorb and alder litter.

Cao and Yuan (1999) reported that the water holding by evaporation of carbonate rock increases 81.3 times and water absorption by 8.1 times for mosses compared to relative fresh rock samples. The amount of water holding by the rock improves 57.2 times with mosses on them.

Copepods

In Japan, Iwatsuki and Ueno (1959) found the fern *Cyrtomium fortunei* (Figure 171) and moss *Fissidens geminiflorus* (see Figure 128, Figure 134, Figure 141, Figure 163) to be dominant, sometimes obtaining a "full growth." They also found cave fauna that associated with the mosses, including the harpacticoid copepod *Bryocamptus zschokkei* (Figure 172), the latter occurring in a carpet of *Fissidens geminiflorus*.

Figure 172. *Bryocamptus zschokkei*, a harpacticoid copepod associated with mosses in caves in Japan. Photo by Joe Connolly, through Creative Commons.

Stoch (2000) reviewed the aquatic fauna of caves in northern Italy, including some that are part of the bryophyte fauna. Watiroyram *et al.* (2012) found 11 species of the copepod *Bryocyclops* (Figure 173) from wet mosses in caves.

Figure 173. *Bryocyclops* sp.; 11 species in this genus occur among mosses caves in Italy. Photo by Watiroyram, S., through Creative Commons.

Tardigrades

One of the best places to look for tardigrades is nestled among the leaves of bryophytes. Cave-dwelling tardigrades are no exception to that (Bartels & Nelson 2007). This affinity for bryophytes, particularly mosses, includes a special adaptation for feeding on the mosses [Tardigrada (Water Bears) 2005]. Members of *Echiniscidae* are adapted to this mode of living by having a long stylet that can penetrate the moss cell wall and suck out the cell contents. In addition to eating moss cell contents, the bryophyte dwellers might eat epiphytic diatoms and bacteria from the moss surface.

Insects

In addition to the copepod, Iwatsuki and Ueno (1959) found the troglophilous fly *Exechia* sp. (fungus fly; Figure 174) associated with the mosses in a cave in Japan.

Figure 174. *Exechia fusca* adult, a fungus fly similar to those that occur with mosses in a Japanese cave. Photo by Jostein Kjaerandsen, through Creative Commons.

Even in Death Valley, California, USA, caves can serve as a refuge for insects. Hungerford (1917) reported the true bug *Mesovelius mulsanti* (Figure 175) from among mosses in a hot spring cave. Later, Polhemus and

Chapman (1979) reported *Mesovelia amoena* (Figure 176) on moss-covered rocks in hot spring caves, also in Death Valley. This species is parthenogenetic in Hawaii, a trait that might make reproduction easier in caves. Kamp (1970) reported cave grasshoppers that were associated with bryophytes in caves in the western United States.

In icefields, ice bugs (*Grylloblattodea*) lay their eggs in the soil or mosses (Ramel 2015). They hide under stones during the day and prefer low temperatures. These insects also occur in caves in Korea. These insects are extremophiles. In the Oregon Caves in the Klamath Mountains of Oregon and California, USA, Schoville (2012) found three new species of *Grylloblattodea*: *Grylloblatta oregonensis* (Figure 177), *G. siskiyouensis*, and *G. marmoreus*. This species occupies the dark zone and twilight zone of caves. Their relationships to the bryophytes in the caves is not known, but they may have the same uses for egg laying as members of the genus found in Korea.

There are two tiphiid wasp species (*Tiphia andersoni* and *T. nona* – see Figure 178) that are able to hibernate beneath rocks surrounded by mosses in caves (Wynne 2013). Moss gardens in lava tubes have the most developed bryophyte communities (Lindsey 1951) and present a biologically unique bryophyte community (Lightfoot *et al.* 1994; Wynne 2013). This includes a high arthropod biological diversity (Wynne 2013).

Figure 178. *Tiphia* sp. Several species in the genus hibernate beneath rocks surrounded by mosses in caves. Photo by XPDA, through Creative Commons.

Other Arthropods

Importantly, this habitat has been identified as supporting at least two presumed relict species (Lightfoot *et al.* 1994, this paper) and high arthropod biological diversity (Wynne 2013).

Benedict (1979) found that the pseudoscorpion *Apochthonius forbesi* (see Figure 179) benefits from the mossy litter layer in sinks in Oregon, USA. This species was described as a new species based on populations in a lava tube sink where it lived at the cold air trap that

retained permanent ice but a mossy litter layer. *Syarinus* (Figure 180) was an accompanying species in this habitat.

Figure 180. *Syarinus* sp.; a species in this genus of pseudoscorpion accompanies *Apochthonius forbesi* in lava tube sinks with permanent ice and a mossy litter layer. Photo by P. M. Brousseau, through Creative Commons.

Wynne and Shear (2016) found a new millipede species, *Austrotyla awishoshola* in "cave moss gardens" in New Mexico, USA. The millipedes need mesic conditions, and these are limited in these caves to locations with mosses. As is the case for mosses, the caves serve as refugia for insects and other fauna that found refuge here following the end of the more moist Pleistocene. Such refugia are known in other parts of the world where mosses have become the restricted environment for relict species (Benedict 1979; Wynne *et al.* 2014).

For the invertebrate cave fauna, the bryophytes provide opportunities for a high diversity. They are also home to the relict spider *Lepthyphantes turbatrix* (Figure 181) (Wynne 2013).

Figure 181. *Lepthyphantes turbatrix*, a spider that uses cave mosses as a home. Photo by Tom Murray, through Creative Commons.

Salamanders

Some salamanders are especially adapted to cave living. Others benefit from the cooler, more moist conditions. Gorman and Camp (1953) found the new species *Hydromantes shastae* (Figure 182-Figure 183) under a mossy log at a cave entrance in California, USA. The salamander *Aneides aeneus* (Figure 184) is known to eat mosses (Lee & Norden 1973), although it may just be the result of foraging there for ants and spiders. This salamander has occurred in Bat Cave in Rutherford County, North Carolina, USA, and is also known from Cooper's Rock, West Virginia, where small caves or cave-like habitats can occur among the rocks.

Frogs

In the borderland between Venezuela and Brazil, Myers and Donnelly (1997) found the frog *Eleutherodactylus cavernibardus* (*cavernibardus* means cave singer; see Figure 185) calling during the day in local caves formed by granite boulders or on mosses. It is likely that the frogs use both of these habitats.

Figure 185. *Eleutherodactylus planirostris*; *Eleutherodactylus cavernibardus* calls from mosses in caves. Photo by Todd Pierson <www.discoverlife.org>, with permission.

Angulo *et al.* (2003) reported *Stefania riae* in a sinkhole at Sarisariñama tepui in Peru. The habitat lacked either flowing or standing water, but the walls of rocks, crevices, and caves were moist and mossy, presumably providing moisture for the frogs, as suggested by Barrio-Amorós and Fuentes (2003).

Reptiles

Little seems to be known about the role of bryophytes for cave reptiles. Storey (2006) reported that reptiles seek refuge in winter in locations such as caves, burrows, grass, or moss hummocks. It might be worthwhile to look for some of the smaller reptiles among the cave mosses in winter. If nothing else, the mosses might be a source of invertebrate food. I wonder if lizards and snakes find the older sinkholes in Florida suitable.

Birds

Even birds can benefit from bryophytes in caves. In Brazil the White-collared Swift [*Streptoprocne zonaris* (Figure 186)] typically breeds in wet caves next to waterfalls (Figure 187) (Biancalana 2014). Nests are made mostly of bryophytes (Figure 188). The birds returned to the same nest sites in subsequent years.

Figure 188. *Streptoprocne zonaris* on nest made of mosses. Photo by Sesernam, through Creative Commons.

On the young island of Surtsey, Iceland, a Herring Gull-Glaucous Gull hybrid pair [*Larus argentatus* (Figure 189) - *Larus hyperboreus* (Figure 190)] nested in a small collapsed cave, using primarily the moss *Racomitrium* (Figure 31-Figure 32) as nesting material (Olafsson 1982). When a Berlese funnel was used to search the nest for arthropods, only a single specimen, that of an **acarid** (mites & ticks) was revealed.

Figure 189. *Larus argentatus*; a hybrid of this species uses *Racomitrium* as nesting material in the volcanic island of Surtsey, Iceland, in a collapsed cave. Photo by Kulac, through Creative Commons.

Figure 190. *Larus hyperboreus* and offspring; a hybrid of this species uses *Racomitrium* as nesting material in the volcanic island of Surtsey, Iceland, in a collapsed cave. Photo by A. Weith, through Creative Commons.

The Biscutate Swift (*Streptoprocne biscutata*; Figure 191) has been studied at its home in a cave in the Paraná State, southern Brazil (Pichorim 2002). The birds use bryophytes, among other plants and lichens, to build its nests. When the birds are nesting in the cave, the cave floor has abundant moss and lichen fragments. The birds collect these materials for nesting and at times even pull pieces of bryophytes from the vertical wall. The unusual observation was that they appeared to chew the fragments soon afterwards. Observations of a viscous substance in the moss fragments in the nests suggest that the chewing was practiced to add the saliva. Fragments in the nests included the liverworts *Frullania brasiliensis* (Figure 192) (most common – 14 of 23 nests), *Herbertus* sp. (Figure 193), *Lejeunea flava* (Figure 194), *Omphalanthus filiformis* (Figure 195), *Plagiochila* sp. (see Figure 74), and *Plagiochila rutilans* (see Figure 74), and the mosses *Campylopus* sp. (see Figure 196), *Campylopus aemulans* (Figure 196), *Leucobryum crispum* (Figure 197), *Leucoloma* sp. (Figure 198), *Macromitrium punctatum* (Figure 199), *Phyllogonium viride* (Figure 200), *Polytrichum juniperinum* (Figure 47-Figure 48), *Porotrichum longirostre* (see Figure 201), *Rhacocarpus* sp. (Figure 202), *Schlotheimia rugifolia* (Figure 203), *Schlotheimia tecta* (Figure 204), *Sematophyllum subpinnatum* (see Figure 205), *Squamidium leucotrichum* (Figure 206), *Syrrhopodon prolifer* (Figure 207), and *Zelometeorium recurvifolium* (Figure 208).

Mammals

Several mammals use caves as their dens. The bear has perhaps the most influence on the bryophytes. The brown bear (*Ursus arctos*; Figure 209) includes mosses to line its den (Czerwik-Marcinkowska *et al.* 2019). This can bring moss spores and fragments into the cave for possible establishment and growth there.

Figure 209. *Ursus arctos* (brown bear) running, a species that uses mosses to line its den in caves. Photo by Malene Thyssen, through Creative Commons.

Sampling Methods

Bryophyte sampling methods have varied among researchers. Many researchers sought only to document the flora, with no attempt to quantify species. Li *et al.* (2020a) used 8 plots, 10 x 10 m, in each section of a sinkhole, totalling 80 plots. In addition to assessing the bryophyte flora, they measured depth, pH, light level, humidity, temperature, and slope, making it possible to find correlations.

Although caves have more constant conditions than those found outside the cave, conditions nevertheless vary between caves and within the caves. Poulson and Culver (1969) measured evaporative rate, substrate moisture, substrate organic content, predictability and stability of food and microclimate, substrate diversity, and intensity of flooding in Mammoth Cave, Kentucky, USA. They found that arthropod diversity exhibited significant correlations with substrate diversity, substrate organic content, and intensity of flooding. To this list, light intensity must be added for photosynthetic organisms, and even for some cave animals. Thus it is instructive to measure these conditions.

Nakanishi (2002) established 14 quadrats in a light intensity gradient. The quadrats were 20 x 20 cm and restricted to clayey soils; they assessed the bryophytes using the Braun-Blanquet method.

Pakeman *et al.* (2019) used Attribute values based on the Ellenberg values (see Schaffers & Sýkora 2000) to describe the nitrogen, light, and moisture in bryophyte habitats in Scotland. These have been used in some cave studies for similar purposes.

Summary

Cave-like conditions are present in a variety of landforms. Among these are mine shafts, subways, fissures, minicaves among rocks and at the base of boulders, among scree, ice caves, windholes, sinkholes, behind water falls, and in animal burrows. These differ in available light, substrate, moisture, nutrients, pH, and toxic substances such as pollutants.

Mine shafts are often vertical structures with light diminishing with depth. The exposure of the substrate to the ore being mined can be a toxic factor. There are few published records of bryophytes in mines, but the presence of the ubiquitous *Ceratodon purpureus* is a not surprising find.

Subways are typically well lit and may have some of the same species as caves. Because the subway age is known, it can provide a suitable laboratory for studying colonization rates.

Small fissures often support surface bryophytes due to their collection of nutrients and soil and a greater moisture-holding ability than the rock surface. Larger fissures as found in lava fields, geothermal areas, and some large rock formations may support bryophytes for a short distance into the fissure, again dependent on light, moisture, and substrate type. Such fissures offer protection from direct sun, reducing sun bleaching, photoinhibition, and drying.

Among the lava rocks and fissures one can find *Saelania glaucescens*, *Distichium inclinatum*, and *Schistostega pennata*, but much more study is needed to relate the bryophyte species to the cave-like locations vs the surface locations. The scree presents a similar problem, although there are more studies that list species found there. Despite the shallowness of its caves, they can provide cool refugia in otherwise hot, dry, exposed fields of rock.

Ice caves typically do not support bryophytes, but *Heterocladium heteropterum* and *Cyrtomnium hymenophylloides* are known in ice caves. On the other hand, the cool air from these caves, especially in summer, can alter the climate and bryophyte composition outside the cave. Windholes have similar effects, providing a cool cave, but also cooling the area near the cave. These cool refugia permit Arctic species to live at much lower latitudes, occurring there as disjuncts.

Sinkholes have much in common with caves, including low light and usually greater moisture. However, they experience seasonal changes much like the surrounding forest. They have many species on their walls that coincide with those in caves. Their responses to these conditions are similar to those of bryophytes in caves: sterility, leaf elongation, longer internodes, elongation of cells, and disappearance or attenuation of the rib or costa. The protection provided by the sinkhole can result in a greater species diversity than that found in the surrounding forest.

Karstification is a process of dissolution of soluble rocks, characterized by underground drainage systems with sinkholes and caves. Bryophytes can play a role in the process, creating stalactites and stalagmites by the accumulation of CaCO₃ around some bryophyte

species, particularly accomplished by *Eucladium verticillatum*. The bryophytes can also destroy rock formations by exuding organic acids or holding water that makes breakdown of the rock easier.

Waterfall caves maintain a moist habitat while reducing light intensity. They seem to be an especially suitable habitat for some *Conocephalum* species. There are probably many records for this habitat, but they are often embedded in studies of the larger area without specific separation of the cave area.

Bryophytes in caves can serve various roles for the cave fauna. For copepods, tardigrades, insects, and other arthropods, they provide cover and moisture and sometimes food. Salamanders may forage there or sometimes use the bryophytes for cover and moisture conservation. Frogs can use them as calling locations and sources of moisture. Reptiles can occasionally be found there. Birds use them for nesting material, as do some mammals, especially bears.

Cave sampling is useful to determine gradient effects on species composition. This sampling typically uses quadrats (plots) of 10 x 10 cm or larger. A distance transect is useful for assessing gradient effects. It is useful to measure both physical and chemical parameters along these transects.

Acknowledgments

Many Bryonettors responded to my call for images for this chapter. They especially contributed to my coverage of sinkholes. Thank you to our Chinese colleagues (Wen Ye, Xinlei Guo, Yang Liu, Xiaoming Shao, and Wang Zhe) who responded to my request for the English translation of the abstract of a Chinese study.

CHAPTER 1

HOUSEHOLD AND PERSONAL USES

Figure 1. Mosses being sold along with fruits and vegetables in a marketplace in China. Photo courtesy of Eric Harris.

Household Uses

I think every bryologist must have been asked "what good are they?" The small size, difficult taxonomy, and inconspicuous position in the ecosystem of bryophytes have caused most people to ignore bryophytes. Nevertheless, the rate at which bryophytes are being harvested from some of our national forests in North America and elsewhere suggests they are useful for something. In the high mountains of Malaysia, simply collecting mosses as a novel pillow filler (Kuen 2002) has caused vast areas of bryophyte destruction in a pristine forest. In New Zealand the small number of peatlands is diminishing from horticultural usage. In the southeastern United States, sheet mosses are removed by the truckload, and in the Pacific Northwest epiphytes are disappearing from old growth forests.

Although *Sphagnum* (Figure 3) seems to be the most commonly used bryophyte, it is not the only moss with

endearing, and enduring, qualities. Including all the known uses of bryophytes, Harris (2008) found that the most commonly mentioned uses of bryophytes are those of *Marchantia* (Figure 2), *Sphagnum* (Figure 3), and *Polytrichum* (Figure 10). Other genera used in more than two countries are *Conocephalum* (Figure 4), *Climacium* (Figure 64), *Hylocomium* (Figure 16), *Hypnum* (Figure 5), *Rhytidiadelphus* (Figure 17, Figure 118), *Thuidium* (Figure 22, Figure 42), *Antitrichia* (Figure 104, Figure 111), *Bryum* (Figure 6), *Dicranum* (Figure 13), *Fontinalis* (Figure 75), *Funaria* (Figure 89), *Philonotis* (Figure 7), *Pleurozium* (Figure 45-Figure 46), and *Rhizomnium* (Figure 8).

Durability and elasticity may have contributed to the Japanese use of *Hypnum* (Figure 5) to stuff balls and dolls (Pant & Tewari 1990). Others have used them for stuffing upholstery and hassocks (Thomas & Jackson 1985).

Figure 8. *Rhizomnium magnifolium*, a moss in a genus used in more than two countries. Photo by Janice Glime.

Robin Stevenson (pers. comm.) shared his surprise at finding a reference to moss use in the "Rough Guide to Moscow." "One of the main roads in central Moscow, which runs parallel to the Kremlin Gardens, separating them from the Lenin Library and the Arbat district, is Mokhovaya ulitsa or Moss Street. So named, apparently, because this is where moss (mokh) was formerly sold. This

moss was used as a caulking material for filling in chinks in wooden buildings, a use which is pretty well documented. However, it was also sold to put between the panes of glass in double-glazed windows."

Clearly, the use of mosses is not just a tale from the past (Welch 1948; Ando 1957, 1972). In the USA today, there are about 200 "mossers" (moss growers) (Epstein 1988), a testimony that the industry has not outlived its usefulness. The Chinese continue their tradition of using mosses and other herbals in medicines and food (Figure 1).

Furnishings

Imagine yourself in a remote village where there are no grocery stores and the nearest mall is 100 miles away by horseback. Villagers carry water on their heads, cushioned by a sirona, and bags of fruits wrapped in native moss. In your hut, you protect a fragile souvenir in a gentle bed of moss. Your mattress and pillow are stuffed with mosses. Mosses collect urine from pigs in the stall. And your child plays with a hand-made doll stuffed with moss. In these conditions, mosses take on an important role in your daily life.

In fact, mosses seem to be useful in maintaining structural integrity in a variety of materials. Siberian Eskimos roll up skins and freeze them into the shape of a sled runner (Figure 9), which they cover with a moss/water mix to protect the skins, smoothing them as they shape them onto the runners (R. Seppelt, pers. comm., based on "Man on the Rim" documentary; Wikipedia 2017). This makes a smoother ride.

Figure 9. Qamutiik with moss and ice on runners. Photo by Adolphus Greeley, through public domain.

In India, mosses are used for door covers and smoke filters (Pant 1989) and the pharki – a door mat (Glime & Saxena 1991). In Sweden, *Polytrichum commune* (Figure 10) has likewise been used as a doormat (Hedenäs 1991). Their use as kindling is surely still valuable to campers (Thomas & Jackson 1985). Both *Neckera crispa* (Figure 11) and *N. complanata* (Figure 12) have been used as bedding in Europe (Dickson 2000).

In some places, the past mixes in strange ways with the present. Among the Inuit at Pangnirtung in the Canadian North, electrical lines run to summer tents to power electric guitars while the tent is heated by ancient kudliks that burn

with a wick of moss (Crowe 1974). A number of mosses make ideal lamp wicks: *Dicranum elongatum* (Figure 13) by the Cree Indians, *Racomitrium lanuginosum* (Figure 14) by Labrador Eskimos (Bland 1971), and, of course, *Sphagnum* (Figure 3) (Crum 1988).

Figure 14. *Racomitrium lanuginosum*, a species used by the Cree Indians as a lamp wick. Photo by Janice Glimme.

A rather unique new use is to create tables using mosses as photovoltaic cells (Figure 15) (Chandler 2012). Bio-Photo-Voltaic (BPV) technology strives to make use of biological materials to trap light energy and convert it to a usable form. The table has a futuristic look with more than 100 round cells with growing mosses in them and a lamp at the edge. The moss is not yet able to power the lamp, but it can power a small clock. Currently it can produce about 520 Joules (J) of energy per day – enough to power a laptop for 20 seconds!

Figure 15. Moss pots as photovoltaic cells. Photo from The hidden power of moss, through Creative Commons.

To create the power in the table, the mosses convert carbon dioxide, using sunlight, to create organic compounds (Biophotovoltaics 2015). Some of these compounds are released into the soil where bacteria break them down and free by-products, including electrons. Conductive fibers inside the moss table capture these electrons and can use them, generating a potential of 0.4-0.6 volts (V) and a current of 5-10 microamps (μA).

Padding and Absorption

The absorbent properties and abundance of *Sphagnum* (Figure 3) make it the most used taxon among the bryophytes (Densmore 1928). The Chippewa Indians in North America used it as an absorbent. It serves as an insulator, as pillow, mattress, and furniture stuffing, to keep milk warm or cool, to stuff into foot mats for cleaning shoes, to weave welcome mats, and in Lapland to line baby cradles, keeping the infant clean, dry, and warm (Stark 1860).

Mosses were sold on Moss Street in Moscow to put between the panes of glass in double-glazed windows, to absorb condensation (Robin Stevenson, pers. comm.). A colleague of mine used lichens (*Cladina*) similarly between the inner window and the storm window for the same purpose.

And Anders Hagborg (Bryonet 11 June 2016) shared his experience with that very use. He remembers in his childhood in Sweden it was common practice to put mosses between the storm window and inside window to absorb the moisture from condensation on the cold glass in winter. He thinks this moss may have been *Sphagnum* (Figure 3).

In Germany, *Sphagnum* (Figure 3) has been used in hospitals as neck and head rests, to support hips and backs, and to elevate the legs of wounded people (Hotson 1921). On the farm it is particularly good for absorbing urine from livestock and pets, a function shared with *Hylocomium splendens* (Figure 16), absorbing up to 55%, *Rhytidiadelphus squarrosus* (Figure 17) 33%, and *Pseudoscleropodium purum* (Figure 18) 6%. And even the Romans used it for toilet paper (Birks 1982)! In the laboratory *Sphagnum* prevents red-leg in frogs, in part by absorbing the urine. In the Philippines, the crocodile breeding station uses peat moss as a cushion or layering material for incubation of crocodile eggs (Tan 2003).

Mattresses

Mosses have been used for sleeping for a long time. Dickson (2000) reported that mosses, especially *Neckera crispa* (Figure 11), were used for mattresses during the Bronze Age.

The Potawatomi Indians in North America used *Sphagnum* (Figure 3) species as fibers for rugs, mats, and bedding (Smith 1933). In the North Central States, USA, the Ojibwe Indians have used dried *Sphagnum dusenii* to make mattresses (Smith 1932).

In parts of the Malay Peninsula, *Leucobryum* (Figure 19) is used together with *Campylopus* (Figure 20) to stuff cushions and mattresses (B. C. Tan, pers. comm.). Burkill (1966) likewise reported that *Calymperes* (Figure 21), *Campylopus* (Figure 20), and *Sphagnum* (Figure 3) are used for stuffing mattresses in Malaysia.

Earlier uses of mosses to stuff mattresses are known from Carlisle, UK, where Woodward (1996) reported that 86 horseloads of moss were delivered to Council in 1584. One of the uses was for bedding as a form of down. Woodward contends that harvesting of mosses and other natural materials was more important in early modern society than we typically realize, providing significant employment for the poor of the land. A load of mosses brought 4 [old] pence.

Figure 21. *Calymperes* sp, a genus used for stuffing mattresses in Malaysia. Photo by Niels Klazenga, with permission.

Table 1. Comparison of weight gain measured as wet weight to dry weight ratio of selected bryophytes (Horikawa 1952).

<i>Atrichum</i>	6.9
<i>Barbula</i>	8.3
<i>Bazzania pompeana</i>	4.0
<i>Haplomitrium mnioides</i>	12.0
<i>Hylocomium cavifolium</i>	9.8
<i>Plagiomnium maximoviczii</i>	6.7
<i>Rhodobryum</i>	10.0
<i>Sphagnum</i>	12.4
<i>Trachycystis microphylla</i>	3.2

In the Azores, *Thuidium tamariscinum* (Figure 22), *Pseudoscleropodium purum* (Figure 18), and *Hypnum cupressiforme* (Figure 5) were used to stuff pillows and mattresses (Allorge 1937). In fact, *Hypnum* was so popular as a pillow stuffing that Dillenius (1741) chose *Hypnum* as its name because of its association with sleep (sleep, from Greek *hypnos*). And Linnaeus copied the bears that sleep among mosses, choosing *Polytrichum commune* (Figure 10) for bedding (Crum 1973), stating that if a quilt could be made of it, nothing could be more comfortable (Black 1979). Both humans and domestic animals have enjoyed the comfort of a moss bed, with the absorptive ability serving an additional function for the animals (Ando & Matsuo 1984). And for all, mosses such as *Brachythecium* (Figure 23), *Dicranum* (Figure 13), *Hypnum* (Figure 5), *Neckera* (Figure 11-Figure 12), *Papillaria* (Figure 24), and *Thuidium*, add the advantages of being insect-repellent and resistant to mold (Pant & Tewari 1989).

Figure 22. *Thuidium tamariscinum* with capsules, an insect-repellant moss used to stuff mattresses and pillows. Photo by Michael Lüth, with permission.

In 1868, Albert G. Morey applied for a patent for an "improved mattress." "Be it known that I, ALBERT G. MOREY, of Chicago, in the county of Cook, in the State of Illinois, have invented a new and useful Improvement in the Construction of Elastic Mattresses or Cushions..." The improvement appears to be the use of layers, with the bottom layer being moss, the middle layer of woody fiber or excelsior, and the top layer of elastic sponge. This sponge was not the synthetic sponge we know today, but the real animal, dead of course. "The object of my invention is to furnish an elastic mattress for beds, or cushion for seats, which, while possessing the peculiar qualities of the sponge mattress or cushion, shall yet be afforded at a less cost."

Figure 23. *Brachythecium rutabulum*, in a genus of insect-repellant mosses used in bedding. Photo by Michael Lüth, with permission.

Shower Mat

A modern use of mosses for absorption is that of Swiss artist/designer La Chanh Nguyen (Nguyen 2014; Telegraph.Co.UK 2009). She used 70 pieces of forest and island moss in cushions 6 cm in diameter to make a bath mat. Each piece is placed in a foam frame to prevent the moss from spreading. She reveres its softness underfoot and lack of unpleasant odor, claiming that it is relaxing and requires little care. Now she is looking for financial backing so she can mass produce it at less than the £220 it cost her to make her own.

But all may not be rosy with this special mat. Bryonettors (Bryonet-L@mtu.edu) quickly expressed their concern about conservation issues and the unlikelihood that the moss would survive indoors in low light. They suggested that most likely it looks alive, when it is really dead.

Such concerns aside, Winter (2014) shares her advice in **making a moss shower mat**. It is her perspective that these mats help you to make the transition from "insanely comfortable shower time" to "everything else you absolutely have to do with your life" by embracing the comfortable feel of a moss mat. Although these mats are available commercially, they are expensive, so she suggests making your own:

Materials needed:

- Substrate for the moss, such as high density foam, about 2.54 cm (1 inch) thick
- Sharp utility knife
- Silicone sealer, like caulk or cement
- Posterboard or cardstock for creating stencils
- Marker or grease pencil
- Spray bottle filled with water
- Moss (many kinds of moss can be used, just choose yours based on the amount of sunlight and average temperature of your bathroom)

How to do it:

- Choose the **size** of your mat. This can be as large or small as you need it to be, given the size of your bathroom. If using foam, be sure that you have enough to make two layers. Bamboo or wood trays will not work quite as well, given their tendency to produce mold and mildew under the conditions required to keep the moss alive.
- Choose the **shape** of your mat. You will need to create several cutouts for your moss. The shape of the cutouts and the edge of the mat are entirely up to you! Any shaping of the edges will need to be done to both pieces of foam, but the cutouts for the moss will only be on the top layer. Use the marker or grease pencil to trace the shapes onto the foam and use the utility knife to cut through the entire thickness. Use as many as you need to cover the mat with moss. Keeping small sections (as opposed to filling a tray with moss) will prevent it from growing excessively.
- **Seal the mat.** An adhesive like silicone caulk is recommended, because it will create a water-tight environment for the moss. Using a product like hot glue or certain other adhesives may melt the foam. Apply the adhesive to the underside of the top layer with the cutouts, making sure each section and the edge of the mat will be properly sealed. Press the top layer to the bottom layer, cleaning up any excess that may have squeezed out the sides. Use books or something heavy to weigh down the mat until the adhesive has dried.
- Prep the mat. Once the mat is ready for the moss, it will need to be properly prepped to ensure its survival. Use the spray bottle to mist the surface of the mat. Keep the spray bottle handy in the bathroom while the moss gets established.
- Plant the moss. Insert the moss into each cutout, until the mat is covered.
- Depending on what species of moss you have used, you might need to water it more than just the drips from your shower once a day. Use the spray bottle to mist the moss for the first couple of months while it gets established. This will keep it moist without over-saturating it.

Urinal Absorption

It seemed unlikely that the desert moss *Syntrichia caninervis* (Figure 25) would have any commercial potential. But it is great at absorbing water. Hence,

Williams (2016) suggested its potential use to make bathroom urinals "less disgusting." It is able to take water from fog, dew, snow, and of course rain, very efficiently (Pan *et al.* 2016). Having this moss in the urinal would seem a good way to prevent the splashback, according to Tadd Truscott, Assistant Professor of Mechanical Engineering at Utah State and one of the study's authors (Hurd *et al.* 2015). But being the technology-oriented society we are, it is likely that the moss will only be a model, with an artificial moss serving the function. Good luck!

Figure 25. *Syntrichia caninervis*, a highly absorbent moss with the potential to prevent backsplash in urinals. Photo by John Game, through Creative Commons.

Cleaning

The absorptive property, and often crunchy texture when dry, makes mosses useful for cleaning pots when camping (Gould, pers. comm.), while the remaining mosses can be used to keep the fishing worms alive. In India villagers use mosses mixed with burned ashes to clean household utensils (Pant 1989).

Brushes and Brooms

Polytrichum, with its long, stiff stems, makes good brooms for dusting curtains and carpets (Crum 1973) and apparently *P. commune* (Figure 10) is still in use for brushes in southern Sweden today (Hedenäs 1991). Stems are stripped of their leaves to make a broom 30-45 cm long (Thieret 1954).

Robin Stevenson (pers. comm.) reminded me that mosses have been used to make brushes.

Oily Humans

Imagine yourself all greasy and dirty, far from any source of soap or hot water. Your clothes are dirty and your hands are encrusted with grime. Fridtjof Nansen (1897) recounts an experience that is best told in the original language: "Fancy being able to throw away all the heavy, oily rags we had to live in, glued as they were to our bodies. Our legs suffered most; for there our trousers stuck fast to our knees, so that when we moved they abraded and tore the skin inside our thighs till it was all raw and

bleeding. I had the greatest difficulty in keeping these sores from becoming altogether too ingrained with fat and dirt, and had to be perpetually washing them with moss, or a rag from one of the bandages (Figure 26) in our medicine-bag, and a little water, which I warmed in a cup over a lamp. I have never before understood what a magnificent invention soap really is. We made all sorts of attempts to wash the worst of the dirt away; but they were all equally unsuccessful. Water had no effect upon all this grease; it was better to scour oneself with **moss** and sand. We could find plenty of sand in the walls of the hut, when we hacked the ice off them. The best method, however, was to get our hands thoroughly lubricated with warm bears' blood and train-oil, and then scrub it off again with moss. They thus became as white and soft as the hands of the most delicate lady, and we could scarcely believe that they belonged to our own bodies. When there was none of this toilet preparation to hand, we found the next best plan was to scrape our skin with a knife." (Contribution from Robin Stevenson, pers. comm.)

Soaps

Stevenson (2012) recalls his recent visit to an antique shop. There he was surprised to find a new use for *Sphagnum* (Figure 3) – Sphagnol Soap – produced by a British company called Peat Products (Sphagnol) Limited (Figure 27-Figure 28) (see also Richardson 1981; The Science Museum 2012). A search on the web produced several useful references to this company and its various products. Each bar contains 15% pure Sphagnol, which is said to consist of 'Emollient Vegetable Tars and Oils.' The 'active ingredient,' Sphagnol, appears to have been a distillate of peat, prepared by the calcination of the peat

itself. Details of the chemistry of this mysterious distillate are not available, leading one to the suspicion that a certain amount of scientific mumbo-jumbo may have been involved. The product was, however, said to be 'delightful in use'. The company was in existence at least as early as 1899, since a testimonial of that date from Dr. Carl Peters, wrapped around each bar, states that it not only helped prevent prickly heat on his expedition to the Zambesi district, but also cured one member of the expedition of piles! (Carl Peters was a German explorer and journalist).

Figure 27. Sphagnol soap ad. Photo courtesy of Robin Stevenson.

Figure 28. Sphagnol soap on display in an antique shop. Photo courtesy of Robin Stevenson.

Kai (1919), in a New Zealand nursing journal advertisement, lists Sphagnol soap, but also ointment, suppositories, and shaving soap made with *Sphagnum* (Figure 3). The claim was that all these products were awarded a "certificate of purity, quality and merit by the Institute of Hygiene."

Pools and Spas

If you are guessing that *Sphagnum* (Figure 3) might be the moss of choice here, you are right. But Dick Andrus warns that not all *Sphagnum* species are created equal. Ecology is important. The "aquatic" species like *S. cuspidatum* (Figure 29), *S. torreyanum* (Figure 30), *S. majus* (Figure 31), and *S. macrophyllum* (Figure 32) appear to have little or no cation exchange capacity. Rather, hummock species like *S. fuscum* (Figure 33), *S. capillifolium* (Figure 3), and *S. rubellum* (Figure 34) should work well.

Figure 29. *Sphagnum cuspidatum*, an aquatic species with little cation exchange capacity. Photo by Michael Lüth, with permission.

Figure 34. *Sphagnum rubellum*, a species with good cation exchange capacity. Photo by Michael Lüth, with permission.

For those of you who are new to the wonders of *Sphagnum* (Figure 3), it has two huge advantages as an absorbent of such things as heavy metals and other contaminants. It has large hyaline cells (Figure 35), especially in dryer habitats, that permit it to absorb large quantities of water. And it is able to exchange hydrogen ions (Figure 36) on its cell walls for other ions with a positive charge, hence removing them from the surrounding water.

Figure 35. *Sphagnum palustre* leaf cells showing green photosynthetic cells and hyaline cells with bars. Photo by Malcolm Storey, through Creative Commons.

Figure 36. View of leaf cross section of *Sphagnum* (left) with two enlarged chlorophyllous cells and hyaline cell on right. Enlargement shows **carboxyl groups** (COOH^+) of the **polyuronic acid** and one Ca^{++} that will exchange for two H^+ ions in cation exchange. Drawing by Janice Glime.

The folks at Creative Water Solutions have been very helpful in telling me about their use of *Sphagnum* (Figure 3, an aquatic species with little cation exchange capacity. Photo by) absorbents. They were concerned with removing biofilms in various water systems (including pools). Research shows that the chemicals typically used actually bind to the biofilms, making the chemicals less effective. Furthermore, the biofilm itself provides an environment that is protective of the bacteria. They can only be attacked by the chemicals when they are freed from the biofilm, causing managers to add more and more chemicals to the water. Enter *Sphagnum*. This moss has permitted them to reduce the need for chemicals by as much as 90%.

Toiletries and Toilets

I have learned from Susana Rams Sánchez that mosses are sold, mixed with a variety of other plant items (Figure 37), and sold in Morocco for washing one's hair. I have to wonder what their role is – antibiotic perhaps? Other items in the mix include fresh flowers, presumably for their sweet odors.

Figure 37. **Upper:** Market place in Azrou, Morocco, where bags of herbals comprise the ingredients for washing hair. **Lower:** Bag of herbals mixed and ready for sale for washing hair. Photos by Susana Rams Sánchez, with permission.

Dillenius (in Crum 1973) stated that ladies of his time used an oil extract of *Polytrichum* (Figure 10) for their hair, applying the Doctrine of Signatures because of the hairs on the calyptra.

One use that will probably remain forever among field personnel is that of toilet "paper" (Open-Air 2007). *Sphagnum* (Figure 29-Figure 34) is particularly suitable, both for its absorptive properties and its antibiotic properties. Use as toilet paper is most likely ancient. Rösch (1988) reported the use of *Neckera* (Figure 11-Figure 12) species for toilet paper. Dickson (2000) reported eleven species of forest mosses mixed with human excrement, indicating their use for toilet paper. Among these, species of *Neckera* were prominent.

The German peat closet is one step further in toilet use. This is a toilet in which peat is used instead of water (Turner 1993). The peat was thus mixed with the human excreta (both feces and urine) and the mix was disposed into a mobile cart.

Pesticides

We have known about the ability of bryophytes to discourage insect pests for centuries. Whereas tracheophyte herbaria require ill-smelling moth balls to protect them from destruction by tiny beetles, bryophytes store safely with no such protection. Such safety suggests

that bryophytes may contain some sort of natural pesticide (Yepsen 1984), or simply be unpalatable. In nature, it is not unusual for capsules to be grazed by slugs – not a common organism in a dry herbarium, but the leafy portion of the same plant is often ignored.

Davidson and coworkers (1989) isolated the antifeedants ferulic and possibly m- or p-coumaric acid from a wall-bound fraction of the leafy shoots of *Brachythecium rutabulum* (Figure 38) and *Mnium hornum* (Figure 39), parts ignored by slugs that readily grazed the capsules. Asakawa has devoted his life to finding a wide variety of phenolic and other ill-tasting or lethal compounds in liverworts. For example, the liverwort *Plagiochila* (Figure 40) contains the sesquiterpene hemiacetyl plagiochiline A (Asakawa et al. 1980b) that inhibits the feeding of an African army worm (Asakawa et al. 1980a) and is an extremely potent poison to mice (Matsuo et al. 1983, unpublished data).

Figure 38. *Brachythecium rutabulum*, a large pleurocarpous moss that produces antifeedants such as ferulic acid. Photo by Michael Lüth, with permission.

Figure 39. *Mnium hornum*, a species that is endowed with antifeedants such as ferulic acid. Photo by Michael Lüth, with permission.

Clearly not all bryophytes are so inhospitable to hungry herbivores. My students and I have found that pillbugs (*Porcellio* spp.; Figure 41) will readily consume *Thuidium delicatulum* (Figure 42) plants and *Polytrichum juniperinum* (Figure 43) leaves while preferring starvation or paper towels to *Polytrichum* stems, *Dicranum polysetum* (Figure 44), or *Pleurozium schreberi* (Figure

45-Figure 46). However, this avoidance is not always the case, suggesting that seasonal differences may occur (Hribljan 2009).

Figure 46. *Pleurozium schreberi* eaten in its forest home by *Porcellio scaber* (see upper left). Photo by courtesy of John Hribljan.

L. Russell found that one insect readily devours *Porella navicularis* (Figure 47) until it eats a species of *Porella* that has a peppery taste (D. H. Wagner, pers. comm.). After eating the peppery species for a few minutes, it stops eating it and henceforth refuses to eat either *Porella* species. (How is it these creatures are such good taxonomists!?)

Figure 47. *Porella navicularis*, in a genus with some edible species and some with an unpalatable peppery taste. Photo by Kent Brothers, Botany Website, UBC, with permission.

It appears that exploration of antiherbivory compounds in bryophytes could prove quite profitable for moving genes to crop plants. But I must ask, if insects don't eat them, what is the reason? Doesn't that mean that the ones that ate them didn't pass on their genes? And do I really want the lethal products of those bryophyte genes in my food? Certainly a long regime of testing stands between us and widespread use for this purpose, I hope!

Fortunately, so far moss genes are only being considered for a commercial level of transplantation into tobacco (Comis 1992) – a step that has already been accomplished. Oliver and colleagues, working at the United States Department of Agriculture in Lubbock, Texas, have isolated (Scott & Oliver 1994) and transplanted (Oliver *et al.* 2000) several genes from *Syntrichia* (formerly in *Tortula*; Figure 48) that are specific for recovery from desiccation. Antiherbivory genes are being considered as well. But will tracheophytes

be able to express these genes in meaningful ways? And what will they do to the safety of our food?

Figure 48. *Syntrichia ruralis*, a moss being studied for possible transfer of genes for drought tolerance and antiherbivory into tobacco. Photo by Michael Lüth, with permission.

Kenneth Adams (pers. comm. 1 November 2013) reports that *Pseudoscleropodium purum* (Figure 18) has been used in tobacco tins for cleaning up maggots for fishing.

Clothing

Can you imagine wearing mosses? In some parts of Germany, wool was woven with *Sphagnum* (Figure 29-Figure 34) to make a good, cheap cloth (Hotson 1921), whereas in Mexico, the dark-colored extract of a rock-inhabiting moss is used to color it (Delgadillo, pers. comm.).

In the Philippines, the tall moss *Spiridens reinwardtii* (Figure 49) is used by some of the natives to decorate head gear and clothing (B. C. Tan, pers. comm.). Likewise, in the area around Mount Wilhelm in Papua New Guinea *Dawsonia* (Figure 50) is used together with other bryophytes to decorate head gear and body wear (Dickson 2000; Tan 2003). In Malaysia, the large mosses *Dawsonia*, *Pogonatum* (Figure 51), and *Spiridens* are used for body decoration and to ward off evil spirits.

Figure 49. *Spiridens reinwardtii*, a moss used to decorate head gear in the Philippines. Photo by Daniel Nickrent, with online permission.

Figure 51. *Pogonatum cirratum*, member of this genus in Malaysia where *Pogonatum* is used for body decoration and to ward off evil spirits. Photo by Li Zhang, with permission.

Several cultures have used *Sphagnum* (Figure 29-Figure 34) (Bland 1971; Carrier Linguistic Committee 1973; Turner 1983; Compton 1993; Smith 1997; Moerman 1998; Marles *et al.* 2000) and *Dicranum scoparium* (Figure 52) for lining diapers (Adelson 2002; Kimmerer 2003), and even modern diapers from Johnson & Johnson in the U.S. and Canada can have *Sphagnum* liners (Johnson Gottesfeld & Vitt 1996). *Sphagnum* is also used for diapers by the Maori of New Zealand (Macdonald 1974; Harris 2008). Alaskan Native Peoples have used blades of grass, rubbed together until soft, mixed with peat moss and squirrels' nests to line a cradle as a diaper (Kari 1985).

Figure 52. *Dicranum scoparium*, a moss used by several Canadian cultures for diapers. Photo by Michael Lüth, with permission.

John Steel provided me with an image of a fashion statement that appeared in the Otago Daily Times, New Zealand, 30 March 2012. It shows a sweater coat with mosses used to create the design.

Figure 53. Moss used as design on clothing, modified from Otago Daily Times, 30 March 2012, p 18 1b. Photo courtesy of John Steel.

Doug Elliott describes the benefits of using *Sphagnum* diapers in his Adventures website (Elliott 2012). The moss wicks the water away from the skin, acting much like talcum powder, and preventing diaper rash. This may be due to its acidity and antibiotic properties. One of its endearing qualities is that the baby's feces become covered with the *Sphagnum* (Figure 29-Figure 34) and are easy to remove and are kept away from the baby's skin. The soiled moss is easily discarded into compost or buried in the soil, even when hiking. Elliott prefers *Sphagnum* to other products for diapers, and he has tried a number of them. In Cree, the word for *Sphagnum* is *otaow*, and would translate to mean "protectively holds" or "embraces."

Elliott warns that the moss should be dried immediately for safe keeping. I would add that any discolored moss should be avoided because it could contain the fungus *Sporothrix schenckii* (Figure 54) that causes **sporotrichosis**. Elliott claims that the fungus can be avoided by gathering the moss in a tarp and spreading it so it dries quickly. That is probably sufficient to protect from adhering spores, but I wouldn't trust it against infected plants (Figure 55-Figure 57). When gathering the moss, care should be taken to minimize impact, gathering small clumps and moving around to avoid creating gaping holes.

Figure 56. *Sphagnum* infected with fungi. Photo by Janice Glime.

Figure 57. *Sphagnum* being used for diaper. Photo courtesy of Doug Elliott.

Elliott describes the diapering process: "Though some of our friends lay the *Sphagnum* (Figure 29-Figure 34) moss on a cotton diaper, we find that a moss-filled nylon diaper cover works best for us. To prepare for diapering, open the diaper cover and place it on a flat surface. Place a couple handfuls of the moss in the diaper cover and arrange it 'strategically' (more in front for boys). Examine the moss carefully to be sure it is free of leaves, pine needles and other potentially uncomfortable debris. (I press the moss into place with the back of my hand to be sure it is soft and free of projections.) Sometimes we use different 'grades' of moss. The softest moss is reserved for the inner layer and the rest is used as the 'backfill.' Sometimes we place a few sheets of toilet paper on top to cover the moss. Then we set the babe down onto the moss and fasten the diaper up as gracefully as possible. Since managing a squirmy baby on an easily scatterable pile of moss is not always easy, having an extra person helping usually makes it easier. (We call it 'tag team diapering.')

Michigan's Chippewa Indians used *Sphagnum* for this purpose to keep the babies clean and warm (Crum 1973). In fact, Johnson Gottesfeld and Vitt (1996) learned that certain species were preferred and some avoided by the indigenous people of North America. The long, pink (not red) plants of *Sphagnum divinum* (Figure 58) were preferred, whereas short, yellow-green, and red plants (Figure 59) were considered unsuitable. Red *Sphagnum nemoreum* (Figure 60) caused irritation.

The New Zealand Maori have used *Lembophyllum clandestinum* (Figure 61) for diapers as well as for baby bedding (Cooper & Cambie 1991) – just think, a dual purpose moss! *Sphagnum* is even used in the modern world in mattress pads for infants (Turner 1993). In California, there is no *Lembophyllum*, but *Alsia* (Figure 62) served the Native Americans for baby bedding (Thieret 1956).

In Germany and Nordic countries, *Sphagnum* (Figure 29-Figure 34)) has become popular to line hiking boots (Figure 63; Hedenäs 1991), not only cushioning the feet, but absorbing moisture and odors while discouraging bacteria. Thanks to Gillis Een, I have been enjoying the boot liners and can attest to their comfort.

Natives of the Philippines use mosses to decorate headwear and clothing (B. Tan, pers. comm.). In New Guinea, *Dawsonia grandis* (see Figure 50) is worn by natives in bracelets and hair (Van Zanten 1973) and to decorate ceremonial masks (Richardson 1981). The British in England used the moss *Climacium dendroides* (Figure 64), artificially colored (Clarke 1902), to decorate a lady's hat (Tripp 1888). And in Boston, the early cultural center of the United States, braids of *Pseudoscleropodium purum* (Figure 18) and cords of *Neckera crispa* (Figure 11) and bits of *Dicranum* (Figure 52) decorated ladies' hats and

bonnets (Clarke 1902). These were woven into bands and sold for \$0.10 per yard. In the villages of Kumaun, India, women stuff such mosses as *Hylocomium* (Figure 16), *Hypnum* (Figure 5), and *Trachypodopsis* (Figure 66) into cloth sacks to make the *sirona*, a head cushion, that both cushions the vessel carried on the head and absorbs water that splashes from it (Pant & Tewari 1989).

Figure 63. Advertisement for shoe lining made from *Sphagnum*. Photo by Janice Glime.

Figure 64. *Climacium dendroides*, a moss dyed and used to decorate ladies' hats in Great Britain. Photo by Michael Lüth, with permission.

The large size of *Dawsonia grandis* (see Figure 65) affords it more utility than most mosses. In New Guinea, it is stripped of its leaves, dried over a glowing fire, stripped of its outer layers, split in two, then plaited into a red rope to decorate net bags and other objects (Van Zanten 1973). In New Zealand, it was other members of the *Polytrichaceae* that proved useful. The shoots and leaves of *Polytrichum commune* (Figure 10) and *Polytrichadelphus magellanicus* (Figure 67) were used in making Maori cloaks, with alternating brown and black serving as decoration (Beever & Gresson 1995). The numerous air spaces, serving the moss for capillary movement and water retention, most likely provided an insulating warmth to the wearer.

Even buttons (Figure 68) can be made from bryophytes. In Europe, peat is pressed into disks and a design stamped into it to make an attractive button for clothing.

Figure 68. Button made of pressed peat. Photo by Janice Glime.

Archaeological evidence tells us that soft mosses such as *Loeskeobryum brevirostre* (Figure 69) were used to pad Mesolithic flint blades, protecting the user's hand (Dickson 1973; Figure 70).

Figure 69. *Loeskeobryum brevirostre*, a moss used to pad Mesolithic flint blades to protect the hand. Photo by Bob Klips, with permission.

Figure 72. *Pohlia nutans* with capsules, member of a genus of the common mosses on the clothes of the Iceman. Photo by Malcolm Storey <www.discoverlife.org>, with online permission.

Tyrolean Iceman's clothes exhibit 30 species of bryophytes (Dickson *et al.* 1996), most likely as involuntary passengers. Nine of these would have been unable to grow at the high altitude where the Iceman was found. Two particularly notable mosses were the low altitude woodland species *Neckera complanata* (Figure 12) and *N. crispa* (Figure 11), indicating Iceman came from the south (now Italy) and not north (Austria). Most common in 30 samples were *Polytrichum piliferum* (Figure 71), *Pohlia* spp. (Figure 72), *Andreaea* spp. (Figure 73), *Racomitrium lanuginosum* (Figure 14), and *Polytrichastrum sexangulare* (Figure 74).

Figure 74. *Polytrichastrum sexangulare*, one of the common mosses on the clothes of the Iceman. Photo by Hermann Schachner, through Creative Commons.

The Iceman had multiple uses for bryophytes (Dickson 2000). Among these was the use of *Neckera complanata* (Figure 12) for leggings and upper body clothing. *Neckera crispa* (Figure 105) was used in upper body clothing, leggings, aprons, twisted thongs, and hair decorations. In fact, *N. crispa* was the most abundantly used bryophyte in that part of the world. Ochsner (1975) reported its use by prehistoric Swiss.

Jewelry

A creative entrepreneur in Iceland is selling jewelry with a moss garden as the main attraction (HAF 2010). These items include a necklace with a small cup of mosses, a ring, and a knuckle garden that bridges four fingers. The included prices were 150€ for the ring and 180€ for the necklace.

Food Source

If even most insects won't eat the bryophytes, it is no wonder that they seldom have been used for human food. The Chinese consider mosses to be a famine food (Bland 1971). Their low caloric value (Forman 1968) and often abominable taste are efficient deterrents to herbivores of all sizes. Mizutani (1961) complained that it was necessary to gargle to get rid of the bitter liverwort taste, no doubt a result of the numerous phenolic compounds in a single species. Thus it is not surprising that the only country where any bryophyte seems to be a significant component of food is in the peat-rich Lapland where *Sphagnum* (Figure 29-Figure 34) was reportedly once used as an ingredient in bread (Bland 1971). However, Jim Dickson (Bryonet 20 February 2015) consulted a Swedish colleague who is an expert on the historic making and composition of bread and she has never heard of such a recipe including *Sphagnum*. Even Linnaeus did not mention any use of *Sphagnum* in making 18th century bread [but then, Linnaeus put the aquatic flowering plant *Potamogeton* in the moss genus *Fontinalis* (Figure 75), so his understanding of mosses appears to be minimal]. John Lindley (1849) says *Sphagnum palustre* (Figure 76) is a "wretched food in barbarous countries." Native Americans used *Camassia quamash*, simmered in blood with moss, to make a soup (Hart 1992).

Figure 75. *Fontinalis antipyretica*, a large aquatic moss. Photo by Michael Lüth, with permission.

Figure 76. *Sphagnum palustre*, a "wretched food." Photo by Michael Lüth, with permission.

Weyrich *et al.* (2017) used DNA in dental calculus to infer the presence of bryophytes (*Physcomitrella patens*; Figure 77) in the diet of Neanderthals from El Sidrón cave, Spain. But Dickson *et al.* (2017) have taken exception to this as evidence of the use of bryophytes as food. They argue that bryophytes are neither palatable nor nutritious and that there is no conclusive evidence that people eat or have eaten mosses. They do not consider the presence of "forest moss" in the dental calculus on one Neanderthal to be an adequate basis to claim it as a dietary component.

Figure 77. *Physcomitrella patens* with capsules, a moss whose DNA was found in the calculus of the teeth of one Neanderthal man in Spain. Photo by Bob Klips, with permission.

Dickson *et al.* (2017) argue that fragments of DNA from a taxonomic group (bryophytes) that is under-represented in sequencing studies is a major limitation in interpreting diet. In the case of *Physcomitrella patens*, it is not a forest moss as claimed, but lives on pool and river margins. It is furthermore so small that it is unlikely to be of interest for food.

On the other hand, Villarroel *et al.* (2007) described the use of *Sphagnum* in making cakes in Latin America. The recipe called for resistant starch, *Sphagnum divinum* (as *S. magellanicum*; Figure 58-Figure 59), and defatted hazel nut flour (*Gevuina avellana*, Mol). The starch, HI Maize, and moss provided rich sources of dietary fiber (8.7%). With these ingredients, the product could be stored at refrigerated temperatures but not at 20°C.

Mummified bodies give us clues into past uses of bryophytes for food. There is evidence that suggests the Iceman consumed bryophytes. *Neckera intermedia*

(Figure 78) occurred in the eviscerated abdomen of a Guanche (aboriginal Berber inhabitant) "mummy" from the Canary Islands. And *Sphagnum* (Figure 29-Figure 34) is known from intestines of Danish and English bog bodies (Dickson 2000).

Figure 78. *Neckera intermedia*, a species found in the eviscerated abdomen of a Guanche "mummy." Photo by Jan-Peter Frahm, with permission.

Scientists retrieved fragments of six moss species from the alimentary tract of the Tyrolean Iceman (5200 years BP) from the eastern Alps, including *Anomodon viticulosus* (Figure 79), *Hymenostylium recurvirostrum* (Figure 80), *Neckera complanata* (Figure 81), and *Sphagnum imbricatum* (Figure 82) (Dickson *et al.* 2009). The reason for having these in his gut remains unknown. Did he use the mosses to stop the bleeding of his wounded hand, then unintentionally ingest them along with his food? Or did they come with the drinking water? Were some of them used to wrap food, then get ingested with it? Or did these people use the mosses like the monkeys (Lamon *et al.* 2017), dipping them in water and squeezing the water into their mouths?

Figure 79. *Anomodon viticulosus*, a moss that occurred in the alimentary tract of the Tyrolean Iceman. Photo by Hermann Schachner, through Creative Commons.

In British Columbia, Canada, an ancient human body, 17-20 years of age, from a glacier likewise displayed bryophytes in the gut (Dickson *et al.* 2004, 2009; Mudie *et al.* 2005). At least twelve species of mosses were in the gut from the duodenum to the rectum. One of these was a member of the *Acutifolia* (Figure 83) section of *Sphagnum*. But this circumstantial evidence does not tell us the reason for the ingestion.

There is an interesting report of bryophytes being eaten by Neanderthal man, based on DNA evidence (Weyrich *et al.* 2017). In this treatise, pine nuts (*Pinus koraiensis*), a mushroom (*Schizophyllum commune*), and the moss *Physcomitrella patens*, identified as "forest moss." Dickson *et al.* (2017) has published the same problems with this interpretation as I have. First, this moss does not grow in forests, but rather in mud flats in the open. Second, it is a tiny moss only a few mm tall, usually in small patches. And finally, this is the moss with its entire genome mapped; many mosses are not even in the database and those that are have been identified by only a small number of genes. On top of these factors making the consumption of this species unlikely, we don't know the reason for finding moss genetic material in the calculus on the teeth of this Neanderthal. Any number of reasons could be considered – perhaps mosses were a primitive tooth brush!

One historic note is that in the second edition of the Dictionary of Dates (Joseph Haydn, London, 1854), Peter, the Wild Boy, is described (C. R. Stevenson, Bryonet 27 November 2006). Peter was a savage creature who lived in the forest of Hertswold, electorate of Hanover, Great Britain. Peter walked on his hands and feet, climbed trees like a squirrel, and was found eating grass and moss in November of 1725. But even this recorded history of human consumption is in question because moss has many meanings to a lay person, and we cannot be sure it was truly a bryophyte being described.

A lot of drinks, especially teas, are made from a variety of odd plant substances with antibiotic properties. Some Native Americans have used *Sphagnum* (Figure 29-Figure 34) leaves to make tea (Carrier Linguistic Committee 1973).

Vitamins

Although bryophytes do not seem to be good candidates for food, some bryophytes may provide specific needs for animals both in the wild and on farms. For example, *Neodictyladiella pendula* has a high content of vitamin B₁₂ and causes no noticeable side effects when fed to puppies and chickens (Sugawa 1960). *Sphagnum* (Figure 29-Figure 34), as milled peat, provides a binder for

iron and vitamins used to supplement the diet of anemic piglets.

Masanobu Higuchi (Bryonet 20 November 2006) reports being served a soup in southwestern Yunnan, China, ordered by his friend. He found something tough and hard to chew in the soup. On close examination, he identified it to be the moss *Rhodobryum giganteum* (Figure 84). He speculated that the chef may be including it as a medicinal herb.

Figure 84. *Rhodobryum giganteum*, a medicinal herb and soup ingredient in China. Photo by David Long, with permission.

Flavoring

Mosses have, however, been used for flavoring, though not commonly. *Sphagnum* (Figure 29-Figure 34, Figure 85) contributes to the flavor of Scotch whisky. Scotch whiskies that contain peat include Ardbeg TEN, Highland Park, Octomore, Laphroaig, and Talisker <Whisky.com>. First, the grains are steeped in water from a *Sphagnum* peatland during the malting stage, but this does not contribute to the smoky flavor (Miller 1981; <Whisky.com>). Drying the malt over a peat fire adds the smoke flavor to the barley grains <Whisky.com>. The degree of smokiness in the flavor depends on the length of time the barley grain is dried over the peat fire. Damp malt usually requires about 30 hours of drying.

Figure 85. Mined peat bog in Ireland. Peat like this is used in the fires used to dry the malt for making whisky. Photo by Amos, through Creative Commons.

In Germany one can buy "drinkable peatbog (Trinkmoor)" as a diet addition (Wolfgang Hofbauer, Bryonet 20 February 2015). This is a suspension made not from fresh *Sphagnum* (Figure 29-Figure 34), but from peat (Figure 85). *Lunularia* (Figure 86) and *Plagiochasma* (Figure 87) are used in preparation of maize beer (Franquemont *et al.* 1990).

Figure 86. *Lunularia cruciata*, a liverwort used in making maize beer. Photo by Michael Lüth, with permission.

Figure 87. *Plagiochasma appendiculatum*, a liverwort used in making maize beer. Photo by Michael Lüth, with permission.

In a drink of wine, *Marchantia polymorpha* (Figure 2) soaks up the wine and makes a tasty, crunchy treat with your drink. Hmm... are our favorite organisms only consumed with alcohol?

Vassilios Sarafis (Bryonet, 19 November 2006) reports having tried capsules of *Polytrichum commune* (Figure 10, Figure 88), finding them tasty. Amanda Hardman (Bryonet, 19 November 2006) claims to fancy eating *Funaria hygrometrica* capsules (Figure 89), but states that you must catch them at just the right ripeness. To her, they can taste "as good as yummy sweet peas." Nevertheless, Rod Seppelt (Bryonet, 19 November 2006) compares preparing bryophytes as a food to that of the recommended way to cook a Galah (otherwise known as a Rose-breasted Cockatoo) in Australia. You put a stone and water in the pot with the Galah, bring to a boil, and when the stone is soft, throw away the Galah and eat the stone! In the case of bryophytes, it is the phenolic compounds that make them unpalatable and of questionable safety for consumption.

Figure 88. *Polytrichum commune* immature capsules, a stage some might consider edible. Photo by Michael Lüth, with permission.

There have certainly been experimental uses of mosses for food flavoring. Stefan Rensing (Bryonet, 21 November 2006) reports that a group of ~50 botanists at a party sampled a newly created drink called "Psycho Physco." This drink contained a teaspoonful of protonemata from a bioreactor liquid culture of the prominent research moss *Physcomitrella patens* (Figure 90). Rensing reports that the taste was "quite interesting (not unpleasant)" and all 50 persons survived unharmed.

Figure 89. *Funaria hygrometrica* with capsules that apparently are suitable as human food. Photo by Hermann Schachner, through Creative Commons.

Figure 90. *Physcomitrella patens*, the lab rat of bryophytes for which the protonema was tested for "taste" in a drink by a group of European botanists. Photo by Michael Lüth, with permission.

A well-known chef in Europe is looking for bryophytes to flavor his dishes, giving them a unique taste (Marta Infante & Patxi Heras, Bryonet, 18 November 2006). He plans to enter them in a gastronomical contest. So far he has tried *Pseudoscleropodium purum* (Figure 91) in tempura and made an infusion with *Boletus edulis* (Figure 92). But there are concerns about possible side effects and bryophytes to avoid.

Figure 91. *Pseudoscleropodium purum*, a large moss being explored for taste contributions to food and still being used in shipping plants and fragile objects. Photo by Michael Lüth, with permission.

Figure 92. *Boletus edulis* with moss, a mushroom cooked with *Pseudoscleropodium purum* by a European chef. Photo by H. Krisp, through Creative Commons.

Chinese Gallnuts

Perhaps the most important use of mosses in the food industry is indirect. Several mosses, especially species of *Plagiomnium* (Figure 93), are winter hosts to the Chinese gallnut aphid (*Schlechtendalia chinensis*), the insect that provides those gallnuts (Figure 94-Figure 96) that are both a delicacy and important medicine in China (Horikawa 1947; Wu 1982; Ando 1983). The gallnuts, formed on the leaves of *Rhus javanica* (Figure 94-Figure 96) are used as pain killers, antiseptic and antidiarrheal agents, and as expectorants, astringents, and preservatives (Min & Longton 1993), and in industry as a source of tannic acid.

Figure 93. *Plagiomnium undulatum*, one of the overwintering host mosses for the Chinese gallnut aphid. Photo by Michael Lüth, with permission.

Figure 94. Leaves of the summer gallnut host, *Rhus javanica*. These plants must be near suitable mosses for the gallnut aphid to survive the winter. Photo by Kenpei, through Creative Commons.

Figure 95. These gallnuts of the aphid *Schlechtendalia chinensis* occur on the branch of the sumac, *Rhus javanica*. Photo by Yingdi Liu, with permission.

Figure 96. These harvested gallnuts are used for eating and medicinal purposes in China. Photo by Yingdi Liu, with permission.

The gallnuts were so important that Takagi (1937) proposed the culture of suitable mosses in order to increase gallnut (Figure 96) production. In China, the aphids are now reared agriculturally on mosses (Tang 1976). In Yunnan the host tree and the most common host mosses (species of *Plagiomnium*, Figure 93) do not have large overlapping distributions, making establishment of the gall aphids difficult. The aphids lay their eggs on the moss and the young nymphs survive during winter using the moss as food. In some areas, mosses are reared in bowls that are placed under the trees for several weeks during autumn until the aphids locate them (Min & Longton 1993). Then the bowls are moved into sheds for the winter. In April the moss is removed from the bowls and placed back under the trees. The bowls are supplied with fresh soil and kept in a more suitable place where the remaining moss fragments regenerate. By October these mosses are sufficiently large to use the same bowls to gather the next winter's crop of aphids.

Food Improvement

There seems to be little interest in cultivating bryophytes themselves for agricultural purposes. However, they do contribute peripherally to our food. They are used as a carrying medium for the nitrogen-fixing *Rhizobium* (Figure 97) inoculants for legume production (Turner 1993). And currently there is research to try to encourage the *Cyanobacterium Nostoc* (Figure 98) to grow on roots and stems of plants. This photosynthetic bacterium, once known as a blue-green alga, is able to convert atmospheric nitrogen into ammonia, making it usable for plants. But what has this to do with bryophytes? Well, there has to be a source of the *Nostoc*, and this should be a species adapted to living in association with a plant. A number of liverwort taxa are known for cyanobacterial partners. In this case, it is *Anthoceros* (Figure 99) that has contributed the *Nostoc*, which Gantar and coworkers (1995) are trying to persuade to live and fix nitrogen on, of all things, wheat roots! That would go a long way toward solving fertilizer problems! And Rao and Burns (1990a, b) have suggested the use of *Anthoceros* as a living agricultural fertilizer because of its *Nostoc* partners. That might even work, since *Anthoceros* likes disturbed areas.

Figure 97. *Rhizobium* nodules on the roots of a legume. Photo by Terraprima, through Creative Commons.

Figure 99. *Anthoceros agrestis*, a hornwort with Cyanobacterial partners that fix atmospheric nitrogen. Photo by Michael Lüth, with permission.

Use of peat mosses for culturing certain foods is common. One environmentally friendly use is the combination of extracts from fisheries by-products with peat compost (Martin 1992). This is especially true in coastal areas where the more usual by-products are limited in availability. Products of this fermentation process can be used successfully to feed, of all things, more fish! Then there are the agricultural uses – growing mushrooms, salad greens, and other specialty crops (Turner 1993) that will be discussed in the sub-chapter on commercial uses.

Peat water is typically brown and looks unfit to drink, but for sailors going on a long journey, it has provided a safer alternative (Dente 1997). It stays free of algae longer than well or spring water.

Extracts from the leafy liverwort *Porella platyphylla* are able to inhibit "radice" (root) seedling growth (Beike *et al.* 2010). On the other hand, extracts of the moss *Brachythecium rutabulum* promote their growth, demonstrating the individuality of the bryophytes.

A major threat to crop plants in many parts of the world is drought. Many kinds of bryophytes are very tolerant of drought, so enterprising scientists endeavored to identify the genes in bryophytes that endowed them with their unique ability to recover from drought. Among these, the model system created with the moss *Physcomitrella patens* (Figure 90) had a high tolerance to such abiotic stresses as salt and osmotic stress (Frank *et al.* 2005b).

Physcomitrella patens (Figure 90) is an ideal laboratory culture organism. Hence, Frank *et al.* (2005a) have developed molecular tools to identify its genes and their roles. Reski and Frank (2005) have identified the genes it uses for drought protection and other stress response genes. Not only does it produce plant metabolites, but it also produces animal, fungal, and algal metabolites, suggesting they might be useful for therapeutic and diagnostic purposes.

One important use of the bryophytes has been to identify the genes involved in drought tolerance and apply this knowledge to other organisms. At the University of Freiburg, 40 scientists and technicians collaborated on identifying genes from *Physcomitrella patens* (Figure 90) that could potentially be used to improve crop plants (Schiermeier 1999). The complete genome was

enumerated in 2007 (Anonymous 2007; Rensing *et al.* 2008).

Following this elucidation, Richardt *et al.* (2010) were able to recognize the vegetative osmotic stress tolerance genes in the moss *Physcomitrella patens* (Figure 90) that were identical to those in maize. Na^+ pumps existed in such early land plants as *P. patens*, but these seem to have been lost as the tracheophytes evolved (Benito & Rodríguez-Navarro 2003; Horie & Schroeder 2004). This discovery led to studies on feasibility of moving stress tolerance genes from *P. patens* into crop plants (Reski & Frank 2005). In 2007, the sequencing of the complete genome of *P. patens* was completed (BIOPRO 2011).

A group of Spanish researchers have identified a Na^+ pump in *Physcomitrella patens* (Figure 90) and Australians have transferred it into maize to make those plants more salt tolerant (Ralf Reski, pers. comm. 14 August 2017).

By now, moss genes have found their way into our food (Ralf Reski, pers. comm. 14 August 2017). The patent <<http://patents.com/us-8835715.html>> for creating unsaturated fatty acids has just been approved:

"Abstract: The present invention relates to an improved process for the preparation of unsaturated fatty acids and to a process for the preparation of triglycerides with an increased content of unsaturated fatty acids. The invention relates to the generation of transgenic organism, preferably of a transgenic plant or of a transgenic microorganism, with an increased content of fatty acids, oils or lipids with .DELTA.6 double bonds owing to the expression of a **moss** .DELTA.-6-desaturase [sic]. The invention furthermore relates to transgenic organisms comprising a .DELTA.6-desaturase gene, and to the use of the unsaturated fatty acids or of the triglycerides with an increased content of unsaturated fatty acids prepared in the process."

"The genomic .DELTA.6-acyllipid desaturase from *Physcomitrella patens* was modified, isolated and used in the process according to the invention on the basis of the published sequence (Girke *et al.*, Plant J., 15, 1998: 39-48) using a polymerase chain reaction and cloning. To this end, a desaturase fragment was first isolated by means of polymerase chain reaction using two gene-specific primers, and inserted into the desaturase gene described in Girke *et al.* (see above)." Permission was granted for "A process of preparing an unsaturated fatty acid, which comprises introducing, into an organism being a yeast or a monocot or dicot plant, at least one nucleic acid sequence encoding a polypeptide having .DELTA.6-desaturase activity..." This patent application was submitted 16 September 2014 and has just been approved (September 2017), added on to a patenting history starting in 1987.

Food Preservation

Modern methods of packing food have actually increased the incidence of botulism more than 12-fold among Alaskan natives since 1966 (Segal 1992). Traditionally, the natives processed fish and sea mammals on the ground where the animals easily made contact with bacteria from the soil or animal viscera. The food was then placed in a shallow pit lined with wood, animal skins, or leaves. These buried animals were then covered with moss or leaves and left to ferment for one or two months. However, the natives switched to modern technology and

used plastic bags to line the pits and enclose the food, eliminating the use of moss and other plant matter. The anaerobic conditions created by this method promoted the growth of *Clostridium botulinum* (Figure 100-Figure 101), permitting the production of the botulism toxin. The natives do not trust the advice of outsiders, so the Health Department feels the best plan to reduce the spread of the disease is to encourage them to return to their traditional use of mosses. The mosses permit aeration and may even have antibiotic effects.

Figure 101. *Clostridium botulinum* SEM. Photo by Christine Schramm, through Creative Commons.

Mark Smits (Bryonet 20 February 2015) reports that *Sphagnum* bogs (Figure 102) were used to preserve food, including butter (Figure 103). Reade (2013) noted the use of "bog butter," especially in Scotland and Ireland. This is butter that has been buried in a peat bog. The earliest known use of this method is from the Middle Iron Age (400-350 BC). Reade reports on the experiment of Daniel C. Fisher that found bacterial counts in meat after one year in a peat bog was comparable to that which had been in a freezer for the same length of time.

It appears that the potential use of *Sphagnum* for preservation is still alive. Børsheim *et al.* (2001) experimented with fish preservation in *Sphagnum*, peat, and holocellulose. Salmon (*Salmo salar*) skin and whole zebra fish (*Brachydanio rerio*) were preserved for many weeks in *Sphagnum palustre* and compared to those in peat that came mostly from *Sphagnum* mosses, acetone-extracted moss, and chlorite holocellulose of the moss. Interestingly, the chlorite holocellulose performed as well or better than the other products. The watersoluble sphagnum in this holocellulose portion produced the same results as the other treatments. Similarly, mackerel (*Scomber scombrus*) skin became brown and completely bio-resistant after repeated immersion in aqueous (3% w/v) sphagnum (with intermittent drying). This process achieved the same effect as smoking the fish. However, the process does not work on filleted fish muscle because the soluble protein diffuses out too quickly and neutralizes the carbonyl groups in the sphagnum.

It appears we should give more consideration to bryophytes for our modern food storage. Not so long ago, before refrigerators were invented, people built root cellars to preserve vegetables through the winter. But today, we can still use mosses for this purpose. Dorothy Allard (12 August 2017) shared with me her use of *Sphagnum* to keep her carrots for several months in a root cellar at 4-16°C. She washed the carrots, cut off their tops, and layered them in a 5-gallon (19-liter) plastic bucket so that the carrots were not touching each other. The carrots did not rot, but they did develop a few small root hairs and eventually developed a "peat mossy" taste. It was easier to clean them than carrots packed in sand.

Cookery and Pottery

The use of peat as a fuel in northern parts of Europe is common, and this includes its use for heat for cooking. The pendant *Antitrichia curtipendula* (Figure 104) was also used by Native Americans in earthen ovens for cooking (Compton 1993).

Figure 104. *Antitrichia curtipendula*, a species used in ovens by Native Americans. Photo by Hermann Schachner, through Creative Commons.

Early uses of mosses in pottery can be traced as far back as the Stone-age people, who apparently used the moss *Neckera crispa* (Figure 105) (Grosse-Brauckmann 1979) in a region now settled by Germany. In the French Stone Age, *Neckera crispa*, *Tortula* (Figure 107), and other mosses were used as we now use sand, apparently to make the pottery less "fat," improving the quality of the pottery (H. J. During pers. comm.; Figure 106). Analysis of ancient pottery demonstrates presence of animal parts, and the defatting agents help in defatting their fats. In both France and Belgium, mixtures of moss containing *Neckera crispa*, in particular, were used to temper pottery (Constantin & Kuijper 2002). Is it possible that the mosses kept the pottery safe after it was used for cooking or serving animal foods, discouraging the multiplication of bacteria and fungi?

In France and Belgium the Epi-Rössen and Michelsberg cultures have used mosses, primarily *Neckera crispa* (Figure 105), as a temper (degreasant = defatter) in making pottery (Figure 108) (Constantin & Kuijper 2002; Jan & Savary 2011; Jan 2016). The mosses were used for tempering the ceramics during the Mid-Neolithic (~4700-3500 BC) (Denis Jan, pers. comm. 14 December 2015). Some of the mosses resemble *Rhytidiadelphus squarrosus*

(Figure 17). Other studies have revealed the use of *Neckera crispa* and *Fissidens dubius* (Figure 109). When mosses are used as a temper they reinforce the clay of vases like a wattle for mud. Combustion of the ceramic causes the plant parts to disintegrate and create a high porosity. This serves two purposes – it makes the vase lighter and absorbs shock waves that would otherwise cause the vase to break.

Packing

One wouldn't expect a plant that harbors a wide range of insects to be a suitable insect repellent, but the Himalayans dried mosses, made them into a coarse powder, and sprinkled them over grains and other containerized goods to repel insects (Pant & Tewari 1989). They covered the top of the container with a plug of mosses. When they were ready to use the grain, they simply blew off the lightweight mosses from the grain. Just consider the safety of this natural way of repelling the insects while protecting the human consumer. In the Pacific Northwest, mosses are collected to pack mushrooms and keep them safe (Cleavitt 1996).

Taxidermy usually requires the use of arsenic to keep hungry beetles from consuming our treasures. But at the British Museum, it was mosses that served this role. Curators stuffed the skins with mosses to ward off the dermestid beetles and at the same time keep the skins plump and natural (Harrington 1985).

Packing materials vary with what is available locally and can even be used to determine the region and habitat of origin. In the western USA, A. J. Grout (in a comment to

Clarke 1902) cited the use of *Dendroalsia abietina* (Figure 110) and *Antitrichia californica* (Figure 111) to pack vegetables that were shipped from California to Seattle. These reportedly came from Boulder's Island. Epiphytic mosses such as *Antitrichia californica*, *Dendroalsia abietina*, and *Metaneckera menziesii* (Figure 112) provided suitable packing material for vegetables by helping to retain moisture (Frye 1920), whereas today similar bryophyte species are used to pack mushrooms (C. W. Smith, pers. comm.).

Figure 110. *Dendroalsia abietina*, a moss used in the Pacific states of the USA as packing material for fresh vegetables. Photo by Paul Wilson, with permission.

Figure 112. *Metaneckera menziesii*, a moss used in the Pacific states of the USA as packing material for fresh vegetables. Photo by Michael Lüth, with permission.

The Himalayans still use both soil and epiphytic mosses such as *Brachythecium salebrosum* (Figure 113), *Cryptoleptodon flexuosus*, *Hypnum cupressiforme* (Figure 5), *Macrothamnium submacrocarpum* (Figure 114), *Taiwanobryum crenulata*, *Trachypodopsis serrulata* var. *crispatula*, *Thuidium tamariscellum*, and *Sphagnum* (Figure 29-Figure 34) to pack apples and plums (Pant & Tewari 1989). But in the tropics, it is the leafy liverworts that play this role because of their abundance (Bland 1971). Large and abundant mosses like *Pseudoscleropodium purum* (Figure 91) (Dickson 1967; Figure 115), *Hylocomium splendens* (Figure 16), and *Rhytidiadelphus squarrosus* (Figure 17) have been dispersed and grow around the world due to their widespread use as packing materials (Seaward & Williams 1976). Allen and Crosby (1987) refer to these worldwide expansions of *Pseudoscleropodium purum* as legendary – even today, it is used for packing young trees destined for Tristan da Cunha, where its establishment is imminent. It seems to have arrived on the West Coast of North America by the late 1800's (Miller & Trigoboff 2001).

In some Asian countries, bryophytes are used for packaging gifts and displays during the Christmas Season (Tan 2003).

Large mosses make good cushions for fragile objects. In Japan, boxes packed with large pendant mosses such as *Aerobryopsis subdivergens* (Figure 116), *Barbella determesii*, and *Meteorium helminthocladulum* (Figure 117) guarded ancient silk clothes, providing a clean and soft packing (Noguchi 1952). Where dirty soil was of less concern, soil mosses such as *Rhytidiadelphus triquetrus* (Figure 118) protected fragile China (Dickson 1973), and Espie (1997) claims it is "most valuable for packing material for porcelain" in New Zealand; it was pre-shredded for packing to protect other delicate objects (Kenneth Adams, pers. comm. 1 November 2013). Other mosses are used for packing fragile items in the Philippines (B. C. Tan, pers. comm.). *Hypnum* (Figure 5), *Plagiomnium undulatum* (Figure 93), and *Sphagnum* (Figure 29-Figure 34) guarded the blades of daggers and scrapers (Dickson 1967). Even the Department of Defense used mosses (*Sphagnum*) to pack fragile bomb sights during World War II (K. Parejko, pers. comm.).

The Open-Air Natural History Museum states that *Sphagnum* (Figure 29-Figure 34) is good for winter storage of carrots to keep them fresh (Open-Air 2007).

The antibiotic properties of *Sphagnum* (Figure 29-Figure 34) make it ideal for shipping small amphibians such as salamanders and frogs from biological supply

houses (Figure 119). It keeps the animals moist and helps prevent diseases like red leg by absorbing the urine and reducing bacterial growth.

Figure 119. *Rana pipiens*, sitting on *Sphagnum*, protected from red leg by the *Sphagnum* substrate in the terrarium. Photo by Janice Glime.

In New Zealand, where *Sphagnum* (Figure 29-Figure 34) has never been common, new commercial uses are surfacing (SFF Project Summary 2006). In a project titled "Economically sustainable novel *Sphagnum* moss products," three new commercial uses are proposed. These include packaging due to the absorbent and antibiotic properties that would reduce fruit spoilage. They likewise suggest using *Sphagnum* for animals, but on the larger scale of veterinarian services, reducing odors and providing absorption. Their third suggestion, already done in several large wars, is to use the moss for bandages, especially those that are particularly "weepy" and thus more prone to infection. In their early experiments, however, they failed to show that *Sphagnum* protects apricots or avocados from post-harvest infections. They are currently looking for a sponsor to research the effects of using *Sphagnum* bandages on burn victims.

In his account of mosses and liverworts W. H. Burrell observed that *Thamnobryum alopecurum* (as *Porotrichum*) is 'used by the gamekeeper as a packing for eggs' (Nicholson 1914). What a nice cushion before the modern-day egg cartons.

Burial Wreath

In Nairobi, Kenya, mosses are used to make wreaths for burial ceremonies (Itombo Malombe, pers. comm. 15 August 2017). These are mostly pendent mosses, including *Neckera* (Figure 11-Figure 12) and *Pilotrichella* (Figure 120). A sack of mosses for this purpose is sold for 10,000 ksh (~\$100 US) and more than ten sacks are used.

Summary

Mosses are used for carrying water, stuffing mattresses, pillows, and dolls, collecting urine from farm animals, making bandages, cushioning fruits, making soap, and packing fragile articles. They even provide vitamin supplements to animal feed. In northern areas they are used for heating, making wicks, and in Morocco they are used to wash hair.

Recently, one of the more important uses is for physiological studies and genetic studies linking genes to processes. This investigation is leading to the possibility of transplanting genes for traits like drought tolerance and antiherbivory into agricultural plants.

Despite the unpleasant taste of most bryophytes, *Sphagnum* has been used in Scotch whisky, *Marchantia polymorpha* has been added to wine, and one European chef is experimenting with new recipes using bryophytes. Capsules may be more tasty if collected at the right stage. Some mosses serve indirectly by providing the overwintering home for gall aphids. The galls made by these insects are used for food and medicine. More commonly, mosses are used for culturing a variety of food plants.

Mosses have been used for making and decorating clothing and pressed buttons. Most importantly, they have been used for diapers and other absorbent roles like lining boots.

Pottery makers use the bryophytes to temper the pottery.

The soft and flexible texture of mosses makes them ideal for packing a variety of items, leading to the spread of some species around the world. Their antibiotic properties make them ideal for shipping amphibians.

Acknowledgments

I am grateful to Robin Stevenson who has sent me several of the stories covered by this chapter. Patxi Heras Pérez and Marta Infante Sánchez alerted me to the use of mosses to temper pottery. John Steel alerted me to the publication on bread and provided me with a copy of the chapter by John Lindley. Jim Dickson has been an invaluable resource in providing anecdotes and references. Denis Jan has provided me with helpful discussion and an unpublished copy of his manuscript. Ralf Reski was very helpful in documentation of bryophyte genes being transferred to crop plants.

CHAPTER 2-1

MEDICAL USES: MEDICAL CONDITIONS

Figure 1. Bryophytes and other herbs on sale in a Yunnan, China, market. The newspaper has the contents of a prescription that is under preparation, including *Rhodobryum*. Photo courtesy of Eric Harris.

New Medical Sources

One of the reasons for exploring biological compounds in bryophytes is the potential for medical use. It's a scary thought, but substances we know as pesticides and fungicides that discourage insect feeding and bacterial or fungal attack are likely to have antibiotic properties that could prove useful in treating human disease. We know bryophytes contain numerous potentially useful compounds, including oligosaccharides, polysaccharides, sugar alcohols, amino acids, fatty acids, aliphatic compounds, phenylquinones, and aromatic and phenolic substances, but much work remains to link medical effects with specific bryophyte species or compounds (Pant & Tewari 1990). For this reason, traditional uses named here should be viewed with caution because we don't know the dosage needed, side effects, or other precautions that need

to be taken. We do know that traditional medicines that may be safe for one race of people may not be for others. After all, those alive today are descendents of survivors. And diet may affect the ways that some of these compounds work, causing geographic differences.

Hansen (1994) suggested that fatty acids produced by members of *Hypnaceae* (Figure 70) and *Brachytheciaceae* (Figure 2) produce high levels of arachidonic acid and EPA and might be used for "producing unique and highly priced compounds for pharmaceutical industry." Mosses contain both n-3 (EPA, 18:3) and n-6 (arachidonic acid, DHGLA, 18:2) fatty acids. Gellerman *et al.* found that *Mnium* (Figure 3), *Polytrichum* (Figure 4), and *Marchantia* (Figure 5) have highly unsaturated lipids. Thus, the potential is real – we need to explore it.

Figure 2. *Eurhynchium striatum*, a member of the **Brachytheciaceae** with a high content of arachidonic acid. Photo by Michael Lüth, with permission.

Figure 3. *Mnium stellare*. The genus *Mnium* is known to have highly unsaturated lipids. Photo by Michael Lüth, with permission.

Figure 4. *Polytrichum commune* is used in China to reduce inflammation and fever, as well as to treat the common cold and kidney and gallstones. Photo by Michael Lüth, with permission.

Asakawa has spent his career studying the secondary compounds of liverworts. In this time he has found that some of them produce a number of terpenoids, aromatic compounds, and acetogenins, several of which show interesting biological activity (Asakawa 2008; Asakawa *et al.* 2013). Among these are agents that cause allergic contact dermatitis, insecticides, insect antifeedants, cytotoxins, piscicides, muscle relaxants, plant growth regulators, anti-HIV agents, DNA polymerase β inhibitory compounds, anti-obesity compounds, neurotrophic agents, NO production inhibitors, antimicrobial agents, and antifungal agents. However, few of these have reached application by the medical practitioners.

Figure 5. *Marchantia polymorpha* thallus illustrating the surface that the Chinese considered to resemble the cross section of the liver. Photo by Michael Lüth, with permission.

Bryophytes can be cultured to produce medical compounds. Using knockout genes, we cannot only sequence the genome of bryophytes, but also determine the function of individual genes. It is also easier to transplant genes into the bryophyte genome than into tracheophytes. This is possible because the bryophyte spends an extended period of time as a leafy plant with only one set of chromosomes. The model system *Physcomitrella patens* (Figure 6, Figure 7) is superior to the traditional mammalian production hosts and cultures can even be stored frozen for ten years, then begin producing again when thawed and cultured (Beike *et al.* 2010).

Figure 6. *Physcomitrella patens* growing in the wild. Photo by Michael Lüth, with permission.

Figure 7. *Physcomitrella patens* growing on agar plates. Photo by Sabisteb, through Creative Commons.

Herbal Medicines

Not surprisingly, herbal medicines of China (Figure 1), India, and Native Americans include bryophytes (Harris 2008). In China, 63 species are known to have medicinal uses. In India, 22 species are known to have medicinal use, but only in the Himalayas. Ayurvedic (holistic medicine of India, over 3000 years old) texts report little or no use. Native Americans have used bryophytes for drugs, fibers, and clothing (University of Michigan, Dearborn, 2003). The mosses *Calymperes* (Figure 8), *Campylopus* (Figure 9), and *Sphagnum* (Figure 10) have been used for medicinal purposes in Malaysia (Burkill 1966; Tan 2003). *Timmiella* (Figure 11) has been used medicinally in Egypt (Harris 2008).

Figure 8. *Calymperes erosum*, considered a medicinal plant in Malaysia. Photo by Li Zhang, with permission.

Figure 9. *Campylopus introflexus*, considered a medicinal plant in Malaysia. Photo by Michael Lüth, with permission.

Native Americans have long traditions of using bryophytes for medical purposes. The languages of the natives of the central coast of British Columbia include words for *Plagiomnium insignne* (Figure 12) that mean tiny, tiny little trees in Oweekeno; this moss is important to them for medicinal use (Turner 1973; Compton 1993; Harris 2008). The users recognize two different forms of the species (Compton 1993; Harris 2008). Those that grow under Douglas fir (*Pseudotsuga menziesii*; Figure 13) are less effective medically than those that grow under spruce (*Picea*; Figure 14).

Figure 10. *Sphagnum centrale*, considered a medicinal plant in Malaysia. Photo courtesy of Betsy St. Pierre.

Figure 14. *Picea sitchensis* forest floor. *Plagiomnium insigne* produces more potent medicine in western spruce forests compared to those of Douglas fir. Photo by Henry Hartley, through Creative Commons.

The Doctrine of Signatures (based on the concept that God provided visual cues through the characteristics of the plants), highly developed during the European Renaissance, has dictated the use of a variety of bryophytes, especially liverworts, in herbal medicine. For example, liverworts resemble the liver, so they have been used to treat liver ailments.

Asakawa (2015) names *Bryum argenteum* (Figure 47) as an antibacterial moss.

Not only do a number of bryophytes serve as medicinal herbs, but *Sphagnum* (Figure 10) has been used to deliver the medicine by using it to make a suppository (Stevenson 2012).

Medicinal Teas

Johannes Enroth (Bryonet 28 January 2009) visited the Yucatan, Mexico, and discovered mosses in use there. The local guide was a "coba-maya" who was familiar with uses of plants. He reported a medical tea made from a moss growing on tree trunks. Enroth collected a bit and identified the moss as *Sematophyllum adnatum* (Figure 15).

Figure 15. *Sematophyllum adnatum*, a moss used to make a medicinal tea in the Yucatan of Mexico. Photo by Bob Klips, with permission.

The moss *Rhodobryum* (Figure 1) is used to make a medicinal tea (Franquemont *et al.* 1990; Harris 2008), and as you will see below, it has tested medicinal properties useful for several medical conditions. *Polytrichum commune* (Figure 4) has been boiled to make a tea for treating colds (Gulabani 1974; Beike *et al.* 2010).

Liver Ailments

The most widely known use of bryophytes determined by its appearance is that of *Marchantia polymorpha* (Figure 5) to treat liver and other ailments; the surface suggests the cross section of liver (Miller & Miller 1979). In China, it is still used to treat the jaundice of hepatitis and as an external cure to reduce inflammation (Hu 1987) and has gained the reputation of cooling and cleansing the liver (Bland 1971). But it has also been used for liver problems in Europe (Thieret 1956) and South America (Garcia Barriga 1992; Roig y Mesa 1945).

Based on the Doctrine of Signatures, it is not surprising that *Marchantia polymorpha* (Figure 5) is not the only species in that genus to be used to treat liver ailments. In India, *M. convoluta* is also used (Rao 2009; Chandra *et al.* 2017). And *Marchantia paleacea* (Figure 16) is used to treat hepatitis (Sabovljević *et al.* 2011; Chandra *et al.* 2017).

Figure 16. *Marchantia paleacea*, a liverwort used to treat hepatitis in India. Photo by Jan-Peter Frahm, with permission.

Perhaps there is more wisdom in these ancient remedies than at first appears. Asakawa (2012) found that some of the isolated terpenoids from liverworts had anti-HIV inhibitory properties. *Fissidens nobilis* (Figure 48) is useful for jaundice (Asakawa 2015).

Stones

In the western Himalayans, native people use *Wiesnerella denudata* (Figure 17) to treat gall stones (Kumar *et al.* 2007). In China, *Polytrichum commune* (Figure 4) is boiled to make a tea that reputedly helps to dissolve stones of the kidney and gall bladder (Gulabani 1974; Chandra *et al.* 2017). Asakawa (2015) reported that *Conocephalum conicum* (Figure 18) is useful in treating gallstones.

Figure 17. *Wiesnerella denudata*, a liverwort used to treat gall stones in the western Himalayas. Photo by Jan-Peter Frahm, with permission.

Figure 18. Thallose liverwort, *Conocephalum conicum*, one of the thallose liverworts used to treat gallstones, bites, boils, burns, cuts, eczema, and wounds. Photo by Janice Glime.

Ringworm

Riccia spp. (Figure 19) were ground to a paste and used in the Himalayas to treat ringworm (*Tinea* spp., a fungus; Figure 20) because of the resemblance of the growth habit of those liverworts to the rings made by the fungus (Shirsat 2008; Chandra *et al.* 2017). Recent tests on *Riccia fluitans* (Figure 21) from Florida indicated no ability to inhibit growth of bacteria [*Pseudomonas aeruginosa* (Figure 22), *Staphylococcus aureus* (Figure 23)] or yeast (*Candida albicans*; Figure 24) (Pates & Madsen 1955). Might *Riccia* species do any better with ringworm?

Figure 19. Circular formations of *Riccia* species, such as this *Riccia austinii*, suggested their use for curing ringworm, according to the Doctrine of Signatures. Photo by Janice Glime.

Heart, Blood, and Cardiovascular Medicine

In China, 30-40 species of bryophytes may be found on the shelves of the local pharmacist (Ding 1982). Among the more common ones are *Rhodobryum giganteum* (Figure 25, Figure 30) and *R. roseum* (Figure 26), used to treat nervous prostration and cardio-vascular diseases, the latter being a use that may have scientific merit (Wu 1982). Among these uses is the treatment of hypertension (high blood pressure) with *R. giganteum* (Wu 1977; Pant 1998; Asakawa 2007b, 2015; Chandra *et al.* 2017).

Figure 25. *Rhodobryum giganteum*, a species widely used medicinally in Yunnan, China. Photo by David Long, with permission.

Figure 26. *Rhodobryum roseum*, a species that is used to treat nervous prostration and cardio-vascular diseases in China. Photo by Michael Lüth, with permission.

In 1977, Wu reported the use of *Rhodobryum giganteum* (Figure 25, Figure 30) to cure cardiovascular disease in China. Chinese scientists have attempted to demonstrate the basis for the healing powers of some of the mosses, including *Rhodobryum giganteum*, used in ancient treatments in China (Ding 1982). Going directly to the peasants in east Szechuan, the staff of the Laboratory of the Fourth Medical School in China learned about mosses used by the peasants (Wu 1982). Through clinical research, they successfully demonstrated that an ether extract of *Rhodobryum giganteum*, used by these peasants to cure angina, contains volatile oils, lactones, and amino acids; when given to white mice, the extract actually reduced the

oxygen resistance by increasing the rate of flow in the aorta by over 30%. Is it time to replace ACE inhibitors, calcium channel blockers, and beta blockers and their side effects?

The term *Hui Xin Cao* in Yunnan refers to the medical effect of *Rhodobryum* species, meaning "return-the-heart-herb" (Harris 2008). The Chinese use *R. roseum* (Figure 26), *R. giganteum* (Figure 25, Figure 30), and *R. ontariense* (Figure 27). Unfortunately, the term *Hui Xin Cao* refers to other plants as well (remember that the name refers to its use, not its morphology), including the moss *Pogonatum cirratum* (Figure 28) and the shrub *Ledum* (Figure 29). Members of the genus *Rhodobryum* are used in Yunnan for minor heart problems (Harris & Yang 2009). Usage depends on location, not on gender, occupation, or ethnicity. And its use also occurs in both rural areas and in traditional Chinese medicine hospitals and medical colleges.

Figure 27. *Rhodobryum ontariense*, a species used in China to treat the heart. Photo by Janice Glime.

Figure 28. *Pogonatum cirratum*, a species used in China to treat the heart. Photo by Li Zhang, with permission.

These reports of traditional usage were supported by a number of studies on *Rhodobryum. giganteum* (Figure 25, Figure 30) that demonstrated its usefulness in treating cardiovascular problems and illustrating the physiological mechanisms involved (Yu & Ma 1993; Yu *et al.* 1994, 1995; Yan *et al.* 1998; Lei *et al.* 2001a, b; Gao *et al.* 2004; Zhou *et al.* 2004; Wang *et al.* 2005; Dai *et al.* 2006; Hu *et al.* 2009). Pejin *et al.* (2011a, 2012c) reported on the

antihypertensive effect of *R. ontariense* (Figure 27) *in vivo* and attempted to find the mechanism used by *R. ontariense* in controlling hypertension (Pejin *et al.* 2012e). They were able to eliminate any effect on human erythrocyte membrane fluidity, there was no reservoir of nitric oxide in the blood, and there was only low ABTS cation scavenging activity and little content of phenolic contents. The actual mechanism remains elusive.

Figure 29. *Ledum* sp., a shrub with the same Chinese name as *Pogonatum cirratum* and several species of *Rhodobryum* because they are all used to treat heart problems. Photo by Meggar, through Creative Commons.

Masanobu Higuchi (Bryonet, 20 November 2006) reports that when he stayed in Zhong Dian, northwestern Yunnan, China, in 1994, he saw local people selling herbal medicines by the roadside. Among these was the moss *Rhodobryum giganteum* (Figure 25, Figure 30) in dry condition, a traditional Tibetan medicine for heart trouble. It was selling for US \$0.50 per 10g. The same species is used in the Himalayas as a neurological and cardiac activant (Kumar *et al.* 2007).

As already noted, their use as medical plants has made *Rhodobryum* species the subject of a number of biochemical studies, revealing a variety of biochemical constituents in *R. ontariense* (Figure 27) [fatty acids 9,12,15-octadecatrien-6-ynoic and α -linolenic acid, having known heart protective activity (Pejin *et al.* 2012a); 1-kestose, a "health promoter" (Pejin *et al.* 2012b); short-chain fructooligosaccharides, well known as prebiotics (Pejin *et al.* 2012c). Thirteen essential oils have been identified in *R. ontariense* (Pejin *et al.* 2011b), but their roles in efficacy of Chinese medicine still remain to be determined.

But wait! Mosses are known accumulators of heavy metals, and we know that high amounts of these are dangerous to human health. Pejin *et al.* (2012d) tested *Rhodobryum ontariense* (Figure 27) for its heavy metal content. Fortunately, they found that the concentrations of arsenic, cadmium, chromium, copper, iron, lead, mercury, nickel, manganese, and zinc in these mosses used in tea were at safe levels for a typical daily intake of the tea. They suggested that manganese was one of the important components in treating hypertension. Nevertheless, these results do not mean that the Chinese populations and

species are safe as the heavy metal concentrations vary by locations and distance from pollution source.

Lisu women in Yunnan Province, China, hike to fens in the alpine area above the Salween River Valley (Nu Jiang) to collect large amounts of *Sphagnum* (Figure 10), which they subsequently dry (James Shevock, Bryonet, 16 January 2007). Despite about 27 species of *Sphagnum* reported in Yunnan, these Lisu women (one of several minority peoples in Yunnan Province) seem able to recognize a particular species in the field; they claim that it is only this species that is used for medicinal purposes. This species of *Sphagnum* is used as a heart tonic, probably brewed like a tea. Once dried and packaged, the moss was to be exported to Canada! (Surely Canada has more *Sphagnum* than Yunnan?)

Figure 30. Dried *Rhodobryum giganteum* (left container) at a shop in Yunnan, China. Photo by David Long, with permission.

In India, bryophytes have also been used to treat heart disease. One such treatment is with *Cratoneuron filicinum* (Figure 31) (Pant 1998; Asakawa 2015; Chandra *et al.* 2017).

Figure 31. *Cratoneuron filicinum*, a species used in India to treat the heart. Photo by Barry Stewart, with permission.

The Indians have also used several bryophytes to stop bleeding. These include the thallose liverwort *Reboulia hemisphaerica* (Figure 32) and the mosses *Funaria hygrometrica* (Figure 33), *Plagiomnium cuspidatum* (Figure 34), *Polytrichum commune* (Figure 4), *Pogonatum cirratum* (Figure 28), and *Taxiphyllum taxirameum* (Figure 35) (Gulabani 1974; Ding 1982; Pant 1998; Asakawa 2007b, 2015; Azuelo *et al.* 2011; Alam 2012; Shirsat 2008; Chandra *et al.* 2017).

Nosebleeds

One odd choice is the use in Cambridge of *Homalothecium sericeum* (Figure 36) from skulls used to treat nosebleeds, with recorded records as early as 1537 (Belcher & Swale 1998). The skulls were placed in damp places to cultivate this moss. But other researchers concluded that the tale was concocted and that no medicinal value was present (Scott 1988). On the other hand, Robert Boyle used it effectively on his own nosebleeds. Perhaps it is just a good absorbent.

Figure 36. *Homalothecium sericeum* from skulls is used to treat nosebleeds in Cambridge. Photo by Michael Lüth, with permission.

In another context, *Plagiomnium cuspidatum* (Figure 34) has been used to treat nosebleeds in India (Pant 1998; Asakawa 2007a, 2015). This casts suspicion on my suggestion of absorbency as this species does not rehydrate easily. On the other hand, as already noted, Asakawa (2015) reported that the mosses *Funaria hygrometrica* (Figure 33), *Oreas martiana* (Figure 38), *Polytrichum commune* (Figure 4), and *Taxiphyllum taxirameum* (Figure 35) and the liverwort *Reboulia hemisphaerica* (Figure 32) stop bleeding.

Neurological Conditions

Few bryophytes seem to be used for neurological conditions. Nevertheless, in Cambridge, England, the moss *Homalothecium sericeum* (Figure 36) from skulls has been used in the treatment of epilepsy (Belcher & Swale 1998). In China, liverworts have been used to treat convulsions, neurasthenia (emotional disturbance typically involving lassitude, fatigue, headache, and irritability), and other nerve conditions (Asakawa 2012). *Rhodobryum roseum* is useful for treating neurasthenia (Asakawa 2015).

Several bryophytes have been used to treat pain. For *Leucobryum bowringii* (Figure 37), a paste is made of leaf tips mixed in a cup of *Phoenix sylvestris* (silver date palm) to treat pain (Lubaina *et al.* 2014; Chandra *et al.* 2017). *Oreas martiana* (Figure 38) is used as an anodyne for treating pain (Asakawa 2007b, 2015; Chandra *et al.* 2017). These authors also reported the use of *Oreas martiana* to treat nervousism and nervous exhaustion as well as epilepsy. *Ditrichum pallidum* (Figure 39) has been used in India to treat convulsions, especially in infants (Pant 1998; Asakawa 2007b, 2015; Chandra *et al.* 2017).

Inflammation and Fever

Today we have freezers and use cold packs to soothe inflammation and reduce fevers, but not so long ago those conveniences were not available. Instead, *Polytrichum commune* (Figure 4) has been used in China to reduce inflammation and fever (Ding 1982; Chandra *et al.* 2017), and the Seminole native people in North America used the small mosses *Barbula unguiculata* (Figure 40) and *Bryum capillare* (Figure 41), as well as larger mosses like *Octoblepharum albidum* (Figure 42), as external applications for fever and body aches (Sturtevant 1954; Chandra *et al.* 2017). *Barbula indica* (Figure 43) and *Weissia controversa* (Figure 44) have also been used in the Western Ghats to treat intermittent fever (Lubaina *et al.* 2014). *Taxiphyllum taxirameum* (Figure 35) is an anti-inflammatory (Asakawa 2015).

Figure 40. *Barbula unguiculata*, a moss used by Seminole native people in North America to treat body aches and fever. Photo by Bob Klips, with permission.

Figure 44. *Weissia controversa*, a moss used in the Western Ghats to treat fever. Photo by Michael Lüth, with permission.

Fontinalis antipyretica (Figure 45) reputedly got its specific name from its ability to work against fever, as recorded in the journal of Linnaeus (Nils Cronberg, pers. comm.). Drobnik and Stebel (2014) found that its use against fever is reported in pre-Linnaean bryophyte floras of central Europe. However, many people have interpreted the name to be derived from its use to insulate chimneys against fire, where in actuality it seems to have little value. On the other hand, it may reduce the heat penetrating into the house. But does it reduce fever? Perhaps it can serve as a cool poultice.

Figure 45. *Fontinalis antipyretica*, reported by Linnaeus as being used to treat fever. Photo by Michael Lüth, with permission.

Sabovljević *et al.* (2011) reported the use of *Marchantia palacea* (Figure 16) to reduce swelling and bring down fever. *Leptodictyum riparium* (Figure 46), an aquatic moss, *Philonotis fontana* (Figure 62), a wetland moss, and the cosmopolitan moss *Bryum argenteum* (Figure 47) are used to treat fever in India (Pant 1998; Asakawa 2007b, 2015; Chandra *et al.* 2017). *Octoblepharum albidum* (Figure 42) was considered in India to have similar ability to reduce fever (Singh 2011; Chandra *et al.* 2017). The mosses *Haplocladium capillatum* (see Figure 52) and *Leptodictyum riparium*, *Polytrichum commune* (Figure 4), *Rhodobryum giganteum* (Figure 25, Figure 30), and *Weissia controversa*

(Figure 44) and the thallose liverworts *Conocephalum conicum* (Figure 18) and *Marchantia polymorpha* (Figure 5) are likewise antifever agents.

Figure 46. *Leptodictyum riparium*, a moss used to treat fever in India. Photo by David T. Holyoak, with permission.

Figure 47. *Bryum argenteum*, a moss used to treat fever in India. Photo by Tushar Wankhede, through Creative Commons.

Urinary and Bowel Treatments

The Chinese also use *Polytrichum commune* (Figure 4) as a detergent diuretic, laxative, and hemostatic agent (Ding 1982; Ando & Matsuo 1984; Hu 1987; Fan *et al.* 2004; Harris 2008). In India, *Fissidens nobilis* (Figure 48) and *Dawsonia longifolia* (Figure 49) are used as diuretics (Pant 1998; Azuelo *et al.* 2011; Chandra *et al.* 2017), and Asakawa (2015) reports *Marchantia polymorpha* (Figure 5) for the same purpose. *Pogonatum cirratum* (Figure 28) has been used as a laxative in India (Azuelo *et al.* 2011; Alam 2012; Chandra *et al.* 2017). Asakawa (2015) reports *Fissidens nobilis* (Figure 48) as a diuretic and *Haplocladium capillatum* (see Figure 52) for treating cystitis and uropathy. *Leptodictyum riparium* (Figure 46) and *Rhodobryum giganteum* (Figure 25, Figure 30) likewise are used to treat uropathy (restricted urine flow) (Asakawa 2015).

Figure 48. *Fissidens nobilis*, a species that is used as a diuretic in India. Photo by Jan-Peter Frahm, with permission.

Figure 49. *Dawsonia longifolia*, a species used as a diuretic in India. Photo by Jan-Peter Frahm, with permission.

I was surprised to find *Polytrichum juniperinum* (Figure 50) listed in *Materia Medica* as a treatment for painful urination of the elderly, obstruction or suppression, and dropsy (Available *Materia Medica*s 2011). The medicine is made by boiling two ounces of the moss in a liter of water until it boils down to only half that – a pint, making a "tincture." One dose (4 ozs, 113 g) should be taken every 8 hours.

Figure 50. *Polytrichum juniperinum*, a hairy cap moss, is used in China to treat urinary and prostate problems. It can be recognized by the brown tips on the leaves and the rolled over leaf edges that cover the lamellae. Photo by Michael Lüth, with permission.

The leafy liverwort *Herbertus* sp. (Figure 51) is used in India as an antiseptic, antidiarrheal agent, expectorant,

and astringent (Azuelo *et al.* 2011; Alam 2012; Chandra *et al.* 2017). In both China and India, **cystitis** (inflammation of the bladder) has been treated with the moss *Haplocladium microphyllum* (Figure 52) (Ding 1982; Pant 1998).

Figure 51. The leafy liverwort *Herbertus sendtneri*. Some members of the genus *Herbertus* are used in India as a filter for smoking. Photo by Michael Lüth, with permission.

Gynecology

The absorbent properties that make *Sphagnum* (Figure 10) an excellent bandage also make it suitable for diapers and sanitary napkins, a product currently sold by Johnson and Johnson Company (D. H. Vitt, pers. comm.).

Figure 53. *Sphagnum* Sanitary napkin. Photo from National Museum of American History, with online permission.

Sphagnum (Figure 10) has also been used, along with grass, sponge, and other plant fiber, as a contraceptive to block the entry of sperm (Stanley 1995). By contrast, following successful pregnancies, the Nitinaht peoples of Vancouver Island, Canada, used *Polytrichum commune* (Figure 4) as a gynecological aid (Turner *et al.* 1983; Chandra *et al.* 2017). Women in labor chewed the moss to speed up the labor process.

In China, *Polytrichum* (Figure 4, Figure 50) has been used to stop bleeding and night sweats, presumably associated with menopause (EBCHSATCM 1999; Cheng *et al.* 2008; Fu *et al.* 2009). It has also been used to treat **uterine prolapse** (the uterus sags due to weakening of muscles or ligaments that support it).

The moss *Oreas martiana* (Figure 38) is used to treat **menorrhagia** (prolonged bleeding with menstrual period) (Asakawa 2007b; Chandra *et al.* 2017). *Barbula indica* (Figure 43) has been used in the Western Ghats to treat menstrual pain (Lubaina *et al.* 2014; Chandra *et al.* 2017).

Disinfectant and Infections

The Native American Nitinahts also used *Sphagnum* (Figure 10) as a disinfectant (Turner *et al.* 1983). *Fissidens* (Figure 54) is used in China as an antibacterial agent for swollen throats and other symptoms of bacterial infection, and in Bolivia it likewise has medicinal uses. Judith Sullivan (Bryonet, 16 January 2007) reported seeing labels on Chinese medicines that included *Grimmia* (Figure 55), *Atrichum* (Figure 56), *Polytrichum* (Figure 4, Figure 50), and *Thuidium* (Figure 57), primarily as anti-bacterial and anti-inflammatory agents. *Polytrichum juniperinum* (Figure 50) is used there for some prostate and urinary difficulties.

Figure 54. *Fissidens osmundoides*, a moss in one genus used as an antibacterial agent to treat sore throats in Bolivia and several Asian countries. Photo by Michael Lüth, with permission.

Figure 55. *Grimmia pilifera*, a Chinese species. Some members of this genus are used in medicines in China. Photo by Henk Greven, with permission.

Figure 56. *Atrichum undulatum*. Some members of this genus are used in medicines in China. Photo by Michael Lüth, with permission.

Figure 57. *Thuidium recognitum*. Some members of *Thuidium* are used as anti-bacterial and anti-inflammatory agents in China. Photo by Jan-Peter Frahm, with permission.

Dried *Sphagnum* (Figure 58) is sold to treat hemorrhages (Bland 1971), and *S. teres* (Figure 58) is used to treat eye diseases and hemorrhoids (Ding 1982). *Haplocladium microphyllum* (Figure 52) is sold to treat bronchitis, tonsillitis, and tympanitis, as well as cystitis (Ding 1982).

Figure 58. *Sphagnum teres* is used to treat eye diseases in Asia. Photo by Michael Lüth, with permission.

As noted in Chapter 1 of this volume, the soap **Sphagnol** is a *Sphagnum* (Figure 10; Figure 58) product used to treat skin problems such as acne, eczema, chilblains (painful inflammation of small blood vessels in the skin), dandruff, insect bites, and ringworm (a fungus) (The Science Museum 2012). This product was used during both World Wars by the British Red Cross to treat facial wounds and is believed to have antibiotic properties.

Kumar *et al.* (2007) reported on antibacterial species used in India, as discussed in Chapter 2-2 on Biologically Active Substances. *Oreas martiana* (Figure 38) and *Taxiphyllum taxirameum* (Figure 35) likewise are used to treat wounds (Asakawa 2015), perhaps having antibiotic properties. the leafy liverwort *Frullania tamarisci* has known antiseptic properties (Asakawa 2015).

Nose and Throat

In both India and North America, the moss *Philonotis fontana* (Figure 62) has been used to treat **adenopharyngitis**, an inflammation of the pharynx and tonsils (Flowers 1957; Pant 1998; Asakawa 2007b; Chandra *et al.* 2017). *Haplocladium capillatum* (see Figure 52) and *Philonotis fontana* likewise can be used to treat adenopharyngitis (Asakawa 2015). *Bryum argenteum* (Figure 47) and *Weissia controversa* (Figure 44) have chemical properties used to treat **rhinitis** (inflammation of the mucous membrane of the nose) (Asakawa 2015).

Lung Diseases

Funaria hygrometrica (Figure 33) has been used in India to treat pulmonary tuberculosis (Pant 1998; Chandra *et al.* 2017), and Asakawa (2015) indicates it has compounds useful for that purpose, as does *Polytrichum commune* (Figure 4). The similarity of *Marchantia polymorpha* (Figure 5) thalli to the texture of lung tissue caused Europeans to use that liverwort to treat pulmonary tuberculosis (Bland 1971). It is likely that this Doctrine of Signatures was also responsible for the Chinese use of liverworts to treat pulmonary tuberculosis (Asakawa 2012). It is interesting that its thallus has been interpreted as resembling both liver tissue and lung tissue.

In Cambridge, England, the moss *Homalothecium sericeum* (Figure 36) was used to treat whooping cough (Belcher & Swale 1998). In the Himalayas the moss *Haplocladium microphyllum* (Figure 52) is used to treat bronchitis (Kumar *et al.* 2007). *Haplocladium microphyllum* has also been used to treat tonsillitis and pneumonia (Ding 1982; Pant 1998; Chandra *et al.* 2017); *H. capillatum* (see Figure 52) is known for its use in treating in pneumonia (Asakawa 2015).

Treatments of colds, not surprisingly, has made use of bryophytes. *Hyophila involuta* (Figure 59) has been used for the symptoms of a cold, cough, and sore throat. This treatment is a leaf decoction with a pinch of ground pepper, used daily (Lubaina *et al.* 2014; Chandra *et al.* 2017). Also in India, natives in the Western Ghats have used *Weissia controversa* (Figure 44) to treat colds.

Figure 59. *Hyophila involuta* drying. This species has been used to treat cold, cough, and sore throat. Photo by Bob Klips, with permission.

The other side of the coin is the ability of some mosses, especially *Sphagnum* (Figure 58), to harbor fungi that cause lung disease. *Sphagnum* was once thought to harbor *Mycobacteria* (Figure 60), the genus in which the tuberculosis bacterium resides, but now it seems that it is not the reservoir for this genus it was thought to be (Deriu *et al.* 1995). On the other hand, the fungus *Sporothrix schenckii* (Figure 61), common on *Sphagnum*, does cause pulmonary **sporotrichosis**, an infection of the lung resulting from breathing the fungi (McCain & Buell 1968).

Figure 60. *Mycobacterium tuberculosis* SEM, member of a pathogenic genus once thought to live among *Sphagnum*. Photo from NIAID, through Creative Commons.

Figure 61. *Sporothrix schenckii* conidia, a species that grows among *Sphagnum* and causes **sporotrichosis**. Photo from USDHHS, through public domain.

Skin Ailments and Burns

The antibiotic properties of many bryophytes suggest that they should promote healing of skin infections. The thallose liverwort *Reboulia hemisphaerica* (Figure 32) is used to treat skin blotches, external wounds, and bruises and *Oreas martiana* (Figure 38) is used to treat external wounds (Asakawa 2007b, 2015; Chandra *et al.* 2017). *Fissidens nobilis*, *Conocephalum conicum* (Figure 18), and *Marchantia polymorpha* (Figure 5) have compounds that help in the healing of burns (Asakawa 2015). *Funaria hygrometrica* (Figure 33) is useful in treating bruises and Athlete's foot. *Rhodobryum giganteum* (Figure 25, Figure 30), *Conocephalum conicum*, and *Marchantia polymorpha* can be used to treat cuts (Asakawa 2015).

Himalayan Indians use a mixture of moss ashes with fat and honey to soothe and heal cuts, burns, and wounds (Pant *et al.* 1986; Pant 1998; Chandra *et al.* 2017), claiming that these ashes heal wounds more quickly (Pant & Tewari 1989). *Taxiphyllum taxirameum* (Figure 35) is among those mosses used to treat surface wounds (Pant 1998; Asakawa 2007b; Chandra *et al.* 2017). In the Himalayas, the Gaddi tribe uses *Philonotis fontana* (Figure 62) and *Plagiochasma appendiculatum* (Figure 63) to treat burns and skin diseases (Flowers 1957; Pant 1998; Asakawa 2007b; Kumar *et al.* 2007; Shirsat 2008; Alam 2012; Chandra *et al.* 2017). *Bryum thomsonii* is used in the Northwest Himalayas for healing wounds (Kumar *et al.* 2007). Himalayan Indians have used *Marchantia polymorpha* (Figure 5; Figure 64) or *M. palmata* to treat boils and abscesses because the young archegoniophore resembles a boil as it emerges from the thallus (Pant & Tewari 1989).

Figure 62. *Philonotis fontana* is a wetland moss used by Gosuite native people to relieve pain of burns. Photo by Michael Lüth, with permission.

In India, the pendent moss *Aerobryum lanosum* is used to treat burns. The whole plant is boiled in goat urine and applied externally (Lubaina *et al.* 2014; Chandra *et al.* 2017). Species of *Mnium* (*sensu lato*?) (Figure 3) have been used in a poultice to reduce pain from bruises, wounds, and burns (Azuelo *et al.* 2011; Chandra *et al.* 2017). Similarly, these authors found that *Plagiomnium* (Figure 12, Figure 34) has been used for treating infections and swellings.

Also in India, the thallose liverwort *Targionia hypophylla* (Figure 65) is used, mixed with leaves of the flowering plant *Actinopterys radiata*, and ground into a paste, then mixed with two tablespoons of coconut oil.

This paste is smeared over the body of the children affected by itching skin, scabies, and other skin diseases (Remesh & Manju 2009; Chandra *et al.* 2017).

Figure 63. *Plagiochasma appendiculatum* with archegoniophores, a species used in the Himalayas to treat burns and skin diseases. Photo by Michael Lüth, with permission.

Figure 64. Young archegoniophores of *Marchantia polymorpha*, somewhat resembling a boil. Photo by Rudolf Macek, with permission.

Figure 65. *Targionia hypophylla*, a species used in India to treat skin diseases. Photo by Martin Hutten, with permission.

Marchantia palmata is made into a fleshy leaf paste and applied directly to acute inflammation caused by heat (burns) (Tag *et al.* 2007; Chandra *et al.* 2017).

Another skin-related use in India is that of the cosmopolitan moss *Funaria hygrometrica* (Figure 33) to treat bruises and skin infections (Pant 1998; Chandra *et al.* 2017).

Among the Native Americans, the Cheyenne in Montana use *Polytrichum juniperinum* (Figure 50) in medicines (Hart 1981). In Utah, USA, the Goshute native peoples used *Bryum* (Figure 41, Figure 47), *Mnium* (Figure 3), *Philonotis* (Figure 62), and various matted hypnaceous forms crushed into a paste applied to reduce the pain of burns, bruises, and wounds (Flowers 1957). *Sphagnum* (Figure 10) was used by Native Americans as a carrier for berries that were rubbed on children's sores (Carrier Linguistic Committee 1973).

As one might expect, the Chinese have used liverworts in the treatment of skin ailments, including cuts, burns, and bruises (Asakawa 2012). A mixture of the thallose liverworts *Conocephalum conicum* (Figure 18) and *Marchantia polymorpha* (Figure 5) with vegetable oils is used in China on bites, boils, burns, cuts, eczema, and wounds (Wu 1977; Ding 1982; Ando 1983; Yan *et al.* 1999).

In China and India, *Conocephalum conicum* (Figure 18) has a number of medical uses. Its antimicrobial, antifungal, antipyretic, and antidotal activities contribute to its usefulness to treat cuts, swollen tissue, scalds, burns, fractures, and poisonous snake bites (Ding 1982; Alam 2012; Chandra *et al.* 2017). Likewise, *Marchantia polymorpha* (Figure 5) has been used to treat snake bites (Hu 1987; Shirsat 2008; Azuelo *et al.* 2011; Asakawa 2015; Chandra *et al.* 2017). *Bryum argenteum* (Figure 47), *Polytrichum commune* (Figure 4), and one or more species of *Philonotis* (Figure 62) have been used as antidotes (Asakawa 2007b, 2015; Chandra *et al.* 2017).

Alaskan native peoples have used *Sphagnum* (Figure 10), mixed with fat, to make a salve (Schofield 1969; Miller & Miller 1979). In Britain *Sphagnum* was used to treat boils (Bland 1971), its derivative **sphagnol** to relieve the itch of a mosquito bite (Crum 1988), and for medicinal baths (Crum 1973; Weber & Ploetner 1976; Turner 1993), although the small amounts of active substances put into an average bath are not likely to have any effect.

Nevertheless, Mitchell and Rook (1979) caution us about the possible allergenic effects of *Sphagnum* (Figure 10), especially because of its ability to harbor the fungus causing **sporotrichosis** (Adams *et al.* 1982). It is a known danger to nursery workers and harvesters who are in constant contact with the *Sphagnum* (D'Alessio *et al.* 1965; McCain & Buell 1968; Tamblyn 1981; Keller 1988; Padhye & Ajello 1990; Coles *et al.* 1992), even affecting areas like the abdomen (Frankel & Frankel 1982). In 1988, sporotrichosis reached sufficient proportions that "*Sphagnum* the culprit" made its debut in the *Milwaukee Journal* (Rosenberg 1988). In 1995, nine of the 65 workers involved in making topiary art at a Florida nursery became infected with lymphocutaneous sporotrichosis (Hajjeh *et al.* 1997). Even forestry workers who don't handle the moss directly can contract the disease from working in peatlands (Powell *et al.* 1978). The threat is sufficient to cause the American Orchid Society to warn its members of this

occupational hazard (Padhye & Ajello 1990). The Macauley Institute in Aberdeen, England, is investigating the use of hydroponics to produce *Sphagnum* that is free of microorganisms and other contaminants. Wearing gloves helps to protect against the lymphocutaneous sporotrichosis (Hajjeh *et al.* 1997), but longer exposures can still lead to pulmonary infections.

Eye Problems and Diseases

In the northwest Himalayas, *Sphagnum teres* (Figure 58) is used to treat ophthalmic diseases (Kumar *et al.* 2007). There seems to be medical evidence that at least some of the bryophytes can be used effectively to treat age-related blindness (age-related macular degeneration) (Albert-Ludwigs-Universität Freiburg 2010). Factor H is necessary to maintain healthy eyes (Coffey 2007). The Freiburg research lab has produced a protein in a bioreactor using factor H from mosses. Factor H is otherwise known only from blood and is important for the immune system. 50 million people suffer blindness due to lack of this protein, especially in industrial countries.

Büttner-Mainik *et al.* (2011) developed a protocol to produce Factor H using *Physcomitrella patens* (Figure 6, Figure 7). Factor H is a protein that is difficult to produce in animal lines, but these researchers successfully produced it in transgenic *P. patens*.

Flatbergium sericeum (Figure 66), a relative of *Sphagnum*, has been used to treat eye diseases (Azuelo *et al.* 2011; Chandra *et al.* 2017). Similarly, *Sphagnum teres* (Figure 58) has been used for this purpose in China (Ding 1982).

Figure 66. *Flatbergium sericeum*, a species that has been used to treat eye diseases. Photo courtesy of Jon Shaw.

Ear Ache and Hearing Problems

Entodon flavescens is used by the Kani tribes in the Western Ghats for treating ear ache (Lubaina *et al.* 2014; Chandra *et al.* 2017). They use a leaf juice as ear drops, especially in cold weather. *Haplocladium capillatum* (see

Figure 52) has been used to treat tinnitus, but recent news reports suggest this is not really related to the ears.

Hair Treatments

Soothing a wound of a different sort (human pride), the Chinese use *Fissidens* (Figure 54; Figure 79), burned, to put on their heads to encourage hair growth! (Harris 2002). In India, *Fissidens nobilis* (Figure 48) has likewise been used to grow hair (Pant 1998; Azuelo *et al.* 2011). And Asakawa (2015) found compounds in *Fissidens nobilis* (Figure 48) that should promote hair growth

Most likely following the Doctrine of Signatures, Himalayan natives use *Polytrichum commune* (Figure 4) to promote hair growth (Kumar *et al.* 2007). The Doctrine of Signatures is a theory that the plant tells us what it is useful for by its morphology or other properties. Since *Polytrichum commune* has a hairy calyptra (Figure 67), that would suggest it is good for growing hair. Similarly, the hairs on the calyptra most likely account for the use of *Dawsonia longifolia* (Figure 69) to grow hair (Azuelo *et al.* 2011; Chandra *et al.* 2017).

Figure 67. *Polytrichum commune* capsules with hairy calyptrae (and one with calyptra removed). This species is used to help grow hair. Photo by Michael Lüth, with permission.

Frullania ericoides (Figure 68) is used to treat the hair and scalp in India (Remesh & Manju 2009; Chandra *et al.* 2017). It purportedly gets rid of head lice and nourishes the hair.

Figure 69. *Dawsonia longifolia* with capsule, showing long hairs on the calyptra. Photo by Vita Plasek, with permission.

Sedatives

The use of bryophytes as sedatives seems to be uncommon. The moss *Hypnum* (Figure 70) was named for sleep, but that is because it was used to stuff pillows, not for any known sedative effect (Dillenius 1741). However, *Plagiopus oederianus* (Figure 71) has been used in India as a sedative, as well as for treating epilepsy (Pant 1998; Asakawa 2015; Chandra *et al.* 2017). And the widely used *Rhodobryum roseum* and *R. giganteum* (Figure 26) likewise have been used as sedatives (Wu 1977; Pant 1998; Asakawa 2007b, 2015; Chandra *et al.* 2017).

Figure 70. *Hypnum cupressiforme*, a moss that filters substances out of items for smoking and is used to stuff pillows. Photo by Michael Lüth, with permission.

Figure 71. *Plagiopus oederianus*, a species used in India as a sedative and to treat epilepsy. Photo by Michael Lüth, with permission.

Antidotes

The mosses *Bryum argenteum* (Figure 47), *Haplocladium capillatum* (see Figure 52), *Philonotis fontana* (Figure 62), *Polytrichum commune* (Figure 4), and *Weissia controversa* (Figure 44) can be used as an antidote, as well as *Conocephalum conicum* (Figure 18) and *Marchantia polymorpha* (Figure 5). But Asakawa does not state what things these will treat (Asakawa 2015). For *Conocephalum conicum*, Asakawa reports that it can be used to treat snake bites.

Filters

Kumaun Indians (also Kumaon) of the Himalayas use slender bryophytes such as *Herbertus* (Figure 51), *Anomodon* (Figure 72), *Entodon* (Figure 76), *Hypnum* (Figure 70), *Meteoriopsis* (Figure 73), and *Scapania* (Figure 74), wrapped in a cone of *Rhododendron campanulatum* (Figure 75) leaves, to serve as a filter for smoking (Pant & Tewari 1989). One must wonder if any of those heated phenolic compounds in bryophytes might be as harmful as the substances they filter out!

One peat product has actually entered modern medicine as a means to cleanse the body of pollutants: humic acids. HUMET-R syrup entered medicine as a transporter of trace elements, reducing excess trace elements that are bombarding the human body from pollutants and other sources (Kleb *et al.* 1999). The active substance is humin acid.

Figure 76. The pleurocarpous moss *Entodon concinnus* is used as a smoking filter. Photo by Michael Lüth, with permission.

Surgical and Larger Wounds

Bryophytes have been used both in treating and in cushioning wounds. In Utah, the Goshute native people used poultices of *Bryum* (Figure 41, Figure 47), *Mnium* (Figure 3), *Philonotis* (Figure 62), and various matted hypnaceous forms as padding under splints to set broken bones.

But it is *Sphagnum* (Figure 10) that has gained fame for its use as a bandage (Figure 77) (Painter 2003). It appears that even before the First World War, *Sphagnum* was used to bandage the wounded in the Russo-Japanese War (1904-05). In the First World War, the Americans (USA) and Canadians used *Sphagnum* (peat moss) to make bandages, conserving the valuable cotton for making and packing gunpowder (Porter 1917; Hotson 1918, 1919, 1921; Nichols 1918a, b, c, d, 1920). The wounds apparently healed better than those with sterile surgical bandages, benefitting from the moisture and fewer infections. The British Army used about 1,000,000 pounds (453590 kg) of dressing per month (Nichols 1918c, 1920), saving about US \$200,000 (Bland 1971), the Canadian Red Cross about 200,000 pounds (90720 kg) per month, and the United States about 500,000 pounds (226800 kg) during the last six months of war (Bland 1971). After the war, these countries returned to traditional gauze bandages, but the Chinese have continued to use *Sphagnum* for this purpose (Ding 1982).

The superiority of *Sphagnum* (Figure 10) bandages is attributed in part to its ability to absorb 3-4 times as much liquid as a cotton bandage at a rate three times as fast (Porter 1917). This is due to the interlaced hyaline cells that are dead and possess pores (Figure 78). These cells retain water and readily absorb water when dry. Hence, the bandage retains liquids longer and more uniformly, necessitating less frequent change. It is more comfortable

for the user because it is cooler, softer, less irritating, and retards bacterial growth (Banerjee 1974). In fact, tests indicate that the amount of wound area covered by new epidermis doubles with use of *Sphagnum* dressing compared to no dressing (Varley & Barnett 1987).

This news article appeared on page 4 of *The Seattle Star* (Washington, USA), 3 April 1918:

"U" STUDENTS TO MAKE 50,000 MOSS DRESSINGS

Fifty thousand sphagnum dressings, for use in France, will be made at the University of Washington before June 15. The dressings will follow a new design and will be submitted for experiment. If successful, it is expected that a call will come for 50,000 each week.

Between 800 and 900 freshman and sophomore girls are now registered for work on sphagnum moss dressings.

Figure 78. Stained cells of *Sphagnum* showing large hyaline cells with pores and small photosynthetic cells. Photo and drawings by Janice Glime.

The pectin complex in the *Sphagnum* (Figure 78) cell wall is similar structurally to immunostimulatory pectin from tracheophytes that has traditionally been used for healing wounds (Painter 2003).

Sphagnum (Figure 10) is not the only moss that has been used for bandages. The Nitinaht native people of Vancouver Island, Canada, used a moss known as maidenhair moss (*Fissidens adianthoides*; Figure 79) to bandage wounds. The Anglo-Saxons gave it the name of maidenhair moss because to them it resembled a maiden's pubic hair.

Figure 79. *Fissidens adianthoides* is the maidenhair moss used by the Nitinaht native people for bandages. Photo by Michael Lüth, with permission.

Perhaps one of the more unusual uses of liverworts is the Chinese use to promote healing of fractures (Asakawa 2012); he reports *Conocephalum conicum* (Figure 18) and *Marchantia polymorpha* (Figure 5) to be useful for this (Asakawa 2015). Lubaina *et al.* (2014) reported the use of the leafy liverwort *Plagiochila beddomei* (see Figure 80) for healing wounds in the Western Ghats.

Figure 80. *Plagiochila* sp. *Plagiochila beddomei* is used in the Western Ghats for healing wounds. Photo by Lin Kyan, with permission.

The use of *Sphagnum* (Figure 10) as a bandage is not without its hazards, as mentioned earlier. Perhaps other mosses may serve an absorptive function as well or better than *Sphagnum* and impose fewer hazards. Horikawa (1952) compared a number of mosses and their ability to

absorb water. He found several that could rival *Sphagnum* in absorptive ability (Table 1).

Table 1. Weight gain measured as wet weight to dry weight ratio of selected bryophytes (Horikawa 1952).

Covid Masks

Professor Hazem Kalaji (2022), from Warsaw University of Life Sciences, filed for a patent with the Japanese Patent Office for a moss anti-virus half mask.

The project was in collaboration with the virologist Dr. Seiya Sato, president of Green's Green Ltd., Niigata, Japan. In this half mask, mosses (apparently *Hypnum plumaeforme*, Figure 86) are placed in a thin layer of transparent material, thus enabling them to photosynthesize. The wearer provides the mosses with CO₂ and moisture while breathing, and the mosses provide oxygen. The virus is adsorbed in the mask due to differences in electrical charge. Viruses have a negative charge and the mosses a positive one. The capsids (envelopes) of the viral proteins are broken and the harmless interior leaks out and disintegrates, leaving non-infectious RNA.

Breaking News

After "completing" the revision of this chapter, I received an email announcing the completion of a safety study for the pharmaceutical use of a bryophyte-produced compound, Moss-aGal (Kirstein 2017). Six patients were monitored for 28 days following a single dose of the pharmaceutical and showed no negative effects. This is only phase 1 of the study, but it provides promise in relieving symptoms in patients suffering from Fabry disease. This is the first moss-based clinical product to be tested in humans. The research has been done at Greenovation, a privately-owned biopharmaceutical company based in Heilbronn, Germany. It was founded in 1999 by Prof. Dr. Ralf Reski and Prof. Dr. Gunter Neuhaus.

Fabry disease is a rare genetic disease causing a deficiency of the enzyme **alpha-galactosidase A** (a-Gal A), hence the name Moss-aGal for the moss compound to treat it. This disease causes a buildup of a type of fat called **globotriaosylceramide** (Gb3, or GL-3) in the body. Fabry disease is classified as a type of lysosomal storage disorder. There is no known cure, only treatments of the deficiency.

Summary

Bryophytes have been traditionally used for their medicinal properties in China, India, and among Native Americans. Their use in Europe became more widespread following the development of the Doctrine of Signatures. Among the most commonly used, *Marchantia polymorpha* was used for liver ailments and is still used in some places, but is also used for boils and abscesses. *Rhodobryum giganteum* is used for cardiovascular problems, a use supported by clinical tests.

Traditional uses of bryophytes include treatment for liver ailments, ringworm, heart problems, inflammation, fever, urinary and digestive problems, female problems, infections, lung disease, skin problems, and as filters and cleansing agents against pollutants.

The ability of *Sphagnum* to promote healing of flesh wounds is well documented. *Sphagnol* is used to treat boils and mosquito bites, and *Sphagnum* in diapers prevents diaper rash.

Acknowledgments

I appreciate the continued support of Robin Stevenson in providing me with interesting articles such as the one on the medical use of mosses growing on skulls. Eric Harris generously shared his papers and images of medicinal bryophytes.

CHAPTER 2-2

MEDICAL USES: BIOLOGICALLY ACTIVE SUBSTANCES

Figure 1. Bryophytes and other herbs on sale in a Yunnan, China, market. *Rhodobryum giganteum* (upper bag) and *Leucobryum* (lower bag), both called Hui Xin Cao. Photo by courtesy of Eric Harris.

Antibiotics and Other Biologically Active Substances

Bryophyte species actually produce broad-range antibiotics (Asakawa 2007a, b, 2008; Asakawa *et al.* 2013). Their usage in surgical dressings, diapers, and other human medicinal applications is well known. And their use has not been confined to Asia (Frahm 2004), but is known in Brazil (Pinheiro da Silva *et al.* 1989), England (Wren 1956), North America (Pejin *et al.* 2011a, b), and Germany

(Frahm 2004), as well as in China (Ding 1982; Wu 1982) and India (Watts 1891). Frahm (2007) has reviewed the literature on bryophytes and their antibiotic activity.

Bryophytes discourage the feeding by a variety of organisms, as discussed in the chapters on terrestrial insects, arthropods, and other interaction chapters. Frahm and Kirchhoff (2002) showed that extracts of the epiphytic

moss *Neckera crispa* (Figure 2) and leafy liverwort *Porella obtusata* (Figure 3) both discouraged feeding by the Portuguese slug *Arion lusitanicus* (Figure 4).

Figure 2. *Neckera crispa*, a species that discourages the Portuguese slug from eating it. Photo by Jan-Peter Frahm, with permission.

One indication of the presence of unique and potentially important pharmaceutically and anti-feedant chemicals in bryophytes is the presence of unique odors. This is especially true for liverworts, with more than several hundred new compounds identified among them (Asakawa 2012). In addition, more than 40 new carbon

skeletal acetogenins, phenolic compounds, and terpenoids were identified. Testing of these compounds has led to the commercial development of a natural pesticide (Frahm 2004).

Leptolejeunea (Figure 5) and *Moerckia* (Figure 6) are distinctly aromatic (Schuster 1966), *Lophozia bicrenata* (Figure 7) has a pleasant odor, species of *Solenostoma* (Figure 8) smell like carrots, *Geocalyx graveolens* (Figure 9) has a turpentine-like odor, and *Conocephalum conicum* (Figure 10) smells like mushrooms. The tropical *Plagiochila rutilans* (Figure 11) smells like peppermint, caused by several menthane monoterpenoids (Heinrichs *et al.* 2001).

Figure 10. *Conocephalum conicum*, a species that smells like mushrooms. Photo by Hermann Schachner, through Creative Commons.

But can you imagine using mosses to lower your cholesterol? Yes, mosses contain polyunsaturated fatty acids that are already known to have important potentials in human medicine, such as preventing atherosclerosis and cardiovascular disease, reducing collagen-induced thrombocyte aggregation, and lowering triacylglycerols and cholesterol in plasma (Radwan 1991).

Figure 11. *Plagiochila* sp. *Plagiochila rutilans* smells like peppermint. Photo by Lin Kyan, with permission.

It appears that these unique odors result from a combination of many compounds, including monoterpene hydrocarbons such as α -pinene, β -pinene, camphene, sabinene, myrcene, alpha-terpinene, limonene, fatty acids, and methyl esters of low molecular weight (Hayashi *et al.* 1977). For example, *Isotachis japonica* (Figure 12) has at least three aromatic esters: benzyl benzoate, benzyl cinnamate, and B-phenylethyl cinnamate (Matsuo *et al.* 1971).

Figure 12. *Isotachis* sp. *Isotachis japonica* has at least three aromatic esters. Photo by George Shepherd, through Creative Commons.

But progress in purifying and identifying bryophyte biochemical components and demonstrating their antibiotic effects has been slow. As early as 1952, Madsen and Pates found inhibition of microorganisms in products of bryophytes, including *Sphagnum portoricense* (Figure 13), *S. strictum* (Figure 14), *Conocephalum conicum* (Figure 10), and *Dumortiera hirsuta* (Figure 15) (see also Sabovljević *et al.* 2011; Chandra *et al.* 2017). Pavletic and Stilinovic (1963) found that *Dicranum scoparium* (Figure 16) strongly inhibited all bacteria tested but Gram-negative *Escherichia coli* (Figure 17). McCleary and Walkington (1966) considered that non-ionized organic acids and polyphenolic compounds might contribute to the antibiotic properties of bryophytes and found eighteen mosses that strongly inhibited one or both of Gram-positive and Gram-negative bacteria, the most active being *Atrichum* (Figure

20), *Dicranum* (Figure 16), *Mnium* (Figure 18), *Polytrichum* (Figure 19), and *Sphagnum*. Reminiscent of *Dicranum scoparium* (Figure 16), *Atrichum undulatum* (Figure 20) was effective on everything tested except *Enterobacter aerogenes* (drug resistant and infectious to people with weak immune systems; Figure 21) and *E. coli*.

Figure 21. *Enterobacter aerogenes*, a bacterium that seems to be resistant to extracts of 18 moss species that negatively affect other bacteria. Photo by Alexa Rakusin Muna, through Creative Commons.

Gupta and Singh (1971) found high occurrence of antibacterial activity in extracts of *Barbula* species (Figure 22), reaching as high as 36.2%, whereas it was only half that in *Timmiella* species (Figure 23) (18.8%). In 1982, Asakawa *et al.* (1982) isolated three prenyl bibenzyls from *Radula* spp. (Figure 24) and demonstrated that these

bibenzyls could inhibit growth of *Staphylococcus aureus* (Figure 25) at concentrations of $20.3 \mu\text{g ml}^{-1}$. Out of more than 80 species tested, Ichikawa (1982) and coworkers (1983) found antimicrobial activity in nearly all. Acyclic acetylenic fatty acid and cyclophentenonyl fatty acid extracts from the mosses completely inhibited the growth of the rice blast fungus *Magnaporthe grisea* (Figure 26). Belcik and Wiegner (1980) reported antimicrobial activity in extracts of the liverworts *Pallavicinia* (Figure 27) and *Reboulia* (Figure 28), and Isoe (1983) reported it from *Porella* (Figure 29).

Another three species of mosses [*Anomodon rostratus* (Figure 30), *Plagiomnium cuspidatum* (Figure 31), *Orthotrichum rupestre* (Figure 32)] produce substances that inhibit bacteria and fungi, but these inhibitors seem to be unstable products that vary considerably among species and possibly also among seasons (McCleary *et al.* 1960). Indeed, it would appear that some of these antibiotic compounds are the very ones that bryophytes produce in response to stress. However useful they may be, it seems that these discoveries have not yet found their way into medical practice.

Figure 30. *Anomodon rostratus*, a species that inhibits bacteria and fungi. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 32. *Orthotrichum rupestre*, a species that inhibits bacteria and fungi. Photo by Michael Lüth, with permission.

Scientists have found innumerable kinds of biological activity in compounds from bryophytes. Even in a single species, one might find multiple kinds of activity. For example, the liverworts *Plagiochasma japonica* and *Marchantia emarginata* subsp. *tosana* (Figure 33) exhibit antitumor activity, antifungal and antimicrobial activity, inhibition of superoxide release, inhibition of thrombin activity, and muscle relaxation (Lahlou *et al.* 2000). As is often the case with herbal medicine, the effect of the total extract is better than that of the isolated compounds, perhaps due to a synergistic effect (Frahm 2004).

Figure 33. *Marchantia emarginata* subsp. *tosana*, a subspecies with a wide range of medicinal properties. Photo by Taiwan Mosses, through Creative Commons.

On the other hand, some researchers claim that antibiotic properties of some mosses, including *Sphagnum* (Figure 13, Figure 14), may actually be the work of associated microorganisms. In some cases, *e.g.* *Sphagnum*, it may be *Penicillium* sp. (Figure 34) effecting this antibiotic ability (Lewington 1990). Or is it the closely associated *Cyanobacteria*, such as *Nostoc* (Figure 35) (Spjut *et al.* 1988; Solheim & Zielke 2002)?

Figure 34. *Penicillium expansum* on pear, in a genus that can grow on *Sphagnum* and may contribute to its antibiotic effects. Photo by H. J. Larsen, through Creative Commons.

Figure 35. *Nostoc pruniforme*, in a genus with close associations with *Sphagnum* and other bryophytes and could contribute to antibiotic properties. Photo by Lairich Rig, through Creative Commons.

Painter (2003) notes that *Sphagnum* (Figure 13, Figure 14) can be 3-4 times as absorbent as cotton equivalents. But its call to fame seems to be its ability to react chemically with all sorts of proteins. *Sphagnum* species have the potential to immobilize whole bacterial cells, enzymes, exotoxins, and lysins that are secreted by most of the invasive pathogens. Once these are immobilized, they are inactivated by a **Maillard reaction**.

The **Maillard reaction** makes this story complex. It is known to suppress the virulence gene expression operon in the bacterium *Listeria monocytogenes* (Figure 36) (Sheikh-Zeinoddin *et al.* 2000), so that is a good thing. On the other hand, a variety of foods form potential cancer-causing acrylamides, especially fried foods (Stadler *et al.* 2002). Such acrylamides can be released by thermally treating certain amino acids such as asparagine, especially in combination with reducing sugars through the Maillard

reaction. The early Maillard reaction products are N-glycosides. Painter (1998) found that the Maillard reaction inhibits microbial growth in animal products preserved in bogs by sequestering ammonia, amino acids, and peptides, whereas the polymeric end-products (melanoidins) inhibit their growth by cross-linking the polypeptide chains and sequestering essential multivalent metal cations. In short, the Maillard reaction appears to be an important component of the *Sphagnum* (Figure 13, Figure 14) antibiotic activity. Furthermore, its preservative ability correlates with α -keto-carboxylate groups in a glycuronoglycan (**sphagnan**) that comprises ~60% of the holocellulose in the *Sphagnum* hyaline cell walls.

Figure 36. *Listeria monocytogenes*, a bacteria species that is inhibited by extracts of the leafy liverwort *Porella cordaeana*. Photo from CDC, through public domain.

Harris (2009) considered phylogenetic, elevational, and latitudinal relationships of the production of flavonoids in medicinal mosses. He was unable to show any significant correlation between phylogenetic independent contrasts of total phenolic content, number of flavonoids, or percent luteolin derivatives. He furthermore found no correlation with elevation or latitude. He could not rule out the possible correlation with fine-scale ecological features, and he considered flavonoid variation to reflect recent evolution.

Labbé *et al.* (2007) tested the thallose liverwort *Riccardia polyclada* for potential pesticidal properties. They identified four compounds that contributed to lethality in the brine shrimp (*Artemia salina*; Figure 37). Two of the compounds had moderate activity as an antifeedant for the African cotton leafworm (*Spodoptera littoralis*; Figure 38). They also inhibited culture growth of the fungal plant pathogen *Cladosporium herbarum* (Figure 39).

Antimicrobial Activity

Our knowledge of antimicrobial activity of bryophytes is mostly based on *Sphagnum* (Figure 13, Figure 14). However other bryophytes are now known to have antibiotic properties. Some of these may just be folklore as they have not been tested experimentally. For example, Cheng *et al.* (2008) reported the folk use of *Polytrichum* to treat pneumonia. And we have already seen that *Polytrichum commune* (Figure 19) is used in a tea for treating colds (Gulabani 1974; Beike *et al.* 2010).

Nevertheless, antibiotic properties have been demonstrated in the laboratory. Moss activity against Gram-positive and Gram-negative bacteria have been demonstrated (Basile *et al.* 1999; Merkuria *et al.* 2005; Zhu *et al.* 2006). Asakawa (2007a, b) has demonstrated many effects of liverworts.

Kumar *et al.* (2007), in their review of classical ethnobotanical Indian uses, reported the antibacterial value of the mosses *Anomodon rostratus* (Figure 30), *Atrichum angustatum* (Figure 40), *A. undulatum* (Figure 41), and *Hyophila involuta* (Figure 42) and the thallose liverworts *Conocephalum conicum* (Figure 10) and *Dumortiera hirsuta* (Figure 15). These bryophytes reportedly produce antibiotics. The leafy liverwort *Radula complanata* (Figure 24) similarly has antimicrobial properties. To these we can add the antiseptic properties of *Frullania tamarisci* (Figure 43) (Asakawa 2007b; Chandra *et al.* 2017) and antimicrobial activity of *Pallavicinia* sp. (Figure 27) (Azuelo *et al.* 2011; Chandra *et al.* 2017).

Figure 43. *Frullania tamarisci*, an epiphytic species with antiseptic properties, having both allergenic and medicinal properties. Photo by Michael Lüth, with permission.

Recent tests on the floating thallose liverwort *Riccia fluitans* (Figure 44) from Florida indicated no ability to inhibit growth of the tested bacteria [*Pseudomonas aeruginosa* (Figure 45), *Staphylococcus aureus* (Figure 25)] or yeast (*Candida albicans*; Figure 46) (Pates & Madsen 1955). Vashistha *et al.* (2007) determined the antimicrobial activity of three other thallose liverworts. They found that water soluble extracts from *Conocephalum conicum* (Figure 10), *Marchantia polymorpha* (Figure 47), and *Plagiochasma appendiculatum* (Figure 48) had no effect on any of the pathogens tested [Gram-negative bacteria *Escherichia coli* (Figure 17) and *Salmonella typhi* (a variant of *S. enterica*; Figure 49)] and fungi *Aspergillus niger* (Figure 50) and yeast *Candida albicans* (Figure 46). However, acetone-soluble extracts of all three bryophyte species were inhibitory against the pathogens. They were more effective against the growth of *S. typhi* than against *E. coli*. *Plagiochasma appendiculatum* had a strong inhibitory effect against *A. niger* and *Conocephalum conicum* was strongly inhibitory to *Candida albicans*.

Bukvicki *et al.* (2012), using solid-phase microextraction-gas chromatography mass spectrometry, explored the volatile components of the leafy liverwort *Porella cordaeana* (Figure 51). Using methanol, ethanol, and ethyl acetate to extract terpenoids, they were able to identify sesquiterpene hydrocarbons and monoterpene

hydrocarbons. These same hydrocarbons were active against the eleven food microorganisms tested, but at different concentrations among the microorganisms. The fungi among these will be discussed below. Affected bacterial strains were *Salmonella enteritidis* (food poisoning that causes diarrhea, fever, and abdominal cramps; Figure 52), *Escherichia coli* (commonly found in lower intestine of warm-blooded organisms with some strains causing food poisoning; Figure 17), and *Listeria monocytogenes* (very virulent food pathogen that causes the infection listeriosis; Figure 36). Methanol extracts showed the best activity.

Figure 51. *Porella cordaeana*, a species that is able to inhibit a variety of yeasts and bacteria. Photo by J. C. Schou, with permission.

Figure 52. *Salmonella enteritidis*, a bacteria species that is inhibited by extracts of *Porella cordaeana*. Photo through OGL (public domain).

It appears that differences in bryophyte extract activity among various pathogens may be common. Extracts of the liverworts *Marchantia polymorpha* (Figure 47), *Porella platyphylla* (Figure 29), and the moss *Dicranum scoparium* (Figure 16) showed antimicrobial effects on the Gram-positive bacteria *Bacillus subtilis* (Figure 53), *Staphylococcus aureus* (Figure 25), and *Micrococcus luteus* (Figure 54) (Pavletic & Stilinovic 1963; Frahm 2004). These same bryophytes exhibited no activity against Gram-negative *Escherichia coli* (Figure 17).

Figure 54. *Micrococcus luteus*, a bacteria species that is inhibited by extracts of several bryophyte species. Photo by Janice Carr, through public domain.

Basile *et al.* (1999) isolated seven pure flavonoids from five species of mosses. Some of these exhibited strong antibacterial effects against the bacteria *Enterobacter cloacae* (Figure 55), *E. aerogenes* (Figure 56), and *Pseudomonas aeruginosa* (Figure 45). They were mainly active against Gram-negative bacteria that caused severe opportunistic infections and were at the same time resistant to commonly used antibacterial therapy. This means that the bryophyte products could become important tools in treating some bacterial infections.

Figure 56. *Enterobacter aerogenes*, a species that is active against Gram-negative bacteria. Photo by Riraq25, through Creative Commons.

Ariyo *et al.* (2011) compared the efficacy of extracts from the Nigerian thallose liverwort *Riccia nigerica* as antimicrobial agents. These extracts were tested against the bacteria *Bacillus subtilis* (Figure 53), *Pseudomonas aeruginosa* (Figure 45), *Shigella dysenteriae* (Figure 57), and *Staphylococcus aureus* (Figure 25) and fungi *Rhizopus* spp. (Figure 58), *Aspergillus flavus* (Figure 59), *A. niger* (Figure 50), *Penicillium* spp. (Figure 34), and demonstrated strong significant antibacterial and antifungal activity.

The leafy liverwort *Ptilidium pulcherrimum* (Figure 60) exhibits antimicrobial activity against both Gram + bacteria and Gram negative bacteria, but the effect is greater on the Gram positive bacteria (Veljić *et al.* 2010).

Figure 60. *Ptilidium pulcherrimum*, a species that is effective against both Gram positive and Gram negative bacteria. Photo by Hermann Schachner, through Creative Commons

Antifungal Activity

Although mosses are known to harbor fungi and will quickly become infected if kept moist in a plastic bag, some fungi are inhibited by many species of bryophytes, including many that cause skin infections. Jennings (1926) reported moss immunity to molds as early as 1926, but the possibility of using them as a source of antifungal activity seems to have been largely overlooked. Among these, the cosmopolitan moss *Hypnum cupressiforme* (Figure 61) has remarkable antibacterial and antifungal effects. Ven Hoof *et al.* (1981) demonstrated strong antibacterial and antifungal effects by extracts of *Hypnum cupressiforme*.

Figure 61. *Hypnum cupressiforme*, a species that is effective against fungi that cause skin infections. Photo by Michael Lüth.

Kumar *et al.* (2007) report antifungal properties for the widespread leafy liverwort *Porella platyphylla* (Figure 29). Ando and Matsuo (1984) demonstrated antifungal effects of bryophytes on human pathogenic fungi, but they warned that while the bryophyte extracts have fungicidal and antifeedant effects, they also may cause allergic reactions and dermatitis for some humans.

Bukvicki *et al.* (2012), using solid-phase microextraction-gas chromatography mass spectrometry, explored the volatile components of the related liverwort *Porella cordaeana* (Figure 51). Using methanol, ethanol, and ethyl acetate to extract terpenoids, they were able to identify sesquiterpene hydrocarbons and monoterpene hydrocarbons. These same hydrocarbons were active against the eleven food microorganisms tested, but at different concentrations among the microorganisms. These included the yeasts *Saccharomyces cerevisiae* (yeast used in wine making, baking, and brewing, but antibodies against *S. cerevisiae* are found in 60-70% of patients with Crohn's disease; Figure 62), *Zygosaccharomyces bailii* (species causing significant spoilage in the food industry; Figure 63), *Aureobasidium pullulans* (an inhabitant of humidifiers or air conditioners that can lead to hypersensitivity pneumonitis; Figure 64), *Pichia membranifaciens* (species causing grey mold of fruits; Figure 65) (2 strains), *Pichia anomala* (used in winemaking) (2 strains), and *Yarrowia lipolytica* (used in industrial microbiology for production of specialty lipids). Methanol extracts showed the best activity.

The leafy liverwort *Ptilidium pulcherrimum* (Figure 60) is not only effective against bacteria, but also against fungi (Veljić *et al.* 2010). Its best antifungal activity was against *Trichoderma viride* (Figure 66), compared to the activity of the synthetic bifonazol.

Figure 66. *Trichoderma viride* conidiophores, a fungal species that is inhibited by *Atrichum undulatum*, *Physcomitrella patens*, and *Marchantia polymorpha*. Photo by Ninjatacoshell, through Creative Commons.

The absence of fungal diseases in liverworts led Pryce (1972) to suggest that **lunularic acid**, a hormone that affects aging in liverworts but not in mosses, might be responsible for liverwort antifungal activity. Banerjee and Sen (1979; Bannerjee 1974) found that the degree of antibiotic activity in a given species may depend on the age of the gametophyte; Matsuo *et al.* (1982a, 1982b, 1983) supported this conclusion by demonstrating that antifungal activity against *Botrytis cinerea* (Figure 67), *Pythium debaryanum* (Figure 68), and *Rhizoctonia solani* (Figure 69) by the liverwort *Herbertus aduncus* (Figure 70) was age-dependent. They subsequently isolated three aging substances from it: (-)-alpha-herbertenol; (-)-Beta-herbertenol, and (-)-alpha-formylherbertenol.

Figure 70. *Herbertus aduncus*, a leafy liverwort that can exercise antifungal activity against several fungi, but activity is age-dependent. Photo by Martin Hutten, with permission.

Vashistha *et al.* (2007) determined the antimicrobial activity for the thallose liverworts *Plagiochasma appendiculatum* (Figure 48), *Marchantia polymorpha* (Figure 47), and *Conocephalum conicum* (Figure 10). Acetone-soluble extracts of all three bryophyte species

were inhibitory against the fungal pathogens tested. *Plagiochasma appendiculatum* had a strong inhibitory effect against *Aspergillus niger* and *C. conicum* was strongly inhibitory to *Candida albicans*. When Niu *et al.* (2006) tested *Marchantia polymorpha* (Figure 47) for antifungal activities against the yeast *Candida albicans* (Figure 46), they found **plagiochin E**, 13,13'-O-isopropylidenericcardin D, and neomarchantin A were active against the yeast. The other identified compounds had only weak effects.

Sabovljević *et al.* (2011) used DMSO extracts of both cultured and wild grown mosses *Atrichum undulatum* (Figure 20) and *Physcomitrella patens* (Figure 71-Figure 72) and thallose liverwort *Marchantia polymorpha* ssp. *ruderalis* (Figure 47) to test for antifungal activity. Using *Aspergillus versicolor* (Figure 73), *Aspergillus fumigatus* (Figure 74), *Penicillium funiculosum* (see Figure 34), *Penicillium ochrochloron*, and *Trichoderma viride* (Figure 66), these researchers demonstrated antifungal activity by all three bryophytes against all five fungal species. Most of the bryophytes grown in culture had greater antibiotic activity than the wild-grown ones.

Alcoholic extracts of all twenty bryophytes tested at Bonn University had antifungal activity on infected crops (Frahm 2004), as demonstrated in a Petri dish (Figure 75). Frahm reports curing a fungal infection of the skin with a bryophyte extract. The success was reported in a TV magazine and a published book, causing a number of people to use the extract for fungal infections, mostly with favorable results. However, Frahm warns that the biologically active substances are terpenoids, and these may cause allergic effects to some people (Ando & Matsuo 1984). One reputedly can cure athlete's foot by walking through a peat bog, presumably because of these same terpenoids (Frahm 2004).

Figure 75. Bryophytes are known to inhibit growth of some kinds of bacteria and fungi. **Left:** Microbes grow uninhibited around a disk with only extraction fluid. **Right:** A zone of inhibition occurs around the disk with bryophyte extract. Photo by Jan-Peter Frahm.

One extract has actually been patented to cure fungal infections of horses (Frahm 2004). An industrious horse owner was inspired by what he read about the Bonn experiments and made a paste of *Ceratodon purpureus* (Figure 76) and *Bryum argenteum* (Figure 77). The fungus disappeared from the horse in 24 hours! This same extract is also sold as a human foot cream to refresh and fight odor. Unfortunately, the use for curing fungal infections cannot be mentioned in advertising because then it would require the extensive testing necessary to meet medical approval, which might be difficult because it can cause allergies and dermatitis in some people. It also works as an antifeedant against slugs. Unfortunately, to date it must be extracted from field-collected material, creating conservation concerns.

Figure 76. *Ceratodon purpureus*, a species was used with *Bryum argenteum* and killed a fungal infection on a horse. Photo by Janice Glime.

It appears that some bryophytes may contribute to antifungal compounds by hosting a fungus that manufactures both antifungal and antitumor compounds (Guo *et al.* 2008). The leafy liverwort *Scapania verrucosa* hosts the fungus *Chaetomium fusiforme* (Figure 78). Not only does the latter produce both antifungal and antitumor compounds, but the liverwort itself likewise produces them. However, the fungus compounds provide superior properties and the liverwort might contribute to the medicinal field through this fungal **endophyte** (organisms growing within cells of plant, ranging from symbiotic to parasitic).

Figure 77. *Bryum argenteum*, a species that was used in a paste with *Ceratodon purpureus* and killed a fungal infection on a horse. Photo by Martin Hutten, with permission.

Figure 78. *Chaetomium globosum*. The fungus *Chaetomium fusiforme* occurs on *Scapania verrucosa* and produces both antifungal and antitumor compounds. Photo by Ulitca, through Creative Commons.

Antiviral Activity

Even viruses may some day be cured by extracts of mosses, but we cannot simply identify them as "moss" as many of our ecologist friends have been wanton to do in reporting the ground cover. The Maoris of New Zealand have used bryophytes to treat venereal disease by packing wet plants on the infected organs (Frahm 2004). Nevertheless, van Hoof and coworkers (1981) found no effect of 20 species of moss extracts on the herpes virus, but earlier Klöcking *et al.* (1976) found that at least some peat humic acids possess antiviral activity against herpes simplex virus types 1 and 2, interfering primarily with the adsorption of viruses to host cells.

Sphagnum (Figure 13, Figure 14) produces several antivirally active humic acids, and *Camptothecium* (Figure 79) extracts can inhibit growth of the poliovirus (Witthauer *et al.* 1976; van Hoof *et al.* 1981). Nevertheless, actual usage of bryophytic extracts has not developed outside of Asia.

Figure 79. *Camptothecium lutescens*, in a genus that can inhibit growth of the poliovirus. Photo by David T. Holyoak, with permission.

Cancer and Anti-tumor Properties

In the same year as the Madsen and Pates (1952) report of antibiotics in bryophytes, Belkin *et al.* (1952-53) reported anticancer activity against Sarcoma 37 in mice, using extracts of *Polytrichum juniperinum* (Figure 80). But application of the antitumor activity fared no better and was apparently not rediscovered in bryophytes until the next century. Finally, Anterola *et al.* (2009) considered the anticancer drug precursors in mosses to be so important that they titled their presentation on them "Turning precursors into gold: Production of anticancer drug precursors in moss."

Figure 80. *Polytrichum juniperinum* with antheridial splash cups, a species that produces anticancer compounds. Photo by Paul Slichter, with permission.

Fu *et al.* (2009) attempted to show anti-cancer capabilities of the moss *Polytrichum commune* (Figure 19). To this end, they isolated two "unusual" flavones and other compounds from this moss. However, when tested against a small panel of cancer cell lines, they failed to find any activity.

Kumar *et al.* (2007) found that Indians have used *Polytrichum juniperinum* (Figure 80) to treat cancer. The anti-tumor use of bryophytes in India included *Chiloscyphus polyanthos* (Figure 81), *Diplophyllum albicans* (Figure 82), *D. taxifolium* (Figure 85), *Marchantia palmata*, and *M. polymorpha* (Figure 47). *Frullania tamarisci* (Figure 43) is used as an antileukemic agent. To this list, others added *Riccardia* sp. (Figure 84) (Azuelo *et al.* 2011; Alam 2012; Chandra *et al.* 2017) and *Plagiochila* sp. (Figure 11) (Asakawa 2007; Alam 2012; Chandra *et al.* 2017).

Figure 81. *Chiloscyphus polyanthos*, a species that may cause allergic reactions. Photo by Barry Stewart, with permission.

Figure 82. *Diplophyllum albicans*, used as an anti-tumor treatment in India and as an agent against epidermoid carcinoma. Photo by Michael Lüth, with permission.

Asakawa (1981) has shown that several compounds from leafy liverworts exhibit antileukemic activity. From the thallose species, Marchantin A from *Marchantia palacea* (Figure 83), *M. polymorpha* (Figure 47), and *M. emarginata* subsp. *tosana* (Figure 33), riccardin from *Riccardia multifida* (Figure 84), and perrottetin E from *Radula perrottetii* all show cytotoxicity against the leukemic KB cells (Asakawa *et al.* 1982).

Figure 83. *Marchantia paleacea*, a thallose liverwort known for its antileukemic activity. Photo by Jan-Peter Frahm, with permission.

Figure 84. *Riccardia multifida*, a thallose liverwort known for its antileukemic activity. Photo by Michael Lüth, with permission.

In 1976, Adamek reported that peat preparations hold some promise against some types of human cancer. In 1977, Ohta and coworkers (1977) reported that diplophyllin, isolated from the liverworts *Diplophyllum albicans* (Figure 82) and *D. taxifolium* (Figure 85), shows significant activity (ED₅₀ 4-16 µg/ml) against human epidermoid carcinoma (KB cell culture).

Figure 85. *Diplophyllum taxifolium*, a species that produces diplophyllin, a compound that is active against human epidermoid carcinoma. Photo by Hermann Schachner, through Creative Commons.

Hughes and Anterola (2010) attempted to transplant genes for producing **Taxol** (a potent anticancer agent) into the moss *Physcomitrella patens* (Figure 71, Figure 72). They found evidence of small amounts of the anticancer precursors in the moss. If the moss can be taught (genetically) to produce Taxol, it could become a laboratory means to manufacture this important anti-cancer drug without destroying the diminishing number of *Taxus* (Figure 86) shrubs that produce it naturally. Bryophytes are ideal organisms for such gene transplants because of their dominant state with a single set of chromosomes and the relative ease with which genes can be put into them.

Figure 86. *Taxus baccata*, member of the genus that produces the anticancer agent Taxol. Photo through Creative Commons.

When Asakawa (1981, 1982) entered the arena, he isolated the sesquiterpenoids costunolide and tulipinolide from *Conocephalum supradecompositum*, *Frullania monocera*, *F. tamarisci* (Figure 43), *Marchantia polymorpha* (Figure 47), *Wiesnerella denudata* (Figure 87) and *Porella japonica* (Figure 88). To this list, Matsuo and coworkers (1980, 1981a, b, c, 1984) added *Lepidozia vitrea* (Figure 89) and *Plagiochila semidecurrans* (Figure 90). These substances, already known from higher plants, have activity to combat carcinoma of the nasopharynx, at least in cell culture.

Figure 87. *Wiesnerella denudata*, a species that produces sesquiterpenoids that are likely to have antibiotic properties. Photo by Ying Jia-dong, through Creative Commons.

When the National Cancer Institute became interested, Spjut and his coworkers (1986) tested 184 species of mosses and 23 species of liverworts for antitumor activity. Of these, 43 species contained active substances, while those of 75 species were toxic to tested mice. The most activity was found in **Brachytheciaceae** (Figure 91), **Dicranaceae** (Figure 16), **Grimmiaceae** (Figure 92), **Hypnaceae** (Figure 61), **Mniaceae** (Figure 18, Figure 31), **Neckeraceae** (Figure 2), **Polytrichaceae** (Figure 19, Figure 80), and **Thuidiaceae** (Figure 93). However, in 1988, doubt was cast on the role of the moss when this team reported that the antitumor activity of the moss *Claopodium crispifolium* (Figure 94) was greatest in samples contaminated with the Cyanobacterium *Nostoc* cf. *microscopicum* (Figure 95), suggesting that *Nostoc* could be the direct source of the activity or a necessary partner for interaction between the species (Spjut *et al.* 1988). Interaction could result from the transfer of a precursor from the *Nostoc* to the moss, which could then transform it into an active substance. Alternatively, the moss might produce the substance as an allelopathic response to the *Nostoc*. In any event, this raises important and intriguing questions, both medically and ecologically.

For some reason, much of the biochemical work has concentrated on the liverworts. Similar studies on activities of moss compounds are sparse and there may be good reason to presume a greater medical treasure chest among the liverworts. Since these compounds generally benefit the bryophytes by discouraging their would-be herbivores, it is the tiny, slow-growing liverworts that stand to benefit most. Where other, larger plants have spent their evolutionary history developing a diversity of structure, it would seem that small size has afforded these plants only the benefits of diversity of biochemistry as a means of combating the hungry herbivores.

Burgess *et al.* (2000) found that the leafy liverwort *Bazzania novae-zelandiae* (Figure 96) produces a sesquiterpene caffeate that has selective activity against certain human tumor cells. The active compound has been identified as the new compound naviculyl caffeate.

Figure 96. *Bazzania novae-zealandiae*, a species that is active against human tumor cells. Photo by Shirley Kerr, with permission.

Even breast cancer sufferers might benefit from bryophytes. Huang *et al.* (2010) found that **marchantin A** produced by *Marchantia emarginata* subsp. *tosana* (Figure 33) induced apoptosis in MCF-7 breast cancer

cells. This compound demonstrates strong antioxidant activity, scavenging free radicals.

The leafy liverwort *Scapania verrucosa* and its endophytic fungal inhabitant *Chaetomium fusiforme* (see Figure 78) produce several compounds that act as antitumor agents (Guo *et al.* 2008).

The thallose liverwort *Dumortiera hirsuta* (Figure 15) produces **riccardin D**, a macrocyclic bisbibenzyl compound that induces apoptosis of human leukemia cells (Xue *et al.* 2012). Xue and coworkers verified anticancer activity by riccardin D against human non-small cell lung cancer. In mice it produced a 44.5% inhibition of cancer growth with no apparent toxicity.

Pharmaceutical Production

Welcome to Greenovation! Moss for a healthy future. So began the website <<http://www.greenovation.com/>> of an upstart company that is growing the tiny *Physcomitrella patens* (Figure 71, Figure 72) for medicinal purposes. Yes, bryophytes have indeed finally penetrated the forefront of modern medicine!

Physcomitrella patens (Figure 71, Figure 72) is able to accept transferred human genes and express them to produce human antibodies in a liquid culture, making the antibodies easy to harvest (ETH Zurich 2009). So far, this is not possible when the genes are transplanted into "higher" organisms. One advantage of *Physcomitrella patens* is its ability to grow in a "bioreactor" (Figure 97; Decker & Reski 2004), a fermenter in which only water and minerals are needed to nourish the moss, of course in the presence of light and CO₂ (Greenovation). These tiny plants are actually superior (and cheaper) production systems for many complex recombinant pharmaceuticals (Bauer *et al.* 2005; Decker & Reski 2007, 2012; Gitzinger *et al.* 2009). Contrary to many mammalian systems that have been used to produce pharmaceuticals but that cause serious immune responses, those produced by *Physcomitrella patens* are non-immunogenic, a huge advantage for the patient, and making them superior to currently used mammalian cell lines for producing antibodies.

Among its many assets, *Physcomitrella patens* (Figure 71, Figure 72) is able to produce human proteins (Hohe *et al.* 2002; Decker *et al.* 2003) and is the only plant being used to produce the blood-clotting factor IX for pharmaceutical use. This discovery, patented by Prof. Reski of the Institute of Biotechnology of Plants at the University of Freiburg in Germany, led to the founding of the Greenovation Company in 1999. By 2002, the company was already employing 30 people to produce this valuable blood factor (Frahm, Bryonet discussion 2002).

Bryophytes offer the researchers, and the company, a number of advantages over "higher" plants. They can be grown without antibiotics, hence avoiding the danger of contamination of the final product. The moss is quite small and thus is cultured only in the lab with little danger of the transgenic plants escaping into the environment. But the real advantage comes from the dominant gametophytic generation of mosses as opposed to the dominant sporophyte of the tracheophytes. As a result, mosses are the only plants known to have a high frequency of homologous recombination. The result – stable integration of inserted genes into the genome. Furthermore, the highly

complex moss system, compared to bacteria and fungi, permits a much wider array of expression than is possible in those systems. Thus, mosses are extremely useful as production systems for targeted substances that can be produced through gene manipulation.

Figure 97. This type of bioreactor is used to grow *Physcomitrella patens* for human proteins and human blood-clotting factor IX. Photo by Ralf Reski.

Unfortunately, most biologically active substances so far obtained have not proved economical for use, at least in part due to the slow-growing nature and difficulty of culturing bryophytes. And, while their pharmaceutical use seems promising, we lack any understanding of their potential harmful side effects.

In the words of Ma *et al.* (2003), "Imagine a world in which any protein, either naturally occurring or designed by man, could be produced safely, inexpensively and in almost unlimited quantities using only simple nutrients, water and sunlight. This could one day become reality as we learn to harness the power of plants for the production of recombinant proteins on an agricultural scale. Molecular farming in plants has already proven to be a successful way of producing a range of technical proteins. The first plant-derived recombinant pharmaceutical proteins are now approaching commercial approval, and many more are expected to follow."

Medical Dangers

Caution is in order in exercising any medicinal use of bryophytes, particularly liverworts, because of their potential for causing allergic reactions (Mitchell *et al.* 1969, 1970; Benezra *et al.* 1985, Asakawa 2012). Often the very compounds that have these medical potentials can cause allergic reactions. For example, it is a sesquiterpene lactone (Asakawa 1981) that gives the common epiphyte *Frullania* (Figure 98-Figure 99) its ability to cause contact dermatitis, especially to forest workers (Mitchell *et al.* 1969). Now there is a patch test with a sesquiterpene lactone mix to determine sensitivity to *Frullania* (Quirce *et al.* 1994).

Yet sesquiterpene lactones are well known for their antimicrobial activity. In southern Europe, *Frullania tamarisci* (Figure 43, Figure 98) imparts an allergic reaction to olive pickers, yet is listed as one of the medicinal species (J. Curnow, pers. comm.). D. H. Wagner (pers. comm.) reports an allergy to *Chiloscyphus polyanthos* (Figure 81), especially when he squeezes it to remove excess water. By 1981, 24 liverwort species were known to have potential allergenic sesquiterpene lactones (Asakawa 1981). These compounds undoubtedly endow the same advantage to bryophytes that they do to flowering plants – discouraging consumption by hungry herbivores.

Figure 98. *Frullania tamarisci*, showing underside of branch with lobules by which the genus may be determined. Photo by Michael Lüth, with permission.

Frullania tamarisci (Figure 43, Figure 98) grows on trees and can cause skin irritations for loggers and even for their wives who handle their clothes. Allergic reactions to *Frullania nisquallensis* (Figure 99) occurred in patch tests on seven forest workers who had contact dermatitis (Mitchell *et al.* 1969). These forest workers exhibited the dermatitis only when they were working on forest areas. The problem was worse in wet weather and appeared within 1-2 days of starting work. The condition persisted for 2-4 weeks after leaving work in forested areas where the liverwort grew. The condition is often known locally in British Columbia, Canada, as cedar poisoning, but in fact it is caused by the liverworts that commonly grow on the cedars (*Thuja*; Figure 100).

Summary

Bryophytes, especially liverworts, often have distinct odors, suggesting aromatic compounds such as phenols. However, few bryophytes have been linked to actual curative properties and identifiable associated compounds.

One danger in using bryophytes is that the same compounds that may have antibiotic properties may also be toxic or allergenic, or be associated with such compounds. Furthermore, peatland mosses may have associated fungi that cause **sporotrichosis**.

Many antibiotics have been isolated from bryophytes, but few have been developed for medical use, despite their demonstrated effectiveness. In Germany, *Ceratodon purpureus* and *Bryum argenteum* are used to cure fungal infections of horses. Several medical uses seem promising, such as antileukemic properties and anticancer agents.

The most promising uses of bryophytes in medicine seem to lie in genetic engineering. Bryophytes are being used already to produce human blood-clotting proteins, while others are known to reduce thrombin activity.

Acknowledgments

I appreciate the continued support of Robin Stevenson in providing me with interesting articles such as the one on the medical use of mosses growing on skulls. Eric Harris generously shared his papers and images of medicinal bryophytes.

CHAPTER 3-1

FINE ARTS: DECORATIVE

Figure 1. Mosses used in a shop window to display trolls. Photo courtesy of Irene Bisang.

Decoration

Sheet mosses [large strips of pleurocarpous moss mats such as *Hypnum* (Figure 2), *Thuidium* (Figure 3), and *Ptilium crista-castrensis* (Figure 4) are still quite popular for decoration in store windows and displays (Figure 1), floral arrangements, Christmas tree and train yards, and Christmas ornaments (Miller in Crum 1973).

Figure 2. *Hypnum imponens*, a popular mat-forming moss used in displays. Photo by Janice Glime.

Figure 3. *Thuidium delicatulum*, a mat-forming moss that is often used in displays. Photo by Janice Glime.

Figure 4. *Ptilium crista-castrensis*, a common decorative moss. Photo by Janice Glime.

Figure 7. *Leptodontium styriacum*, member of a genus commonly used to simulate grass in nativity scenes. Photo by Michael Lüth, with permission.

Nativity

I still have the manger scene that belonged to my parents. Among its figures is a crèche, with baby Jesus nestled in a cradle filled with moss. How much nicer that would have been for the real Jesus instead of a bed of straw. In Mexico (and many other places), mosses are used to simulate vegetation in nativity scenes (Figure 5) (Delgadillo & Cárdenas 1990; Tan 2003) or to cover the roof of the nativity. These commonly include *Hypnum* (Figure 2), *Thuidium* (Figure 3), *Campylopus* (Figure 6), *Leptodontium* (Figure 7), and *Polytrichum* (Figure 8).

Figure 5. A nativity scene in Spain, using mosses for the vegetation. Photo courtesy of Francisco Lara.

Figure 8. *Polytrichum strictum*, member of a genus commonly used to cover nativity roofs or to simulate grass. Photo by Michael Lüth, with permission.

Lara *et al.* (2006) reported on the bryophytes used in nativity sets in Spain. They found that 66 bryophytes, 3 ferns, and 37 flowering plants were in use there. Most of the moss species seemed to be collected accidentally among the four favorite mosses and are similar to those used in Mexico: *Thuidium tamariscinum* (Figure 11), *Eurhynchium striatum* (Figure 12), *Hypnum cupressiforme* (Figure 13), and *Pseudoscleropodium purum* (Figure 14). Rees (1976) lists *Campylopus* sp., *Dendropogonella rufescens*, *Dicranum* sp. (Figure 15), *Hypnum* sp., and *Leptodontium* sp. (Figure 7) as the bryophytes being sold in the markets in Oaxaca city, Mexico, at Christmas.

Figure 6. *Campylopus pyriformis*, member of a genus that is used to simulate grass or cover the roof of the nativity. Photo by Michael Lüth, with permission.

Figure 9. Village scenes use mosses for vegetation in Spain. Such scenes are often used in miniature train yards. Photo courtesy of Francisco Lara.

Figure 14. *Pseudoscleropodium purum*, a species commonly used in nativity scenes in Spain. Photo by Michael Lüth, with permission.

Figure 12. *Eurhynchium striatum*, a species commonly used in nativity scenes in Spain. Photo by Michael Lüth, with permission.

Figure 15. *Dicranum*, a genus that is sold for decoration at Christmastime in Mexico. Photo by Janice Glime.

Salazar Allen (2001) reported the use of mosses for nativity in Panama, including *Thuidium delicatulum* (Figure 3), *Hypnum* sp. (Figure 2), *Leptodontium* sp. (Figure 7), *Breutelia tomentosa* (see Figure 16),

Rhacocarpus purpurascens (Figure 17), *Sematophyllum cuspidiferum* (see Figure 18), and the liverworts *Frullania* (Figure 19) and *Lepidozia* (Figure 20). Similar packages of sheet mosses are sold in the USA (Figure 21).

Figure 21. This bag of sheet moss is *Thuidium* sp., for sale in a gardening shop in Columbus, Ohio, USA. Photo by Janice Glime.

Christmas Decorations

Other Christmas-related uses also have emerged. There are wreaths made with mosses (Figure 22-Figure 23). And mosses provide a nice covering at the tree base (Figure 24), perhaps helping to reduce evaporation and to cover

bare soil for live trees. Others have created a variety of uses in making decorations and ornaments (Figure 25-Figure 27). Tan (2003) reports the use of mosses at Christmas for window dressing, showcasing gift displays, and packaging.

Figure 22. Moss in wreath in garden shop, Columbus, Ohio, USA. Photo by Janice Glime.

Figure 23. This twig wreath, decorated with mosses, was available at Christmastime at Michael's Hobby Shop in Reynoldsburg, Ohio, USA. Photo by Janice Glime.

Figure 27. Moss bird house, a potential tree decoration, at Michael's Hobby Shop in Reynoldsburg, Ohio, USA. Photo by Janice Glime.

Household Decorations

I have seen a moss table runner (Figure 28). I debated putting it in the chapter on household uses, but I consider it

more decorative than practical, so I have included it here. The distributor must expect it to be popular since the label is printed in three languages (Figure 29).

Figure 28. Moss table runner at Michael's Hobby Shop in Reynoldsburg, Ohio, USA. Photo by Janice Glime.

Figure 29. Moss table runner for sale at Michael's Hobby Shop in Reynoldsburg, Ohio, USA. Photo by Janice Glime.

If you want "matching" accessories, there are vine and moss baskets where you can store your fruit (Figure 30). Other entrepreneurial Americans have created a number of decorative pieces (Figure 31-Figure 35).

Figure 30. Moss basket at Michael's Hobby Shop in Reynoldsburg, Ohio, USA. Photo by Janice Glime.

Figure 35. Moss balls, useful in floral arrangements and Christmas decorations, at Michael's Hobby Shop in Reynoldsburg, Ohio, USA. Photo by Janice Glime.

Moss Walls

Some moss walls are art in their own right, with elaborate designs using different species with various shades of green, red, and brown. But some are simply green walls, as seen in Figure 36-Figure 37. I have seen pictures of similar green walls flanking one side of a bath tub. What a relaxing background for a bath!

Figure 36. Gaia moss wall in Singapore. Photo courtesy of Ben Tan.

Figure 37. Ben Tan and Etzel at the Gaia moss wall in Singapore. Photo courtesy of Ben Tan.

In Japan, you can buy a kit for making your own moss wall (Figure 38). Thanks to Hironori Deguchi, we can enjoy this vicariously (Figure 39-Figure 42).

Figure 38. *Sphagnum* Greening Unit for Green Wall Kit. Photo courtesy of Hironori Deguchi.

Figure 39. *Sphagnum* Wall Kit final product on display in Japan. Photo courtesy of Hironori Deguchi.

Figure 41. Moss wall in Mayo Clinic, Rochester, Minnesota, USA. Photo courtesy of Janet Marr.

Shop Windows and Displays

From *Leucobryum glaucum* (Figure 43, Figure 57) in a tailor's window to *Rhytidiadelphus* (Figure 44) in a craft display, to *Hypnum cupressiforme* (Figure 13), *Isoetes myosuroides* (Figure 45), *Pleurozium schreberi* (Figure 46), and *Pseudoscleropodium purum* (Figure 14) in a shop window (Ando 1972), mosses will probably remain popular adornments to add a fresh look to displays (Figure 47). In Japan, even the sporophytes are used to make decorative arrangements (Manzoku 1963).

Figure 40. *Sphagnum* Green Wall Kit by Takeda. Photo courtesy of Hironori Deguchi.

The Mayo Clinic in Rochester, Minnesota, USA, has used mosses and ferns to create a relaxing atmosphere in the clinic. These can be found on walls along stairways and in lobbies around the facility. They are billed as being maintenance-free – the mosses are preserved.

Like flowers, mosses are used in floral arrangements to create aesthetic appeal or create a relaxing atmosphere (Figure 49-Figure 48).

Floral Industry

Tan (2003) considered horticulture to be the largest market for moss products. Some of these are for gardening, but others are decorative in pots and displays.

Use of bryophytes in the floral industry spans the globe, from *Climacium americanum* (Figure 50) in North America to make wreaths and crosses to *Climacium japonicum* (Figure 51) in Japan to make ornamental water flowers (Mizutani 1963). *Hylocomium splendens* (Figure 52) has been used similarly in North America to make moss roses, but it is also a preferred species in floral arrangements (Welch 1948; Thieret 1956). *Bryum argenteum* (Figure 53) is used in Missouri, USA, for floral arrangements. More commonly, *Dicranum scoparium* (Figure 54), *Hylocomium splendens*, *Rhytidiadelphus loreus* (Figure 55), and *R. triquetrus* (Figure 44) are popular for floral exhibitions because they form large carpets of green (Welch 1948; Thieret 1956).

The role of mosses in decorations pervades hotels, shop windows (Figure 52, Figure 57-Figure 58), optometry displays (Figure 59), tea houses (Figure 60) (Tan 2003; Irene Bisang & Lars Hedenäs, pers. comm.), and even displays in the Ford automobile showroom (Kenneth Adams, pers. comm. 1 November 2013). They can enhance the flowers that often serve to greet those entering a building (Figure 61).

Figure 56. A variety of mosses adorn this shop display. Photo courtesy of Irene Bisang.

Figure 60. Mosses add to the display of a tea shop window. Photo courtesy of Irene Bisang.

Figure 61. Floral display in Göteborg showing *Leucobryum*. Photo courtesy of Lars Hedenäs and Irene Bisang.

Mosses are ideal for nursery and floral shop displays (Figure 62-Figure 63). Denoyer's Nursery in Columbus, Ohio, USA, uses some of the same sheet mosses they sell to make displays of their garden decorations (Figure 64-Figure 67).

Moss Rocks

Mosses conjure up a peaceful experience, as recognized so clearly in the Japanese moss gardens. Some entrepreneurs have capitalized on this feeling by creating indoor miniature gardens that are stylized versions of a moss and rock habitat (Figure 68). Such are the creations at Moss & Stone Gardens (Spain 2012). The rocks in Figure 68 show these stylized rocks. Prices range from US \$14.99 for the smallest (6 cm) to \$39.99 for the largest (16.5 cm).

Figure 68. Three sizes of moss rocks available from the Moss & Stone Gardens, Raleigh, NC, USA. Photo by Moss & Stone Gardens.

Flower Pots

The use of mosses to encase flower pots seems to be popular. The mosses are attractive and look natural without detracting from the flower as the center of attention (Figure 69-Figure 75). For clay pots they can reduce evaporation and absorb spills. If they are outside, they may even provide insulation.

Figure 69. Moss flower pots at Michael's Hobby Shop in Reynoldsburg, Ohio, USA. Photo by Janice Glime.

Figure 75. Mat of twigs with epiphytic mosses, presumably to put under a flower pot. Are there enough mosses to absorb spills? Photo by Janice Glime.

Jewelry

Mosses imbedded in glass or clear plastic have been around for some time. But some enterprising artists have endeavored to create jewelry with living mosses. One example of this is a ring (Figure 76), maintained long enough to produce sporophytes (Figure 77). Mariaela creates jewelry with living mosses in the necklace pendant (Figure 78).

Figure 76. Moss ring with live *Ditrichum pallidum*. Photo by Brandon Holschuh.

Figure 77. Moss ring with living mosses (*Ditrichum pallidum*), including capsules! Photo by Brandon Holschuh.

Figure 78. Moss necklace from Mariaela at <www.etsy.com>.

Collection Dangers

Bryologists in Venezuela are concerned that moss harvesting in the Andes during the Christmas season for use in nativity scenes is endangering the fragile cloud forest and páramos ecosystems (León & Ussher 2005). Similar harvesting occurs in the Pacific Northwest of the USA (Figure 79).

Figure 79. Branch showing removal of bryophytes harvested for use as sheet moss. Photo courtesy of JeriLynn Peck.

Sheet moss (e.g. Figure 4) can be collected at any time, but preferably in summer (I know not why – perhaps because it is dry and light weight then), with a single wholesaler supplying about 14,000 pounds of dry moss per year (Nelson & Carpenter 1965).

These mosses may be packaged and sold for individuals to use in flower pots, tree yards, or other displays (Figure 80-Figure 82). The ones pictured here range US \$6.95-\$9.95 (Figure 80). But some of the "Supermoss" packages contain other things with the common name of "moss" (Figure 80-Figure 82).

Moss Celebration Day

Khoroshyy Petro announced to Bryonet that 22 January was Moss Celebration Day in a short-lived calendar created following the French Revolution, in the French Republican calendar (Khoroshyy Petro, Bryonet 21 January 2021 EST). This calendar, designed to celebrate the arts and nature, lasted only a decade because the church objected. The calendar did not include the traditional recognition of important dates.

Summary

Sheet mosses such as *Hypnum* spp. have been common in decorations, especially nativity scenes, shop windows, and floral arrangements. Some are used for wreaths and crosses and even jewelry. Gathering of bryophytes for Christmas decorations in some countries can lead to conservation concerns due to over collecting and collection of rare species lurking among the common ones being collected.

Acknowledgments

Many Bryonettters have contributed to this and other chapters through Bryonet discussions, pictures, and help in finding references. Thank you to Bob and Janet Marr for taking pictures for me at the Mayo Clinic moss walls.

CHAPTER 3-2

FINE ARTS: ART

Figure 1. Floats made of foam present artistic figures with mosses for hair and other accents. Artwork and photograph courtesy of Minoru Takeda.

In Artwork

Mosses would seem to be a natural for art work (Saito 1973), but they are actually rather difficult to portray. I once helped run a workshop using mosses for water color subjects and tools. The seemingly delicate moss leaves and branches, pressed into water color paints, then onto paper, did little more than make a smudge at the hands of these beginning artists. And painting their delicate structure is no less of a challenge.

Beatrix Potter, of Peter Rabbit fame, rendered mosses in her beautiful watercolors (Edwards 1993).

Most recently, I have seen an advertisement for moss graffiti. The "artist" is experimenting with a formula for painting moss parts onto a building, wall, or even a coffee pot (!) instead of paint to serve as decoration. The creator

provides a recipe involving a blend of mosses, beer, and sugar that are then applied with a paintbrush. The promoter advises to visit your handiwork over the next few weeks to be sure it has ample water. The pictures provided, however, are an artist's rendition with real paint, as the moss artist is still perfecting the moss paint formula.

One Finnish artist, Barbro Eriksson, is creating a sculpture in which mosses will be used to fill in the design on a slab of rock, thus providing the relief (Figure 2).

Other artwork includes picture frames, decorations of bookmarks (Figure 3), and even wall hangings. Pressed, dried bryophytes are often used in framed artwork (Saito 1973), and I was privileged to receive a poem about mosses, framed in the same, from one of my students.

Figure 2. Model of sculpture that will become a living sculpture of mosses growing in the crevices that create the design. Artwork and photo courtesy of Barbro Eriksson.

Figure 3. The moss *Homaliodendron scapellifolium* is used here to make a bookmark. Photo by Janice Glime.

Rarely does a moss receive such a place of honor as a coin, but in 1990, a species of *Polytrichum* decorated one side of the Finnish 50 penny coin, with the national animal, a brown bear (*Ursus arctos*), on the other (Hyvönen 1990; Figure 4). It would be nice to think the intention was to honor the moss, but in fact, it was the bear that was "honored" and the moss inclusion was really a product of language. In several Scandinavian languages, the word moss is affiliated with the word for bear, e.g. björnmossa, bjørnemose, and karhunsammal. Hyvönen speculated that the name of the bear may have been associated with the moss because bears sometimes bury their food under carpets of *Polytrichum commune* (Figure 5) in wet forests. Linnaeus reported that bears gather *Polytrichum* to line their winter holes. However, it seems that bears now are not so discriminate, using the more common *Pleurozium schreberi* (Figure 6) and *Hylocomium splendens* (Figure 7).

Figure 4. The Finnish 50 cent coin exhibits a bear on one side and the moss *Polytrichum* on the other. Photo courtesy of Jaakko Hyvönen.

Foam Novelties

Not surprisingly, the Japanese use bryophytes in their artwork. Minoru Takeda is a master at growing art pieces with bryophytes (Deguchi 2007; Figure 1, Figure 8). He has kindly contributed the many photographs that follow. Among these are foam figures that float on ponds (Figure 9 - Figure 11) or in glass dishes to decorate a table (Figure 12).

Figure 8. Floats and mascots with moss highlights, usually forming hair. Artwork and photo courtesy of Minoru Takeda.

Figure 9. Moss floats on a pond in Japan. Artwork and photo courtesy of Minoru Takeda.

Figure 11. Moss floats on a pond in Japan. Artwork and photo courtesy of Minoru Takeda.

Figure 12. Japanese moss float decoration. Artwork and photo courtesy of Minoru Takeda.

The use of bryophytes in artwork, particularly moss pots and ceramic designs (Figure 13 - Figure 15), is popular enough that there are classes where students of all ages learn the art (Figure 16 - Figure 18). Even streets may be decorated with this unusual form of art (Figure 19).

Glass Bryophytes

For teaching purposes, various museums and other institutions have engaged artists to make glass bryophytes. These endeavor to illustrate the special structures on a scale that can easily be seen without a handlens and in three dimensions (Figure 23-Figure 30).

Corpus Christi Festival

In Béjar, Salamanca, Spain, mosses are a major part of the Corpus Christi celebration (Martínez Abaigar & Núñez Olivera 2001). The border between the Moslem and Christian kingdoms had been under siege for more than 300 years. According to the legend of the Moss Men, Christians were hidden in the mountains at El Castañar, 3 km from the present town of Béjar. On the day of the feast of St. Marina of Bitinia, the Christians gathered to celebrate mass at La Centenna. After the ceremony, they covered their clothes and weapons with mosses from nearby stones. So camouflaged, they went to the Moslem fortress and lay on the walls and rocks. When the gates opened at dawn, they were able to enter and surprise the watchtowers. In a day-long struggle, the Christians took the streets one-by-one. Thus, on the ninth Sunday after Easter each year the event is celebrated with Moss Men as part of the Corpus Christi festival. Six Moss Men volunteers from the region of Béjar each year use more than 200 m² of moss made into moss plates, including such common ones as *Hypnum cupressiforme* (Figure 31), *Antitrichia californica* (Figure 32), *A. curtipendula* (Figure 33), and *Homalothecium sericeum* (Figure 34). They use these plates to dress

Figure 28. *Pogonatum subfuscum* model in Chinese educational display. Photo courtesy of Zhang Li.

themselves in commemoration of this historic event (Figure 35 - Figure 40). Fortunately, these moss plates are kept at the Convent of San Francisco, and only damaged parts need be replaced by new mosses each year.

In what is apparently a different ceremonial use of bryophytes in New Guinea, the villagers of Payakona Village hold a singing ceremony (Laman 2012). They are not covered with bryophytes, but rather wear what appear to be mosses in strategic positions to create beards, hair, and decorative pieces on the head or over the chest. In what appears to be a reverse of the usual confusion, the decorations labelled lichens and Spanish moss appear to be real mosses.

Body Art

In The Philippines, *Dawsonia* (Figure 43), *Pogonatum* (Figure 44), and *Spiridens* (Figure 45) are used both as body decoration and to ward off evil spirits.

Statues or Topiary?

Bryophytes can be fashioned into various forms with the help of wires and some sort of central core – or just moss. These are sometimes stained so they remain green, but they also can remain alive for a period of time, the duration depending on the suitability of conditions. Such statues (are these really topiary, since they are planted that way instead of cut to make the shapes?) are used to decorate gardens and lawns or used in displays indoors.

Atproot (2009) reports that mosses and lichens can have a different relationship to statues and outdoor art. They may be introduced with stones used in outdoor art. And rock carvings may be damaged by the invasion of bryophytes and lichens, as witnessed at Tennes in Balsfjord, Troms, Norway (Bjerke 2000).

Film-making

To make a film of King Kong, film makers had to actually miniaturize the mosses (Simpson 2006). Real mosses posed two problems – they were at the wrong scale for the landscape, shrubs, logs, and trees created for the set, and they dried too rapidly under the studio lights. They used a material called flocking that they attached to dacon with adhesive. But in Lord of Rings trilogy, the scene

when a member of the Fellowship of Rings dies on a bed of pleurocarpous mosses used real mosses. Moss Man in Masters of Universe also had real moss. However the toy made in his image used green flock.

Figure 55. Moss monkey in garden shop in Columbus, Ohio, USA. Photo by Janice Glime

Summary

Artists have used bryophytes in framing, accenting relief in sculptures, and providing texture. Even a Finnish coin sports a moss. The Japanese use them to simulate hair and other adornments on foam statues and floats.

The Corpus Christi Festival in Béjar, Salamanca, Spain celebrates the capture of the Moslem fortress by donning sheets of moss and parading through town.

Mosses have been used in movies and in others miniature artificial mosses were used. For educational purposes, some museums and other teaching organizations have ade model mosses of glass or ceramics.

Moss topiary can be made into almost any shape.

Acknowledgments

Inkeri Ahonen helped me obtain the picture and information from the sculptor, Barbro Eriksson.

Hironori Deguchi provided me with the pictures of artwork from Minoru Takeda.

Javier Martínez-Abaigar helped me with information regarding the Corpus Christi Festival and to obtain the pictures and permission for their use.

CHAPTER 3-3

FINE ARTS: LITERATURE

Figure 1. Rugged shorelines such as this with a bank of moss (*Grimmia maritima*) inspire poems that relate the ruggedness of the moss. Photo by Michael Lüth, with permission.

Stories and Verse

For some, mosses inspire poetic thoughts. Allan Fife (bryonet, 26 June 2008) has provided us with "a more or less contemporary thought on the study of mosses" by Thomas Taylor, a botanist in the British Isles, apparently written in the year he died, and published in the *London Journal of Botany* in 1848:

"They who consider attention paid to such minute objects a trifling with time, should recollect, that a moss is as much a species as a man, and the work of the same divine Creator; also, that the attentive study of the little leads to the discovery of general laws applicable to the great; and the knowledge of such laws arms the mind and the hand with power convertible to the highest purposes of life."

I began my search for mention of mosses in the Haiku poetry book I found at a used book sale, but alas, not a single poem mentioned a moss. However, a less likely occurrence is the theme of a Japanese opera developed around a moss! In Volume 1, Chapter 9-5 on light I have

described this story, which is developed around the luminous properties of the cave moss, *Schistostega pennata* (Figure 2-Figure 3). According to legend, the luminescence of the moss (protonemata) saved the life of the man in its foreground.

Figure 2. *Schistostega pennata* mature gametophytes. Photo courtesy of Martine Lapointe.

Figure 3. *Schistostega pennata* protonemata reflecting light. Photo from Rausu, Japan, by Janice Glime.

Philip Stanley, in his message to Bryonet on 13 July 2008, tells us of an unusual 203-page novel written by the Reverend W. R. Megaw of Belfast, who was also a bryologist. The novel was published in 1934 by The Quota Press of Belfast. In this novel, "*Ulota* is a story, *Ulota* is a moss, and again *Ulota* is an Irish cottage (Figure 4). How the story, the moss, and the cottage are blended into one... this is the secret charm of the book" – the comment on the dustcover of the book.

Figure 4. *Ulota phyllantha* at Traeth Gaslyn Nature Reserve, Wales. Photo by Janice Glime.

One famous quote, permeating many cultures, includes a moss: "The rolling stone gathereth no moss." Although old, this quote is still used to remind us that we need to keep busy, that accomplishments require our energy. It is too bad that it treats the moss as a symbol of laziness. I prefer to think of it as enduring, settled, or peaceful.

Hawthorne (1996) uses mosses to describe a scene in "The Old Manse, Preface to Mosses:" "Looking down into the river, I once discovered some heavy fragments of the timbers, all green with half-a-century's growth of water-moss; for during that length of time, the tramp of horses and human footsteps have ceased, along this ancient highway." This theme of representing the passage of time is a common use of mosses in poetry.

John Ruskin discovered mosses late in life, stating "It is mortifying enough to write, - but I think thus much ought to be written, - concerning myself as the author of Modern Painters. In three months I shall be fifty years old; and I

don't at this hour – ten o'clock in the morning of the two hundred and sixty-eighth day of my forty-ninth year – know what 'moss' is. He did indeed get introduced to moss, examining the "emerald green velvet" of a brick, and later wrote, "No words that I know of will say what these mosses are. None are delicate enough, none perfect enough, none rich enough." Kendall (1926) says of him, "To Ruskin, mosses were no mere botanical pigeonhole – they were a fresh pasture for his thought. With the bright thread of his fancy he wove them into the very texture of life."

Ruskin sees mosses as having particular roles in the natural world, with the adornment of rock as their principal role. Like many other poets, he refers to them as "soft mosses." And like so many others, he compares them to death, stating, "No other plants have so endless variety on so similar a structure as the mosses; and none teach us so well the Humility of Death. As for the death of our bodies, we have learned, wisely, or unwisely, to look the fact of that in the face."

Mosses often represent the passing of time, as will be seen in several of the poems here. Judson Crews, in his book, *The Clock of Moss*, writes about native peoples, farmers, and Penitentes in the Southwest, picturing the changing of the Southwest and the difficult journeys of the these people.

Shakespeare seems not to appreciate mosses as objects of beauty, but like so many poets considers them as signs of age.

In *Comedy of Errors*, Act II, Sc. 2:

"It is dross, usurping ivy, brier, or idle moss."

In *Titus Andronicus*, Act II, Sc. 3:

A barren, detested vale . . .

The trees, though summer, yet forlorn

Oercome with moss, and baleful mistletoe.

Occasionally an entire poem or story may be dedicated to moss, although it is more likely that mosses are used in the imagery. Some of these attempt to describe bryophytes in ways to rest the soul, but others tell stories from the perspective of the moss. Such is the poetic prose by the Indian writer Uma Narayan (*The Adirondack Review*):

Gathering Moss

Surely the stone would not suddenly find itself encased in a velvet muff of moss if it merely stopped rolling; after all, it might come to a standstill in a spot that lacked the moist good moss requires. Piles of sedentary stone have stood in sandy deserts, bleached by sun, unspeckled by moss. There was no moss on indolent moon rocks; lunar vegetation would have made the headlines, provoked thoughtful interviews with Carl Sagan. Evidently, many stationary stones manage to miss out on moss. There is more to moss than mere halting – unplanned fluke, serendipity. Knowing that, it may make more sense to accept the loss of moss, and enjoy the rough adventures of rolling, despite the implications of downward mobility. You wake up in a different place each day and never grow bored or outstay your welcome. You travel without a passport, see the world without paying for transport. You careen down mountains scaring hikers, go rafting in unruly waters, surrender to slope, to gravity. Moss requires tradeoffs, and one of them is staying put in a damp spot. Some stones may find real satisfaction in settled tranquility,

in providing space for green growth. Other pebbles have precipitate souls, value exuberance, cultivate the arts of falling fluently, and embrace the spry delights of a mossless life. In this matter of moss, as in many others, there are pluralities of possibility, a rich variety of ways to be stone.

Gathering Moss is also the title of a popular book by Robin Wall Kimmerer (2003). It is the Winner of the 2005 John Burroughs Medal Award for Natural History Writing. Its description in the online advertisement:

Living at the limits of our ordinary perception, mosses are a common but largely unnoticed element of the natural world. *Gathering Moss* is a beautifully written mix of science and personal reflection that invites readers to explore and learn from the elegantly simple lives of mosses. Robin Wall Kimmerer's book is not an identification guide, nor is it a scientific treatise. Rather, it is a series of linked personal essays that will lead general readers and scientists alike to an understanding of how mosses live and how their lives are intertwined with the lives of countless other beings, from salmon and hummingbirds to redwoods and rednecks. Kimmerer clearly and artfully explains the biology of mosses, while at the same time reflecting on what these fascinating organisms have to teach us. Drawing on her diverse experiences as a scientist, mother, teacher, and writer of Native American heritage, Kimmerer explains the stories of mosses in scientific terms as well as in the framework of indigenous ways of knowing. In her book, the natural history and cultural relationships of mosses become a powerful metaphor for ways of living in the world. *Gathering Moss* appeals to a wide range of readers, from bryologists to those interested in natural history and the environment, Native Americans, and contemporary nature and science writing.

Elizabeth Gilbert (2013) has contributed *The Signature of All Things*. This fictional book is not much about mosses themselves, although some are mentioned specifically. What it does include is the story of a girl, then a woman, who became a botanist and met some of the great personalities in bryology.

Edwards (1992) has analyzed the role of mosses in literature. He suggests that they moved from the maligned, being associated with death, to the benign, representing the accumulation of time. They also have represented stagnation and barrenness, but likewise may represent the "spark of green, or optimism in an otherwise bleak place." They can represent solitude, but they also represent haunting, which Edwards suggests may be due to their habit of growing on tombstones.

Ando (1990) summarizes similar associations with "koke," the Japanese word for moss. These comprise four groups: 1) old age, antiquity, solemnity, 2) Beauty, quiet, elegance, 3) seclusion, simplicity, loneliness, and 4) desolation, retrospection, mutability, death.

Fillers

The editors of *The Bryologist* from 1966 to 1975 found a great use of bryological literature. These were placed to fill empty spaces at the ends of articles, especially near the ends of issues. Since these contributions are not cited in

the regular indices of *The Bryologist*, Reese (1994) published the references in *Evansia*. These numbered 79, including both bryophytes and lichens.

Poetry

The poets seem to think of mosses in two extremes, one as the delicate beings on the forest floor, requiring moisture and refuge from the sun (Figure 5), and the other as rugged and enduring, living where nothing else can (Figure 1). This short verse by Willis Boyd Allen describes the delicate nature of woodland mosses:

Children of lowly birth,
Pitifully weak;
Humblest creatures of the wood
To your peaceful brotherhood
Sweet the promise that was given
Like the dew from heaven:
'Blessed are the meek,
They shall inherit the earth'
Thus are the words fulfilled:
Over all the earth
Mosses find a home secure.
On the desolate mountain crest,
Avalanche-ploughed and tempest-tilled,
The sweet **mosses** rest;
On shadowy banks of streamlets pure,
Kissed by the cataracts shifting spray,
For the bird's small foot a soft highway
For the many and one distressed.
Little sermon of peace.

Figure 5. "On shadowy banks of streamlets pure, Kissed by the cataracts shifting spray." Here *Platyhypnidium riparioides* fulfills the poet's verse. Photo by Michael Lüth, with permission.

A. Muriel Saunders wrote "*Sphagnum Moss* (Figure 6)," describing the virtues of using peatmosses for bandages:

The doctors and the nurses
Look North with eager eyes,
And call on us to send them
The dressing that they prize,
No other is its equal –
In modest bulk it goes,
Until it meets the gaping wound
Where the red life blood flows,
Then spreading, swelling in its might,
It checks the fatal loss,

And kills the germ, and heals the hurt –
The kindly *Sphagnum* Moss (Figure 6).

Figure 6. *Sphagnum* in a poor fen. Photo by Janice Glime.

Marshall (1907) includes a varied collection of poetry and prose where mosses help to describe the nature of things. When he discusses using moss for chinking and filling cracks, he compares this to uses by birds in building their nests (Figure 7) by quoting a poem by Claire, *The Thrush's Nest*:

Within a thick and spreading hawthorn bush
That overhung a molehill large and round,
I heard from morn to morn a merry thrush
Sing hymns of rapture, while I drank the
Sound with joy – and oft an unintruding guest,
I watched her secret toils from day to day;
How true she warped the **moss** to form her nest,
And modell'd it within with wood and clay.

Figure 7. "How true she warped the **moss** to form her nest," this bird's nest is constructed of dead plant material with living **mosses** woven among it. Photo courtesy of Jeri Peck.

Marshall (1907) begins his chapter entitled "*Leafy Mosses*" with this poem (Figure 8):

The tiny **moss**, whose silken verdure clothes
The time-worn rock, and whose bright capsules rise,
Like fairy urns, on stalks of golden sheen,
Demand our admiration and our praise,
As much as cedar, kissing the blue sky,

Or Krubul's giant flower. God made them all,
And what He deigns to make should ne'er be deemed
Unworthy of our study and our love.

Figure 8. "The time-worn rock, and whose bright capsules rise, Like fairy urns, on stalks of golden sheen," aptly describes this *Ortrhotrichum pulchellum*, although this species grows on bark of trees. Photo by Michael Lüth, with permission.

Humble Moss

The delicate and peaceful nature of mosses has inspired poets. Smallness and closeness to the ground have labelled bryophytes as humble in many literary treatments. Thus begins the poem of Richard Henry Dana, Sr. (1787-1879), a lecturer, lawyer, and journalist, but also a poet, from Massachusetts. He found the moss a worthy literary subject in his poem, *The Moss Supplicateth for the Poet*. (Figure 9):

Though I am humble, slight me not,
But love me for the Poet's sake;
Forget me not till he's forgot,
For care of slight with him I take.

For oft he passed the blossoms by
And turned to me with kindly look;
Left flaunting flowers and open sky,
And wooed me by the shady brook.

They said the world he fain would shun,
And seek the still and twilight wood, -
His spirit, weary of the sun,
In humblest things found chiefest good;

That I was of a lowly frame,
And far more constant than the flower,
Which, vain with many a boastful name,
But fluttered out its idle hour;

That I was kind to old decay,
And wrapped it softly round in green, -
On naked root, and trunk of gray,
Spread out a garniture and screen.

He praised my varied hues, - the green,
The silver hoar, the golden, brown;
Said, lovelier hues were never seen;
Then gently pressed my tender down.

And where I sent up little shoots,
He called them trees, in fond conceit:
Like silly lovers in their suits
He talked, his care awhile to cheat.

I said, I'd deck me in the dews,
Could I but chase away his care,
And clothe me in a thousand hues,
To bring him joys that I might share.

He answered, earth no blessing had
To cure his lone and aching heart;
That I was one, when he was sad,
Oft stole him from his pain, in part.

But e'en from thee, he said, I go,
To meet the world, its care and strife,
No more to watch this little flow,
Or spend with thee a gentle life.

That I was of a lowly frame,
And far more constant than the flower,
Which, vain with many a boastful name,
But fluttered out its idle hour;

That I was kind to old decay,
And wrapped it softly round in green,
On naked root, and trunk of gray,
Spread out a garniture and screen.

They said, that he was withering fast,
Without a sheltering friend like me;
That on his manhood fell a blast,
And left him bare, like yonder tree;

That spring would clothe his boughs no more,
Nor ring his boughs with song of bird, -
Sounds like the melancholy shore
Alone were through his branches heard.

Methought, as then he stood to trace
The withered stems, there stole a tear, -
That I could read in his sad face,
Brothers, our sorrows make us near.

And then he stretched him all along,
And laid his head upon my breast,
Listening the water's peaceful song: -
How glad was I to tend his rest!

Then happier grew his soothed soul;
He turned and watched the sunlight play
Upon my face, as in it stole.
Whispering, Above is brighter day!

He praised my varied hues, - the green,
The silver hoar, the golden, brown;
Said, Lovelier hues were never seen;
Then gently pressed my tender down.

And where I sent up little shoots,
He called them trees, in fond conceit:
Like silly lovers in their suits
He talked, his care awhile to cheat.

I said, I'd deck me in the dews,
Could I but chase away his care,
And clothe me in a thousand hues,
To bring him joys that I might share.

He answered, earth no blessing had
To cure his lone and aching heart;
That I was one, when he was sad,
Oft stole him from his pain, in part.

But e'ven from thee, he said, I go,
To meet the world, its care and strife,
No more to watch this little flow,
Or spend with thee a gentle life.

And yet the brook is gliding on,
And I, without a care, at rest,
While he to toiling life is gone;
Nor finds his head a faithful breast.

Deal gently with him, world, I pray;
Ye cares, like softened shadows come;
His spirit, well nigh worn away,
Asks with ye but awhile a home.

O, may I live, and when he dies
Be at his feet a humble sod;
O, may I lay me where he lies,
To die when he awakes in God!

Figure 9. *Grimmia elongata* demonstrates "He praised my varied hues, - the green, the silver hoar, the golden, brown." Photo by Michael Lüth, with permission.

Carol Reed-Jones tells how she develops a list poem, in this case first listing all the things she sees in the woods. Then she must think how they relate to each other and how she can use the senses to describe them. Thus, she adds moisture and texture to the green color of the moss to make the image come alive (Figure 10):

In the Woods

In the woods, scraps of fog
drape themselves
like gray scarves on the trees.
In the woods,
frogs sing and crows squawk,
and one heron flaps past on silent wings.
In the woods, blooming plants
exhale a sweet perfume,
and the taste of green growing things
is in the air.
In the woods, each tree
wears soft, moist green **moss**
over its rough, dry bark.

Figure 10. Here every tree "wears the soft, green moss" *Eurhynchium praelongum*. Photo by Michael Lüth, with permission.

One reference that seems common in the use of mosses in literature is that they are "soft underfoot," as Edwards (1993a) points out. He found fifteen occurrences of such a reference.

From Twenty Lessons on British Mosses (1846)

by William Gardiner (1808-1852)

O! Let us love the silken **moss**
That clothes the time-worn wall
For great its Mighty Author is,
Although the plant be small.

The God who made the glorious sun
That shines so clear and bright,
And silver moon, and sparkling stars,
That gem the brow of night-

Did also give the sweet green **moss**
Its little form so fair;
And, though so tiny in all its parts,
Is not beneath His care.

When wandering in the fragrant wood,
Where pale primroses grow
To hear the tender ring-dove coo,
And happy small birds sing,

We tread a fresh and downy floor,
By soft green **mosses** made ;
And, when we rest by woodland stream,
Our couch with them is spread.

In valley deep, on mountain high-
The **mosses** still are there :
The dear delightful little things-
We meet them everywhere!

And when we mark them in our walks,
So beautiful, though small,
Our grateful hearts should glow with love
To Him who made them all.

The American poet Amy Clampitt begins her poem, **Cloudberry Summer**, part of her collection 'What the Light Was Like,' as follows:

Cloudberry Summer
First ventured into
in mid-July, the bog's sodden hollow
muffled the uproar of the shore
it hunkered in the lee of. Wrung residues
of *Sphagnum* moss steeped in self-
manufactured acids stained the habitat's
suffusing waters brown...

Rugged Mosses

It seems it is often the smallness that is stressed, and seldom the ruggedness, but these poems show that the tenacity of such a small plant gives hope that we too can survive adversity. This wonderful little poem, Ode to *Grimmia*, Anonymous, p. 433, describing *Grimmia* (Figure 11) as only a bryologist could, obviously had an author, but I had only a photocopy and a page number, with no indication of where it came from. A year after my plea for help in identifying the author (first edition of this chapter), Andi Cairns found a scrap of paper with the poem and the author Peter Albert, but no source. Fortunately, I misread her email as a name familiar to me, Peter Alpert. I was able to track him down and contact him. Peter responded that this was the first and last poem he ever wrote, a contribution to his doctoral thesis (Alpert 1982).

Ode to *Grimmia* – by Peter Alpert

The most casual talker, if he be a walker,
is surely acquainted with moss;
He will say it's a thing that to grow needs a spring,
leafy shade, and a log to emboss.
But he's wrong three times over; he's yet to discover
there's a moss which is doughty and tough;
One he's likely to see, and dismiss thoughtlessly
as dead, brown, old fungus-like stuff.
Bravely crowning a rock, this is pure mossy stock,
air, it's dry, yes, but far from inert;
Give one drop of rain – it will turn green again!
And resume making moss leaves, unhurt.
It can manage drought slyly, knowing poikilohydry,
like its kin in the genus of *Grimmia*,,
Which from bare alpine col to the seer chaparral
make hard boulders seem soft and familiar.

Figure 11. *Grimmia arenaria* demonstrates the brown-black moss as described in *Ode to Grimmia*. Photo by Michael Lüth, with permission.

Thomas James Allen seems also to find moss in those dreary places in his four poem parts called "Moss Upon the Brick." But in the end, the endurance of the moss gives him hope:

Moss Upon The Brick - Part 1

In an older part of town,
Covered far and green and thick,
An ancient house, an antique home,
With **moss** upon the brick.

A window's broken, boards are split,
The clocks inside have stopped,
The pictures hung upon the walls
Have bent their nails and dropped.

A fence outside surrounds the house,
The gate squeaks with the breeze,
The yard is filled from left to right
With dying grass and trees.

The road untravelled past the house
Is muddy, brown and slick,
And the sidewalk from the house
Has **moss** upon the brick.

Moss Upon The Brick - Part 2

The children discover the ancient house
That townsfolk pass by quick,
A haunted place with summer weeds,
And **moss** upon the brick.

They sneak inside through an open door
That leads into a hall,
An empty spiderweb above
Is stretched from wall to wall.

They wander past the dining room,
That's lit through broken panes,
The rug on the floor below the chairs
Is soiled by coffee stains.

The kitchen with its well-worn tiles
Is empty, dark and cold;
A hardened breadcrumb on the floor
Is covered with blue mold.

The children wander past the stairs,
They're walking hand in hand;
They're frightened by an old umbrella,
Discarded in a corner stand.

All at once the wind blows hard
And slams a door upstairs;
The children race back through the rooms,
Disturbing rugs and chairs.

Back home they run with screaming cries,
For Nature's played a trick;
They'll never come to play in the house
With **moss** upon the brick.

Moss Upon The Brick - Part 3

A November walk down an old rutted road
Through a fog, though misty and thick,
I've ventured to see that old rustic house,
With **moss** upon the brick.

The sun has been swallowed behind the dark clouds,
The air is bitter and chilled,
The winds change from North to East to South-
South-West, but never are stilled.

The weeds growing thick by the edge of the house,
Live now, while others cannot,
They thrive in the cold with the wind and the snow,
Instead of the summertime hot.

The apple trees dropped their fruits in the yard
When nobody came to call,
The red and the yellow lie mixed with the brown
Of the leaves that were dropped in the Fall.

A November day in the life of the house,
Like others of future or past,
Does little to change the brick and the wood,
Or the darkened shadows cast.

An early Fall snow still clings to the roof,
And ice makes the sidewalk slick,
But the wind and the cold can never remove
The **moss** upon the brick.

Moss Upon The Brick - Part 4

Now I have grown old, my hair has turned gray,
The passage of time was so quick;
I wonder if years have weathered the house
With **moss** upon the brick?

I remember the house as it was in my youth,
I'm drawn down the muddy lane;
The trees, the walk, the peeling paint,
The broken window pane.

Why, even in my day, the boards on the porch,
From lying so long were sore,
They'd bent their necks and arched their backs,
Pulling their nails from the floor.

I wonder if years have caved in the roof?
If the weeds are growing thick?
If wind and rain have even left
A brick upon a brick?

I'm nearing the house, I'm afraid to look,
I laugh, my fearing is odd;
I'd always supposed the house would stand strong,
Like mountains, or faith in a god.

But mountains with time have melted away,
And I've had my faith in God shaken,
And someday the earth will not turn 'round the sun,
Oh what is this risk that I've taken?

If I shatter a memory by returning to see
Whether my childhood world is the same,
And finding that things are not as I left them,
I've only myself to blame.

My hand on the gate, I look up the walk,
My heart turns the clock back a tick;
My faith, my life saved! - for there stands the house,
With **moss** upon the brick.

Among the more famous bryological poems (at least among bryologists) is the one by Mungo Park, written

about his African travels when he thought he would surely die in the desert, with no compass and no food, but who gained the hope he needed upon seeing a lowly moss, a small *Fissidens* (Figure 12), green and growing (Crum 1973). Park wrote in his journal, "Can that Being (thought I), who planted, watered, and brought to perfection in this obscure part of the world a thing which appears of so small importance, look with unconcern upon the situation and sufferings of creatures formed after his own image? Surely not! Reflections like these would not allow me despair. I started up, and disregarding both hunger and fatigue, travelled forward, assured that relief was at hand." He did indeed survive to reach hospitable land:

Sad, faint and weary, on the sand
Our traveller sat him down; his hand
Cover'd his burning head.
Above, beneath, behind, around,
No resting for the eye he found;
All nature seemed as dead.

One tiny tuft of **moss** alone,
Mantling with freshest green a stone,
Fix'd his delighted gaze;
Through bursting tears of joy he smiled,
And while he raised the tendril wild,
His lips o'erflowed with praise.

Oh! shall not He who keeps thee green,
Here in the waste, unknown, unseen,
Thy fellow-exile save?
He who commands the dew to feed
Thy gentle flower, can surely lead
Me from a scorching grave.

Thy tender stalks, and fibres fine,
Here find a shelter from the storm;
Perhaps no human eye but mine
Ere gazed upon thy lovely form.

He that form'd thee, little plant,
And bade thee flourish in this place,
Who sees and knows my every want,
Can still support me with His grace.

Figure 12. *Fissidens bryoides*, identified by W. J. Hooker, surviving in the desert soil, brought hope to Mungo Park as he was about to give up all hope. Photo by Michael Lüth, with permission.

Winter seems to inspire mention of mosses, when all else is dark and grey, as in this verse by George Crabbe called **Tales of the Hall**:

All green was banished save of pine and yew,
That still displayed their melancholy hue;
Save the green holly with its berries red,
And the green **moss** that o'er the gravel spread.

But Whittier, in **Mogg Megone**, Pt. III, speaks of spring, when other plants overtake the mosses:

'Tis spring-time on the eastern hills!
Like torrents gush the summer rills,
Through winter's **moss** and dry dead leaves
The bladed grass revives and lives,
Pushes the mouldering waste away,
And glimpses to the April day.

The freshness of rainfall likewise makes the mosses stand out, inspiring the poet, as Alfred Tennyson writes in **The Lotos Eaters: Choric song**:

Here are cool **mosses** deep,
And thro' the **moss** the ivies creep.

One anonymous poem appeared in the Bryological Times 96 in 1998 as lyrics of a song sung by the students in a peatlands bryophyte course in Finland in 1997:

Ten Keen Bryologists

Ten keen bryologists
Were learning bryophytes,
one of them got stuck in those,
but nine spent all their nights!

Nine freak bryologists
went out into a mire,
one of them got grilled in there,
but eight survived the fire!

Eight smart bryologists went out into a bog,
one found too much *Sphagnum* there,
the rest got through the fog!

Seven dumb bryologists went out into a fen,
one discovered two bears there,
the others passed the den!

Six sane bryologists collected more mass samples,
one mistook it all for spinach
five needed no example!

Five lax bryologists
took a break with sauna,
one got broiled like a fish,
the rest remained living fauna!

Four wise bryologists,
jumped into a river,
one of them jumped down the rapids,
three cared not a shiver!

Three sure bryologists
identified Mniaceae,
one took *Mnium* (Figure 13) for a *Bryum* (Figure 14),
two were like Timo so crazy!

Two brave bryologists
were walking near the border,
one saw a Russian endemic,
the other returned in order!

One lone bryologist
liked bryophytes, so then
he looked for nine more bryophiles
and started again as ten!

Some poetry is just for fun and expresses the author's state of mind. This anonymous 1996 poem, published in Bull. Brit. Bryol. Soc. 67: 45, perhaps by a frustrated student, expresses the trials and tribulations of dealing with bryophyte systematics (Figure 15 - Figure 18):

Modern studies in *Drepanocladus*
Lars Hedenäs of Sweden,
By the Nine Gods he swore,
The genus *Drepanocladus*
Should trouble us no more.

The concept was old-fashioned
Just taxonomic tedium,
So he split it into several parts,
And one of them's *Scorpidium* (Figure 16).

Perplexed and puzzled by the rest,
He paused to scratch his ear,
And after labours long and hard,
Arrived at *Warnstorfia* (Figure 17).

Axillary hairs he laboured o'er,
And peristomial matters,
And other trivial details which
Will drive us mad as hatters.

At last he faced the final rump
'Now what on earth'll I call this?'
Then final inspiration struck –
And gave us *Hamatocaulis* (Figure 18).

Now sound his reasons may well be,
For splitting, and not lumping,
But as I struggle with new names,
I'm half inclined to thump him.

Figure 15. The traditional genus *Drepanocladus* has few remaining species, now including this *D. sendtneri*, as Hedenäs has attempted to "trouble us no more." Photo by Michael Lüth, with permission.

Figure 16. Hedenäs concluded that this member of *Drepanocladus* should be moved to *Scorpidium* as *S. revolvens*. Others, such as Blockeel (2000) still include it in *Drepanocladus*. Photo by Michael Lüth, with permission.

Figure 17. Once called *Drepanocladus exannulatus*, Hedenäs has renamed this one *Warnstorfia exannulatus*. Photo by Michael Lüth, with permission.

Figure 18. And another once named *Drepanocladus vernicosus*, this one is now *Hamatocaulis vernicosus*. It seems that Hedenäs has solved the problems of *Drepanocladus* by removing most of its species! This seems to have resulted in no less consternation by his student, as lamented in the poem, *Modern Studies in Drepanocladus*. Photo by Michael Lüth, with permission.

There are many translations of a poem by the Chinese poet Wang Wei, where in the end it is the moss that is given importance (Figure 19). I prefer this one by W. J. B. Fletcher in 1919:

So Lone seem the hills; there is no one in sight there.
But whence is the echo of voices I hear?
The rays of the sunset pierce slanting the forest,
And in their reflection green **mosses** appear.

Figure 19. *Hypnodendron menziesii*, showing "The rays of the sunset pierce slanting the forest, And in their reflection green mosses appear." Photo by Jan-Peter Frahm, with permission.

In a discussion on Bryonnet in June 2008, Dan Paquette was more a realist in this contribution:

Dirty Little Moss
By Dan Paquette

Dirty little **moss**
on the cottonwood trunk,
my spray bottle
washes away the debris.

Your stem snuggles close
to your siblings, green
unbrushed curls
of sun-loving leaves.

Your generation lies
criss-crossed above

tired wet scaffolding
twisted remnants
of your first borne branches
and some great, great
uncles and aunts
in mucous, brown

intertwined stems, leaves—
limp banners
of whom
they once were—

mosses.

One day, your skin
will be coal pudding
for some thermal bacteria

long after you and I

It is seldom that mosses figure in such touching dramas and struggles as seen in the works of Walt Whitman in his twelve-poem sequence, "Live Oak, with Moss." In 1858 or 1859, Whitman described one man's love for another, the happiness they shared, and the aftermath of that relationship (Parker 1996). But that sequence, in its original form and presentation of honest struggles, was never published. Rather, a revised version, missing the comma, was ultimately published as "Live Oak with Moss" within a forty-five poem "Calamus" section of the 1860 *Leaves of Grass*. The original "Live Oak, with Moss," finally published by Bowers in 1953 (see Parker 1996), gives an honest rendition of the struggle and feelings of a man's love for a man while living in a world of homophobia.

In contrast to the usual imagery and friendly moss names, it seems that in recent works in Great Britain, scientific names of mosses may appear in literary works. For example, in Dulcie Domum's "Bad Housekeeping" (*The Guardian*, 8 February 1992), she writes "Gertrude was seated on a mat of *Grimmia pulvinata* (Figure 20) gazing thoughtfully out across glittering Rough Dike reservoir." (Edwards 1993a; Figure 20). Even less recently, Dutton, in "The Craggie" (1976) wrote "Remarkable woman," mused the Doctor, turning again to the wall. "Had an entire liverwort subspecies named after her – *Dicranodontium uncinatum* McHattii (Figure 21); should have been a genus – *Agenesia*." It is too bad that *Dicranodontium* is a moss, not a liverwort (Figure 21).

Figure 20. This *Grimmia pulvinata* hardly gives the image of "Gertrude was seated on a mat of *Grimmia pulvinata* gazing thoughtfully out across glittering Rough Dike reservoir," but it can form extensive mats, and those spiny looking hair tips are actually quite soft. Photo by Michael Lüth, with permission.

Figure 21. This moss, *Dicranodontium uncinatum*, is clearly not the liverwort as referenced in the words of Dutton. Perhaps it is best that poets stick to common names. They cannot be easily challenged and are usually more poetic. Photo by Michael Lüth, with permission.

Perhaps more commonly, mosses are used as a means of describing something else. In her poem describing the habit of burying daughters live with their dead fathers in Arabia, Anne Sexton (1981) again uses mosses as a means of showing the passing of time, writing:

The **Moss** of his Skin
It was only important
to smile and hold still,
to lie down beside him
and to rest awhile,
to be folded up together
as if we were silk,
to sink from the eyes of mother
and not to talk.
The black room took us
like a cave or a mouth
or an indoor belly.
I held my breath
and daddy was there,
his thumbs, his fat skull,
his teeth, his hair growing

like a field or a shawl.
I lay by the **moss**
of his skin until
it grew strange. My sisters
will never know that I fall
out of myself and pretend
that Allah will not see
how I hold my daddy
like an old stone tree.

Even in poetry, mosses are often associated with death and decay. John Greenleaf Whittier wrote, in **A Dream of Summer**:

The Night is Mother of the Day,
The Winter of the Spring,
And ever upon old Decay,
The greenest **mosses** cling.

And John Masfield wrote in **Vagabond**:

Dunno about Life – it's jest a tramp alone
From wakin'-time to doss,
Dunno about Death – it's jest a quiet stone
All over-grey wi' **moss**.

Emily Dickinson often wrote of death, so it is not surprising that mosses entered into her imagery. In "**I died for Beauty – but was scarce**," she uses it as her final image, signifying the passage of time as the moss covers our names (on the tombstone):

Adjusted in the Tomb
When one who died for Truth, was lain
In an adjoining Room –
He questioned softly "Why I failed"?
"For Beauty", I replied –
"And I – for Truth – Themselves are One –
We Brethren, are," He said –
And so, as Kinsmen, met a Night –
We talked between the Rooms –
Until the **Moss** had reached our lips –
And covered up – our names

A pleasant contrast to these morbid references to mosses is "The Thorn" by William Wordsworth (Everything2 2005). In this poem, of 22 stanzas, he starts by describing the thorn tree as sad, aging, and decrepit with lichens. Later, however, he describes the heap of earth the size of a child's grave by that same tree as more beautiful than any he has seen because the **moss** growing there shines with all kinds of colors – olive green and scarlet bright. The **moss** looks like a skillfully woven patchwork with beautiful colors of green, red, and pearly white. Here, the **moss** seems to symbolize that life goes on despite death around it.

Johann Greilhuber on Bryonet 15 July 2008, "The nice mossy poem by Siegfried von Vegesack, posted by Goda Sporn on June 30, 2008, was probably incomprehensible to those, who had no training in German language. Therefore I tried a free paraphrasing translation (I hope, with not too many errors) as follows:"

Moss

Have you already **mosses** seen?
Have you already down there been,
looking not just from above,
not being close enough –

no – kneeling down, so that you look
at them as if you read the letters in a book?
O wizard fonts! O wondersigns!
A matchless jungle grows, where branch to branch aligns,
and thrives and sprouts abundantly
in forest dawn.

Throughout the year you see
the curled fringes, peaked cones,
the silverhelmets, bells, pompones,
the tangled branchlets, crossed shafts
with petticoats of laced tufts.

This lowly grows on soil and stones --
just **mossy** stuff.
And huge above
the forest thrones.

But now and then a slender deer
walks below the bushes here,
bows under the leafy roof,
stamps into the **moss** its hoof.

And a guileless leveret might
bleed under the foxes bite.
Crawling over liverworts
a paunchy hedgehog lightly snorts,
and in endless caravans
march here legions of ants.

A weasel jumps and rips the prey,
while cool and impressively may
a snake find through the **moss** its way.
What happens here in brushweed deep
on **mossy** stones
nobody learns, the **mosses** secrets keep.
And huge above the forest thrones.

Have you already down there been?
Have you already **mosses** seen?

The original by Siegfried von Vegesack:

Moos

Hast du schon jemals **Moos** gesehen?
Nicht bloss so im Voruebergelien,
so nebenbei, von oben her,
so ungefaehr -
nein, dicht vor Augen, hingekniet,
wie man sich eine Schrift besieht?

Oh Wunderschrift! Oh Zauberzeichen!
Da waechst ein Urwald ohnegleichen,
und wuchert wild und wunderbar
im Tannendunkel, Jahr fuer Jahr,
mit krausen Fransen, spitzen Huetchen,
mit silbernen Trompetentuetchen,
mit wirren Zweigen, krummen Stoeckchen,
mit Sammethaerchen, Bluetengloeckchen,
und waechst so klein und ungesehen -

ein Huempel **Moos**.

Und riesengross
die Baeume stehen.

Doch manchmal kommt es wohl auch vor,
dass sich ein Reh hierher verlor,
sich unter diese Zweige bueckt,
ins **Moos** die spitzen Fuesse drueckt
und dass ein Has, vom Fuchs gehetzt,
dies **Moos** mit seinem Blute netzt...

Und schnaufend kriecht vielleicht hier auch
ein sammetweicher Igelbauch,
indes der Ameis' Karawanen
sich unentwegt durchs Dickicht bahnen.

Ein Wiesel pfeift, ein Sprung und Stoss...
und kalt und gross
gleitet die Schlange durchs **Moos**...
Wer weiss, was alles hier geschieht,
was nur das **Moos** im Dunkeln sieht:
Kein Wort verraet das **Moos**.
Und riesengross die Baeume stehen.
Hast du schon jemals **Moos** gesehen?

Sir Orfeo (translated by J.R.R. Tolkien 1975) written by a
medieval poet whose name is unknown:

He once had ermine worn and vair,
on bed had purple linen fair,
now on the heather hard doth lie,
in leaves is wrapped and grasses dry.
He once had castles owned and towers,
water and wild, and woods, and flowers,
now though it turn to frost or snow,
this king with **moss** his bed must strow.

In the *Bible*

Old names and changes in language make it difficult to
determine if any bryophytes are truly mentioned in the
Bible. Most references to them seem shaky at best. Sean
Edwards (1993b) has demonstrated this difficulty with
several examples.

In the *Bible*, hyssop has dubious meaning. In Exodus
12:22, Leviticus 14:4, 6, 49-52, Numbers 19:6,18, and
Hebrews 9:19, hyssop refers to use in procedures involving
dipping it into blood or water and sprinkling it about.
Again in Psalms 41:7 it was used to purge or cleanse, and
in John 19:29 it was used as a sponge for vinegar. Scholars
think different plants may have been used in these different
examples, and there is no clear evidence any was a moss.

However, in I Kings 4:33, the "hyssop that springeth
out of the wall" narrows the habitat enough to encourage
the suggestion of a moss. Other possibilities include small
wall ferns, and even species today known as hyssop are
possible. However, Linnaeus, who was not known for his
understanding of mosses, identified this text to refer to the
moss *Bryum truncatulum*, later known as *Pottia truncata*,
and now known as *Hennediella truncata* (Figure 22),
stating that "The houses and walls of Jerusalem are clothed
at their base with green moss, the smallest of all;

Hasselquist sent me some and it is *Bryum truncatum*. He similarly concludes that the other references to hyssop refer to moss, using the argument that all mosses absorb liquids and can be used as absorbents. The argument is, however, hardly proof.

Figure 22. *Hennediella truncata*, once known as *Pottia truncata*, and before that as *Bryum truncatum*, was the guess of Linnaeus for the "hyssop that springeth out of the wall" (1 Kings 4:33). Photo by Michael Lüth, with permission.

The saga does not end there, however, as Mr. Dickson subsequently identified what appears to be the same moss, collected from the location described in the Bible, as *Bryum pyriforme*, figured by Hedwig as *Gymnostomum fasciculare*, and now named as *Entosthodon fascicularis* (Figure 23) (Edwards 1999).

Figure 23. This possible "hyssop that springeth out of the wall" is possibly *Entosthodon fascicularis*, a moss. However, it is possible that the plant in question in the Bible was not a moss at all, but a tracheophyte, perhaps even a fern. Photo by Michael Lüth, with permission.

On the other hand, I (Janice Glime) just loaded searchable pdf files of the old and new testaments. Then I did a search for "moss." Zero records were found. So if moss is named in the King James Bible, the reference must be indirect.

Literature References from Bryonettters

In April 2016, Bryonettters opened a discussion on proverbs and folk sayings regarding mosses. These included introductory comments by Robin Stevenson, Bryonet 4 April 2016:

Proverbs, and similar folk sayings, are a way of preserving fundamental truths or pieces of advice. In English the only moss-related example which springs to mind is: **'Rolling stones gather no moss.'**

A non-proverbial observation which verges on a 'Law' is that 'Leaning trees gather most moss', whilst an undoubted element of name-magic frequently surfaces in the course of field meetings; someone will say 'Has anybody seen *Bryum elixir-vitae* yet?' and it is usually found very soon afterwards.

Javier Martínez-Abaigar, Bryonet 4 April 2016, reported that "in Spanish we have a similar saying as that reported by Robin (**'rolling stones gather no moss'**): "piedra movediza nunca moho la cobija." Curiously, this saying is mentioned in the act XV of the "Tragicomedy of Calisto and Melibea," known in Spain as "La Celestina," published in 1499. Also curiously, the term "moho" (English "mould") mentioned in that saying was used in ancient Spanish with the meaning of "musgo" (English "moss"). This use was maintained until probably the XVIII century, when the meaning of these two words (moho-musgo) was clearly different (mould-moss).

Pierre Morisset, Bryonet 4 April 2016, reported that "the same saying is used in French: "Pierre qui roule n'amasse pas mousse." As mentioned in <<http://www.expressio.fr/expressions/pierre-qui-roule-n-amasse-pas-mousse.php>>, it also occurs in German, Italian, Portuguese, Dutch, Walloon... and Latin.

Norbert Stapper, pers. comm. 4 April 2016, agreed that "Pierre is right, but I actually never heard someone using this nice phrase in Germany. Hasty research reveals that it is not necessarily meant in a negative way (i.e. that 'people who don't shave get a beard,' or "that someone gets rusty bones due to being lazy"). Instead, it can also be used to indicate that a restless and constantly moving person lacks the requisite for a successful life and the ability to take permanent responsibility."

Chris Preston added that as Pierre says, 'A rolling stone...' is known in several languages and in his pioneer 'A collection of English proverbs' (1670) the naturalist John Ray included Italian, French, Latin, and Greek versions:

Chris Preston contributed several occurrences of "moss" in literature:

Ray also includes Scottish proverbs including 'Better woove over middling nor over **moss**' - I assume that moss here is equivalent to bog, as in Guy's proverb, and that middling is a midden or rubbish heap, but the proverb still seems rather obscure. Maybe Gordon could assist here? Some of the Scottish proverbs are more direct, such as 'Better sit idle than work for nought.'

Ray's third moss proverb – which may only be in the second edition (1678) – is 'I took him napping, as **Moss** took his mare' but as Ray comments, 'Who this **Moss** was is not very materiall to know.'

Two quotes from Shakespeare were recalled by Ann Gordon, Bryonet 4 April 2016:

•in As You Like It: "Under an old oak, whose boughs were **mossed** with age..."

•in The Comedy of Errors: "Usurping ivy, brier, or idle **moss**..."

Moss in Music

In his tribute to Wilf Schofield, Adolf Ceska reports that mosses are only seldom mentioned in classical music. One mention, however, is in Richard Wagner's Parsifal. Kundry describes to Parsifal the way his mother cared for him as a child:

Gebettet sanft auf weichen **Moosen**
den hold geschlafert sie mit Kosen.

or

Gently bedded in soft **moss**
she lulls carressingly her darling boy.

The Czech composer Bedrich Smetana was a follower of Wagner and as such had a similar moss theme. In his opera "Hubicka (Kiss)," the smugglers walk through a forest and sing (quite loudly) a nice chorus:

"Quiet, quiet, [step] on **moss** ..."

Uses of the Word Moss

The word moss is used by many ecologists to mean bryophyte, but an even broader use is to mean any small plant. It is also used to refer to bogs and fens, to moss heaths, or other mossy habitats.

Johannes Enroth, Bryonet 4 April 2016, contributed this Finnish use of the word for moss:

Well, in Finnish colloquial speech moss translates to "sammal," from which stems the verb "sammaltaa," meaning speaking in a very unclear manner, especially when one is heavily drunk. You speak as if you had your mouth full of moss or something like that.

From Norway, Hans K. Stenøien, Bryonet 4 April 2016, contributed this:

In Norwegian one might say that there are "owls in the moss" ("ugler i mosen"), meaning that something is not right, suspicious.

(Note, the burrowing owl uses mosses in its nest – JG)

Later, Stenøien added:

My literate friends Hans Blom and Gustaf Granath have pointed out to me that "ugler i mosen" (Norwegian) and "ugglor i mossen" (Swedish) is actually derived from Danish: "ulve i mosen," and that "ugler" ("owls") is a complicated way of saying "uller," which is dialect for "ulver" or wolves.

The original Danish (medieval?) saying would therefore be "wolves in the mire" rather than "owls in the moss," with the meaning being the same: something fishy (suspicious).

Stefan Schneckenburger, Bryonet 4 April 2016, offered some German things:

- Moos haben – to have moss – to have money, to be rich
- ein bemoostes Haupt haben/sein: to have/to be a mossy head: to be old
- das Moss der Maennlichkeit – the moss of maleness: beard
- Ohne Moss nix los: Nothing happens without moss. Here Moos means money

To the last German statement, Norbert Stapper (Bryonet 4 April 2016) added:

A second meaning of moss ("Moos") in colloquial German means money, and the phrase "ohne Moos nix los" (= life is dull without money or, similar, in French: "sans pognon pas de trognon") is used frequently. This use of Moos goes back to the Yiddish language.

With regard to the word moss in German everyday use Stapper contributed "I would like to add that moss (Moos) is widely accepted, as long as it grows in the woods or in a similar natural habitat. People then talk about e.g. "Moosteppich" (moss carpet), positive connotation. But as soon as you enter the direct human environment, the words "bemoost" (=covered by moss) or "übermoost" (totally covered by mosses) are often linked to dirt or deterioration. Then they are used to illustrate the transition from a well-maintained building to a ruin with wet walls etc. If something is grown by mosses, it is in a bad state.

This brings us to one of the reasons to get rid of mosses on e.g. cobblestones or on the small houses of litter bins. Principle: Keep the wild out! Moss symbolizes the wild. There seems to be a difference between the European countries in tolerance to mosses in human/urban environment, maybe it is linked to recent history, the fact to have rebuilt the country after the war?

In parallel to the differing interpretations of the proverb with the word moss (see my mail from the afternoon), the use and the connotation of the word Moos itself appears to be conflicting – at least in the language of the people in the part of Deutschland where I live.

As a followup to the comments by Stapper, Stefan Schneckenburger, Bryonet 4 April 2016, commented that Shakespeare didn't really discriminate between mosses and lichens. "At the moment I am studying the Bard's plants when curating an exhibition in the German Botanic Gardens: <http://www.verband-botanischer-gaerten.de/pages/bg_woche.html>."

Possibly he owed Gerads "Herball" from 1597 (as Peter Ackroyd pointed out in his biography). Here you can

find *Lycopodium* species, mosses, and lichens under "Mosses" – even a specific moss on human skulls (the German text relies on the borrowing of German woodcuts by the British publisher and printer). Even algae are listed under "sea mosses." Hepatics are treated separately; including *Cetraria* e.g. Here you can find the "Herball" from 1597; the mosses are treated on p. 1369-ff.

Very impressive is a scene in bloody "Titus Andronicus": A forest is first described as sunny, warm, and sexually stimulating (Tamora is waiting for her lover). 80 verses later, the same forest is the location of murder and rape (act II, sc. 3):

My louely Aaron,
Wherefore look'st thou sad,
When euerything doth make a Gleefull boast?
The Birds chaunt melody on euery bush,
The Snake lies rolled in the chearefull Sunne,
The greene leaues quiuer.with the cooling winde,
And make a cheker'd shadow on the ground:
Vnder their sweete shade, Aaron let vs sit,
And whil'st the babling Eccho mock's the Hounds,
Replying shrilly to the well tun'd-Hornes,
As if a double hunt were heard at once,
Let vs sit downe, and marke their yelping noyse:
And after conflict, such as was suppos'd.
The wandring Prince and Dido once enioy'd,

Haue I not reason thinke you to looke pale.
These two haue tic'd me hither to this place,
A barren, detested vale you see it is.
The Trees though Sommer, yet forlorne and leane,
Ore-come with **Mosse**, and balefull Misselto.
Heere neuer shines the Sunne, heere nothing breeds,
Vnlesse the nightly Owle, or fatall Rauen:
And when they shew'd me this abhorred pit,
They told me heere at dead time of the night.

Schneckenburger added, "If you will visit Germany during June or later – please inform you beforehand, in which Botanic Garden you can see my exhibition on Shakespeare's plants! I add "bonus material," prepared for of my exhibition, dealing with mosses. Even if you are not able to read German, you will find two plates from Gerard's Herball."

To the word usage of "moss," Mark Seaward (Bryonet 5 April 2016) added "Stefan is right: it should be remembered, when reading any old texts and correspondence, certainly in Britain, that in the past "growths" on trees, rocks, and indeed skeletons did not differentiate between mosses and lichens, and mostly referred to both. Furthermore, common names for lichens are named "Moss" even to this day, such as:

Iceland Moss – *Cetraria islandica*
Reindeer Moss – *Cladonia* subgenus *Cladina*

And Norbert Stapper (Bryonet 5 April 2016) added Eichenmoos (Oak moss) = *Evernia prunastri*.

This is one of the few German lichen names that, like "Gelbflechte" (*X. parietina*), seems to be part of common language (if there is anything "common" with lichens at all). As you will know for sure, some people, among them

Volker, have created a list of German names of lichens. I hope I will never be compelled to use 'em in textwork...

Ambroise Baker, Bryonet 5 April 2016, reflected on similar usage in Switzerland. "We have sweets called Mousse d'Islande (Islandisch Moos, Muschio Islandese), which I read from the ingredients contain 0.17% of 'Iceland lichen extract.' How to tell which moss lores refer to moss proper? Most people won't tell moss from lichen apart. – I'll ponder over it sucking on my Swiss sweets..."

Adolf Ceska, Bryonet 4 April 2016, reported that the "national anthem of Japan is a song entitled 'Kimigayo.' It was formally designated the national anthem in 1893, during the reign of the Meiji Emperor. The song was composed by an Imperial Court Musician of the Meiji era. The lyrics are from a poem that was written over 1000 years ago. The words mean 'May your reign continue for a thousand, nay, eight thousand generations and for the eternity that it takes for small pebbles to grow into a great rock and become covered with **moss**.'"

Masaki Shimamura, Bryonet 5 April 2016, clarified the words in the national anthem of Japan:

Many people might think the phrase "small pebbles to grow into a great rock" is unscientific. This is the problem with translation. In here, a Japanese term "Sazare-Ishi" have been simply translated in "small pebbles." Strictly speaking, "Sazare-Ishi" means "conglomerate rock" (small pebbles cemented by calcium carbonate or Iron oxide-hydroxide) and "Sazare-Ishi no Iwao" means "a giant conglomerate rock" (may be calcareous). In this poem, the giant and mossy conglomerate rock represents the eternity.

In honor of bryologist Wilf Schofield, Adolf Ceska (1997) <<http://bomi.ou.edu/ben/ben168.html>> reminded us of Schofield's love of music and poetry. Ceska cited the anthology "A Book of Luminous Things" (edited by Czeslaw Milozs) as having a poem "Moss-Gathering" by Theodore Roethke (1944). The poem describes techniques of moss collecting. This technique is exactly the same as that applied by Dr. Wilf Schofield (see also Peck 2006):

To loosen with all ten fingers held wide and limber
And lift up a patch, dark-green, the kind for lining
cemetery baskets,
Thick and cushiony, like an old-fashioned doormat,
The crumbling small hollow sticks on the underside mixed
with roots,
And wintergreen berries and leaves still stuck to the top,-
That was **moss**-gathering.

[Roethke feels remorse for gathering so much moss:]

But something always went out of me when I dug those
loose carpets
Of green, or plunged my elbows in the spongy yellowish
moss of the marshes:

And afterwards I always felt mean, jogging back over the
logging road,

As if I had broken the natural order of things
in that swampland;

Disturbed some rhythm, old and of vast importance.
By pulling off flesh from the living planet (Figure 24);
As if I had committed, against the whole scheme of life,
a desecration.

Figure 24. Jeri Peck would agree with Roethke as he writes, "Disturbed some rhythm, old and of vast importance, By pulling off flesh from the living planet." Here she records data on the impact of harvesting in the Pacific Northwest, USA, while examining a patch that has been loosened "with all ten fingers held wide and limber" and lifted up. Photo courtesy of Jeri Peck.

From North America, Guy Brassard, Bryonet 4 April 2016, contributed this:

There is an interesting old one from Newfoundland (Canada): **moss child**: an illegitimate child; presumably originating because such children were often conceived on the fens or bogs.

Also from North America, Annie Martin (Bryonet 5 April 2016) added colloquial uses of the word moss:

Most people in my moss world are moss lovers, not scientists. As I share my interest in moss gardening with others, I use scientific terminology to describe the botany of bryophytes and advocate proper nomenclature instead of common names. However, I have my own moss "slang" words – nouns, verbs and adjectives:

Mosser: Any person who engages in the enjoyment of mosses; collects/harvests/rescues mosses; creates moss landscapes

Mossin': The act of enjoying, collecting, harvesting, rescuing, creating with mosses.

Moss-scape: A landscape that features mosses.

Moss-some: Exceptional moss landscapes; exclamation of joy or admiration synonymous with awesome.

"I am a **mosser** who goes **mossin'** on a daily basis. My greatest pleasure is to create **moss-scapes** that are **moss-some**."

When I was writing my book, *The Magical World of Moss Gardening*, I used the reference – "Mossy Smile." The publisher discouraged this usage. In my mind, it meant a beaming face with a big smile because the person's spirit was happy over mosses. Well, "mossy smile" means grungy, green teeth in several cultures. So I resisted using this term to avoid any negative connotation.

The Urban Dictionary offers quite a few interpretations of the word "moss" used in recent years. **Mainly, moss means to chill out or relax.** However, there are other very different meanings, including several references for un-sportsman-like behavior. I've cited a few "new" meanings for moss and related moss words. Some uses of the word "moss" were not fit for polite company and therefore are not mentioned. To review all comments, visit: Urban Dictionary <<http://www.urbandictionary.com/>>.

When someone is funny in an awkward and charming way.

"That boy was so **Moss** when he tripped in front of the girl he likes and blushed to make her laugh."

Describes one's hair.

"Dennis Eckersly had some serious moss in the 80's."

Someone who is a know it all, but when challenged on a topic they profess to be a genius about, they can't front up – just like moss they have no depth / roots

"He's moss."

moss ayre: Arabic familiar expression used by friends to greet each other

Mossbird: Looking at things from a higher perspective. Eating the seeds of knowledge and using it to accomplish goals.

"Just look at it from a Mossbird's perspective."

To jump up and catch a football over a defender.

"He jumped up and mossed him to score the touchdown."

Originally used in football, it is now being used to indicate that you have destroyed someone in a verbal, or physical manner. Bad-sportsmanship-like behavior.

The act of puking, usually associated with the flu or heavy drinking.

"Dude, that guy just mossed all over the place"

A super secret slang word for marijuana. Getting mossed equates to getting high.

"Hey man... you got any moss over there?"

Translations to other languages can introduce confusion. Masaki Shimamura, Bryonet 6 April 2016, tells us that "in eastern Asia, the notations of Chinese character corresponding to liverworts and mosses vary depending on the region. In Japan, '苔' means 'bryophytes' (without distinctly differentiating mosses and liverworts) as informal term. In the academic field, '苔' means 'liverworts' and '蘚' means 'mosses,' '角苔' means 'hornworts.' However, in Taiwan that is completely the opposite to Japanese usage. In Taiwan, '苔' means 'mosses' and '蘚' means 'liverworts.' Maybe, the usage in Taiwan is correct with respect to the original meaning of Chinese characters (The researchers of Taiwan strongly insisted so). Although the detailed reason is not known, in the process of establishing the modern Botany in Japan, Japanese old botanists may have mistook the original meaning of the Chinese character. If this

opinion is right, as far as I know, the usage originated from the misunderstanding of Japanese also has been spread widely in Mainland China."

Zhang Li, Bryonet 7 April 2016, contributed this on the Chinese characters: "The confirmed earliest Chinese character relevant to bryophytes is 落 (liverworts, pronounced tai, equivalent to 苔 later) which occurred in a poem written by Ms Ban Jueyu (born 48 BC, died 2 AD) who is the Hancheng Empire's princess. Originally, 落 indicates all small plants in moist and shady habitats. Most of them are bryophytes of course. I don't believe the ancient people can differ liverworts from mosses correctly, including lichens and small ferns.

Interestingly, the term 苔 (liverworts) is quite popular in ancient poems from the Tang Dynasty (618-907 AD) and afterwards. Dr PAN Fujun, a colleague in Taiwan, investigated the plants occurring in poems written in the Tang Dynasty. There are totally 398 plant species mentioned in 53,000 pieces of poems, and the top five plants are willow, bamboo, pine, lotus and peach, and 苔 (liverworts) ranks the sixth, occurring in 1,248 pieces of poems.

Ann Gordon, Bryonet 6 April 2016, Contributed this personal story. "When our first grandchild was about to be born, my daughter asked me what I wanted to be called for my 'grandmother' name. I said that the first grandchild might pick the best, but if they needed a 'choice' from me, I would pick MOSSY, because learning about and experiencing mosses is such a passion of mine."

"Things went along fine until...! my older son, who lives in China, suggested I doublecheck The Urban Dictionary for current 'meanings' before I really got comfortable with Mossy as my name. So I did, and to my dismay, I discovered that 'mossy' and therefore moss, was being given a really bad rap!!! I think at that time there were 6 definitions for mossy and EACH was derogatory to the -nth degree in MY book! I was furious! I either had to give in to cultural norms, give up my name, and let moss have a bad rap, OR submit my OWN definition! So I DID. And they accepted it. It has now moved to #1 definition. Here it is as I submitted it:

(Check out Urban Dictionary under 'mossy' and see some terrible definitions. Thumbs up votes for my definition will help us keep moss in the realm of meanings it deserves!"

mossy: n.

1. a person of great integrity; resilience, sustainability; true blue, forever, dependable.
2. a bearer of enthusiasm, delight; a supporter of new life on the earth.
3. in ancient times, it has been said to be used as a name for a loving grandmother, always there to support the earth's little ones.

adj.: like, similar to the moss of the earth, resilient, bringing forth new seeds of life, able to survive even when other living forms can't.

n. She was called Mossy, the one who delighted in all the young offspring. Mossy nurtured their bodies, their souls, and their dreams in a way that only a good grandmother could do!

adj. The mossy bank was always there. It held the moisture from the air even when all else was drying and dying off from the drought. Seeds blew to the mossy beds to grow their roots and start new life.

Literature and Bryophyte Names

Literature often plays a role in the naming of organisms. Sometimes it is because the organism reminds someone of a character or story. Sometimes the story dictates the behavior of the author. Such was the naming of *Buxbaumia* (Figure 25) (Crum 1973). Johann Christian Buxbaum discovered the genus in 1712 and described it in 1728. He chose to name it after his father, but he recalled the story of the fox who was derided for asking for grapes, not for himself, of course, but for his sick mother. The modest Buxbaum left the moss unnamed. It was 1744 when Haller finally named the moss *Buxbaumia*.

Figure 25. *Buxbaumia aphylla*, named for its discoverer Johann Christian Buxbaum. Photo by Štěpán Koval, with permission.

The Greek term for bryophytes is *Bruon*, but its meaning in the time of Aristotle is much wider than that (Scott 1987). Furthermore, this term does not seem to appear in the botanical literature of that period. It was not until about the first century B.C. that the Latin term *Muscus* was introduced into general use, particularly by poets.

Summary

Bryophytes have been mentioned in literature to create imagery. Often they are used to create images of passing time, death, or other indications of aging. In some cases they are used to create an image of serenity. They sometimes appears in titles when they have no part in the actual story.

In older literature, and in common usage today, the word moss has multiple meanings. It is commonly used to mean any small plant. And in the vernacular, it has been used to create mental images in rather creative ways.

The Bible seems to overlook them, with only a few references that use the word hyssop, which has multiple interpretations.

Acknowledgments

Thank you to Brent Mishler for his contribution to Bryonet of the poem by William Gardiner, to Robin Stevenson for the verse from "Cloudberry Summer" by Amy Clampitt, and to Lee Ellis for completing the poem "The Moss Supplicateth the Poet" by Richard Henry Dana, Sr. Thank you Andi Cairns for helping me track down the author to "Ode to *Grimmia*" and to Peter Alpert for completing the story. And thank you to many Bryonetters for their contributions.

CHAPTER 4

AQUARIA

Figure 1. The dangle moss *Fontinalis antipyretica* (willow moss) adds interest and hiding places in aquaria. Photo by Li Zhang, with permission.

Aquarium Bryophytes

In aquaria, mosses not only are decorative, but provide oxygen, hiding places, and egg-laying substrates (Benl 1958). Fish such as danios and killies will lay their eggs in the moss (Tinkerfish). Many taxa can be used, provided the water is not too warm and copper content is low, including common taxa: *Bryum pseudotriquetrum* (Figure 2), *Fontinalis antipyretica* (Figure 1), *Leptodictyum riparium* (Figure 3), *Platyhypnidium riparioides* (Figure 6), *Riccia fluitans* (Figure 7), *Ricciocarpos natans* (Figure 8), *Taxiphyllum barbieri* (Figure 9-Figure 10), and *Vesicularia dubyana* (Figure 11) (Benl 1958; Cook *et al.* 1974; Takaki *et al.* 1982; Gradstein *et al.* 2003; Tan 2003; Tan *et al.* 2004).

One should be aware that scientific names provided by aquarium stores are often wrong. I have seen *Leptodictyum riparium* (Figure 3) labelled *Fontinalis* (Figure 1) and *Taxiphyllum barbieri* (Figure 9-Figure 10) is often misnamed as *Vesicularia dubyana* (Figure 11).

Figure 2. *Bryum pseudotriquetrum* grows in marshes and in shallow water at lake and stream edges. It can make an interesting small forest on the bottom of an aquarium. Photo by Michael Lüth, with permission.

Figure 3. *Leptodictyum riparium* (stringy moss) adorning an unusual aquarium. Photo by Sze Wei Tan <www.aquamoss.net>, with permission.

Figure 4. *Leptodictyum riparium* showing its growth habit in an aquarium. Photo by Tan Sze Wei <www.aquamoss.net>, with permission.

Figure 5. *Leptodictyum riparium* leaves showing the rib and leaf arrangement. Photo by Tan Sze Wei <www.aquamoss.net>, with permission.

Figure 6. *Platyhypnidium riparioides* (also known as *Rhynchostegium riparioides* and *Eurhynchium riparioides*) is a stream moss that grows in dense clumps. However, some people have succeeded in keeping it as an aquarium moss. Photo by Michael Lüth, with permission.

Figure 7. *Riccia fluitans* can be grown floating or in balls at the bottom of the aquarium in medium soft to hard water, pH 6-8, 15-30°C (Aquatic Community). Photo by Janice Glime

Figure 8. *Ricciocarpos natans*, a thallose liverwort sometimes used in aquaria. Photo by Janice Glime.

Figure 9. *Taxiphyllum barbieri* (Java moss) provides dimension to the aquarium and permits little fish to hide from larger aggressive fish. Photo by Sze Wei Tan <www.aquamoss.net>, with permission.

Java moss [often incorrectly identified as *Vesicularia dubyana* (Figure 11), Iwatsuki 1970; Tan *et al.* 2004] is a popular tropical moss that is highly tolerant of a wide array of water chemistries and temperatures and may even help to absorb the ammonia derived from the fish. Singh (in Tan 2006a) describes growing conditions as with or without fertilizer, with or without added CO₂, with or without added light, temperatures to 30°C, and tap water. It grows rapidly and will fill the tank in short order, but is easily removed. Compared to the wild mosses I have tried to grow, this is much easier.

Unfortunately, the name Java moss has been applied to a variety of aquatic mosses sold for aquaria (Tan *et al.* 2004; Akiyama 2009). "Java moss" most likely was originally applied to *Vesicularia dubyana* (Figure 11), but the faster-growing *Taxiphyllum barbieri* (Figure 9-Figure 10) was later used in its place (Stephan Mifsud, pers. comm. 14 December 2007). The current Java moss (*Taxiphyllum barbieri*; Figure 9-Figure 10) has flattened, oval-oblong leaves arranged on two sides of the stem and branches, and possesses two short costae (Figure 10). Its narrowly oblong leaf cells differ from the shorter ones of *Vesicularia* spp. (Figure 11).

The true Java moss is the easiest to grow of all aquatic mosses (Tan 2006; Tan & Leong 2007). It thrives not only in cool water, but in low light at tropical temperatures of 28-30°C, temperatures that would soon result in death of the common temperate moss *Fontinalis antipyretica* (willow moss; Figure 1). In my aquarium, I need to remove vast quantities of Java moss approximately every month. It adheres to driftwood, stones, or rests on the bottom. As an aquarium plant, it provides a nice green,

filmy look and provides good hiding places for small fish and fish eggs (Takaki *et al.* 1982). On the other hand, I have had spiny fish get caught in it and die struggling to get free.

Figure 10. The leaf of *Taxiphyllum barbieri*, the true Java moss, has two short costae and narrowly oblong leaf cells. Photo by Sze Wei Tan <www.aquamoss.net>, with permission.

Figure 11. The moss often mistakenly called Java moss is *Vesicularia dubyana* (Singapore moss) and has shorter cells. Photo by Sze Wei Tan <www.aquamoss.net>, with permission.

Cliff Townsend sent me a short note (22 Nov 2004) that attests to the aggressive nature of this group of "Java mosses," given the right conditions:

"A slant on British 'Java Moss' is given by C. R. Stevenson & E. W. Jones in *Journal of Bryology* 15: 624-626 (1989). The material of *Vesicularia reticulata*, mentioned by them as having been distributed by me through the B.B.S. exchange in 1962 as *V. dubyana*, was collected from the former orchid pits at Kew (since demolished), where this moss grew in great quantity and fruiting very freely. It still occurs in other greenhouses at Kew, and I was informed by P. J. Edwards of the pteridophyte department in the Kew Herbarium that both this and *Racopilum cuspidigerum* (Schwaegr.) Aongstr. (det. B. O. Zanten from a gathering of mine) are quite valuable for water retention."

"Fairly recently, this *Vesicularia* was sent to me for opinion by the late Theo Arts, who had collected it in the *Victoria amazonica* house at the Nationale Plantentuin van Belgie, Domein non Bouchout, Meise, Belgium in 1987. I have also received material from the same greenhouse collected by H. Stieperaere in 1996. It is of interest that I recorded the species from a bank by a millstream near Mogul Gardens, Wah, Pakistan in 1973 in *Journal of Bryology* 17: 677 (1993). Unfortunately, this and other mosses from the same spot (which included an *Entodon* as yet unidentified) were grubbed up in a hurry and not named until I got home, so there is no means of knowing if the moss was native there (the place is within its area) or was an escape from the gardens, having been introduced to them with phanerogams."

"Gangulee (Mosses of eastern India: 2001) reports *Vesicularia montagnei* as occurring 'on the floors of nurseries in Calcutta and in Howrah National Botanic Garden.' In the description, he cites it as 'forming thin but very extensive mat covering whole nursery floor and brick edging...'. The leaf-shape depicted by Gangulee looks very like that of *V. reticulata*, whereas that given of *reticulata* itself shows the leaves much too narrow. One cannot but wonder if the Calcutta nursery plant is in fact *reticulata*, perhaps even the source from which it has reached other botanic gardens."

"It would no doubt take more time than it is worth to trace the source from which *V. reticulata* entered the aquarium trade, but it seems very likely that it has been propagated from material occurring as a weed in some nursery or botanic garden."

The Christmas moss (*Vesicularia montagnei*, Figure 12-Figure 13) is often used to provide a backdrop to aquaria (Tan & Leong 2007). It is semi-aquatic and grows on shaded, wet banks. In an aquarium, it becomes distinctly pinnate to subpinnate, giving a miniature fernlike appearance. Unlike the hanging habit of *Vesicularia montagnei*, the habit of *Vesicularia reticulata* (erect moss; Figure 14) is upright, giving it a different role when tied to driftwood or other substrate under water (Tan & Leong 2007). The true *Vesicularia dubyana* (Figure 16), now dubbed Singapore moss, looks like a smaller version of Christmas moss.

Figure 16. *Vesicularia dubyana* (Singapore moss). Photo by Sze Wei Tan, with permission <www.aquamoss.net>.

Taxiphyllum cf. alternans (Figure 17) is a beautiful, soft moss that is sought after by hobbyists, but is more expensive (Tan *et al.* 2004). Its true identity remains uncertain because no capsules have been available to permit certain affiliation.

Figure 17. *Taxiphyllum alternans* (Taiwan moss) is a pinnately divided moss often sold for aquaria. Photo by Sze Wei Tan <www.aquamoss.net>, with permission.

Many mosses can be grown successfully in an aquarium. The limits may depend on the water quality, whether it is acid or alkaline, on the temperature, and on your ability to keep algae from taking over. Table 1 includes the more common ones available in North America, Europe, and Asian areas. Nevertheless, aquarium stores in other parts of the world sell some of these, and local aquatic mosses may be added to them.

Several liverworts are suitable, including the rare *Monosolenium tenerum* (Figure 18), originally from Asia (Wikipedia). While this species is hard to find in the wild and should be protected, it seems to do well in aquaria and can be easily grown from a small clump of plants. You may find it sold as *Pellia* because it was originally misidentified as *Pellia endiviifolia* (Figure 19) (Stephan Mifsud, pers. comm. 14 December 2007).

Figure 41. *Vesicularia*, creeping moss, a common aquarium moss. Photo by Tan Sze Wei <www.aquamoss.net>, with permission.

Mifsud (pers. comm. 7 December 2007) found that *Hyophila involuta* (cemetery moss) is sold on ebay, often mislabelled as star moss (*Tortula ruralis*). He has successfully grown *Barbula*, probably *Barbula bolleana*. Others that grow well but lack an attractive form are *Rhynchostegiella curviseta*, *Didymodon tophaceus*, *Pohlia melanodon*, and *Leptodictyum humile*. These species are either too small or become stringy (probably due to low light). In addition to the *Vesicularia* mix up, *Monosolenium tenerum* is often sold as *Pellia* due to its original misidentification as *Pellia endiviifolia*.

This list of mosses may not match the names being used in aquarium shops. We cannot expect these shop owners to keep up with changes in bryological nomenclature. That is not their area of expertise. For example, *Glossadelphus zollingeri* is now under the name *Ectoprotecium zollingeri* (see www.tropicos.org).

Preparing a Moss Wall

One aquarium website describes a method to make a wall of mosses in the aquarium (Tan 2006b). A plastic mesh of 7 -10 mm, preferably black or other neutral color, is used as the foundation (Figure 42). The author suggests cutting the mesh to twice the size of the aquarium, folding

it, and putting the moss in between taco style (like a sandwich; Figure 43). The wall can be affixed with suction cups or rocks at the bottom with clamps at the top (Figure 44). The sandwich can be tied together where needed with fishing line so that fish cannot enter and get stuck. Mosses will grow through the mesh and soon fill in the spaces (Figure 45; Figure 46). Mosses can be grown on the bottom in a similar manner, again making sure fish cannot get under the layers of mesh (Figure 47).

To add interest, you might want to add some wood (without bark) where your mosses can grow. The best is wood that has soaked in a lake, then been sun-baked. More fresh wood must be soaked several days to remove the tannins (Sheng 2007). Moss can be tied to the wood with fishing line. Wait a week or so before introducing fauna to give the mosses a chance to attach. Sheng (2007) suggests setting the light at 9 watts to slow the growth of the moss (and algae).

Figure 42. To make a moss wall for an aquarium, one needs scissors, moss, screening, something to sew the screening together, and something to affix the moss wall to the aquarium wall. Photo by Sze Wei Tan <www.aquamoss.net>, with permission.

Figure 46. An established moss wall can extend into the aquarium and provide hiding places for fish and nesting sites for eggs. Photo by Sze Wei Tan <www.aquamoss.net>, with permission.

Maintenance

Most mosses are not as easy to cultivate as Java moss. If you are successful, the mosses often will grow long and fill a tank, collecting lots of organic matter from the fish. One trick to give them a fluffier look is to keep them trimmed (Jelsoft Enterprises Ltd. 2007).

Moss and other aquatic plant growth is usually enhanced by additional CO₂, up to 15-30 ppm (Stephan Mifsud, pers. comm. 14 December 2007). Light needs vary, so pay attention to the field light conditions for any wild mosses you use. *Vesicularia reticulata* (erect moss; Figure 14), for example, requires a brighter light than other species. Most of the aquarium mosses cannot tolerate temperatures greater than 26-28°C and stream mosses usually do better at temperatures closer to 15°C.

The mosses will typically collect detritus from fish feces and algae. Some of the small shrimp discussed below can help to clean these up, but check to be sure they aren't eating the mosses.

Dangers from other Organisms

Tan (2006a) warns against including the Siamese algae eater (*Crossocheilus siamensis*) in a tank with aquatic mosses (Figure 48). They will devour the moss and leave only a stubble of plants. Another moss scavenger, when the algae and other plants are scarce, is the Yamato shrimp (Yamato numa-ebi in Japanese), also known as Amano shrimp, Algae shrimp, or Japanese marsh shrimp (*Caridina multidentata*; Figure 49). When there is ample food, these shrimp will keep the mosses clean from algae without eating the mosses (Stephan Mifsud, pers. comm. 14 December 2007). Crystal red shrimps (*Caridina cantonensis* sp. Crystal Red; Figure 50-Figure 51) and red cherry shrimps (*Neocaridina davidi*; Figure 52) are a nice color contrast in small aquaria with mosses. I would suggest also being careful about including snails, especially with *Fissidens*, as they can likewise consume the mosses, although they seem to avoid *Fontinalis* (Figure 1) (Lohammar 1956).

Algae Problems

Maintaining the moss is not difficult once you have established the right water conditions. However, eliminating the algae that can overgrow the moss is another story indeed. My own Java moss soon became so covered with algae that it no longer looked like a moss (Figure 53). Tan (2006a) recommends using a 5% solution of bleach. The alga-covered moss is placed into the solution and stirred in the solution for about two minutes. When the algae begin to turn white, the moss should be removed and placed into a rinse bucket. It should be rinsed several times in fresh water to remove all the bleach. This method is too harsh for some mosses, and in much less than two minutes. It was the moss *Fontinalis antipyretica* (Figure 1) that I found to be white; the algae, fungi, and bacteria seemed to survive quite well! Be sure to bleach the aquarium also to reduce new infections, and replace the water in the aquarium with clean water. The same goes for any rocks collected from outside or from an aquarium with algal growths. Let these sit for a while to let the chlorine escape before introducing fish, or use one of the agents for removing chlorine.

In my own research, I have found that high nutrient levels encourage algae at the expense of the mosses. These soon cover the mosses and rob them of CO₂ and light.

Mosses are usually low nutrient plants and will probably do best in the water they came from. However that water may carry disease organisms for which your fish have no immunity, so it might help to boil the water first for about 20 minutes. **Cyanobacteria**, those smelly blue-green things, can be especially problematic and take over your aquarium. Filter feeders can have problems because the gelatinous matrix around them can clog their feeding mechanisms and in some cases can clog gills.

Sheng (2007) cautions against putting your aquarium where it will receive direct sunlight, as that encourages the growth of algae. However, some mosses will need more light than is available to the typical indoor aquarium and may benefit from the addition of LED or other higher intensity light.

Figure 53. *Taxiphyllum barbieri* (Java moss) is soon densely covered with algae in an aquarium. Photo by Janice Glime.

Some organisms are browsers on the algae and will eat them without harming the moss. The small shrimp have already been mentioned as cleaners. In addition, some snails will keep the mosses clean. The Ramshorn snail, *Planorbis* sp. (Figure 54), will not eat mosses, but it will eat both **Cyanobacteria** (Figure 55) and **diatoms** (Stephan Misud, pers. comm. 14 December 2007). The shrimp are best for the filamentous algae. Mifsud finds that high CO₂ (15-30 ppm) will lower the pH enough to make it unsuitable for most of the invading algae.

Commercial Fisheries

Little has been published on use of bryophytes for the commercial rearing of fish or use in fish hatcheries. However, persons interested in spawning fish for such purposes might learn something from the aquarium industry. In one of the few studies in the laboratory, Bohlen (1999) describes breeding the spined loach, *Cobitis taenia* (Figure 57). He used thick tufts of moss on top of gauze-covered plastic boxes as spawning sites. Those eggs that were nonadhesive fell through the gauze into the box. The oviposition occurred in the most dense areas of moss and produced numerous young.

Figure 57. *Cobitis taenia*, a fish that benefits from breeding in a bed of aquarium mosses. Photo by Ron Offermans, through Creative Commons.

Summary

Mosses in aquaria help to decorate while providing oxygen and hiding places, especially for laying eggs. They can be used to make walls, attached to logs and rocks, or grown from the sand on the floor of the aquarium. Most aquatic bryophytes prefer cool temperatures, low nutrients, and medium light; more light encourages algal growth. A mesh wall can hold the mosses or they can be allowed to grow free.

Some animals (fish, snails, algae shrimp) may eat the mosses. Others can be used to keep the mosses clean. Algae can be removed with a weak bleach solution.

Use of mosses as spawning grounds for commercial rearing of fish warrants further exploration.

Acknowledgments

Tan Sze Wei kindly allowed me to use any pictures I wished from his Aquamoss website. Stephan Mifsud wrote to me to add many bryophyte species to the list, updated nomenclature, provided advice on cleaner shrimp, and suggested growing conditions. I rarely get suggestions on my chapters, so his comments were greatly appreciated and have strengthened this chapter.

CHAPTER 5

CONSTRUCTION

Figure 1. A log cabin in Norway illustrates the use of bryophytes for chinking between the logs, and more recently for the construction of green roofs. Photo by Michael Lüth, with permission.

Construction

One would hardly expect the non-lignified mosses to be useful in construction (Figure 1), but in fact, they can be quite utilitarian, especially in polar climates and remote areas. In the Antarctic, Granite House at Granite Harbour, Cape Geology, still has remnants of mosses placed there (Figure 5) by Scott's last Antarctic Expedition when they built the house in 1911. Stuffed into the cracks in the walls are *Bryum argenteum* (Figure 2), *B. pseudotriquetrum* (Figure 3), and *Hennediella heimii* (Figure 4) (Rod Seppelt, pers. comm.). The Inuktitut Indians in western Canada used *Sphagnum* (Figure 6) for chinking (Wilson 1978). The Shuswap Indians in British Columbia, Canada, use the mosses *Aulacomnium* (Figure 7) and *Dicranum* (Figure 8) for chinking by mixing it with clay (Palmer 1975). And, they were used by early settlers on Isle Royale, Michigan, USA, as chinking (Figure 9).

Figure 9. Moss chinking with a variety of species in a fishery hut on the dock near the Rock Harbor Light House, Isle Royale National Park, Michigan, USA. Photo courtesy of Diane Lucas.

The use of mosses in caulking (chinking) is ancient. Dickson (2000) reports it from the Bronze Age by Iceman (also known as Ötzi; ~3,300 BC). *Neckera crispa* (Figure 10) was the most abundantly used, but *N. complanata* (Figure 11) was also used in wattle walls (woven wall daubed with sticky material; Figure 12) for construction. Could mosses have served as the first rebar? Von Ochsner (1975) also reported the use of *Neckera crispa* in construction of lake dwellings in Switzerland and wondered why this moss had been chosen over other bryophytes.

Figure 10. *Neckera crispa*, a rock-dwelling moss species used for chinking during the Bronze Age. Photo by Des Callaghan, with permission.

Figure 12. Wattle and daub construction, with sometimes uses mosses in the mud daub. Photo by Pany Goff, through Creative Commons.

In northern Europe some houses still have chinking of *Homalothecium sericeum* (Figure 13), *Isothecium myosuroides* (Figure 14), and *Pleurozium schreberi* (Figure 15) (Richardson 1981) or *Fontinalis antipyretica* (Figure 16) as fire insulation between the chimney and walls, hence its name (Thieret 1956). But even in our modern technological times, Philippine construction still uses them as fillers between wooden posts of walls and roof shingles (B. Tan, pers. comm.), Alaskans still use *Hylocomium splendens* (Figure 17), *Racomitrium canescens* (Figure 18), *Rhytidiadelphus loreus* (Figure 19), and *Sphagnum* (Figure 6) as chinking (Lewis 1981), and shepherds in the Himalayan highlands use local species for chinking in temporary summer homes (Pant & Tewari 1989). In the more recent habitation of Isle Royale, Michigan, where there are no cars or commercial enterprises, mosses have been used for chinking in a fishery hut (Figure 9, Diane Lucas, pers. comm.).

Jan (2016) indicates that mosses can be used as additives to "building earth," as seen on the site of Chalais 3 (see Bailly 1997). In the Philippines, one of the "tallest" mosses known, *Spiridens reinwardtii* (Figure 20), is still used as a binding material (B. C. Tan, pers. comm.). It also serves as a filler between wooden posts and shingles in building the local huts (Tan 2003).

Figure 20. *Spiridens reinwardtii*, an epiphytic moss used as binding material and a filler in the Philippines. Photo by Daniel Nickrent, with online permission.

Li Zhang, on Bryonet 6 January 2017, reported that the local Tuvan people, Xinjiang Province, NW China, use *Climacium dendroides* (Figure 21), *Hylocomium splendens* (Figure 17, Figure 22), and *Pleurozium schreberi* (Figure 15) in the caulking of houses (Figure 9) (See Zhang *et al.* 2015).

Figure 21. *Climacium dendroides*, a moss used in chinking. Photo by Li Zhang, with permission.

Figure 22. A log house that has caulking (chinking) with *Hylocomium splendens* in China. Photo courtesy of Li Zhang.

For chinking, mosses are pressed between the logs with the fingers or an instrument and left to dry, where they remain compressed and still green. Use of peat for construction will be further described in the Uses: Technological & Commercial chapter.

Robin Stevenson provided me with this church reference and an interesting reference to use of mosses in their slate roofs (Figure 23). Churches sometimes laid a bed of mosses on which to lay slate of roofs (**mosseying**) (Friar 2003). The addition of mosses provided protection against melting snow, but they had to be renewed periodically, often replaced with hay or straw.

Figure 23. St. Fagans Tannery, Wales, slate roof with mosses that have arrived after construction, along with many crustose lichens. It appears that this one might be laid on a bed of mosses beneath the slate. Photo by Zureks, through Creative Commons.

Modern Building Construction

In Japan, mosses are used on walls, embankments, and roofs for both aesthetic purposes and practical ones (Deguchi, personal communication 2005). Deguchi has actually published in the Green Architecture Tribune 22: 8, a newsletter among the building industries in Japan, encouraging the use of bryophytes. Mosses not only give the building an "old" and quiet appearance, but they also reduce heat loss in winter and air conditioning needs in summer. Typical mosses for these purposes are *Hypnum plumaeforme* (Figure 24) and *Racomitrium japonicum* (Figure 25).

Figure 24. An epiphyte, *Hypnum plumaeforme*, is a moss among those used to repair a log dam in Japan and is also used on living walls there to give a cooling effect. Photo by Janice Glime.

Figure 25. *Racomitrium japonicum*, a moss used for insulation in Green Architecture. Photo from Digital Museum, Hiroshima University, with permission.

Custom Stone Handlers, Squirrel Mountain Stone, in Tennessee, will provide choices of boulders with intact moss. It appears that most of these are intended for gardens, but they could be used in construction as well. A die-hard bryologist might even choose them for fireplace construction. This could work well outside, but indoors they would require frequent misting with rainwater.

Insulation

I have had inquiries from people interested in using bryophytes for insulation. This has raised questions of longevity, renewable harvesting, and conservation issues. Rod Seppelt (Bryonet 12 January 2010) expressed concern over the widespread mining of living *Sphagnum* (Figure 6) in some areas and suggested instead that crop waste could be used. For example, in Australia mashed up leaf and stem waste from sugar cane are being used as garden mulch. But could they serve as insulation without creating a greater fire hazard or insect infestation?

Proof that mosses are still used for insulation comes from a web article by Stephanie (2017). She cautions that one encounters several problems – birds removing the mosses, the problem of uneven stacking of logs, and the need to replace the mosses (*Sphagnum*; Figure 6) periodically as they are lost. Furthermore, the mosses become brittle and also shrink, likewise requiring replacement or additional mosses. On the other hand, the moss does not rot, thus protecting the wood, and provides good ventilation.

Travertine Rock

In calcareous waters, certain mosses are tufa formers (Crum 1973). The species *Didymodon tophaceus* (Figure 26-Figure 27) makes such deposits, forming **didymodontoliths**! The tufa is formed by CaCO_3 deposits on the moss surface as photosynthesis removes the CO_2 from the water. These deposits result in a soft limestone that hardens into a porous brownish stone known as **travertine** (Figure 28-Figure 29). This elegant-appearing travertine was once a common flooring material in many public buildings, especially banks. But its use was not just modern; the Roman Coliseum was built of travertine. This travertine rock, formed by the mosses, is not to be confused with the volcanic tufa that was a fragile rock also used by the Romans (Michel Chiaffredo, personal communication 2007).

Problems in Construction

But mosses are not always welcome in construction. Not only are they considered a problem on roofs, but their moisture and organic acids contribute to the degradation of statues, tombstones, and walls (Perry 1987). On my own campus, student workers were instructed to spray them with herbicides in the cracks in the sidewalks because they made the walks look "unsightly." Fortunately, from my biased point of view, the mosses usually survive the herbicide treatments. And to my eyes, the mosses looked much better than the anthills that appeared in their absence! But, alas, this year they are being dug out. Obviously, our maintenance folks do not agree with Vivian (1996), or me!

Moss Walls

Planted walls, or living walls, have been gaining popularity in recent years (Figure 30-Figure 31). In addition to their aesthetic contributions, they help to insulate and to remove pollutants, including CO₂, from the atmosphere. And bryophytes have entered into this trend. For example, the City Hall in Iceland is decorated with mosses (Figure 32).

Figure 30. Living wall, dezeen Green Cast by Kengo Kuma. Photo courtesy of Sandra Manso Blanco.

Figure 31. Closer view of living wall, dezeen Green Cast by Kengo Kuma. Photo courtesy of Sandra Manso Blanco.

Figure 32. Moss wall decorating the Reykjavik City Hall in Iceland. Photo courtesy of Steffi Wilberscheid.

Vertical exterior walls of vegetation (Figure 33) became popular as a means to improve air quality and improve the aesthetic appeal of cityscapes. They also help to control runoff from roofs, reducing street flooding and blockage of storm sewers.

Mosses are common volunteers, and on older walls they can be quite extensive and charming (Figure 34). But the modern moss walls are often intended vertical walls, indoors or out, covered with mosses. Many have been inspired by rocks in nature (Figure 35).

Figure 33. Green walls of Dezeen House in Travessa do Patrocínio by Luis Rebelo de Andrade. Photo courtesy of Sandra Manso Blanco.

Figure 34. Mossy wall in Kusel, Germany. Photo courtesy of Kristi Bevard.

Figure 35. Natural model of mosses and lichens inspiring moss wall designs. Photo by Sandra Manso Blanco, with permission.

Elizabeth Brown began a discussion on Bryonet (8 March 2010) when she became allied with an architectural firm wishing to build a moss wall. Originally it was going to be a project to beautify an alley wall in the city, but the local city council couldn't cope with anything more problematic than a colorful mural. But the determination of the firm to build a moss wall was undaunted, so they decided to build a 2 X 2 m moss wall in their office.

The first hurdle was that the commercial firms who build living walls in Australia have no experience doing so with bryophytes. This brought questions about the substrate, water, lighting, and nutrient requirements to run such a wall long term.

In 2012, Sandra Manso Blanco, a Ph. D. student at Barcelona Tech, was struggling with a similar problem and contacted me for any advice. By 2013, she had made some progress in achieving colonization of her investigated substrate material. This material was a new type of concrete that could capture water and support the growth of bryophytes (Manso Blanco 2013). These "moss walls" (Figure 36-Figure 37) have a waterproof layer that separates the bryophytes (and other colonizers) from the inner structural part of the concrete (Manso *et al.* 2014a). The outer layer allows the rain water to enter it and holds it there. This layer is made with magnesium phosphate cement that has a slightly acidic pH (Manso *et al.* 2014b). This outer mix also absorbs carbon dioxide from the atmosphere and acts as an insulating material and a thermal regulator.

Figure 36. Centro Cultural Aeronáutico, Barcelona, showing biological concrete. Photo from Escofet 1886, S.A., courtesy of Sandra Manso Blanco.

The desire for these walls was rapid colonization (less than a year) and a changing face (Manso *et al.* 2014a). Color changes with seasons and natural succession of species could achieve the latter. And it is so constructed that rooted plants that could damage the structure are disfavored. Field tests indicated that the response was different from that in the laboratory (Manso *et al.* 2015). What these researchers learned was that the environment and the interactions between organisms were the most important determinants of success.

Roberto Vallejo Díez, Bryonet 4 March 2013, also a student in Spain, reported a similar project to develop a vertical garden system and was seeking advice on an appropriate substrate.

Figure 37. Simulation of a vegetated facade at the Ako-Suites Aparthotel in Barcelona, Spain. Photo from Escofet 1886, S.A., courtesy of Sandra Manso Blanco.

One method that has been used to encourage moss growth on rocks, and more recently may have been applied to vertical walls, is to paint the substrate with a mix of buttermilk and bryophyte fragments. But users have gotten mixed results. Annie Martin (Bryonet 9 March 2010) related the experiences of some of her moss-loving friends. One used the technique successfully on a small plastic waterfall feature. But another friend reported that when he coated his rocks with buttermilk moss, all he got was "biscuits." When I used a recommended egg white mix, the mosses looked for several weeks. Then one day they mat had holes in it. I lifted it and dozens of pillbugs (*Porcellio* sp.; Figure 38) fell off. Yet another neighbor painted only buttermilk on boulders and six years later the huge rocks were covered with a variety of bryophytes. Moss Acres in Honesdale, PA, USA actually sells a Moss Milkshake.

Figure 38. *Porcellio scaber*, known as a woodlouse or pillbug, on bryophytes. Photo by Bernard Dupont, through Creative Commons.

David Long (Bryonet 9 March 2010) describes his own sandstone and basalt moss wall, bound together with lime mortar, and most likely colonized completely naturally over the past 200 years. It sports at least 30 different species of bryophytes in its southern Scotland home. Its inhabitants include species like *Hypnum cupressiforme* (Figure 39), *Mnium hornum* (Figure 40), and *Polytrichastrum formosum* (Figure 41) growing on top. The mortar is highly calcareous, supporting many calcicoles such as *Anomodon viticulosus* (Figure 42), *Bryum capillare* (Figure 43), *Ctenidium molluscum* (Figure 44), *Encalypta streptocarpa* (Figure 45), *Thamnobryum alopecurum* (Figure 46), and *Zygodon viridissimus* (Figure 47). "The combination of acidic stone and calcareous mortar works really well. Some parts of the wall are heavily shaded by trees, others more open, but humidity is important."

Unfortunately, mosses used on the sides of buildings do not always meet the aesthetic goal we would hope for. In Munich, Germany, a huge tufa stone wall of an insurance building was covered with mosses (Figure 49) (J.-P. Frahm, pers. comm.). However, eventually the mosses, so carefully cultivated on the rock (Figure 49), were washed off. The contractor, Michel Chiaffredo, blamed this on the heavy metal pollution and especially the copper that mosses accumulated before dying (Michel Chiaffredo, personal communication 2007). The water used for the irrigation was the water retrieved from roofs, then stored in a tank. The quantity of copper and other heavy metals in these mosses, indicated by the analysis conducted by the Pasteur Institute, killed the *Aloina ambigua* (Figure 50) used for the green wall (Figure 48). Unfortunately, nobody wanted to assume the responsibility for the copper sulfate and other metals. *Aloina ambigua* is well adapted to a calcareous tufa, but it is not a copper moss. A new gardener tried to replace the lost mosses with *Brachythecium rutabulum* (Figure 51), installing an expensive system to wet the stone, but this water dissolved the carbonates of the tufa rock, which then crystallized on the mosses and killed them (J.-P. Frahm, pers. comm. 2007). It appears that the new gardener did not understand the ecology of the moss – or the rock.

Roads and Paths

Most of us have seen bryophytes growing along roads or between the stones (Figure 52) and along the edges of paths. Older patios and walkways around buildings were often constructed of bricks. Mosses eventually filled in the spaces between the bricks, adding a rustic and restful look (Figure 53). Vivian (1996) proclaims the need for such walkways, criticizing the sterile, formal appearance of straight concrete or blacktop. Such mosses seem to be a frequent subject for poets. See the subchapter on Uses: Literature.

Figure 53. *Bryum*, *Barbula*, and other small plants and seedlings in crack between concrete bricks in patio. Photo by Janice Glime.

Mosses had invaded the cracks between sections of concrete in the walks on my campus and I noted that where there were no mosses, ant hills prevailed. How much nicer the mosses looked!

Erosion and Ecocity

Use of mosses to control erosion (Conard 1935; Figure 54), muffle traffic noise, and retain cooling moisture forms the basis of a modern philosophy that may be labelled "ecocity." It follows the premise that mosses form a natural part of the ecosystem and that they have an important role in that ecosystem that can make life more

pleasant for the human species, as well as maintaining a healthier ecosystem.

Figure 54. Soil bank where mosses such as *Polytrichum* help to maintain stability. Photo by Janice Glime.

At Ilsong (Ilsong 2004), in Korea, mosses are being touted for their ability to stabilize and beautify the environment in an environmentally friendly way. The Codra system starts with a soil embankment, such as one would find along a highway, and covers it with a layer of concrete formed like a rock outcrop, *i.e.*, not flat, but with undulations like rocks. To this, mosses are added and eventually make a soothing green mat that catches water and helps to stabilize the bank. Presumably, even if the concrete develops cracks, the mosses will be able to fill in and maintain the stability. Mosses such as *Hyophila* (Figure 55) readily grow on such concrete coverings in Japan and presumably elsewhere that this moss occurs naturally. The moss catch system consists of blocks forming vertical walls that are covered with mosses. These systems require early maintenance that assures sufficient water until the moss system becomes established.

Figure 55. The drought-tolerant, calciphilic moss, *Hyophila involuta*, grows easily on concrete. Photo by Michael Lüth, with permission.

Among her many projects, Annie Martin (Mountain Moss Enterprise, Brevard, NC, USA) set out to stabilize a vertical cut in a clay bank (Figure 56-Figure 57), of course using bryophytes. She followed the natural contours first, then created depressions to establish a somewhat uniform cover (Figure 58-Figure 59). Mosses were then added in

that remaining space (Figure 60). The mosses were affixed with slanted toothpicks (Figure 61-Figure 62). Mosses in the completed wall (Figure 63-Figure 65) will spread to hold the soil even in heavy rainfall.

Figure 56. This recently cut clay bank is begging for erosion protection. The stone wall at the bottom will only catch the clay after it has been washed down. Photo from MountainMoss, courtesy of Annie Martin.

Green Roofs

In 1584, Carlisle, UK, 86 horseloads of mosses, costing 4 pence (old currency) per load, were delivered to the Council for use as weather-proofing of roof slates, among other purposes (Woodward 1996). This early use of mosses is experiencing somewhat of a comeback in the form of "green roofs."

Annika Jaagerbrand, Bryonet 9 September 1999, relayed a story from Raymond Clarysse. He was curious because in northern countries there is a moss that grows on the roofs. People do not remove it because they consider it to be protection against the cold. Even some modern constructions are now cultivating mosses on roofs. Des Callaghan provides a diagram of a workable substrate for a moss culture on the roof (Figure 66).

Figure 66. Green Roof diagram. Image courtesy of Des Callaghan.

Not all mosses are welcome. On wooden shingles, roof invaders can hold water, increasing the possibility of rotting. In western Washington, USA, these include *Dicranoweisia cirrhata* (Figure 67) among the first, with *Ceratodon purpureus* (Figure 75), *Racomitrium ericoides* (Figure 68), *Bryum argenteum* (Figure 2, Figure 52) arriving somewhat later (Frye 1920).

I am a little disappointed when I know of someone risking life or limb on the roof, trying to remove mosses from the shingles. Although mosses have traditionally been considered a nuisance on roofs, with people spending hundreds of dollars to remove them, more recently they have made a new debut in Germany, the United States, and other places. Their new acclaim offers the advantage of cleaning the atmosphere of pollution while buffering the temperature, fireproofing, reducing roof runoff, and creating a sound barrier. For more southern locations

where slate roofs are common, they offer a lighter and cheaper alternative to the slate (Posth 1993).

Figure 67. *Dicranoweisia cirrata*, a moss that can hold water, causing damage to wooden roof shingles. Photo by Michael Luth, with permission.

Figure 68. *Racomitrium ericoides*, a moss that can hold water, causing damage to wooden roof shingles. Photo by David Holyoak, with permission.

Moss green roofs are now being produced commercially in Germany (Behrens Systemtechnik) (Frahm 2004; Figure 69). Interestingly, it is this German company that is installing moss roofs in Michigan, USA. However, most people still consider mosses on roofs a nuisance because they add weight and increase the growth of fungi, and many consider the roof to look dirty.

Figure 69. Jan-Peter Frahm demonstrates a sheet of moss that is ready to be used in "green roof" construction. Photo courtesy of Jan-Peter Frahm.

Michel Chiaffredo and Franck-Olivier Denayer (2004) treat the mosses as both aesthetically beautiful and ecologically sound additions to urban roofs (Figure 70; Figure 71). And they are getting customers in the "green roof revolution" who agree with them (Chiaffredo 2004). To quote them, "It is thus possible to set up on roofs, in one go, a combination of all the living elements that nature would introduce spontaneously over a far longer period of time: veil of micro-organisms associated with mosses, and wild seeds of dependent xerophilous plants. The natural environment thus reconstituted will evolve very slowly according to the ecological conditions of the site, requiring neither maintenance nor the introduction of fertilizers. This innovative phytocological engineering makes it truly possible to maintain biodiversity, unlike all the agronomic or horticultural processes, even within the very heart of towns and cities." (Chiaffredo & Denayer 2004; Figure 72).

Figure 70. This modern building has a green moss roof. Photo courtesy of Michel Chiaffredo.

Figure 71. This green roof has bryophytes with skylights. Photo courtesy of Michel Chiaffredo.

Figure 72. This bryophyte plantation prepares bryophytes for green roof construction. Photo by Jan-Peter Frahm, with permission.

Chiaffredo and Denayer point out the advantages of using such vegetation on one's roof:

- *Regulate rainwater:* Collection of water by rooftop vegetation, especially bryophytes, will prevent the movement of water from large surfaces onto a small area of ground below and permit the return of water slowly to the atmosphere by evapotranspiration.
- *Increase biodiversity:* Opportunities for diversity in urban areas is limited, and rooftops add an opportunity for additional flora and fauna.
- *Decrease the greenhouse effect:* Bryophytes are heat sinks that will cool by evapotranspiration on the one hand and retain heat by insulation in winter on the other, reducing the heat flux in and out of the building.
- *Improve air quality:* Bryophytes produce oxygen, use CO₂, and trap dust particles, thus helping to clean the atmosphere.
- *Reduce sound pollution:* Roofs can serve as sounding boards to bounce sounds, whereas the rough surface of a bryophyte mat absorbs sound, thus reducing the sound pollution of traffic or noisy equipment.

When the roof is flat, the moss garden can be aesthetically pleasing as well (Figure 73). Mosses for green roof gardening can be grown in plantations (Figure 72) where natural diversity develops (Figure 74). The area then provides green space for relaxation and can be enhanced with stone benches and statuary.

In 2004, Bryonettors contributed their ideas regarding the species of mosses suitable for roofs. John Christy suggested that *Ceratodon purpureus* (Figure 75) was a good candidate because of its ability to form sods on concrete, gravel, asphalt, and wood. It tolerates nitrogen, so air pollution and bird droppings would be less of a problem than for some mosses. Use of zinc-plated metal around roof vents, chimneys, skylights, and other objects must be avoided because they will kill the mosses. Spreading mosses by fragments will accelerate their establishment. Other weedy species such as the acrocarpous *Bryum argenteum* (Figure 2),

Tortula/Syntrichia (Figure 76), and *Racomitrium* (Figure 78) will colonize the more exposed areas, whereas horizontally growing or pleurocarpous taxa such as *Mniaceae* (Figure 40) and *Brachythecium* (Figure 51) will colonize shadier sites.

Figure 73. This completed green roof has a formal design, but many are more casual. Photo by Jan-Peter Frahm, with permission.

Figure 74. This mat of mixed mosses is ready for transplantation to make a "green roof." Photo courtesy of Jan-Peter Frahm.

Figure 75. *Ceratodon purpureus*, a good choice for green roofs because of its wide tolerance. Photo by Janice Glime.

David Wagner has captured the effect of zinc on the mosses growing on a roof for ~25 years. On an office building at the Andrews Experimental Forest in Oregon,

USA, the galvanized zinc plates were used with guy wires to steady the chimney and prevented moss growth down-roof from them (Figure 77). This moss mat is dominated by *Racomitrium elongatum* (Figure 78) and *Dicranoweisia cirrata* (Figure 79) (David Wagner, Bryonet 29 June 2017).

Figure 76. *Syntrichia ruralis*. *Syntrichia* and *Tortula* are suitable for green roofs because of their drought tolerance and are able to colonize the exposed portions. Photo by Michael Lüth, with permission.

Figure 79. *Dicranoweisia cirrata*, one of the mosses in the mat on the roof above (Figure 77). Photo by Michael Lüth, with permission.

Henk Greven suggested that *Polytrichastrum formosum* (Figure 41) is easily transplanted and he would expect it to do well on roofs. Michel Chiaffredo has shown this to be the case (Figure 80-Figure 81).

Controversies have arisen regarding the best upkeep for the green roof. Ideally, these roofs are low or no maintenance ecosystems. Thus, we would anticipate no need for fertilizers, which generally seem detrimental to bryophytes anyway. However, many of the roof gardens that have been in existence seem to be deteriorating (Koehler 2003), leading the roof gardeners to promoting fertilization. Chiaffredo and Denayer (2004) disagree with this approach, concluding that it is "contrary to the very definition of extensive vegetalization." The International Green Roof Association lists the moss-sedum-herbs and grasses community as a low maintenance, low cost green-roof plant community (IGRA).

Figure 80. These large mats of *Polytrichum* are ready for transplantation to a "green roof" site. Photo by Jan-Peter Frahm, with permission.

Figure 81. A *Polytrichum* species displays a marvelous collection of capsules with hairy caps in the background and numerous male splash cups in the foreground. Photo by Jan-Peter Frahm, with permission.

The principle of the green roof for some companies relies on the well-known ability of mosses to colonize such a substrate with no help from us (Figure 82). At this stage, they are pioneers and require no watering or fertilizer (Figure 83). Diversity develops normally, hence providing stability (Figure 84). Their development can be compared to that of the cryptogamic crust (Figure 85) that is so important in anchoring and nurturing the soil of prairies and semideserts in the North American Southwest, Israel, and parts of China and Australia. These crusts remove CO₂ (Johansen 1993) from the atmosphere, convert atmospheric N to ammonia and nitrates (Verrecchia *et al.* 1995), and generally improve the quality of the habitat for invading organisms (Evans & Lange 2001), while improving the air quality for humans.

Using the studies on bryophytes as pioneers in these natural habitats as models, green roof landscapers have conducted studies on the best substrates for the roofs. The most popular and successful roofing material is a mineral one of volcanic origin, having a granulometric variation of 1-16 mm. Fentiman Consulting advocates a thin layer of concrete as a substrate for moss establishment (Grant 2006).

In London, England, the CUE Building of the Morniman Museum did not begin with bryophytes on its green roof (Grant 2006). However, successful establishment of tracheophytes led to natural succession and invasion of native species, including bryophytes. Mosses became frequent in the more open areas, including *Bryum capillare* (Figure 43), *Ceratodon purpureus* (Figure 75), *Hypnum cupressiforme* (Figure 39), *Pseudoscleropodium purum* (Figure 86), and *Brachythecium rutabulum* (Figure 51). The wetter north-facing section sported, in addition to a number of grasses, a luxuriant growth of mosses made up of *Brachythecium albicans* (Figure 87), *B. rutabulum*, *Calliergonella*

cuspidata (Figure 88), *Eurhynchium praelongum* (Figure 89), and *Rhytidiadelphus squarrosus* (Figure 90).

Hironori Deguchi shared the experience of construction of a *Sphagnum* (Figure 6) bog on a roof in Japan (Figure 91). As you might guess, this required some maintenance to insure both a restful appearance and its survival (Figure 92-Figure 93).

Annie Martin shows the process of making a moss roof in the North Carolina Botanical Garden (Figure 94). First the metal roof is covered with a planting cloth (Figure 95- Figure 96). The mosses have already been planted in flats (Figure 97) and are ready for placement. They are organized by colors and textures to make the roof design easier (Figure 98- Figure 101).

Utilizing bryophytes (mosses) that like direct sun exposure [*Polytrichum* (Figure 80-Figure 81), *Atrichum* (Figure 102), *Climacium* (Figure 21), *Entodon* (Figure 108-Figure 109), *Hedwigia* (Figure 109), *Leucobryum* (Figure 139), *Ceratodon* (Figure 75), and *Ditrichum* (Figure 129)], Mountain Moss has transformed a glaringly bright tin roof into a verdant expanse of moss art. With various shades of green and textures, the mosses will provide additional delight with brilliant reds, golds and bronzes when in sporophytic reproductive stage. When other garden plants are dormant or dead, the mosses will keep on giving joy, even in winter months.

There is a Ford Green Roof Project at Michigan State University. Bryophytes were not planted originally, but they have introduced themselves since the project began. Annie Martin credits Michigan State, along with NC State and Penn State Universities as leading the way in green roof research in the United States.

Dr. Brad Rowe heads up the Michigan State (MSU) research team. He elaborates on the advantages of the green roof. These include:

- greatly aiding storm water management by absorbing rainwater that would normally run off buildings and create flooding in the streets in

urban areas. They can reduce total runoff by 60% and detain 85% of short showers or initial rainfall

- retention of pollutants from rainwater, roofing materials, and atmospheric deposition
- reduction of urban heat island effect
- improving air quality by capturing pollutants, filtering noxious gases, and reducing the ambient temperature
- increasing energy efficiency
- reducing waste by prolonging life of waterproofing membranes, using recycled materials, and prolonging the service life of HVAC systems through decreased use
- blocking electromagnetic radiation
- reducing noise
- retarding fire
- increasing space for growing vegetables or relaxing
- aesthetic improvement

The number of deaths in Europe that can be attributed to airborne micro-particles approaches 300,000 each year (Colbond 2009). This is a particular problem for the elderly and weak. Wolfgang Behrens and Jan-Peter Frahm (pers. comm.) were researching green roofs with the potential to partially cleanse the air of these dangerous particulates.

Grant (2006) sums up the green roof concept, stating "Green roofs are arguably the best example of multifunctional urban design, whereby elements on, in, and around the built environment serve several purposes. A roof (or external wall) can and should be more than just a weather-proof surface or structural element – it can be part of a living, cooling, cleansing skin that not only helps reduce flooding, urban heat-island effects, and air and noise pollution, but also provides wildlife habitat and tranquility." As proof of this utility, we have learned that at the Michigan Ford Rouge auto manufacturing plant, the green roof reduces power needs (Cesere 2006) through its function as a heat sink and evaporative cooling ability (Roofscapes 2004)!

Sadly, it seems that using mosses for green roof construction has not become a common practice in the USA. Rather, xerophytic tracheophytes dominate greenroof landscaping there. But the idea has been planted, and ecologically minded green-roofers are considering the advantages in heat control vs. the disadvantages in introduction of pests, added weight, and moisture damage to roofing shingles.

The Downside?

But alas, mosses on roofs have gotten a bad reputation among urbanites. If the neighbors aren't complaining that the mosses make the house look unclean and therefore devalue their property, then the house owner is concerned that they are destroying the roof. But is this really the case? It might depend on where you are. I used to delight when I could view the roof over the entryway of the building where I taught because it was covered with a multi-colored carpet of mosses that I could view as I descended the stairs. I'm pretty certain that the flat roof never leaked, and the building is 50 years old.

Annie Martin, Bryonet 19 November 2009, rescues unwanted mosses from roofs (Figure 103, Figure 105) and has seen no evidence that mosses deteriorate the surface of shingles (Figure 104, Figure 107). Rather, they add insulation and even evaporative cooling. One roofer even admitted to her that he did not see any problem until the moss was removed; it was then that the roof started to leak. Martin has seen slight, but not significant, deterioration of concrete. The mosses seem to occur where there is partial shade on the roof. And some of them are species one might find on logs (*Entodon*; Figure 108-Figure 109) or rocks (*Hedwigia ciliata*; Figure 109).

Suitable Species

Studlar and Peck (2009) reviewed some of the green roof literature. They found that bryophyte roofs are more common in Europe than in the USA. The bryophytes are usually mixed with *Sedum* (Figure 110), a succulent flowering plant. They also examined natural (volunteer) roof moss communities near Terra Alta, West Virginia, USA. There they found ten moss and one liverwort species on four partly shaded roofs. These roofs had been relatively undisturbed for more than 40 years. They found the most frequent and abundant taxa to be *Brachythecium laetum* (Figure 111), *Hedwigia ciliata* (Figure 112), *Plagiomnium cuspidatum* (Figure 113), and *Platygyrium repens* (Figure 114), but each roof had a different dominant species among these. They recommended *Hedwigia ciliata* for further investigation for making extensive green roofs, suggesting that its growth form and drought tolerance were similar to that of *Racomitrium* (Figure 18, Figure 25), which is used for green roofs in Japan.

Figure 114. *Platygyrium repens* with bulbils, a species tolerant of sun exposure and high temperatures on exposed roofs. Photo by Michael Lüth, with permission.

Bill McKnight, Bryonet 28 June 2017, added *Funaria hygrometrica* (Figure 115) as being common on roofs in Indiana, USA. Graduate student Jillian Simpson (Bryonet 10 March 2010) also recommended studying *Funaria hygrometrica* for the potential of its use in green roofs. Her reasoning was that it is easy to grow, completes its life cycle in only 4 months with leafy gametophytes on the protonema in three weeks, is drought tolerant, and adds nitrogen through its epiphytes of *Anabaena* (Figure 116) and *Nostoc* (Figure 117). It prefers low-nutrient substrate and an alkaline pH. The biggest drawback may be that it is an annual, suggesting it is not suitable for vertical walls.

Annie Martin, Bryonet 28 June 2017) is very familiar with the roof mosses in her area of North Carolina, USA. "Tolerant of high heat index and sun exposures, most often I find *Bryum argenteum* (Figure 2), *Ceratodon purpureus* (Figure 75), *Entodon seductrix* (Figure 118), *Grimmia* sp. (Figure 124), *Hedwigia ciliata* (Figure 112), *Platygyrium repens* (Figure 114), and a few others. On roofs that are located under the shade of a tree canopy, I find *Plagiomnium* (Figure 113), *Thuidium* (Figure 119), and *Mnium* (Figure 40) species." These two lists are similar to those found by Studlar and Peck (2009) in West Virginia.

Figure 119. *Thuidium delicatulum*, a species that grows on shaded roofs. Photo by Hermann Schachner, through Creative Commons.

On the other side of the Atlantic, Sean O'Leary, Bryonet 28 June 2017, considered his home region in Buckinghamshire, UK, to be rather dull with regard to roof mosses. Instead, the mosses *Grimmia trichophylla* (Figure 120), *Racomitrium fasciculare* (Figure 121), and *R. heterostichum* (Figure 122) seem to be confined to roof tiles in old churches. He found *Grimmia decipiens* (Figure 123) only once on a roof.

Figure 120. *Grimmia trichophylla* with capsules, a species on roof tiles of old churches in the UK. Photo by John Game, through Creative Commons.

Figure 123. *Grimmia decipiens* with capsules, a species that rarely occurs on roof tiles of old churches in the UK. Photo by Henk Grevens, with permission.

Michael Lüth finds roof tiles to be interesting habitats for mosses. *Grimmia laevigata* (Figure 124) and *G. ovalis* (Figure 125) grow on hand-made clay roof tiles around Freiburg, Germany, appearing only on the southern exposure of steep roofs. But outside the roof tile habitat, these two species are rare in the area, growing in just a few steep, sunny rocks in the Black Forest. The tiles are more than 100 years old and are chemically more suitable than the newer ones. On the other hand, lichens also grow on the tiles, but they destroy the tile surface. Nevertheless, even roofs more than 200 years old are still okay. Similar substrates, measured in geological time scales, do indeed show wear due to the bryophytes (and lichens) (Lenton *et al.* 2012).

The most extensive list I have found is from Sweden (Table 1).

Eliminating Moss

Unfortunately, not everyone shares the perception of the aesthetic appeal of mosses and liverworts. When they occur on roofs, and even in the cracks in the sidewalks, some people will declare war. I have been asked how to eliminate them on a roof, and my answer is "Why do you want to?" Of course on roofs they add weight, especially when wet, and can get in the way when shovelling heavy snow off during six months of winter, but still!

Bryonettors seem to be in agreement that the bryophytes do no harm on roofs (e.g. Rod Seppelt, 4 October 2010; Bill McKnight, 28 June 2017; Michael Richardson, 28 June 2017). Annie Martin (Bryonet 28 June 2017), who spends lots of time crawling around on roofs to rescue mosses, reports that "Ironically, rather than damaging the roof, I have observed that shingles underneath moss colonies are not degraded or in a state of deterioration. Instead, the shingles are almost pristinely new. The surrounding asphalt shingles show evidence of degradation due to UV, wind, rain, snow, etc. It is my opinion that mosses protect the shingles. Tiny rhizoids hold tightly to the surface but do not compromise the integrity of the roof."

But roofers and urbanites like to convince us otherwise. And even a Bryonetter explains reasons why bryophytes might need to be removed (Mark Smits, Bryonet 28 June 2017). Smits explains that at one part of his house he has to remove bryophytes because they block the water flow, causing the roof to leak. Ken Kellman (Bryonet 28 June 2017) agreed; damming can force water under the tiles. And bryophytes can build up enough soil that tracheophytes can take root. Johannes Enroth (Bryonet 28 June 2017) added his experience to this. On a roof with tiles made of concrete, the mosses get wet, freeze, and thaw repeatedly. This causes damage to the tiles, especially in eroding the tile edges. Vinegar (50%) eliminated the mosses, but the lichens remained unharmed.

For those anti-bryophyte folks, there are a few solutions. Shunda Lee, Bryonet 19 April 2001, reports that Clorox works successfully in Singapore. So if you must get rid of the mosses, we have already seen that zinc works, and now we know that bleach works. Today's Homeowner <www.todayshomeowner.com> recommends a 50:50% water:bleach mix. To keep mosses off, they recommend a copper or zinc strip across the peak of the roof. They also recommend removing any branches that shade the roof.

Several bryocides seem to be successful. The one most familiar to me is lime (CaCO_3), partly because most bryophytes prefer more acid conditions, but perhaps even more important are the desiccating properties of lime. Bogdanov (1963) describes liming to eliminate mosses in forest stands (!) of drained swamps.

Several people and web sites advocate zinc or copper strips placed near the peak of the roof. Rainwater dissolves enough zinc to form zinc carbonate, which washes down the roof, killing the mosses. Of course, it accumulates on the ground below and will ultimately get into the water supply, so the solution can be a deadly one if many people begin this practice.

Rod Seppelt, Bryonet 4 October 2010, points out that bryophytes will only grow on the roof if it is moist and shaded. If the mosses must be removed, he recommends experimenting with non-herbicides. Try fertilizer or detergent. Aerate the substrate. If you need to remove them from a lawn, avoid mowing so they don't get enough light. Raise the pH – add lime, or add calcium. Use an iron sulfate spray. Johannes Enroth, Bryonet 5 October 2010, reports that a 1:1 vinegar:water solution is a fast, easy way to kill mosses.

One web site advocates using a standard scrub brush on a long handle to remove the moss. I cannot help but wonder if the brush doesn't do more damage to the asphalt than the moss does. And how practical is it for a steep roof like the one in Figure 137?

Figure 137. This house in Bretagne has mosses invading the roof. Photo by Michael Lüth, with permission.

But while we are discussing green roofs, some folks don't want mosses on their property in any form! Terry McIntosh, Bryonet 9 March 2010, lamented the difficulty of persuading these people to appreciate mosses. He cited a website where someone described how to get rid of the moss on the oak trees:

"Oak trees are functional as well as attractive. Their leafy green foliage provides shade and color to the natural environment. Sometimes the presence of ball moss causes the tree to appear less than attractive. Getting rid of this unsightly moss is something that can be done in a relatively short time with the right tools and equipment." (Meason 2017). To each his own!

Golf Courses

In September 2006, Bryonet subscribers were asked to recommend the ideal moss for a golf course. Susan Moyle-Studlar (Bryonet, 14 September 2006) contributed several suggestions. She suggested *Polytrichum* (Figure 41)

species because they tolerate the high light levels of a golf course and are trampling resistant, being firmly anchored to the substrate. In fact, the trampling can help to propagate them by creating fragments that can produce new plants. They are common plants along trails and railroad tracks. However, she cautioned that they are a bit tall and will require frequent watering. I wonder how they would respond to being mowed – perhaps make a shorter, denser turf?

A shorter and softer turf, relatively trampling resistant, is formed by *Dicranella heteromalla* (Figure 138) along forest trails, but she cautions that it is not well-anchored, possibly leading to a "choppy turf" following the activity of golfers. But, like *Polytrichum* (Figure 41) species, these would also need watering and additionally would need shade.

Figure 138. *Dicranella heteromalla*, known as green thread moss, grows here on a vertical bank. Photo by Michael Lüth, with permission.

Leucobryum (Figure 139) can tolerate trampling, as exhibited by its proliferation near a picnic shelter in West Virginia, USA. Moyle-Studlar considers this a possible candidate because of its tolerance of greater aridity than the former two, its retention of its attractiveness when dry, and its ability to reproduce from broken leaves. Nevertheless, the chopping effect of golf clubs would most likely be quite destructive; hopefully winter would give it a chance to recover in areas where golfing is not a winter sport.

Figure 139. *Leucobryum glaucum*, a species that is often successful on golf courses because it can tolerate trampling. Photo by Janice Glime.

Pleurocarpous mosses such as *Hypnum imponens* (Figure 140) and *Thuidium delicatulum* (Figure 119) likewise seem to return from trampling damage, but they also pose the same problems of the above mosses and lack a secure anchoring system.

Figure 140. *Hypnum imponens* appears here with *H. jutlandica* in the background. Photo by Michael Lüth, with permission.

John Christy (Bryonet, 15 September 2006) reported seeing *Bryum argenteum* (Figure 2) forming tightly-packed, extensive turfs growing among the closely clipped grass on golf greens on the west coast of North America. The moss seemed to grow well on the hard but well-drained surface. Diana Horton (Bryonet, 15 September 2006) reported the same species from a golf course in Arizona, where it formed a "beautiful, short and dense sod." Only this time the manager wanted advice on how to eliminate it!

Researchers are looking for ways to reduce moss cover in putting greens without damaging the desired bentgrass (Nus 2009). To this end, the Chicago District Golf Association has tried baking soda, a herbicide (carfentrazone-ethyl; Quicksilver), and a fungicide (chlorothalonil; Daconil Ultrex). So far the researchers have concluded that there are multiple strategies available to suppress the mosses, but that none of them eliminate the mosses. They have advised that treatments should be in spring and fall when the mosses have active growth; summer treatment is probably unnecessary. They also found that baking soda need be applied only twice in spring to suppress moss growth all season, but unfortunately, it is toxic to the bentgrass and requires spot application onto the moss patches, making it more labor intensive. Chlorothalonil alone or in combination with fungicides requires at least three applications at 2-week intervals to suppress growth for that year. Applications of Quicksilver (6 oz per acre) in spring and fall (4 total) is also effective at suppressing the mosses without harming the bentgrass. But it appears that *Bryum argenteum* (Figure 2) is more tolerant, with no single product being effective in controlling it in the tested golf greens in Illinois, USA (Settle *et al.* 2009). This moss is problematic throughout

the country because it interrupts surface aesthetics and smoothness.

A recent ad on the internet, however, seems to me a slightly better solution, if you must. This is a product called Moss Aside™, an herbicidal soap (Gardens Alive 2017). It will let you grow thicker lawns!

Roman Wells

In ruins near Abingdon, Great Britain, mosses were tucked between and behind the stones of a Roman well. Dickson (1981) concluded that the mosses were placed there deliberately because they were not the ones that one would expect there naturally. Hence, he suggested they might have been used to filter the water. One might expect them to help hold the rocks together as well.

Herman Stieperaere (pers. comm.) reported his involvement in the analysis of extensive carpets of bryophytes surrounding a late Roman well (5th century AD; Figure 141-Figure 146). This bryophyte surrounding is a filter to prevent pollution of the central well. In fact, in a prior occupation period of the Roman fort, the area was heavily polluted by iron forges. The moss and sand layer acted as a barrier/filter against infiltrating polluted water.

Dickson (2000) identified the mosses in one Roman well near Stuttgart, Germany, as *Neckera crispa* (Figure 10). He found other Roman wells in England that used *Neckera complanata* (Figure 11).

Figure 146. Moss in Roman well. Photo from Flemish Heritage Institute (VIOE), courtesy of Herman Stieperaere.

Log Dams

Bryophytes can have advantages in emergencies because of their absorptive ability and small size. For example, when a temporary log dam developed a leak during a timber harvest in Japan, the resourceful workers used *Hypnum plumaeforme* (Figure 24), *Loeskeobryum brevirostre* (Figure 147), *Rhytidiadelphus japonicus* (Figure 148), and *Thuidium kanedae* (Figure 149) to stop the leak (Ando 1957). And forest workers in Pennsylvania, USA, deliberately use rocks with *Fontinalis* (Figure 16) on them to help stabilize newly constructed weirs. The mosses quickly spread to other rocks, effectively gluing them together.

Figure 147. *Loeskeobryum brevirostre*, one of the species used to stop a leak in a log dam. Photo by Blanka Shaw, with permission.

Figure 148. *Rhytidiadelphus japonicus*, one of the species used to stop a leak in a log dam. Photo from Digital Museum, Hiroshima University, with permission.

Figure 149. *Thuidium kanedae*, one of the species used to stop a leak in a log dam. Photo from Red Book of the Sakhalin Oblast, through Creative Commons.

It appears that the use of mosses in weirs was not new in the past century. Woodward (1996) reported that in 1555, a "gang" of 68 women and 13 children spent nearly 10 weeks gathering mosses to pack the cracks between the boulders of a new weir.

Boat Construction

Use of mosses in boat construction is well documented (e.g. Dickson & Ransom 1968). In the Scottish Highlands, mosses were prepared by steeping in tar, then used for caulk (Crum 1973; Figure 150). As in those used for houses, they were usually relatively large, pleurocarpous mosses such as *Eurhynchium striatum* (Figure 151) and *Neckera complanata* (Figure 11) (Pant & Tewari 1990). Saatkamp *et al.* (2011) reported on 15 boats, conserved as wrecks, in the upper French Rhône and Saône (Eastern France) from the 3rd to the 20th century. Among these, the use of *Neckera crispa* (Figure 10) as caulking to make boats tight was common. While the use of *N. crispa* in much of Europe has strongly decreased as a caulking material from the 14th century onwards, this was not the case in their study area. This was most likely because suitable forests remained in the Jura mountains.

Figure 150. In this boat, mosses were used as rope caulk. Redrawn by Janice Glime from Dickson 1973.

Figure 151. *Eurhynchium striatum*, one of the large, pleurocarpous mosses used in boat construction. Photo by Michael Lüth, with permission.

Dickson (2000) found that sewn boats in the Bronze Age (3300 BC – 1200 BC) were caulked with essentially pure *Neckera complanata* (Figure 11) in all the seams. And *Polytrichum commune* (Figure 152) served for making the ropes (Figure 153) (Dickson 1973, 2000).

Mosses were even imported into Holland from Belgium after the 16th Century for caulking the carvel-built boats (Dickson 1973). The online Deutsches Schiffahrtsmuseum, accessed on 20 March 2013 at <www.dsm.de/MA/schlachte.htm> displayed a rope made of this moss and carbon-dated to 1770.

Figure 152. *Polytrichum commune*, a moss that has been used in making rope caulk. Photo by Christopher Tracey through Creative Commons.

Figure 153. *Polytrichum* was used as rope caulk. Photo by Per Hoffmann.

The native Yaghan people in Chile used mosses to build their canoes in quite a different way (Metzner Productions 2006). They buried tree bark in peat for a season, allowing the acidity to preserve the bark while the moisture made it flexible. They could then form it into a canoe.

Dickson *et al.* (2013) described a dug-out boat made of an alder (*Alnus*) trunk about 4,000 years ago. The space between the stern transom board and the slot cut into the hull was caulked with mosses comprised primarily of *Anomodon viticulosus* (Figure 42), but 13 other mosses and 1 liverwort were also present.

In Northern Spain, Heras-Pérez *et al.* (2009) examined two wooden pieces from the hull of a 15th Century iron transport vessel. The was the first evidence of the use of mosses in boats in Spain and revealed fragments of eight different moss species: *Eurhynchium praelongum* (Figure 89), *E. striatum* (Figure 151), *Hylocomium splendens* (Figure 17), *Hypnum cupressiforme* var. *cupressiforme*

(Figure 39), *Neckera complanata* (Figure 11), *Pseudoscleropodium purum* (Figure 86), *Rhytidiadelphus triquetrus* (Figure 154), and *Thuidium tamariscinum* (Figure 155).

Summary

In construction, mosses can provide chinking and even building material, as well as ameliorating the climate. They have been mixed with mud in building and chinking, much like using rebar. Green Roof technology uses the process of natural succession to vegetate roofs and disturbed areas. Caution must be exercised in choosing bryophytes that are adapted to the type of substrate being used, climatic conditions, and microclimate. Shaded roofs often develop moss mats without human help, and in urban areas these are often considered unsightly. They can be discouraged by using a strip of zinc across the peak of the roof or removed with Clorox or vinegar.

Green roofs meet with the same restrictions as roofs. They can be arranged in artistic patterns, and both green roofs and living walls can remove air pollution, insulate the interior, reduce CO₂, and reduce runoff to the street.

On golf courses, bryophytes require no mowing and withstand at least some trampling, but they can make the surface uneven. Bryophyte ropes have been used to construct boats.

Roman wells and log and rock dams and weirs may be packed with mosses that help to hold the rocks in place. In the wells they may function to purify the water that seeps in from the sides.

Acknowledgments

Thank you to Steffi Wilberscheid for taking pictures of the Reykjavik City Hall for me while she was in Iceland, and to Jan-Peter Frahm for making contact with Steffi for me. Jim Dickson has been an invaluable resource in providing anecdotes and references. Annie Martin shared her first-hand observations of roof mosses, and many Bryonettors contributed their observations.

CHAPTER 6

TECHNOLOGICAL AND COMMERCIAL

Figure 1. Commercial cranberry farm near Black River Falls, Wisconsin, USA. *Sphagnum* peatlands are necessary to protect the cranberries and maintain sufficient water for their growth. Photo by Janice Glime.

***Sphagnum* Peatlands**

First, a definition of peat and peatlands is in order. **Peat** is comprised of partly decomposed vegetable matter containing a variety of plants (Figure 2) that may or may not include *Sphagnum* (Figure 3). Peat is brown and soil-like and is derived from boggy, acidic ground (Figure 1). **Peat mosses**, on the other hand, are species of *Sphagnum* (Figure 3). **Peatlands** are lands consisting largely of peat or peat bogs (Figure 4). They may be dominated by *Sphagnum* (Figure 3), but there are also peatlands that have no *Sphagnum*.

Figure 2. Harvesting peat in Saterland, Germany. Photo by Pyt, through public domain.

Figure 3. *Sphagnum magellanicum*, one of many species of *Sphagnum* from *Sphagnum* peatlands and in widespread usage in horticulture, fuel, and other applications. Photo by James K. Lindsey, with permission.

Certainly the best-known and widespread uses for mosses in both modern and ancient times are the uses of *Sphagnum* (Figure 3). This is not surprising since it occupies 3% of the Earth's surface, mostly in the northern hemisphere (Clymo 1987). Its abundance, longevity, cation exchange (Clymo 1963; Fischer et al. 1968), and ability to hold water make it ideal for commercial exploitation. Its largest usage in North America is for horticulture and cranberry culture (Figure 1; Figure 5), but in Europe, fuel is an important use as well (Clarke 2008).

Figure 4. Peatlands in Manitoba, Canada. Photo by subarcticmike, MSG Family, Mukhrino FS, through Creative Commons.

Figure 5. Cranberries (*Vaccinium macrocarpon*) growing among *Sphagnum* and *Polytrichum*. Photo by Janice Glime.

Turner (1993) reviewed the human uses of peat. In addition to 100 million tons a year used as fuel in Ireland, peat provides a source of waxes and resins. The by-products provide oily materials for dyes, varnish, and leather treatments. More recent uses include making biofilters.

In the UK, *Sphagnum* (Figure 3) has been recommended as a litter for milking cows. Peltola (1986) reported that compared to straw and sawdust, peat provides better absorption of urine and binding of ammonia than the other litters. The spent litter is good for growing plants because it contains more than the average amounts of nitrogen and magnesium in a form readily used by plants.

In Japan, the Technical Academy of Sphagnum and the Marsh Bowz Factory illustrate uses, including peat grown on clay shapes, a restful boardwalk through the green moss (Figure 6), a cover for an aquarium that presumably reduces water loss while still permitting the entry of fresh air, and a peat roof garden with stepping-stones.

Figure 6. Boardwalk on the Fort River Birding and Nature Trail, Hadley, Massachusetts, USA, a restful walk with protection of peatlands and other delicate plants. Photo from USFWS, through public domain.

Heavy Metal Detection and Cleanup

Cleaning up heavy metals from waterways is one of the most important environmental problems facing Americans (and others) today (Trujillo *et al.* 1991). Such methods as chemical precipitation, ion exchange, reverse osmosis, and solvent extract have been widely used, but are less than desirable. Their metal removal is incomplete, they require large quantities of reagents or high amounts of energy, and they generate toxic sludge and waste products that require expensive and dangerous disposal. The U.S. Bureau of Mines is using *Sphagnum* (Figure 3) that has been immobilized in porous polysulfone beads. These are able to remove zinc, cadmium, and other metals selectively from zinc mine wastewater, reducing the concentrations to well below the national drinking water standards. Furthermore, the adsorptive capacity of the beads appeared to increase after the first few cycles.

The cation exchange ability of *Sphagnum* (Figure 3), with its walls packed with polyuronic acids, gives it unique properties unmatched by its tracheophyte counterparts, and often even by the connivances of humans. It serves well in an electrode for the detection of lead, offering a detectability level of 2 ng ml^{-1} (Ramos *et al.* 1993). The 10% moss electrode is easily regenerated by immersion in 0.05 M perchloric acid for only 60 seconds.

Now that the lead has been detected, one can remove it and other heavy metals with the biomass beads made of dried, ground *Sphagnum* (Figure 3) in a porous polysulfone matrix (Spinti *et al.* 1995). However, they seem to have lower capacity than other commercially available ion exchange resins.

Filtration

The ability of peat mosses to bind heavy metals and other substances on their cation exchange sites makes them ideal organisms for cleaning up a variety of heavy metals and organic compounds in liquids. I have used peat mosses to clean up creosote in a very small pond. The peat removed the toxicity and took the toxic substance with the peat when I removed the mosses. Before I used the mosses, the fish all died, even when fresh water sat in the pond for a month. After subsequently letting the mosses soak in the pond water for a month, the new fish survived.

Farmers may use both inorganic and organic (including *Sphagnum*; Figure 3) amendments to reduce the loss of ammonia from liquid hog manure and to keep the hog pens fresh by controlling odors (Al-Kanani *et al.* 1992a, b)

Other forms of wastewater benefit from peat filtration. A counter-current system is used to purify water, with peat serving to both absorb and adsorb contaminants (Asplund *et al.* 1976; Brown & Farnham 1976; Coupal & Lalancette 1976). Even organic waste such as pentachlorophenol can be removed by using peat as a filter (Viraraghavan & Tanjore 1994). Peat is used to filter out heavy metals, microbes, pesticides, organic acids, oils, and odors (Turner 1993).

Oil Cleanup

Mele, in his book *Polluting for Pleasure* (1993), claims that 420 million gallons of oil from pleasure boating enter our waterways in America each year. This staggering number is equivalent to 40 Exxon Valdez disasters! Peat mosses are among the very best absorbents of the oil and can even be used to rescue birds (Figure 7) and other animals covered in oil. As early as 1972, D'Hennezel and Coupal recognized their utility for cleanup. They are readily available, and bales could be stored near a harbor, ready for small spills. Today, there are also commercial peat moss "fences" available from several sources, especially in Canada, to contain oil spills.

Figure 7. Sea bird covered in oil from Black Sea oil spill. Photo by Pauk, through Creative Commons.

One supplier advertises that Hydro-Weed (Figure 8), made from a blonde *Sphagnum* (Figure 3) peat from Newfoundland, is a lightweight, natural hydrocarbon absorbent (Hydro-Weed 2007). The processing sterilizes the plants and kills the insects. Hydro-Weed is currently used by all branches of the United States Navy, Army, National Guard, Marines, and Air Force.

Figure 8. This pile of Hydro-Weed, made with *Sphagnum*, is a good absorbent of oil while repelling water. Photo from Hydro-Weed 2007.

Hydro-Weed is extremely effective at absorbing oil and other hydrocarbons. One pound will absorb 8-12 times its weight in medium weight oil, fifteen times more than clay absorbents! But it won't absorb water! Anyone knowing the ecology of *Sphagnum* (Figure 3) would immediately become skeptical, and I can only conjecture on this water-repelling shift. We know that oil and water don't mix. If the oil is absorbed preferentially, then the oil would undoubtedly contribute to the loss of water absorption by actually repelling it. Furthermore, if dry peat is used, it would float, and so would the oil, so the oil would be contacted first and make the plants as repellent as a duck's back.

A further advantage of Hydro-Weed is that it will not release the oil. The company suggests putting it along a fencerow where microbes will break down the oil or other absorbed chemical, leaving the peat moss to benefit the soil. And a bird landing on the floating or discarded Hydro-Weed will leave without "a single drop of oil on its feathers."

The saturated Hydro-Weed can be put to even more valuable uses. It can be incinerated as fuel, contributing 7,200 BTU's per pound during incineration (excluding hydrocarbons). It is clean, generating only 0.42% of ash residual per pound after incineration. This makes it a good fuel for cement kilns and coal-generating fossil fuel plants.

Marcus (2002), in a science fair project, compared several materials [Sea Sweep, Spill Magic, saw dust, Enviro-Bond (a polymer that bonds to hydrocarbons), and peat moss] at two temperatures to determine which took the greatest weight of crude oil in salt water. When compared by weight of sorbent, at 6.6°C the Enviro-Bond worked best, but at 21°C the peat moss absorbed the most. Most of the sorbents worked best at 6.6°C.

While this was just a science fair project, use of peat mosses has a sound basis in practice. Hunt (1995-2007, 2000, 2002-2007) reported the use of *Sphagnum* (Figure 3) from SpillSorb Canada Inc. to clean up an oil spill at the Dassen and Robben Islands off the coast of South Africa where 41% of the African penguins reside. First, the penguins themselves were dusted with peat dust, rendering them dry and safe to return to the water (Ark Enterprises Inc. 2004). Next, peat-based absorbents were used to clear oil from rocks (Crawford *et al.* 2000). Although the spill occurred on 23 June 2000, the shore was clean by 5 July that year (Hunt 1995-2007, 2000, 2002-2007). The hyaline cells of the *Sphagnum* leaves readily absorb the oil, up to

10 or even 20X the oven-dry weight of the moss. The *Sphagnum* also aids in the conversion of the oil to safe products. Rich in humic acids, it becomes a natural catalyst to aid in breaking down the hydrocarbon molecules of the oil; with the help of some microbes, it can aid the conversion of the oil to fatty acids, CO₂, and water. Peat Sorb is one such *Sphagnum* product (SANCCOB 2006).

Oclansorb Plus from Canada (Hi Point Industries 1991) is an oil-absorbent peat moss designed for application to surface oil and fuel spills in fresh and salt water marshes, wetlands, and any open water environment which cannot be efficiently cleaned by manual techniques. It blends a time-release system of peat moss that begins soaking up the oil within seconds, non-pathogenic bacteria bred specifically to metabolize petroleum hydrocarbons, N, P, trace nutrients, and pH buffers to enhance efficiency of bacterial degradation, and non-toxic gelling agents that facilitate adhesion of Oclansorb Plus to exposed tree roots, aquatic plants, and shoreline rocks.

In New Hampshire, the Department of Environmental Services made a novel use of peat moss. They rehearsed their response to an oil spill in Portsmouth's Great Bay Estuary (Dillon 2003), using peat moss and oranges to simulate the spread of the oil! The peat moss spread across the water like thin oil and the oranges simulated the bobbing tar balls, both without harming the environment.

The terrestrial environment is not immune to oil problems. A diesel oil spill in an Alaskan subalpine meadow had poor recovery after nine years, but the moss *Racomitrium sudeticum* (Figure 9) was one of the three species that survived (Belsky 1982). The moss was one of the few plants making the area green.

Figure 9. *Racomitrium sudeticum*, a species that is able to survive an oil spill. Photo by Hermann Schachner, through Creative Commons.

Leaking crude oil production wells can create contaminated soils that must be cleaned up. For example, in McKean County, Pennsylvania, the use of fertilizers and leaf detritus or peat moss boosts the nitrogen content of the soils. This, combined with aeration by rototilling has been very successful in reducing total petroleum hydrocarbons (TPH) in soils. "Healing" is evident in a few weeks and the area can be replanted with grass seed the same season. The

Maryland Department of the Environment (2004) suggests peat moss, among other things, for heating-oil cleanup. In New Zealand, Enviropeat™ is sold for cleanup of service stations, driveways, forecourts, maintenance areas, parking areas, refuelling areas, vehicle repair shops, ports & marinas, shoreline, and open sea oil spills (Enviropeat 2004). Unfortunately, using *Sphagnum* (Figure 3) to clean up large oil spills is not practical. Thus, spills like those in the gulf require other methods.

Fuel

The use of mosses for fuel is not just ancient history. Nearly half the world's peat production (Figure 10) is used for fuel (Figure 11-Figure 12), particularly in Scotland (Figure 13) and Ireland, providing the equivalent of 100-200 million tons of oil (UNERG report 1984). In Canada the peat deposits store more energy than do the forests and natural gas reserves combined (Taylor & Smith 1980). Nevertheless, the use of peat as fuel is down in Scotland, from 70,000 tonnes in 1955 to 20,000 tonnes in 1999 (Macleod 2006).

Figure 12. Peat fire. Photo by Cqui, through public domain.

Figure 13. Peat harvested in Lewis, Scotland. Photo by Wojsyl, through Creative Commons.

We might cringe that Ireland burns over 100 million tons of peat each year to generate power (Turner 1993), requiring large peatlands (Figure 14). What a scourge on the landscape! And it certainly does not renew at that rate, if ever. It is also used for waxes, resins, and oily materials for dyes and varnish and in treatment of leather.

Figure 14. Large peatlands like this one at Farwell, Michigan, USA, are rapidly disappearing due to development. Photo by Janice Glime.

At least it doesn't further pollute the environment. For example, in Minnesota it is used to remove chromium from power station wastes (Turner 1993), and it has been

important in rescuing penguins in South Africa by cleaning up oil spills (Hunt 2004).

Peat is a promising replacement for our dwindling oil supplies, packing more than 8,000 BTU per dry pound, and is renewable when harvested carefully. It is such a clean-burning fuel that some have attributed the lovely complexions of Irish and Swedish women to use of peat as fuel (Drlica 1982). Its attractive feature as a fuel is that it is low in sulfur content, cleaner burning, and superior in heating value compared to wood, similar to lignite.

No longer restrained in use to the developing countries, liverworts and mosses are important sources of fuel in northern Europe, especially in Finland, Germany, Ireland, Poland, Russia, and Sweden. In Ireland, 25% of the fuel source is mosses (Richardson 1981). It serves not only to produce heat, but also electricity, with the former Soviet Union burning ~70 million tons and Ireland 3.5 million tons of mosses for that purpose in 1975 (Boffey 1975). If Hinrichsen (1981) was correct, the world should have been using peat in the equivalent of 60-70 million tons of oil by the year 2000.

Although peat is often considered to be a clean fuel, such is not the case with CO_2 emissions. Peat burning emits $106 \text{ g CO}_2 \text{ MJ}^{-1}$ whereas coal emits only 94.6 and natural gas only $56.1 \text{ g CO}_2 \text{ MJ}^{-1}$ (VTT 2004).

Peat is currently considered a slow renewable resource. Although peat is renewable, little of it has been harvested with a renewal plan in mind. Hence, many scientific studies are currently focusing on regeneration of various *Sphagnum* (Figure 3) species in the hope of restoring some of our lost peatlands. Unfortunately, little of it regenerates at the rate it is being used.

Hence, we need improved methods for harvesting, drying, and conversion to a burnable fuel (Lindstrom 1980). Although harvesting is easy, compared to that for coal, forests, and hunting for oil, we need to find ways that do not destroy the wetlands and convert them to non-peat-producing vegetation.

The Finns, in their attempt to become 40-50% self sufficient (Miller 1981) and provide a cleaner fuel (Johansson & Sipilae 1991), have suggested that placement of processing stations on the peatlands will reduce transport cost (Taylor & Smith 1980). They have introduced a dewatering process that produces dry pellets of partly carbonized peat (Taylor & Smith 1980). Finland is also exporting pulverized peat to northern Sweden, where it is used in industry and municipal heating, power generation, and oil burners of pulp and paper companies (Summerton 1981). However, for heating houses alone, replacement of light fuel oil with peat will require up to 6.2 million tons of peat pellets per year (Kinnunen *et al.* 1982). If this is reduced to only a 5% replacement of fuel oil, that consumption could be reduced to 310,000 tons per yr.

It took a coal miners' strike in 1903 to interest Americans to use peat as a fuel, but the cheaper availability of other fuels has prevented its widespread use (Thieret 1956). Nevertheless, planning for the future, the U. S. Geological Survey and other organizations have mapped North American peat deposits and estimated their extent (Miller 1981). This time it was an energy crisis with the possibility of diminished oil trade that fueled interest in peat fuel in the 1970's. In 1975, First Colony Farm in North Carolina began peat harvest to make methane and to

generate electricity; their land has an estimated 400 million tons of peat, enough to fuel a 400 megawatt power plant for 40 years (Carter 1978). The Minnesota Gas Company planned for its use of methane by applying for a long-term lease on 200,000 acres of peatland (Boffey 1975). Use of peats for production of methane eliminates the chopping that is required for other plants, and peat products can be used to produce ethylene, hydrogen, methanol, synthetic or natural gas, and low and intermediate BTU gas.

Ralf Pope (pers. comm. 12 July 2012) told me that there is an 860-acre peat mining operation in Deblois, Maine, USA (Figure 15-Figure 16). The Worcester Peat Company harvested peat there until ~2002 and used it to run a 22.8 megawatt peat-fired power plant. When the plant re-opens, they plan to use a mix of peat and septic sludge, billing it as green renewable power.

Peat in Construction

Whereas other mosses have played minor roles in construction, mostly for chinking, *Sphagnum* (Figure 17) has the potential to enter the arena big time (conservation

issues aside). As early as 1903, the Swedes ground peat with asphalt to make a durable street pavement (Drlica 1982). Peat Crete, a mixture of peat with light concrete that is hydraulically pressed with Portland cement and water, provides a low-cost material that boasts easy sawing, nailing, casting, and molding, does not need to dry, is inflammable, and of low density (0.7 to 1.2 sp. gr.; 45-70 lb/ft³) (Ruel *et al.* 1977). Its only negative quality is its low mechanical strength, but this seems more than balanced by its light weight for use in places where transportation is a problem. In dry places, flammability could be a problem.

Figure 17. *Sphagnum magellanicum* is a large moss that can be used in making various construction products. Photo by Janice Glime.

In June, 1972, Andrew Gilchrist, Chair of the Highlands and Islands Development Board at Bridge House, Bank Street, Inverness, Scotland, presented to the Right Honourable Gordon T. C. Campbell, Her Majesty's Secretary of State for Scotland, a report in which he referred to the possibility of production of Peat Crete as a means of improving the economy, stating: "We continue to watch over prospects for possible uses of peat, including the Building Research Centre's work on 'peatcrete.'" Unfortunately, or perhaps fortunately, a Google search does not indicate any commercial sources of this commodity.

In 1920, peat-based pasteboard and wrapping paper appeared in Michigan, USA, near Capac (Miller 1981). Peat boards have been used in chicken houses to help insulate them (Moore & Bellamy 1974).

Like many other mosses, *Sphagnum* (Figure 3) was used in chinking in log cabins (Lewis 1981), and the northern Europeans, living where peat is abundant to this day, stuffed it between the timbers of their houses to deaden sound (Thieret 1954). To this purpose, the Russians added slabs that they heated and pressed for insulation of refrigerators, and of course their houses (Sukhanov 1972; Ruel *et al.* 1977).

Peat then made its debut in place of particle board, as peatwood (Ruel *et al.* 1977). Dried *Sphagnum* (Figure 3) is blended with a phenolic resin and pressed into a heating mold; it offers quick hardening, attractive texture, good strength, easily nailed, screwed, and glued, and light weight (40-60 lb ft⁻³). Other construction materials include the ultra-light peatfoam (peat moss and foamed resin) and

peatcork (made from the coarse fraction of peat (Ruel *et al.* 1977).

Harvesting Peat and Peatland Destruction

In 1991, a survey of Finnish peatlands revealed that only 26% of the peatlands remained in natural condition (Eurola *et al.* 1991). The majority are drier, less productive, and more forested than just 30 years ago. Most of the loss of peatlands is due to forestry (Finland) and agriculture (France) (Francez & Vasander (1995), although peat harvesting for fuel is a growing concern in northern Europe. In North America, most of the harvest is for horticulture (Ferland & Rochefort 1997). This horticultural loss began early in the 20th century, with the practice of leaving the peatlands to regenerate in their own way when the mining operation was over (Lavoie & Rochefort 1996). Upon examining a typical "regenerating" peatland in Quebec, Lavoie and Rochefort found that although the block-cut trenches had more than 50% cover and were occupied by typical peatland species, *Sphagnum* (Figure 17-Figure 19) was much more common in the natural conditions than in the cutover peatland. They concluded that this location was not returning to a functional peatland ecosystem.

Loss of peatlands affects the forestry species that were growing there. For example, in the New Jersey pinelands, *Chamaecyparis* swamps may suffer from loss of *Sphagnum* (Figure 3) cover because the tops of hummocks become more prone to drought, making them less suitable for seedling regeneration (Ehrenfeld 1995).

Even large browsers like caribou depend on refuge in peatlands (Dyer *et al.* 2001), but these losses have ramifications far beyond the simple loss of peatlands. Their loss is a contributor to global warming. Reduction in peatlands means that less carbon will be tied up in that carbon sink, instead going to rapidly cycling grasses. Furthermore, it leads to greater decomposition of accumulated peat, releasing yet more greenhouse gases. Ohlson and Økland (1998) found that it can take 40 years of peat accumulation before any significant amounts are lost through decay, resulting in a net carbon sink. In hummocks of *Sphagnum fuscum* (Figure 18) and *S. rubellum* (Figure 19), carbon accumulation exceeded 2 g dm⁻² yr⁻¹ during a 50-year growth period.

Figure 18. *Sphagnum fuscum*, a hummock species that takes 40 years to recover from harvesting. Photo by Oscar Gran, through Creative Commons.

"Harvest" is usually a misnomer for what is more accurately called peatland mining. With a vertical accumulation rate of 10-40 cm per thousand years in Finnish peatlands, repeatable harvests must be discussed in geologic time scales (Crum 1988). Consequently, peatlands the world over are diminishing. Knight (1991) bemoaned the dwindling number of peat bogs in Britain due to exploitation for horticulture.

Others have more encouraging numbers, considering peat formation of ~1-2 mm per year (note, that is not rate of growth). Using this estimate, they consider that harvested (not mined) peat can be replaced in ~20 years. In Ireland, 1 million m³ of peat is used for horticulture and another 7-9 million pounds are exported yearly (Richardson 1981), not to mention the use for fuel that seriously threatens that country's 3 million acres of peatland (Drlica 1982). Yet 90% of the world's marketed peat comes from Wisconsin, USA, primarily from Jackson and Monroe Counties (Epstein 1988). The series of pictures below shows one company's attempt to maintain a sustainable crop that can be harvested again in about ten years (Figure 20-Figure 27). But this is a labor intensive method that most "miners" would shun.

Figure 20. At this peat harvesting operation in Wisconsin, USA, peat can be reharvested in about a 10-year cycle. The rake being used is wooden and pulls both *Sphagnum* and accompanying sedges. Photo by Janice Glime.

Climate Reconstruction

Peatlands are history books, recording for us what has occurred long before humans considered maintaining a written record (Grosse-Brauckmann 1979; Janssens 1988; Klinger *et al.* 1990). While this often has only heuristic value, it can be invaluable in attempting to interpret our tempestuous climatic variation in the present decades. Whereas fossil and other paleoecological records are scanty and difficult to interpret in other habitats, buried peat can provide us with clear chronosequences of vegetation, giving us indications of alternating dry and wet periods and even of warming and cooling. The pattern of cores can easily be calibrated between locations (Ellis & Tallis 2000). The peat stratigraphy of a blanket mire in Scotland, coupled with radiocarbon dating, indicates eight wet shifts that began about 3250, 2550, 2150, 1400, 1150, 875, 600, and 325 years ago. Seven of these correlate closely with similar indications from peat in Britain and Ireland.

Likewise, in the coastal region of Maine, USA, bryophytes, along with pollen, diatoms, and other plant fossils, have been useful in reconstructing past conditions (Tolonen & Tolonen 1984). In this case, the bryoflora support the other taxa to indicate that the flora is predominately that restricted to calcareous habitats.

Jonsgard and Birks (1995) were able to reconstruct the climate (moisture, temperature, light availability, and pH) from partially decomposed fossil mosses at Krakenes, western Norway, by comparing the taxa with bryophyte communities at various present-day altitudes. They found that mosses are able to colonize new habitats as rapidly as their tracheophyte counterparts. The advantage to using mosses for this purpose is that they provide evidence for microhabitats that cannot be obtained from tracheophyte fossils.

Jonsgard and Birks (1995; Birks 1982) also used fossil mosses to characterize late-glacial climate, pH, light availability, and continentality of Norway, using the mosses as ecological indicators.

Glaciers are often the site of modern dispersal of moss fragments. This wide, smooth surface also permitted ease of travel of fragments that became fossils in the frozen water, preserving the communities surrounding them. Thus, ice cores serve as historic records of the surrounding communities, much as peatlands do in other areas (Lindskog & Eriksen 1995).

While studying the Quelccaya ice cap in Peru, Ohio State University glaciologist Lonnie Thompson found mosses that had appeared out of ice laid down 5200 years earlier (Rozell 2005). This date of preserving a green moss coincides with the age of the Ice Man found recently in a melting ice field in the Austrian Alps. Thompson used the moss example to demonstrate the rapid response of a sensitive environment. When he returned to the site, he found more of the exposed mosses. Upon sending them to Woods Hole Oceanographic Institute for dating, he learned that one of them was 50,000 years old! In disbelief, Thompson sent the moss to Lawrence Livermore National Laboratory in California. Results were the same. Thompson reasoned that the only way these 5200-year-old mosses and the 50,000-year-old ones could appear together is that the ice field has not been smaller than it is today in the last 50,000 years and that it had to be colder than it is today for the past 50,000 years! Indications are that the ice cap is melting 40 times faster than it was in 1963.

Graves, Burial, and Preservation

Tombstones more than 100 years old typically are encrusted with lichens and mosses (Figure 28). In a recent bryonet discussion, Sean Edwards (Bryonet on 20 April 2005) sought a way to expedite this process (2005). In an old churchyard, strips of marble on a tomb had been replaced and no longer matched the weathered and lichen/moss-covered older marble. He was seeking ways to encourage the mosses and lichens to grow to age the stone.

Figure 28. Moss *Schistidium apocarpum* and lichens on cemetery marker, with the moss mostly established in the indentations. Photo by Janice Glime.

Burial ceremonies seem to have been a part of human culture for a long time. Hence, it might be expected that the resourceful human found mosses to be a suitable way to preserve the bodies of loved ones. In the Canary Islands, the Guanche mummy (1380 ± 80 years B.P.) was preserved with the epiphyte *Neckera intermedia* (Figure 29) in its abdominal cavity (Horne & Ireland 1991). However, an earlier report of a frozen Eskimo woman with moss in her lungs seems instead to have been the result of inhalation of the moss as she was being accidentally buried alive (Zimmerman & Smith 1975; Horne & Ireland 1991).

Figure 29. *Neckera intermedia*, the moss used in the abdominal cavity to preserve the Guanche mummy. Photo by Jan-Peter Frahm, with permission.

In one case, a strange coincidence got a man to confess to the murder of his wife (Dente 1997). Police in Macclesfield, England, had investigated reports that Peter Reyn-Bardt had boasted of murdering his wife 23 years earlier and buried her dismembered body in his backyard. But the police could find no such evidence. However, the backyard bordered a peat excavation site where only a short time later an excavation uncovered a well preserved skull of a 30-50-year-old female. After the man confessed to the murder of his wife, the Oxford University Research Laboratory for Archaeology determined that the skull was actually 1660-1820 years old!

More recently, it appears that mosses have been used to clothe the last resting place. In Siberia 2,500 years ago, large mosses like *Pleurozium schreberi* (Figure 30), *Ptilium crista-castrensis* (Figure 31), and *Rhytidium rugosum* (Figure 32) were used with sheets of bark to line the roofs of tombs (Rudenko 1970). In Alaska and Japan, they have provided a burial bed (Bland 1971; Ando & Matsuo 1984) with larger mosses such as the pendant *Aerobryopsis subdivergens* (Figure 33) (Iwatsuki & Inoue 1971).

The expansive peatlands of northern Europe seem to have provided a grave for hundreds of men, taking us back to the days of Roman rule – The Iron Age (Glob 1969). At first, these men were assumed to be peat cutters who had in recent years been trapped in the muck (Robinson 2002). But with 1500 bodies (Robinson 2002), speculation about the reasons for the early demise of these "bogmen" soon abounded (Painter 1991). Sanders (2002) relates that the Nazis used them as propaganda, claiming that two men found together in a Dutch peatland had been executed for their crime of homosexuality, whereas Heinrich Himmler was more cautious in a 1937 speech, stating that the deaths had been "not a punishment, but simply the termination of such an abnormal life."

In 1835, a well preserved woman in a Danish moor was identified as Queen Gunhild, a monarch in a Norse legend (Sanders 2002). When the Danish King, Frederick VI, learned of this find, he prepared her for a royal burial beside Danish royalty in a churchyard. However, carbon dating belies the royalty theory, placing the lady in a much earlier time.

In Tollund Fen in Bjaeldskor Dale in Denmark, two brothers (peat cutters) were surprised in 1952 by a body that surely was a recent victim of an onerous crime (The Discovery of Tollund Man). On closer inspection, the man had a twisted leather noose about his neck, but his face bespoke peace, as if death was his salvation (Figure 34- Figure 35). Police work turned to archaeologists who determined the "crime" to be 2000 years old. That look and the grains in his stomach have led many to conclude that he was a holy man sacrificed and preserved in the peat.

The Tollund Man

Seamus Heaney

I

Some day I will go to Aarhus
To see his peat-brown head,
The mild pods of his eye-lids,
His pointed skin cap.

In the flat country near by
Where they dug him out,
His last gruel of winter seeds
Caked in his stomach,

Naked except for
The cap, noose and girdle,
I will stand a long time.
Bridegroom to the goddess,
She tightened her torc on him
And opened her fen,
Those dark juices working
Him to a saint's kept body,
Trove of the turfcutters'
Honeycombed workings.
Now his stained face
Reposes at Aarhus.

II

I could risk blasphemy,
Consecrate the cauldron bog
Our holy ground and pray
Him to make germinate
The scattered, ambushed
Flesh of labourers,
Stockinged corpses
Laid out in the farmyards,
Tell-tale skin and teeth
Flecking the sleepers
Of four young brothers, trailed
For miles along the lines.

III

Something of his sad freedom
As he rode the tumbril
Should come to me, driving,
Saying the names
Tollund, Grauballe, Nebelgard,
Watching the pointing hands
Of country people,
Not knowing their tongue.
Out here in Jutland
In the old man-killing parishes
I will feel lost,
Unhappy and at home.

Copyright

In the same year, 1952, Grauballe Man (Figure 36) was found in a similar manner by peat cutters (Grauballe Man 2002). His body was dated to about 210-410 AD. His stomach was full of porridge of 63 different grains, but no fruits or leafy green material, no meats, suggesting a winter meal or a poor harvest? A gruel with that recipe tastes horrible (Lienhard 1988). Unlike the Tollund Man, his face expressed terror and pain (Grauballe Man 2002). His throat had been cut and his skull was fractured. Later, in 1984, Lindow Man was found under similar circumstances in England (Lindow Man 2002). Like the Grauballe Man, his skin betrayed a man of high rank, not one who labored. He was at least 2000 years old, yet preserved well by the peat. He had died a violent death, with two blows to the head, his throat cut, and a thong for hanging. Was he a human sacrifice, or victim of a brutal murder?

Figure 36. Grauballe Man as he was discovered. Photo through public domain.

As history unfolds and great minds conjecture, it seems that Druid priests, important in the Celtic tribes, may have died in this manner, chosen as a sacrifice to the Earth Goddess (Robinson 2002). The Lindow Man had a last meal consisting only of a small cake containing bits of charred flour that would have required 400°C – much hotter than one would ever consider for baking. Archaeologists Ann Ross and Don Robbins speculate that this cake was used in a lottery to determine who should be sacrificed – perhaps explaining the look of pain and terror! Parts of such a ceremony still existed in England in the 20th century, but without the ultimate sacrifice.

Peatlands have a number of qualities that make them ideal preservation sites (Robinson 2002). Although the low oxygen and high acidity discourage most bacteria, it is the peat itself that imparts the preservation. The *Sphagnum* resulting from phenolic breakdown binds the sparse minerals in the water. Lacking their essential minerals, bacteria are unable to grow. Much like the tanning of cowhide to leather, the body is turned to leather by the tannins from the *Sphagnum* (Figure 3), preserving wool and leather garments along with the skin. The calcified bone, however, loses its calcium in the acid water, becoming rubbery and crumpled under the weight of the peat. And linen, faring less well than wool, disappears due to decay, accounting for the Tollund Man wearing nothing but his leather belt and hat when he re-appeared in the 20th century.

Sphagnum (Figure 3) even has a modern use in commemoration of the dead. In Wisconsin, USA, thousands of cemetery wreaths are made. These usually have various decorations and flowers attached to them, with the *Sphagnum* peat retaining water to keep them fresh.

Anthropology and Archaeology

An archaeologist investigating Paleolithic settlements reported finding animal and human bones in cave sediments (Patxi Heras & Marta Infante, Bryonet, 5 April 2006). These are often eroded with shallow depressions and holes. The zoologist she consulted disclaimed the marks, suggesting they were created by plant growth. Since there is typically abundant moss growth in the cave entrances, the archaeologist considered that they could make the marks. While no one could confirm that mosses make such marks on bones, we do know that mosses in the *Splachnaceae* (Figure 37), among others, can grow on bones.

Figure 37. *Tetraplodon angustatus* on caribou skull, Jasper, Canada. Photo by Janice Glime.

Peat mosses (*Sphagnum* species; Figure 3) are well known for their ability to preserve the dead (Folger 1992). When a giant mastodon (Figure 38) was found in Ohio, USA, it likewise had been preserved in *Sphagnum* for 11,000 years. It was so well preserved that its last meal remained.

Figure 38. Burning Tree Mastodon excavation, Heath, east-central Ohio, USA, where that animal was preserved in peat. Photo by James St. John, through Creative Commons.

Hawes *et al.* (2002) attempted to use bryophyte growth markers to hindcast ice melt patterns in Arctic lakes, but they were unable to establish any correlation, concluding that the relationship was more complex.

Forensics

I have always loved mystery books, but I never dreamed I could be part of a criminal investigation, especially not a likely murder. But one day I opened my email and found a plea for help from a detective from one of the Michigan police departments. He introduced me to the case in which a father had left with his baby daughter and she had never been seen again. He had been convicted for unlawful imprisonment, but the police were seeking evidence that would help them find the child and convict him of murder. His missing daughter was believed to be discarded in a swamp. This belief was based on items adhering to the shoes of the father. These included the sedge *Carex*, a 2-needle pine, a fern, and moss, all of which are known from a wet conifer environment. I wasn't able to participate in the search, but I referred them to Matt von Konrat, who was able to identify *Sphagnum affine* (Figure 39), *Warnstorfia fluitans* (Figure 40), and *Plagiomnium rostratum* (Figure 41) from the clothing. This enabled the botanists to narrow the search to one location. A search, including von Konrat on the team, ensued in wetlands that matched the known plants from the shoes, but the baby was never found.

In Finland, a man disappeared and his body was later found in a woodland (Korpelainen & Virtanen 2003b). Three suspects were arrested, but there was no direct evidence to connect them. However, the bryophytes *Brachythecium albicans* (Figure 42), *Calliergonella lindbergii* (Figure 43), and *Ceratodon purpureus* (Figure 68, Figure 95) were identified from their shoes, clothes, and also in their car. Using DNA fingerprinting analyses on the two pleurocarpous species (*B. albicans*, *C. lindbergii*) that primarily reproduce clonally, they were able to determine that these two species were likely to have originated from populations of the same two species found near the body (Korpelainen & Virtanen 2003a, b). Based largely on the moss evidence, the three suspects were convicted.

Figure 45. *Climacium dendroides* from Beppo Japan, a species tested for its genetic variability among locations. Photo by Janice Glime.

Following that court case, Virtanen and Korpelainen were able to obtain a grant to design species-specific microsatellite markers for a group of bryophytes that are globally common so that they can be used in forensic applications (Virtanen *et al.* 2004). They selected 12 species for which they obtained 20 specimens to represent the entire distribution area of each species, thus representing the range of genetic variation. The selected species were the mosses *Aulacomnium palustre* (Figure 44), *Brachythecium albicans* (Figure 42), *Climacium dendroides* (Figure 45), *Dicranum polysetum* (Figure 46), *Hylocomium splendens* (Figure 47), *Plagiomnium cuspidatum* (Figure 48), *Pleurozium schreberi* (Figure 30), *Racomitrium microcarpon* (Figure 49), *Rhytidiadelphus squarrosus* (Figure 50), and *Sphagnum fuscum* (Figure 18), and the leafy liverworts *Plagiochila asplenioides* (Figure 51) and *Ptilidium ciliare* (Figure 52).

In another case, the FBI was interested in bryophytes in the soil covering a number of bodies that had been relocated from their graves. More than 200 bodies were discovered in shallow graves outside the cemetery. The FBI alleged that the cemetery workers had dug up the bodies and relocated the remains so that they could resell the graves at an historic African-American cemetery. However, some of the defendants claimed that the bodies had been moved before they began working there. Thus, it was important to determine when the relocation occurred. The anthropologist Anne Grauer discovered something green on some of the bodies ~20 cm beneath the surface and determined it to be a moss. The FBI then delivered the moss to bryologist Matt von Konrat at the Chicago Field Museum (Figure 53). He was able to identify it as *Fissidens taxifolius* (compare Figure 54 to Figure 55), but the important question was how long the buried mosses had been there. How long does a buried moss stay green? With the help of a physiologist, von Konrat experimented with the moss and also compared it to herbarium specimens of various ages (Figure 56). Ultimately he determined the moss to have been buried alive between six months and two years earlier, refuting the claim that the bodies had been moved after employment began for the accused.

Furthermore, no *Fissidens taxifolius* could be found growing near the bodies, but it did grow in the main cemetery. Matt von Konrat (Figure 56) was declared an expert witness by the court and the moss evidence led to convictions.

One of the uses of plants in forensics is to establish the "post mortem interval (PMI)." Cardoso *et al.* (2009) found bryophytes to be useful in determining the time of death of an adult male in Portugal in an advanced state of skeletonization. The skeleton had green algae, bryophytes, and shrub roots in, around, and through the remains. The bryophytes and shrub roots were aged at three years, making the remains at least three years old. Time to colonization and state of decomposition of the remains put death at six years earlier, coinciding with the time the person went missing.

In another case, the aquatic moss *Leptodictyum riparium* (Figure 57) was used to estimate the PMI of skeletal remains in a wooded area in Central Italy (Lancia *et al.* 2013). Lacking specific growth rates for *L. riparium*, the authors used the known rate for *Hypnum cupressiforme* (Figure 58), a moss with similar structure and growth habit. By counting the annual segments of the stem, they determined the moss to be 24-30 months old, narrowing the search for missing person records to those known to be missing for at least 2.5 years.

Bryophytes can accomplish their own form of DNA fingerprinting (Korpelainen & Virtanen 2003a). Mosses can be used in much the same way as tracheophytes in crime investigation. Virtanen and coworkers (2004) are developing protocol for linking patches of bryophytes from the crime scene with fragments found on a suspect. Their approach is to find specific microsatellites to identify globally common bryophytes. Many species fragment easily and stick to clothing, making DNA analysis possible long after the event of fragmentation. Such evidence can tie the suspect to the scene of a crime.

Bryophytes could be useful forensic tools, but do we know enough about them, or is there still much work to do? Ann Mills (Bryonet 17 August 2011) reports identifying *Brachythecium rutabulum* (Figure 59) growing "in profusion" around an area where a human skeleton was discovered. To be useful forensically, we need to know how fast this moss might grow over the skeleton in this red spruce (*Picea rubens*) forest. In this case, Furness and Grime (1982) give us some information on growth rate of *B. rutabulum*. Rod Seppelt (Bryonet 17 August 2011) adds that this species is an opportunist that propagates easily from fragments. To this, Steve Newmaster (Bryonet 18 August 2011) added observations from the long-term biodiversity research plot in Ontario, Canada. There *Brachythecium rutabulum* colonizes disturbed areas on organic soil, remaining there for several years. The mean increase per year is ~15% in southern Ontario (285 plots).

If we are to use bryophytes as a regular forensic tool, we need to determine how well they adhere to clothing, especially footwear, and how long the DNA can remain before breakdown destroys it. Virtanen *et al.* (2007) set out to contribute to answering these questions. Sixteen persons walked outdoors wearing rubber boots or hiking boots to determine what would adhere to the footwear. All plant fragments were collected after 24 hours of wear. In a second experiment, fresh bryophyte material from nine species was stored in a shed in adverse conditions for 18 months, and then DNA was extracted and subjected to genotyping. Both experiments supported the usability of bryophytes for forensics. Footwear did indeed collect bryophytes, and the bryophytes remained despite the

wearer walking on dry ground and roads after walking on the bryophytes. And the DNA was still in good condition after 18 months of unfavorable storage conditions.

Figure 59. *Brachythecium rutabulum*, a moss used to determine how long a corpse had been at that location. Photo by Michael Lüth, with permission.

Fuselier *et al.* (2011) used a forensic theme to make an investigative lab for Fuselier's students. The students had to pose the question, evaluate the evidence, and report the results. She based the study on Virtanen *et al.* (2007) and Korpelainen and Virtanen (2003a). The students learned how to use bryophytes in forensics and developed proficiency in DNA isolation, polymerase chain reaction, gel electrophoresis, capillary electrophoresis, and genotyping. The students paid more attention to accuracy in their methods than in standard labs. The researchers found that the students who participated in the bryophyte forensic lab performed well on content-based assessment (Figure 60) and exhibited positive attitudes toward the experience, indicative of engaged learning.

Figure 60. Student performance after bryophyte forensic lab, compared to performance of students who did not have the lab. Modified from Fuselier *et al.* 2011.

Archaeological Preservation

A recent recommendation for the use of *Sphagnum* (Figure 3) extracts is in the preservation of artwork (Zaitseva 2009). Extracts of polysaccharides (**Sphagnan**) were tested first on 17 fungal species and several bacteria species that could be found on ethnographic museum objects and archaeological objects from Arctic excavations. The bacteria *Escherichia coli* (Figure 61) and *Pseudomonas aeruginosa* (Figure 62) were negatively affected, whereas *Staphylococcus aureus* (Figure 63) was unaffected.

Twelve of the fungal species were inhibited (Zaitseva 2009). In one experiment, 1 ml of the nutritious broth with 40µl of 3% solution of polysaccharides in water killed 10,000 fungal spores in 6 hours. The Sphagnan was then added to conservation waxes as a preservative. With three weeks of exposure, the wax alone experienced a 44% consumption by the fungus *Aspergillus* (Figure 64). But when ~0.1% Sphagnan was included in the wax mix, the weight loss from the wax was only 4%. Zaitseva recommended using Sphagnan in art conservation. Additional discussion on the antibiotic properties of bryophytes are in the Chapter on Medicine in this volume.

Erosion Control

The role of bryophytes in erosion control is well known (Figure 65), and several people have considered their commercial use along roadsides and other steep slopes through transplantation or propagation from fragments.

Figure 65. Erosion control on steep streamsides is an important use for bryophytes, both naturally, and on manmade slopes along canals or roads. Here, naturally occurring *Polytrichum* does the job. Photo by Janice Glime.

On dunes, seaside bluffs, and other areas where tourists often disturb the clinging vegetation, few plants, commercial or natural, survive the unstable conditions. Nevertheless, certain mosses may cling there when most other plants have been destroyed. Michel Chiaffredo and coworkers have a patent for Procédé BRYOTEC (BRYOTEC Process) that uses bryophytes instead of tracheophytes to stabilize such fragile sites (Chiaffredo 2007). The company MCK Environnement, using the BRYOTEC Process, has managed to restore, in only five years, the indigenous vegetation of a cliff top in a maritime setting in the Vendée region of France (Figure 66), where the tourist trampling had completely eradicated the original vegetation. This restoration involved the introduction of bryophytes with a small number of seeds from the native vegetation.

Figure 66. Restoration of a trampled cliff using a mix of bryophytes and other naturally occurring plants. Photo courtesy of Michel Chiaffredo.

The association *Ceratodonto-Polytrichetea piliferi* (Figure 67-Figure 68) (Dierßen 2001) is one that has proved particularly successful in helping to restore lost vegetation on a disturbed site.

Figure 68. Wet *Ceratodon purpureus* with capsules at left and *Polytrichum piliferum* at middle right. Photo by Michael Lüth, with permission.

In France, one may observe granitic embankments along a highway with the grass *Festuca ovina duriuscula* enduring the summer sun, but only in crevasses where mosses share the space. Perhaps the moss is necessary to provide sufficient moisture for seed germination of the grass (see Figure 69).

Figure 69. *Festuca ovina guestfalica* established in a crevice. The subspecies *Festuca ovina duriuscula* invades crevices in granitic embankments where it shares space with mosses. Photo by Andrea Moro, through Creative Commons.

One approach to rehabilitation has been to accelerate the establishment and growth of mosses by introducing mosses to the damaged area. However, the technique has used fragmented or chopped mosses and has met only limited success, despite the humid climate (rain on 80% of days). Furthermore, it has required collection of great quantities of samples from nature, which is contrary to the objectives of such a project. The BRYOTEC Process, on the other hand, produces large quantities of pioneer mosses from small samples of several cm². It therefore enjoys the status of a non-destructive biotechnology.

In addition to controlling erosion, mosses may help to stabilize and build soil on mine spoil. Peat mosses have been used for recultivation of ash dumps from brown and hard coal, a difficult substrate to colonize (Biernacka 1976).

Revegetation

Occasionally mosses are used to revegetate mining spoils. In a discussion on Bryonet in August 2007, several people suggested *Polytrichum* species (Figure 70), measuring some degree of success in the United States and Canada, as pointed out by Jean Faubert. Justin Wynns reports that in Boone, NC, USA, large carpets of *Polytrichum* have been planted in full sun, covered with large pieces of cloth to stabilize and retain moisture. Steve Timme suggested that naturally appearing mosses on mine tailings of one South Kansas site included *Ceratodon purpureus* (Figure 68), *Bryum argenteum* (Figure 71), and *Bryum pseudotriquetrum* (Figure 72), making those good choices to start. Shana Gross has found that she can get *Ceratodon purpureus* and *Bryum argenteum* to grow easily from fragments in the greenhouse, but they do not easily form thick mats. It is even more difficult to get such mats in the field.

Road cuts, construction, and other forms of "progress" often leave huge scars on the landscape that do not quickly heal and soon become unstable detractants from the landscape around them. Thus, it is desirable to solve both the technical stabilization problem and to create an attractive replacement for the former vegetation. To this end, the Bryotec Corporation has introduced mosses as a solution to both problems. They have found that such bare terrain can be stabilized in a few months with a bed of bryophytes combined with other vegetation to form a pre-sod. The mat is both stable and attractive and helps to prepare the landscape for larger plant species (Michel Chiaffredo, Bryotec Corp., Pers. Comm.)

Recreation

Bryophyte forays have been part of many cultures for a long time (Glime 1982). These have been organized groups that included beginners through top experts who gathered to catalog bryophytes in an area, to learn new species, and to share interests with fellow bryologists.

But in Japan, a new trend has begun. These are excursions, led by an expert, for recreation of non-bryologists, and usually many non-bryologists (Pfanner 2015). In 2013, the Hoshino Resorts Oirase Keiryu Hotel in Aomori Prefecture initiated a one-night stay that included a moss tour on a riverside in the forest region (Matsumoto 2015). Most of the participants are women who find the tours a relaxing way to escape the normal stresses and competition of daily life. But they are shy about sharing their interest in mosses to friends and family.

It is not surprising to me that this interest in mosses by non-biologists has arisen in Japan. Japan is the land of famous moss gardens. It is the land where women traditionally have learned the finer things in life. And as pointed out by Nozu and Thompson (2015), it is a culture that values age and history. And mosses themselves are a thing of beauty with vibrant colors that vary from brown to bright green to red. And mosses make a soft and inviting surface. The slow growth and longevity give the mosses an inherent virtue. There is even a moss reserve around lake Shirakoma that has been designated by the Bryological Society of Japan and is known as a "precious moss-covered forest."

Pesticides and Antifeedants

Frahm (2004) extolled the virtues of bryophytes as anti-snail and anti-fungal sources. He reported that bryophyte extracts only spoil the appetite of the slug *Arion lusitanicus* (Figure 73) without killing it (Figure 74). The tested extracts came from the rock-dwelling moss *Neckera crispa* (Figure 75) and the leafy liverwort *Porella obtusata* (Figure 76) (Frahm & Kirchhoff 2002).

Figure 76. *Porella obtusata*, a leafy liverwort source of a slug antifeedant. Photo by Kristian Hassel, through Creative Commons.

When fungal spores fall on bryophyte leaves, the bryophyte releases phenolic compounds when the surface becomes wet, inhibiting spore germination. To support the anti-fungal use, Frahm encouraged the head of the Department of Phytopathology at the University of Bonn to test their properties in greenhouse experiments. Crop plants such as green peppers, tomatoes, and wheat were infected with such fungal plant pathogens as *Phytophthora infestans* (Figure 77, Figure 78), *Botrytis cinerea* (Figure 79), and *Blumeria graminis* (Figure 80). These infected plants were treated with alcoholic extracts from 20 European species of bryophytes (e.g. Figure 78). The extracts had various effects, with liverworts (Figure 76) being most effective (Figure 81), followed by *Sphagnum* (Figure 3), then other mosses (Tadesse 2002). Two of the liverworts caused systemic effects. Plants that were sprayed prior to their inoculation were not affected at all by the fungi; the leaves that developed after the application of the extract were resistant, suggesting that the antibiotic substance was translocated within the plant. The ability of moss extracts to inhibit fungal growth is easily demonstrated by saturated disks on inoculated Petri plates (Figure 82).

Once the news of this antifungal activity was distributed to the news media, there was a huge response, indicating a great need for such an alternative product. The moss extracts are a safer alternative to the copper sulfate and other heavy metal salts currently being used. The heavy metals accumulate in the soil, whereas the bryophyte extracts quickly degrade in the soil. Furthermore, it is easy to produce and farmers in third world countries could even produce it themselves. Are these anti-herbivore compounds safe for our consumption?

A private German development company, Red de Accio'n en Alternativas al uso de Agroquímicos (RAAA) persuaded the Universidad Nacional de San Martín in Peru to test extracts of local bryophytes on coffee and tomatoes as protection against tropical plant diseases in the field. Unfortunately, they tried only mosses and not the more potent liverworts, but they still achieved positive results. Sadly, the high cost of the alcohol prevented wide-scale use in Peru.

In Bolivia, the Unidad de Investigacio'n y Desarrollo FAN made extracts of *Frullania brasiliensis* (Figure 83) and *Sphagnum* sp. (Figure 3) and applied them to tomatoes and potatoes. While controls were infected, the treated plants exhibited no visible bacterial or fungal infections (Figure 78; Figure 81).

Figure 83. *Frullania brasiliensis*, a species that prevented infections on tomatoes and potatoes. Photo by Jan-Peter Frahm, with permission.

Frahm, failing to persuade any German company to produce the product, took the product to a company that produces herb liquors. It was sold by a chain of drugstores(!) as an alternative to fungicides. Finally, a new commercial company received permission from Biologische Bundesanstalt to produce the product commercially. Several thousand liters of bryophyte extract were sold during the first 8 months. This product is diluted 1:100 for use. A major limitation is obtaining enough plant material in the field. Although the moss used is abundant in silvicultural fir forests, the quantities needed for agriculture is enormous.

Frahm's group is conducting further testing to produce the moss horticulturally and hopefully to find clones with higher biological activity. Such commercial production would also eliminate the need for cleaning, reducing costs and time.

Rearing Fish

The Nashua National Salmon Hatchery has considered using the aquatic moss *Fontinalis* (Figure 84) in the salmon raceways (Abigail Walker, Intern, Nashua National Fish Hatchery, 19 April 2005). It grows there on the cement and they hope to use it as both a nutrient sink and a natural cover for young fry in the rearing tank.

Figure 84. *Fontinalis antipyretica* is a moss used in fish hatcheries today, but formerly used for chimney chinking with the belief it would insulate against fire or heat. Photo by Michael Lüth.

As described in the Aquarium subchapter, Bohlen (1999) reported the use of aquaria equipped with a thick moss tuft for spawning of the spined loach *Cobitis taenia* (Figure 85). The moss was placed on top of a gauze-covered plastic box. The fish laid their eggs in the most dense vegetation available. The dead eggs fell through the gauze and collected in the box.

Figure 85. *Cobitis taenia*, a species that benefits from mosses in aquaria for spawning. Photo by Ron Offermans, through Creative Commons.

The bryophytes may well be protected from herbivory by the fish at the same time. Asakawa *et al.* (1985) has shown that at least one liverwort (*Riccardia lobata* var. *yakushimensis*), although not itself aquatic, has piscicidal secondary compounds (diterpenedial).

Toxicity Testing

Numerous studies have used bryophytes as indicators of pollution, with symptoms indicating, in many cases, the type of pollution. These are so numerous as to warrant several chapters, if not an entire volume. It is almost predictable that one of the organisms that has been studied for this potential is the bryological lab rat, *Physcomitrella patens* (Figure 86). Morgan *et al.* (1990) used cultures of this moss to examine effects of various salt solutions (aluminium sulfate, barium chloride, boric acid, cadmium chloride, cobalt chloride, as well as lead nitrate, mineralized-acidic leachate, and coal combustion fly ash leachate) on various life cycle stages (Figure 86). Aberrations such as altered morphology, loss of regeneration ability, reduced dry weight, and altered chlorophyll contents indicated damage by the salts. Surprisingly, the spore and gametophore cultures differed little in their responses. Cadmium chloride and aluminum sulfate caused the greatest reduction in chlorophyll concentration and dry weight, whereas boric acid and barium chloride were least toxic. Fly ash likewise seemed to cause no harm to the plants.

Figure 86. Mosses such as *Physcomitrella patens* can be used to test effects of salt concentrations, acidic leachates, heavy metals, and fly ash on morphological alterations and changes in chlorophyll concentrations. Photo by Ralf Reski, with permission.

Kenneth Adams (pers. comm. 1 November 2013) used balls of acid-washed *Sphagnum* (Figure 3) in bun hair nets in the 1970's to accumulate airborne heavy metals in locations of interest. These were placed in concentric survey locations around smelters in the U. K. and assayed with flame photometry. This was used routinely to assay for petrol lead levels along roadsides. He even found a zinc source from burned car tires in east London.

There is considerable literature on the use of bryophytes for biomonitoring, including moss bags and *in situ* assessment in concentric rings or distances along a transect starting from a pollution source. These have been useful in both aquatic and terrestrial studies. Several reviews and books (e.g. Leblanc & Rao 1974; Nash & Wirth 1988; Tyler 1990; Bates & Farmer 1992; Greven 1992; Onianwa 2001; Zechmeister *et al.* 2003; Tuba *et al.* 2011; Harmens *et al.* 2013) have been written on these studies, so I will not elaborate here. Hopefully I will write a volume on this after other volumes are completed.

Filters

Copper is toxic to plants except in small quantities. Itouga *et al.* (2006) tested the copper mosses *Scopelophila cataractae* (Figure 87) and *S. ligulata* (Figure 88) for their effect in removing the copper toxicity in copper-polluted water used for growing rice. Using bryophyte columns packed with each of these two species, the researchers determined that *S. cataractae* was superior at copper toxicity removal. Furthermore, *S. cataractae* filtrate was no longer toxic to the rice. We still need to know the practicality of this method – how much moss would be required and how long would the column be effective. Nevertheless, this could be a practical solution for small applications such as home aquaria and pools.

Many studies exist on the sorption of metal ions by mosses. These have been reviewed in several books on bryophytes and pollution. However, their use as filters has received much less attention. Al-Asheh and Duvnjak (1997) discussed the adsorption of metal ions by mosses. Such publications led to the exploration of bryophytes as filters against metal ions. Abdel-Jabbar *et al.* (2001) successfully modelled the copper adsorption of a moss-packed bed. This model accounted for differences such as axial dispersion, external film, and within-particle diffusion. In a different study, Ho and McKay (2000) developed a sorption model for copper using *Sphagnum*

(Figure 3). They determined that sorption through chemical bonding might be rate limiting. Nevertheless, they were able to develop a model that could predict the sorption capacity of metal ions sorbed.

Figure 88. *Scopelophila ligulata*, a copper moss that is less effective than *S. cataractae* in removing copper toxicity from water used to culture rice. Photo by Michael Lüth, with permission.

Electricity

Using mosses to produce electricity might be a pipe dream, but it has at least limited possibilities. Mosses are able to produce enough energy through photosynthesis to power a clock, but the same amount would only keep a laptop alive for about 20 seconds (Chandler 2012).

In another example, mosses have been placed in a glasstop table (University of Cambridge 2011). They are able to power the lamp through photosynthesis (Inhabitat 2017). Mosses photosynthesize and release organic compounds into their substrate. Bacteria in that soil break down these organic compounds, liberating by-products, including electrons. The table is designed to capture these electrons and use them to produce an electrical current. This research is led jointly by Dr. Adrian Fisher, Professor Christopher Howe, and Professor Alison Smith at Cambridge, and Dr. Petra Cameron at Bath.

Scientific Use

Today, bryophytes are receiving considerable attention from the scientific world. *Marchantia polymorpha* (Figure 89) has long been a subject of physiological studies. *Funaria hygrometrica* (Figure 90) and *Physcomitrella patens* (Figure 91) are everyday names to the plant physiologists. And *Syntrichia* (syn.=*Tortula*; Figure 92) is being studied by the Department of Agriculture (Comis 1992; Hoffman 1992)! What is it that has caused this sudden agricultural interest in bryophytes?

Figure 89. *Marchantia polymorpha*, a common liverwort, is used for teaching and scientific research. Photo by Michael Lüth, with permission.

Figure 90. *Funaria hygrometrica*, a moss that has often been used in plant physiological studies. Photo by Michael Lüth, with permission.

Figure 91. *Physcomitrella patens*, a moss with a fully mapped genome and that has often been used in plant physiological studies. Photo by Michael Lüth, with permission.

Figure 92. *Syntrichia ruralis*, a desiccation-tolerant moss that has been used in many physiological studies. Photo by Michael Lüth, with permission.

The ability to grow bryophytes from spores and fragments has made some kinds of physiological studies easy. Much of what we know about tropisms has been learned from studies on moss protonemata, which respond to gravity and demonstrate what occurs inside the cell. With only one cell in thickness, and an easily observable and measurable linear structure, the moss protonema provides an ideal study organism for this purpose. But agriculture? It seems that mosses have characteristics that are desirable for crop plants. They tolerate desiccation better than almost any crop plant and can withstand freezing while still in a state of hydration, yet recover almost instantly (Rütten & Santarius 1992). Furthermore, they seem seldom to be eaten, especially by insects. With our new tools for moving genes around almost anywhere we want with the help of bacteria and bryophytes, the genes of mosses suddenly became an attractive commodity.

The bryophytes, and especially *Physcomitrella patens* (Figure 91), and to a lesser extent *Ceratodon purpureus* (Figure 68), have been a true boon to unravelling the genetic control of physiology and development by identifying which genes control which actions (Cove & Cuming 2014). With only one set of chromosomes, inserting a new gene so that it is expressed is a much simpler task in bryophytes than doing the same thing in a flowering plant with two sets of chromosomes. Furthermore, it is easy to grow large quantities of these mosses in culture. And both species experience a high frequency in gene targetting, permitting researchers to knock out a gene to determine its function (e.g. Brücher *et al.* 2005). *Physcomitrella patens* has been completely sequenced and much of the genome of *C. purpureus* is likewise known (Cove & Cuming 2014).

Model Systems

It seems fitting, yet ironic, that these plants of ancient use may reach the forefront of technology. But this time, their uses are much less obvious and much more sophisticated.

In the early part of the last century, bryophytes led the arena of genetic research (Wettstein 1932). Mutagenic effects of X-rays [on *Sphaerocarpos donnellii* (Figure 93; Knapp 1935, Schieder 1973); on *Marchantia polymorpha*

(Figure 89; Miller *et al.* 1962a, b); on *Physcomitrium pyriforme* (Figure 94; Barthelmess 1941a); and on *Physcomitrella patens* (Figure 91; Engel 1968)], α particles on *Physcomitrium pyriforme* (Barthelmess 1938), and γ -rays on *Brachythecium rutabulum* (Figure 59; Moutschen 1954), and chemical mutagenesis on *Physcomitrium pyriforme*, and *Physcomitrella patens*, among others, Barthelmess 1941a, b, 1953) were more easily studied on these haploid organisms, and their multi-year life exposed to the atmosphere made them ideal for integrating effects over time. Both morphological and physiological effects were manifest (Cove 1983).

Figure 93. *Sphaerocarpos donnellii*, a species used to determine mutagenic effects of X-rays. Photo by Belinda Lo, through Creative Commons.

Figure 94. *Physcomitrium pyriforme*, a moss used to test the mutagenic effects of α particles. Photo by Janice Glime.

Although bryophytes seldom reach the headlines, they have served as model systems in many branches of biology for a long time. The first sex chromosomes in plants were described from a liverwort, then the continuity of chromosomes during mitosis, then the discovery of non-Mendelian inheritance (Reski 1998). Mutagenesis, using UV, was first demonstrated in mosses (Reski 2005).

Many aspects of plant physiology have been elucidated using mosses as model systems. It seems that photorespiration was first recognized in *Fontinalis* (Figure 84) (Buch 1945), although Buch is not given credit in modern literature. And it is much easier to study tropisms, amyloplasts, and statoliths in the one-cell-wide protonema (Walker & Sack 1990; Young & Sack 1992; Sack 1993; Chaban *et al.* 1998; Kern *et al.* 2001). This system likewise is ideal for trying to understand the early developmental pathways and their hormonal controls (Bopp 1974). The moss provides a simple plant system in

which to understand mechanisms of Ca regulation and signal transduction in plants (Schumaker & Gizinski 1995).

Thus, in recent years bryophytes have become established as model plants for the study of many physiological aspects of plants, especially in linking genes to function, including developmental processes [cell polarity and plastid development (Jenkins & Cove 1983)], homologous recombination, and cellular (calcium signaling) processes. Expression of characters in the haploid state makes it much easier to understand gene expression (*e.g.* Wood *et al.* 2004 on GAPN enzyme effects), and isolation of mutants has facilitated the breakdown of developmental and biochemical pathways. Now, the ability to transplant genes or target knockout genes in mosses, especially in *Physcomitrella patens* (Figure 91), permits us to understand gene/pathway/phenotypic response relationships through the use of reverse genetics (Reski 2005).

Sineshchekov *et al.* (2000) transplanted the moss *Ceratodon purpureus* (Figure 95) CP2 gene to the yeast *Saccharomyces cerevisiae* (Figure 96) to reconstitute **phycocyanobilin**. This permitted examination of emission spectra of the pigment in isolation from the influence of other pigments. Studies such as this are being used to understand a variety of gene functions in plants, with bryophytes expressing transplanted genes more easily than do other plants. Hence, they have been invaluable in advancing our understanding of plant functions.

Figure 96. *Saccharomyces cerevisiae* SEM, a yeast that received genes for phycocyanobilin from the moss *Ceratodon purpureus* so that the emission spectrum could be isolated and analyzed. Photo by Mogana Das Murtey and Patchamuthu Ramasamy, through Creative Commons.

Genetic Engineering

While genetic engineers are making the headlines with marketable fruits, vegetables, and even modified animals, the genetic engineers of bryophytes remain quietly in the background figuring out "what makes things tick." Although few people have any interest in how a moss functions, the ability of using mosses to figure out how a tracheophyte, especially a crop plant, goes about its daily life is of enormous importance to the agriculture industry.

Cove and coworkers (1997) have suggested that mosses "hold many attractions" as model organisms, arguing that position as the simplest of land plants permitted them to shed light on the development of terrestrial plants from formerly aquatic ancestors. But this simple evolutionary approach soon blossomed into a new and strategic use of bryophytes in understanding not only evolution, but in understanding the functioning of plants in general (Reski & Frank 2005).

To quote Reski (1998), "due to the simplicity of the plants, development can be pinpointed to the differentiation of a single cell and be analyzed in living tissues, making mosses ideal candidates for analysis of development in an integrated approach of cell and molecular biology." In fact, it is the humble moss *Physcomitrella patens* (Figure 91) that is proving to be an appropriate model for studying the molecular development of not just mosses, but plants in general. The nuclear genes of this moss can be targeted for homologous recombination, making reverse genetics a viable tool for plant physiologists.

In the past, we have studied gene function by identifying the gene product, then trying to identify the gene involved. With reverse genetics, we instead identify the gene on the basis of its position. We can then remove it or insert it in another organism to determine the effect that gene has on phenotypic expression. As haploid organisms, mosses are ideal for this approach because the gene is not masked by a second allele that may alter or prevent its expression. It is as easy in this moss to target nuclear genes for recombination as it is in yeast, providing a powerful tool for understanding plant gene function (Reski & Frank 2005). Using *Physcomitrella patens* (Figure 91) to confirm the transgene in chloroplast transformation, Cho and coworkers (1999) were able to demonstrate the applicability of this moss as a model system for basic biological research.

The model moss *Physcomitrella patens* (Figure 91) not only is useful for expressing genes transferred from other plants, but it also has genes of its own to contribute. Its high tolerance against drought, osmotic stress, and salt (Frank *et al.* 2005) suggest that it has genes that could be useful in other plants. Because it is easier to identify specific genes and link them to their functions in haploid plants, it could serve as a source for genes that could be moved into crop plants to endow them with these desirable traits.

One advantage of using mosses to understand physiology is their ability to exhibit conditional lethal genes (King 1986). Such mutants permit physiologists to understand processes because the gene is lethal until the problem is corrected.

Beike *et al.* (2010) discussed the use of bryophytes in biotechnology, known as bryotechnology. Many of these

uses have been discussed earlier in this chapter or in the chapter on medicine. Beike noted some of the potential uses in agriculture. For example, the leafy liverwort *Porella platyphylla* (Figure 97) inhibits the growth of radish seedlings, whereas an extract from the moss *Brachythecium rutabulum* (Figure 59) promotes the growth. Stress tolerance is more common among bryophytes and genes effecting that ability have potential for introduction into flowering plants, including food plants. But there are tradeoffs we must not ignore. If a plant puts its energy into making the products of those new genes, what other aspects of the plant might be sacrificed? Will the plant still be safe to eat? Will it still have the same nutritional value? Will it become allergenic?

Figure 97. *Porella platyphylla*, a species that can inhibit the growth of radish seedlings. Photo by Janice Glime.

One such stress-responsive gene is ALDH21A1 from *Syntrichia ruralis* (Figure 92) (Chen *et al.* 2002). This appears to be a unique stress tolerance gene not present in tracheophytes. It is important in the detoxification of aldehydes that are created in response to desiccation and salinity stress.

Modification of non-food crop plants poses fewer risks. Yang *et al.* (2012, 2016) have isolated the ScALDH21 gene from the very drought-tolerant *Syntrichia caninervis* (Figure 98) that grows in deserts of Central Asia and North America. This gene was effectively transplanted into cotton (*Gossypium hirsutum*; Figure 99). Testing indicated that the gene was expressed, and under drought stress the cotton with the new gene accumulated ~11.8-304% more of the amino acid proline than did the unmodified cotton. It furthermore produced a lower concentration of lipid peroxidation-derived reactive aldehydes than untreated plants, and it had a higher peroxidase activity under oxidative stress. These modified plants exhibited greater plant height, larger bolls, and greater cotton fiber yield, while losing nothing in fiber quality.

Manufacturing Human Protein

Most recently, the mosses, and especially *Physcomitrella patens* (Figure 91), are being used to culture needed human proteins because they are much easier systems than tracheophytes for gene manipulation (Figure 100) (Reski 1998; Baur *et al.* 2005). And mosses are much cheaper and easier to culture than human cell systems.

Reski and Frank (2005) have identified three public demands in modern plant biotechnology:

1. More people in the population require more food, but they also reduce the area of arable land, constraining the food production.
2. The mean age of the population is increasing, requiring a higher quality of food to prevent typical

"diseases of civilization" such as cardiovascular diseases and cancer.

3. Medical science is experiencing a paradigm shift from broad-based treatments to very patient-specific treatments, requiring safe and cost-effective production of complex pharmaceuticals.

Reski and Frank (2005) suggest that *Physcomitrella patens* (Figure 91) can contribute in all three of these needs. "Virtually every gene can be knocked out by targeted ... approaches in attempts to establish saturated mutant collections." And the phenotypes can be screened within weeks! Gene targeting in this moss is about five orders of magnitude more efficient than in any seed plant and about two orders of magnitude more than in embryonic mice stem cells.

Figure 100. *Physcomitrella patens* is cultured for gene manipulation and proteomics. Photo courtesy of Ralf Reski.

It appears that there are already over 200,000 expressed sequence tags in *Physcomitrella patens* (Figure 91) (Reski & Frank 2005). There are about 6000 protein-encoding genes which are not identifiable in the public databases, most likely representing novel genes, out of the 30,000 protein-encoding genes present in the moss. It is interesting that about 100 genes in this moss can be matched only to non-plant organisms, including humans!

One advantage to working with a moss such as *Physcomitrella patens* (Figure 91) is the ability to culture it in a bioreactor (Figure 101), thus eliminating the problems of contamination from soil or other growth media (Reski & Frank 2005). This makes the study of proteomics (examination of the protein complement of a genome) much easier.

Figure 101. Moss bioreactors provide sterile cultures of *Physcomitrella patens*, avoiding the contamination problem prevalent with soil-grown plants. Photo by Ralf Reski, with permission.

Mosses may help us to address needs in the human diet that are not available from other plants. For example, eicosapentaenoic acid (EPA) and arachidonic acid (AA) are only produced by non-seed plants, including bryophytes. Yet these acids play a role in human eicosanoid metabolism. Furthermore, polyunsaturated acids are most abundant in non-seed plants, including mosses, and likewise are beneficial for human growth and continued good health. As our fish (also large sources of polyunsaturated acids) dwindle and become contaminated with metal pollutants, these plants may become an essential source of these important fatty acids. Genes from *Physcomitrella patens* (Figure 91), identified to have this function of producing polyunsaturated fatty acids, have already been planted and expressed in tobacco (*Nicotiana tabacum*; Figure 102) and linseed (*Linum usitatissimum*; Figure 103) (Abbadi *et al.* 2004).

One problem with many plant cell culture systems is genetic instability (Reski & Frank 2005). The *Physcomitrella patens* (Figure 91) bioreactor, on the other hand, maintains well-differentiated and genetically stable cell types. The culture conditions are much simpler than those required for mammalian cells.

Figure 102. Tobacco, *Nicotiana tabacum*, a species that is able to express genes for producing polyunsaturated fatty acids, transplanted from the moss *Physcomitrella patens*. Photo by Magnus Manske, through Creative Commons.

Figure 103. *Linum usitatissimum*, a species that is able to express genes for producing polyunsaturated fatty acids, transplanted from the moss *Physcomitrella patens*. Photo through Creative Commons.

Targetted gene removal or transfer can render the moss products safe for humans, avoiding production of allergenic products that are unsafe for humans (Reski & Frank 2005). For example, xylose and fucose form allergenic residues of plant glycoproteins in most plants, but in the mosses, a targetted double knockout provides moss plants with no fucose or xylose residues attached to their proteins. This modified moss was still able to produce the same level of recombinant human growth factor, serving as a living reservoir for this purpose.

Model for Pipettes

Plants have been used as models in engineering, but use of a bryophyte for this purpose is unusual. Nakamura *et al.* (2018) used *Marchantia polymorpha* (Figure 104) to understand the mechanism of fertilization in its archegonial head. This study not only challenges some of our traditional concepts about fertilization in this species, but also provides a model for a very effective small pipette.

Figure 104. *Marchantia polymorpha* archegoniophores at the stage used in experiments by Nakamura and coworkers. Photo by Janice Glime.

This liverwort has an archegoniophore shaped like a parasol, but with finger-like appendages radiating from its head (Nakamura *et al.* 2018). When it is young, the fingers of the archegonial head tend to hang downward and provide an ideal water-trapping device through the cohesive and adhesive properties of water. This collection of water droplets provides a suitable medium for sperm to swim to the archegonia on the lower surfaces of the fingers. Nakamura and coworkers developed a similar parasol-like object to grab, transport, and release water droplets up to about 1 cm in diameter. Their simulated "archegoniophore," like the plant that serves as its model, is "largely insensitive" to such properties of water as surface tension and viscosity. This permits bubble-free capture and drop of liquids that is useful in laboratories and in soft robotics.

Goodyear Tires

Thank you to my alert former graduate student, Geert Raeymaekers, I am reporting to you on the use of "moss" in Goodyear tires (Figure 105). The "mosses" are packed into the sidewalls of the tires, where they can photosynthesize, absorb CO₂, and put O₂ into the atmosphere (Leary 2018). The tires are made of recycled tires and can't go flat, thus requiring fewer needs for new tires. Goodyear estimates that in a city about the size of Paris, the tires could absorb more than 4,000 tons of CO₂ and release ~3,000 tons of O₂ per year.

Figure 105. Goodyear Oxygen tire, showing "moss" in sidewall. Photo from Goodyear, through Creative Commons at Futurism.

I have several concerns about this innovation. First, they look more like an *Evernia*-type lichen, or perhaps reindeer "moss" – also a lichen. But more importantly, whether a true moss or a lichen, to work they must be alive. I would think that the heat created in a tire, the salt on winter roads, mud puddles, and rapid drying on a revolving wheel would make an unsuitable habitat for either.

Summary

Sphagnum is the most widely used moss, including uses for bandages, diapers, boot liners, sanitary napkins, horticultural soil mixes, cranberry farms, orchid and mushroom culture, green roofs, flower arrangements, fuel, peatwood, peatcrete, litter for animals, lead detection electrodes, filtration, and oil spill cleanup. Products such as Hydro-Weed, SpillSorb, Oclansorb Plus, and Peat Sorb are peat products designed for hydrocarbon cleanup projects. These properties also make it an effective filter for removing heavy metals and other pollutants. Sphagnum makes a good preservative and is probably responsible for the preservation of the Tollund man.

Peat is a renewable fuel and horticultural source, but it must be harvested with sustainability in mind. Hand raking and light-weight wagons travelling on restricted paths can leave sufficient live plant material that harvesting may be repeated in 10-20 years. Lack of care about renewability has caused mass destruction of peatlands, along with destruction caused by development of industry, business, and housing land.

In addition to burning the peat, peatlands can be used to generate methane for fuel. Peat has been used in construction to make asphalt, peatcrete (light concrete), peatfoam, peatcork, and peatwood. Their natural role to control erosion has recently been copied in road construction.

Peatlands harbor a rich history and because of their antiquity can be used for aging and determining past vegetation and climate. And bryophytes on Ötzi and other icemen can tell us about their origins and suggest some of their uses of bryophytes.

The Japanese have capitalized on the beauty of bryophytes to lead excursions for people who have become interested in the natural world.

Bryophytes produce a wide range of antibiotics that have been used against fungi, slugs, and other invertebrate herbivores. The antibiotic and absorbent capabilities make bryophytes good agents of preservation, as seen in ancient tombs, stuffed mummies, and the preservation of bogmen. Photosynthesis of bryophytes has been used indirectly to power small users such as lights and clocks.

Because of their *ln* state, bryophytes are useful in unravelling the roles of individual genes in plant physiology. And subsequently, adaptive genes are being moved into crop plants to increase drought tolerance (cotton) or lower targeted fatty acids. In other cases, genes are moved into bryophytes to make them create a needed human protein without causing an immune response in the human recipient.

Modern science is now using bryophytes in forensics to put suspects at the scene of a crime, using the techniques of DNA fingerprinting to match fragments on

clothing to a particular location. They can also help to determine the post mortem interval.

Bryophytes are good organisms for testing the toxicity of various substances, using the bryological "lab rat" *Physcomitrella patens*. Other scientific uses include unravelling the mysteries of gene function and plant physiology by studies with knock-out genes and gene transplants. Mosses are ideal for this because of their dominant 1n generation. This same advantage permits us to put genes for producing human substances such as blood protein into a moss and produce it in culture, avoiding any animal rights violations.

Marchantia polymorpha archegoniophores serve as a good model for a laboratory pipette. Goodyear is experimenting with using "mosses" in the sidewalls of tires to clean the air of CO₂ and replenish it with O₂.

Acknowledgments

I appreciate the contributions of Michel Chiaffredo, Jan-Peter Frahm, and Ralf Reski in making this chapter timely and for their contributions of photographs. If anyone can provide me with the original source of the photograph of the bogman, I would greatly appreciate it so that I can gain permission and give proper credit. I appreciate Andrew Wood's efforts to bring me up to date on GMO's using bryophytes. Geert Raeymaekers sent me the link to the Goodyear tire story. Claudio Delgadillo Moya sent me the link to the story about the *Marchantia* model for a pipette.

CHAPTER 7-1

GARDENING: HORTICULTURAL USES

Figure 1. *Sphagnum* species such as this *S. russowii* are commonly used in horticulture as bedding material. Photo by Michael Lüth.

Horticultural Uses

I was surprised that in my search for moss uses in horticulture I stumbled on a patent for culturing "moss seedlings" (Hiraoka 1995). The patent was to culture mosses that could henceforth be transplanted and grown in a nursery. Hiraoka presented this as a means of reducing the necessity of collecting wild mosses and creating undesirable forest conditions due to drying soils and erosion. This consideration should serve as a warning for all who desire to use bryophytes for any commercial purpose, and even on a small personal scale, collection can produce local damage.

"People have probably used organic materials as an aid for plant culture since the eve of human history, but documentation is scarce" (Raviv *et al.* 1986). Use of organic materials, including mosses, may not have started that early, but if monkeys can discover the advantage of mosses for getting water to drink, why not? At the beginning of the 18th Century, we find reference to using

peat moss as an amendment for clay soils, whereas animal dung was used for sandy soils (Raviv *et al.* 1986). Since then, the need to keep plants alive during transfer made bryophytes a desirable medium because of their ability to retain moisture.

It is surprising how difficult it is today to find literature on the use of bryophytes in plant cultivation, despite the widespread sale of peat mosses for gardening, potting, air layering, and other uses. Rather, the use of mosses, especially peat moss, seems to be assumed and publications concentrate on finding substitutions for it (*e.g.* Tripepi *et al.* 1996) or creating the right mix of moss and amendments (*e.g.* Chong & Lumis 2000; Shujun *et al.* 2004).

Horticulture is the largest market for moss products in Asia (Tan 2003), and probably in most North American countries (Muir *et al.* 2006). In horticulture, mosses find a niche unparalleled in any other living bryophyte industry (Nelson & Carpenter 1965; Tan 2003). In some parts of

the world, they are routinely mined (Clarke 2008). Bryophytes, especially peat mosses (Figure 1), have played a major role in horticulture for centuries (Perin 1962; Arzeni 1963; Adderley 1964, 1965). Although their use as part of the landscape in gardens has traditionally been mostly an Asian practice, they have commonly been used as soil additives and bedding for greenhouse crops, potted ornamental plants, and seedling beds (Cox & Westing 1963; Sjors 1980). They are stuffed into wire frames to make totem poles to support climbing plants (at the Mossers Lee Plant), topiary (Figure 2), moss-filled wreaths, or baskets (Thomason 1994), or for covering the soil in floral arrangements. One company advertises a birch bark pedestal topped by a moss globe.

Figure 2. A swan topiary exhibited in a pedestrian area of Minneapolis, Minnesota, USA. Photo courtesy of David Long.

Overuse of mosses is concerning in several countries. Thus, some horticulturists seek substitutes. The use of rice hulls may provide a more renewable alternative to *Sphagnum* (Figure 1) peat for horticulture usage (Sambo *et al.* 2008). Peat has more total pore space and a lower air-filled pore space compared to rice hulls, coinciding with a higher water-holding capacity and the highest water content at container capacity. Nevertheless, peat had a lower available water content than the rice hulls, while releasing its water more slowly.

Shipping and Protecting

Sphagnum (Figure 1) is almost indispensable for shipping live plants, keeping them moist, yet free from mold. In countries where peat is abundant, the damp peat is burned to produce a smoke screen against frost, hence protecting the plants (Thieret 1954). This is one of its uses in Asian countries as well (Tan 2003).

Soil Conditioning

The Shuswap Indians of North America use *Aulacomnium* (Figure 3) and *Dicranum* (Figure 4) mixed with dirt to make plants healthier (Palmer 1975). As a soil conditioner, coarse-textured mosses increase water storage capacity; fine-textured mosses provide air spaces (Ishikawa 1974; Bernier 1992; Bernier *et al.* 1995). Although supporting experiments seem to be lacking, we assume that mosses improve the nutrient condition of outdoor soils by

holding nutrients, especially from dust and rainfall, then releasing them slowly over a much longer period than normal nutrient residency near the soil surface (Stewart 1977; Rieley *et al.* 1979; Scafione unpubl. data).

Figure 3. *Aulacomnium palustre*. Species of *Dicranum* used by the Shuswap Indians of North America to condition the soil for plant growth. Photo by Michael Lüth, with permission.

Figure 4. *Dicranum scoparium*. Species of *Dicranum* used by the Shuswap Indians of North America to condition the soil for plant growth. Photo by Janice Glime.

Their ability to sequester nutrients varies with species and type of nutrient. For most taxa, they do not compete for soil nutrients like phosphorus, but can accumulate from rainfall the potassium, magnesium, and calcium (Timmer 1970). When the mosses later dehydrate, their membranes are damaged, making them leaky. When they rehydrate, nutrients can be dissolved and washed into the soil. It takes a few hours to a day to repair the damaged membranes, giving the roots beneath a chance to retrieve the nutrients that are slowly being washed down from the dusty, leaky mosses. This is dependent also on the force of the rain, with light rains more likely to remain on the mosses long enough for them to absorb the nutrients. This seems to be especially important for potassium, the most soluble and most easily leached nutrient. (See Nutrient chapter in Volume 1 for details.)

Peat, in particular, offers a number of properties important to the growth of plants. To be suitable for most root growth, the peat needs to have about equal proportions of air and water retention. The Peat Research Institute determined that the inclusion of shrubs and cotton grass

from the field site could make the peat inconsistent and alter the water-holding capacity and aeration needed for good plant growth. Therefore, they recommended that the proportion of subshrub residues not exceed 3% wet weight, that the proportion of cotton grass and sedge residues not exceed 6%, and that the proportion of *Sphagnum* (Figure 1) residues be at least 90% (Puustjarvi 1982).

In remote places, including national parks, remote villages, and other places where sewage systems are not in place, peat may be mixed with human waste to form compost (Wikipedia 2017). The extra aeration provided by the spaces among the peat plants helps the process of breaking down the sewage. Nevertheless, human pathogens can be a problem, with the greatest of these being *Ascaris* eggs (a nematode parasite; Figure 5-Figure 6) (Hill 2013). A long time or high temperatures are needed to destroy these pathogens. Berger (2011) claims that the compost should be free of live pathogens after at least two weeks at 55°C or one week at 60°C.

In England, the Wye College, University of London, and Southern Water have cooperated to develop a compost that takes advantage of sewage, mixed with peat mosses, providing a valuable soil conditioner and slow-release fertilizer that can be used for container-grown plants (Lopez-Real *et al.* 1989).

One use for the nasty-smelling fish offal takes advantage of the absorptive properties of *Sphagnum* (Figure 1) to create a superior compost (Martin & Chintalapati 1990), a real boon for getting rid of fish waste. And, when mixed with fish processing wastes, peat mosses are superior to sawdust and wood shavings in conserving nitrogen, but are a bit more expensive (Liao *et al.* 1995).

Martin (1992) considered that it should be an easy and inexpensive process to use fish by-products (fish offal) with *Sphagnum* (Figure 1) peat as a substrate to grow microorganisms for submerged fermentation. Martin conducted experiments on growing fungi and yeast as potential sources of microbial biomass protein for feeding animals. These products, which the fish were willing to include in their diet, served successfully as proteinaceous food for feeding farmed fish.

One of the microorganisms tested was the acid-tolerant fungus *Scytalidium acidophilum* (Figure 7) (Martin & Chintalapati 1989). Martin and Chintalapati found that the culture did not produce any better concentration of the fungus dry weight than when they used a diluted *Sphagnum* (Figure 1) peat hydrolysate as the substrate source. Martin and Chintalapati (1990) considered that the higher production of nutrients such as nitrogen in the fish offal mixed with peat made this a "promising" source of protein produced by *Scytalidium acidophilum*.

Figure 7. *Scytalidium* sp. *Scytalidium acidophilum* is a promising source of protein when grown in fish offal with peat. Photo by Gerardo Garcia-Aguirre, Virginia Vanzinni-Zago, Hugo Quiroz-Mercado, through Creative Commons.

Johnson *et al.* (1992) similarly worked with people from the Wisconsin Sea Grant Inst to find a suitable use for fish by-products to provide a useful compost. They found that the wide range of values for the C:N ratios and other properties related mostly to the initial C:N ratio and the time the mix of peat and fish by-products had been allowed to cure. The *Sphagnum* (Figure 1) peat fish by-product composts, especially those with higher C:N ratios, compared well with commercial fertilized mixes.

As with human waste, destruction of pathogens is important for the fish waste, but Liao and coworkers (Liao 1997; Liao *et al.* 1997) found that the rise in temperature during composting, plus the ammonia and volatile fatty acids produced, were sufficient to destroy the pathogens. Addition of fir (*Abies*) or alder (*Alnus*) chips (Figure 8) caused the compost to stabilize sooner.

Figure 8. Wood chips like those used to stabilize the fish offal/*Sphagnum* compost and destroy pathogens. Photo through Creative Commons.

The addition of *Sphagnum fuscum* (Figure 9) peat to hog manure reduced the volatile loss of ammonia, a primary source of nitrogen, by 75%, mainly due to lowered pH, making it a more suitable fertilizer (Al-Kanani *et al.* 1992a). It offers the added advantage of preventing release of offensive odors caused by 1,2-ethanediamine, methyl hydrazine, N-methyl methanamine, 3-methyl 2-butanamine, ethanethioic acid, and methanethiol (Al-Kanani *et al.* 1992b).

Figure 9. *Sphagnum fuscum* combined with hog manure makes a suitable fertilizer high in nitrogen. Photo by Michael Lüth, with permission.

Rao and Burns (1990) found yet another way of providing nitrogen in the culture of oil-seed rape. They provide *Cyanobacteria* (nitrogen fixers; Figure 10) and bryophytes in the growing medium. Bryophytes are well known for their ability to harbor *Cyanobacteria*.

Miller (1981) found that bryophytes can even increase the buffering capacity of the soil, surprisingly even against the abrupt changes resulting from fertilizer. And as a mulch, the slow decomposition of peat mosses makes them much more long-lasting than leaf litter and compost.

Figure 10. SEM image of *Synechocystis* (*Cyanobacteria*) on substrate. Photo from BASF, through Creative Commons.

Mosses such as *Sphagnum* (Figure 1) retain moisture and prevent weed growth, while at the same time discouraging damping-off fungi (Miller & Miller 1979).

Culturing

Some mosses, for example the epiphytic *Octoblepharum albidum* (Figure 11), are especially suitable for growing hard-to-grow epiphytic ferns (Arzeni 1963). In the Philippines, *Leucophanes octoblepharioides* (see Figure 12) and other members of the family are used by gardeners and plant growers instead of peat moss in potting new plants (Ben C. Tan, pers. comm.). *Leucobryum* (Figure 13) is a suitable medium for inducing good root sprouts on orchid cuttings, sold at U.S. \$0.50 per kilo (in 1963), increased to US \$1 in 1986 (Tan 2003). The most popular moss medium for growing orchids, most of which are likewise epiphytes, is *Sphagnum* (Figure 1), but mosses like *Homalothecium arenarium* (Figure 14), *Hypnum imponens* (Figure 15-Figure 16), *Leucobryum* spp. (Figure 13), *Rhytidiopsis robusta* (Figure 17), and *Thuidium delicatulum* (Figure 18) are also useful (Perin 1962; Adderley 1964, 1965). Chen and Chang (2000a, b) had almost 100% survival success when growing the orchid *Oncidium* (Figure 19) from callus explants on *Sphagnum* peat. Whereas most of their culture media produced abnormal shoots, both embryo- and shoot-bud-derived regenerants developed into healthy plantlets when potted in *Sphagnum* and acclimatized in the greenhouse.

Figure 19. New *Oncidium* hybrid pseudobulb that must form a mycorrhizal connection. Photo by Consuelo Tugnoli, through Creative Commons.

But one consideration is that orchids are **mycorrhizal** (see Figure 20). That means they require an appropriate fungal partner in order to successfully form plants from seeds or cuttings. Kreier (2003) reasoned that a fungus that was mycorrhizal to bryophytes might be a good place to find a proper associate for the orchids. Several members of the liverwort family **Aneuraceae** (Figure 21) are mycorrhizal in association with the fungal genus *Tulasnella* (Figure 21-Figure 22). Kreier reasoned that if the orchids have the same mycorrhizal fungi, then it should be possible to use those liverwort associations to inoculate the orchids with mycorrhizae from the liverworts. Oberwinkler *et al.* (2017) reported *Tulasnella* species are worldwide and likewise are associated with orchids on a global scale. The possibilities look good.

Air Layering

Horticulturists may have learned some lessons from nature. Mosses in nature provide suitable media for air layering of plants like the heath shrub *Calluna* (Figure 23) (Scandrett & Gimingham 1991; MacDonald *et al.* 1995) and even some tropical trees. MacDonald and coworkers (1995) demonstrated that layering was actually associated with the absence or low abundance of the mosses *Hypnum cupressiforme* (Figure 24) and *H. jutlandicum* (Figure 25) and *Cladonia* lichens (e.g. Figure 26). On the other hand, there seems to be a weak connection with layering in *Sphagnum* spp. (Figure 1), *Leucobryum glaucum* (Figure 27), and pleurocarpous mosses other than *Hypnum*.

Figure 23. *Calluna vulgaris*, a species that undergoes air layering in mosses in nature. Photo by Willow, through Creative Commons.

Figure 24. *Hypnum cupressiforme*, a moss that is negatively associated with air layering of *Calluna* in nature. Photo by Michael Lüth, with permission.

Figure 27. *Leucobryum glaucum*, a moss that can contribute to air layering of *Calluna*. Photo by Janice Glime.

Despite these somewhat weak connections for *Calluna* (Figure 23), mosses, especially *Sphagnum* (Figure 1), are used almost exclusively for air layering as a means of propagation of plants. The moss is wrapped (Figure 28) around the area where roots (Figure 29) are to be encouraged, often held in place with cloth mesh, wire, or dark plastic (Figure 30). The moss provides a continuous supply of moisture and encourages the development of adventitious roots while discouraging fungi. Once the roots have formed, the stem can be cut below that point and the explant grown into a new individual (Figure 31). Pant (1989) reports similar use for grafting fruit trees.

Figure 28. Wrapping the tree with *Sphagnum* for air layering to make a bonsai. Photo from Bonsai Eejit, through Creative Commons.

Figure 30. Bonsai showing air layering with *Sphagnum*. Photo from Bonsai Eejit, through Creative Commons.

Figure 31. Air layer of oak using moss to make bonsai. Photo from Bonsai Eejit, through Creative Commons.

In addition to its ability to promote root sprouts in orchid cuttings, *Sphagnum* (Figure 1) is suitable for air layering of a number of kinds of plants, including trees for bonsai (Tan 2003). The moisture and antimicrobial properties are beneficial in the development of new shoots and roots.

It appears that preparing a tree for bonsai often involves air layering with mosses (Morrow 2001; Hasegawa 2002; Relf 2009). In their book on bonsai, Yoshimura and Halford (1957) provide instructions for making a bonsai. Mosses, usually *Sphagnum* (Figure 1), are wrapped around the stem, including a location with young buds, and covered with a material like plastic to retain the moisture. If the plastic is transparent, you can see when the new roots and branches have formed. The lower part of the old stem is then cut off and the layering removed. The bonsai is ready for planting.

Pot Culture

Mosses can also encourage growth of potted plants. Pant (1989) reports that *Begonia* (Figure 32) and *Fuchsia* (Figure 33) bud and flower more profusely in pots where mosses are used to separate the humus-rich top soil from the bottom soil. Members of the Ericaceae, in particular, benefit from the acid of peat mosses. But in Japan, *Hypnum plumaeforme* (Figure 34), *Leucobryum bowringii* (Figure 35), *L. neilgherrense*, and occasionally *L. scabrum* (Figure 36) fragments are used, mixed with sand or soil, to cultivate *Rhododendron* (Figure 37) shrubs (Ando 1957). Could it be that these mosses also acidify the soil?

Figure 37. *Rhododendron*, a genus that benefits from having mosses in the potting mix. Photo by Pete Bobb, through Creative Commons.

The forestry industry likewise finds peat invaluable for culturing young seedlings (see also Reforestation below). Heiskanen and Rikala (2000) found *Sphagnum* (Figure 1) peat to be superior to fine sand or peat with perlite, the latter resulting in more weakened seedlings as a consequence of the lower water retention of the medium. However, peat is not always readily available. Israeli researchers found that composted cattle manure mixed with grape marc were good substitutes for peat in that country where peat must be imported; the substitutes were likewise effective at suppressing plant pathogens (Chen *et al.* 1992).

In other cases, the pots themselves (Figure 38) are made of mosses. These are good for starting seedlings and can be planted without removing the plants. Roots will eventually penetrate the pot and grow into the soil.

Potting Medium

In parts of Asia, horticultural mosses include *Vesicularia* (Figure 39), *Bazzania* (Figure 40), *Heteroscyphus* (Figure 41), and *Pallavicinia* (Figure 42) (Tan 2003). Orchid growers in particular use *Leucobryum* (Figure 35-Figure 36, Figure 43) and *Sphagnum* (Figure 1, Figure 44), especially for their ability to store large amounts of water in their **hyaline cells** (Figure 43-Figure 44).

Sphagnum (Figure 1) and *Leucobryum* (Figure 35-Figure 36) seem to be particularly preferred as a potting medium for orchids (Tan 2003). Tan reported the use of *Leucobryum* as a substitute for peat moss to grow orchid cuttings in Asia. The mosses, especially *Sphagnum*, were good as a potting medium for a variety of seeds.

But in North America, diversity of mosses as a potting medium seems to be absent. I searched with Google for "potting medium moss" and stopped after the 20th hit. All 20 of the mosses were named as peat moss or *Sphagnum* (Figure 1).

Dangers of Peat Culturing

There are drawbacks to using mosses in culturing of some plants. We have seen that *Sphagnum* (Figure 1) can be dangerous because of its cohabiting fungus that causes **sporotrichosis** (Chapter 1 of this volume). In containers of conifer seedlings, they can choke young seedlings, compete for nutrients, and repel water (Haglund *et al.* 1981). But they can also pose serious dangers. But causing fires? As Michael Richardson shared with Bryonet on 20 June 2013,

peat, including shrubs and other debris along with the mosses, is good potting material, but it can be flammable under the wrong circumstances. The oxygen available in the pot can permit decay to occur, causing heat that is amplified if the pot is in the sun. An article in the *Northumberland News* reported a house fire in June 2013 that was attributed to a pot with peat mosses on a second floor balcony. The deputy chief of the fire department said that the dry peat can easily ignite and can, after being in direct sunlight long enough, ignite by itself. This was not his first experience with flower beds on fire. His advice is to use non-combustible flower pots (not plastic), such as concrete or metal.

Covering Pot Soil

Sheet mosses are frequently used to cover the soil in pots housing flowering plants (Nelson & Carpenter 1965). This is especially true when they are sold by florists. Species of *Leucobryum* (not a sheet moss; Figure 35-Figure 36) can be used for this purpose, providing a pale green color contrast to the green of most tracheophyte leaves. In some cases, the strong anti-microbial properties of bryophytes might reduce invasions of bacteria and fungi.

Mat-forming mosses are typically sold as sheet mosses (Figure 45) (Peck *et al.* 2001). These are pleurocarpous mosses that grow horizontally, often on logs. Collectors strip the logs, and sometimes low branches, of their mats. In the eastern USA, one of the mosses used is *Thuidium* (Figure 46).

Figure 45. A package of sheet moss being sold in a gardening shop in Ohio, USA. Photo by Janice Glime.

Figure 46. *Thuidium* sheet moss, sold at a gardening shop in Ohio, USA. Photo by Janice Glime.

Culturing Mushrooms and Other Fungi

Sphagnum (Figure 1) peat is the substrate of choice as casing medium for cultivating the common grocery store mushroom, *Agaricus bisporus* (Figure 47) (Eicker & van Greuning 1989; Reddy & Patrick 1990; Jarial *et al.* 2005). (Casing is the process in which a non-nutritious layer, in this case peat, is applied over the colonized substrate so that the mycelium has access to more moisture, thereby increasing the size and number of growths.) Sungrow had a multi-million-dollar contract from Campbell (of Campbell soup fame) to improve mushroom culturing using a *Sphagnum* mix (Vitt, pers. comm.; Miller 1981). However, in places such as South Africa, where there is no peat, substitutes are necessary. The need for peat substitutes led Eicker and van Greuning (1989) to test other substrata and compare, but peat still gave the highest yields compared to eight other materials, with only weathered, spent compost offering similar results. Other types of mushrooms are grown in peat as well, such as *Pleurotus ostreatus* (Figure 48) (Manu-Tawiah & Martin 1986).

Figure 47. *Agaricus bisporus*, a species commonly grown in *Sphagnum*. Photo by I. G. Safonov, through Creative Commons.

Figure 48. *Pleurotus ostreatus* on a mossy tree trunk. This species can be cultivated in peat. Photo from Charl de Mille-Isles.

In an attempt to make further improvements in mushroom success, Beyer (1997) sought ways to reduce the effect of accumulated substances on late mushroom crops. Surprisingly, he found that the addition of *Hypnum* (Figure 15-Figure 16, Figure 24-Figure 25) peat to the compost improved later break yield, but the addition of *Sphagnum* (Figure 1) did not. One of the concerns is that the peat becomes infested with nematodes (Figure 49) and may carry *Pseudomonas tolaasii* (see Figure 50), the cause of bacterial blotch, both of which cause serious diseases to the mushrooms (Nikandrow *et al.* 1982).

Figure 49. Soil nematode, a common pest in *Sphagnum* that may carry the bacterium *Pseudomonas tolaasii*. Photo by Christina Menta, through Creative Commons.

Figure 50. *Pseudomonas*, a bacterium carried by soil nematodes. Photo by Janice Carr, through public domain.

Martin and Bailey (1983) succeeded in using peat as a fermentation medium in which acclimated fungi could be grown. They were more successful with the common mushroom *Agaricus campestris* (Figure 51) than with the morel *Morchella esculenta* (Figure 52) (Martin 1982). Martin and Bailey considered that growth inhibitors might be present in peat. Using sulfuric acid hydrolysates with autoclaved peat released a liquid that, when supplemented with nutrients, would enhance growth and crude protein content of these two edible fungi. Nutrient-supplemented peat hydrolysates enhance growth and crude protein content of fungal biomass.

Figure 51. *Agaricus campestris*, a species that grows well in a peat fermentation medium. Photo by Andreas Kunze, through Creative Commons.

Figure 52. *Morchella esculenta*, the common morel, can be cultured in a bed of peat. Photo by Janice Glime.

A mixture of *Sphagnum* (Figure 1) with fish offal promises to be a suitable substrate for culturing the acid-tolerant fungus *Scytalidium acidophilum* (see Figure 7), which is considered to be a promising source of microbial protein (Martin & Chintalapati 1990). However, not all fungal cultures seem to benefit from peat mixtures. In one commercial operation, the yield of mushrooms improved when the peat was omitted from the cultivation medium (Smith 1983).

Reforestation

The genus *Tulasnella* (Figure 21-Figure 22) is a mycorrhizal partner with several members of the thallose liverwort family *Aneuraceae* (Figure 21). If this fungus is likewise a partner with trees, then it should be possible to use those liverworts to help the trees to become established (Kreier 2003). In fact, *Cryptothallus* (Figure 21), a member of the *Aneuraceae*, shares its fungal partner with at least some members of the birch (*Betula*; Figure 53) and pine (*Pinus*; Figure 54) genera. Kreier found that both liverworts *Riccardia palmata* (Figure 55) and *R. latifrons* (Figure 56) grew on rotten wood and were well infected by

mycorrhizal fungi. Kreier also figured it would be relatively easy to disperse these liverworts on the forest floor, and that they would spread easily, preparing the soil with mycorrhizae that could partner with the trees. At that time, the fungi had been grown in culture but not the field. However, the discovery of rhizoidal bridges in tropical *Aneura* (**Aneuraceae**; Figure 57) provided a hopeful twist. In 2017, Oberwinkler *et al.* noted that *Tulasnella* species are worldwide in distribution and that they may occur in many forest ecosystems in association with wood. And we have already noted that they form mycorrhizal associations with orchids.

Container Gardens

Mosses are commonly used in container gardens with **bonsai** (dwarfed ornamental tree; Figure 58) and **bonkei** (tray landscape; Figure 59), where they help to stabilize the soil and retain moisture for the shallow roots.

Figure 58. Bonsai at Dawes Arboretum, Ohio, USA, showing dwarfed tree and mosses at base. Photo by Janice Glime.

Figure 59. Outdoor bonkei in a Japanese private garden. *Selaginella*, a relative of club mosses and not a true moss, is used to represent a tree, with mosses growing on the rocks that form the basin for a small "lake." Photo by Janice Glime.

Designers select the species of mosses to serve particular functions in the container landscapes. Large, upright mosses such as *Atrichum* (Figure 60), *Climacium* (Figure 61), *Dicranum* (Figure 4), *Polytrichum* (Figure 62), and *Rhodobryum* (Figure 63) simulate forests. *Bryum argenteum* (Figure 64) has a silvery, compact look that can simulate grasslands, and *Leucobryum* (Figure 27) usually has the role of a mountain. For snow-capped mountains, *Racomitrium canescens* (Figure 65) provides a frosted look. *Physcomitrium* (Figure 66-Figure 67), often a volunteer in greenhouse flower pots, is so miniature as to appear like a moss, or maybe a grass, in a landscape of *Leucobryum* mountains. *Barbula unguiculata* (Figure 68), *Funaria hygrometrica* (Figure 69), and *Weissia controversa* (Figure 70) can contribute to needs of intermediate size. In Mexico, some mosses are even used for fake bonsai: *Campylopus* (Figure 71), *Dendropogonella rufescens*, *Hypnum* (Figure 15-Figure 16, Figure 24-Figure 25, Figure 34), and *Thuidium* (Figure

18) (C. Delgadillo, pers. comm.). In the Pacific Northwest of North America, *Leptobryum pyriforme* (Figure 72), known as Kyoto moss, is sold for bonsai trays (J. Christy, pers. comm.). I would expect *Climacium* and *Polytrichum* to serve well as trees in miniature landscapes as well.

Bonkei

Miniature tray landscapes [bonkei or **saikei** (art of creating tray landscapes that combine miniature living trees with soil, rocks, water, and related vegetation); Figure 73- Figure 76] in Japan use mosses to provide appropriate texture and color with little danger of damage due to drying (Kawamoto 1980; Oishi 1981). Such trays can delight the bed-ridden. Gerritson (1928) arranged sixteen species of mosses in various stages of maturity to provide a changing landscape for a hospitalized friend: "Each day the mosses had changed appearance; so each day added a new joy. The nurses came from time to time to see and admire. Other patients shared its freshness and beauty. Visitors, too were invited to see the charm of a 'platter of mosses.'"

Figure 75. Bonkei simulating a volcano and surrounding mountains and forests. Photo courtesy of Hironori Deguchi.

Figure 76. *Selaginella* (a club moss relative) and moss bonsai, Kyushu, Japan. Photo by Janice Glime.

For making these miniature landscapes, Schenk (1997) recommends the usual potting mix of humus, including peat moss, ground-up tree bark, or rotted sawdust. He cautions that sand, vermiculite, or perlite can be used, but that they must be kept moist because they tend to have larger spaces and dry quickly near the surface, leaving the moss with no source of moisture.

Even in this seemingly harmless occupation, one must use caution against allergens. Tray gardens and other forms of bonsai and dish gardens may use *Sphagnum* (Figure 1) peat as a medium or even as the plants of interest (Figure 77). This moss is well known for its ability to harbor the fungus that causes sporotrichosis (Dong *et al.* 1995).

Figure 77. *Sphagnum* moss pot in Japan, a potential source of allergens. Photo courtesy of Hironori Deguchi.

Dish Gardens

Dish gardens (Figure 78) are a scaled down version of bonkei. The size may not be scaled down, but they typically do not represent a landscape and may have only one bryophyte species (Figure 78), sometimes as ground cover for flowering plants like spring bulbs (Figure 79).

Figure 78. Dish garden of moss. Photo courtesy of J. Paul Moore.

Figure 82. Children creating their first dish garden, under the tutelage of Annie Martin, MountainMoss. Photo courtesy of Annie Martin.

Figure 83. The proud owner of a new dish garden that she created. Photo courtesy of Annie Martin.

Similar to the dish gardens, moss rocks (Figure 84-Figure 85) have become popular in some places. These typically have a species of moss growing in a depression or on the surface of a rock.

Figure 84. *Dicranodontium denudatum* stone pots in shop in Hakone, Japan. These are a variation on the dish garden, but the mosses are grown on the surface or in a depression of a natural rock and typically have only one moss species. Photo courtesy of Hironori Deguchi.

Bonsai

The term **bonsai** (Figure 86) refers to a dwarfed ornamental tree or shrub grown in a pot and prevented from reaching its normal size. Inoue (1972) pointed out that moss bonsai and moss bonkei (tray landscapes) are popular in Japan by both amateurs and professional horticulturists. But even bonsai trees are potted in wide pots and the soil is typically covered with mosses (Figure 86-Figure 89).

Figure 86. Bonsai at Dawes Arboretum, Ohio, USA, showing the dwarfed tree and mosses at its base. Photo by Janice Glime.

Figure 88. Bonsai at Dawes Arboretum, Ohio, USA. This bonsai uses a deciduous tree, and bryophytes can warn its owner to water it before the leaves begin to drop or become crispy. Photo by Janice Glime.

Figure 89. Bonsai using the fern *Osmunda lancea*. Courtesy of Hironori Deguchi.

The mosses can contribute to the success of the bonsai. When the mosses appear dry, you can be sure your bonsai needs water (Figure 90-Figure 91). However, mosses are not always the friends of the bonsai. The continuous moisture of the mosses can inhibit root growth and promote sudden fungal attacks. The experts advise removing the mosses each autumn to reduce fungal damage (Bland 1971).

Figure 90. Bonsai in Dawes Arboretum, Ohio, USA. Mosses on the roots are a good indicator when the soil is becoming dry and the tree needs water. Photo by Janice Glime.

Figure 91. Bonsai on wood, increasing the need for bryophytes to maintain root moisture and warn when it is time to water it. Photo courtesy of Annie Martin, MountainMoss.

In India, bonsai is included in horticultural texts. Dhanda (1984) suggests that the bonsai may be finished off with a layer of moss on top (Figure 92). Yoshimura and Halford (1957) likewise consider the mosses growing around the bonsai to be important. The mosses provide several advantages. They add aesthetic appeal, creating a more natural looking landscape. And they make watering easier, permitting a raised base on the tree while catching the water and protecting the furniture.

Figure 92. Bonsai at Dawes Arboretum, Ohio, USA, illustrating mosses covering the pot and signalling when the tree roots need more water. Photo by Janice Glime.

In Malaysia, bonsai makers typically use the acrocarpous mosses *Bryum* (Figure 93) and *Philonotis* (Figure 94), and sometimes the pleurocarpous mosses *Isopterygium/Pseudotaxiphyllum* (Figure 95) and *Vesicularia* (Figure 39) and the thallose liverwort *Riccia* (Figure 96) (Tan 2003). In Singapore, the moss *Ochrobryum kurzianum* is imported from Thailand for ornamental use in bonsai arrangements. In Japan, *Leucobryum* (Figure 27) is common in bonsai landscape design.

Hanging Baskets

Mosses are often used in the construction of hanging baskets for flowers (Smith 1996). In California, USA, meter-long "strips" 8-10 cm wide are used to make hundreds of baskets per week!

In Asia, species of *Sphagnum* (Figure 1) are used to line hanging baskets (Tan 2003). Its ability to hold water and its antimicrobial activity make this a good substrate for the roots of flowering plants.

A wire frame is used to give the basket support, with mosses wound among the wires or laid within to provide the structure. Not only do they make an attractive, natural-looking basket, but they reduce the need for frequent watering (Lohr & Pearson-Mims 2001). Species of *Hypnum* (Figure 15-Figure 16, Figure 24-Figure 25, Figure 34) and *Sphagnum* (Figure 1) are commonly used for this purpose.

The long, stiff stems of *Polytrichum* (Figure 62) permitted the early Romans to weave it into baskets (Bland 1971), but these most likely did not have a horticultural purpose.

Terraria

The **terrarium**, a drier plant version of the aquarium, is often arranged like an enclosed garden (Figure 97), a miniature garden like the container gardens. Because of its small size, bryophytes are often used to give the look of mountains (Figure 98); dry brooks made of pebbles ramble between clumps of various hues of green. But bryophytes are not easy to grow in such conditions. If the container is fully open (Figure 98, Figure 99), mosses soon dry out and become crispy. If it is sealed (Figure 97, Figure 100-Figure 103), as many terraria are, fungi can easily grow. The best choice is to leave the top partially open to permit air circulation.

Figure 103. Tall moss terrarium that not only permits taller plants like ferns, but also provides more air space, reducing fungal takeover. Photo by Ken Gergle, through David Spain.

It seems appropriate to cite the first terrarium, known as the **Wardian case** (Figure 104), invented by Nathaniel Bagshaw Ward (1791-1868) (Hershey 1996). He had fallen in love with plants on a trip to Jamaica and despite ultimately pursuing a profession as a physician, he pursued plants through his attempts at gardening. But, sadly, his attempts at a moss and fern garden failed, due severe air pollution in the outskirts of London. It was this failure that led him to invent the Wardian case, or terrarium. He had placed a "chrysalis" (actually a moth pupa) in a bottle and observed it daily. Then, to his surprise, a "seedling" fern and a grass appeared. He considered the conditions and noted the need for "a moist atmosphere free from soot or other extraneous particles; light; heat; moisture; periods of rest; and change of air." He moved the bottle to the outside of a northern window and there the plants thrived for four years with no additional attention!

Figure 104. Wardian Case, similar to the first terrarium by Nathaniel Bagshaw Ward. Image through public domain.

Choice of mosses depends in part on how moist you intend to keep it and in part on the effect you want to achieve. *Polytrichum* (Figure 62) can survive in a somewhat dry terrarium but will easily be covered with mold when it is too damp. Likewise, *Leucobryum* (Figure 27) likes it airy with good circulation. *Ceratodon purpureus* (Figure 105) is sometimes successful, again requiring at least some air circulation. Schenk (1997) states, "I must tell the whole truth by identifying the great enemy of terrarium gardening with native woodlanders, for there is one: mold." He admonishes that most terraria have a short life due to this problem. My own experience certainly agrees.

Figure 105. *Ceratodon purpureus*, a species used in bonsai in Malaysia. Photo by Michael Lüth, with permission.

Funaria hygrometrica (Figure 69) can be encouraged in more moist conditions, but it still needs circulation. With a little luck it will even produce capsules. We successfully maintained *F. hygrometrica* in an uncovered aquarium in our university greenhouse. These lasted for several years, but we avoided getting tap water on them and only used misting from distilled water or tap water that had been allowed to sit to allow the chlorine to escape.

Schenk (1997) suggests that a container the size of an aquarium (Figure 106) is best, smaller ones being more subject to mold. Air space is of the essence, and it needs to circulate. He considers a potting mix to be suitable, whereas it does not tend to work well in open-air gardens. On the other hand, if the bryophytes have their own deep brown portions (Figure 107), no substrate is necessary. Charcoal may be added to the substrate to absorb excessive acidity and gases produced by decay. Little water is needed as it will recycle (Figure 108) within the nearly sealed container. Adding flowering plants can add color (Figure 109). Mosses that are collected wet generally do not need additional water and may even need to be dried by leaving the terrarium open wide for a day or two. Slightly dry mosses can be moistened with 30-35 ml (2-3 tablespoons) of water; totally dry ones may require up to 70 ml (1/4 cup) (Schenk 1997).

Figure 109. Mix of a variety of plants with color (red-leafed *Begonias*, pale *Tillandsias*) and rocks in kitchen terrarium built in an aquarium. Photo by Janice Glime.

Maintenance for the first few days after planting is essential to avoid an immediate mold attack. Schenk (1997) advises that if a heavy dew (Figure 108, Figure 110) appears on the walls of the container, open it and dry the walls. This should be repeated daily until morning brings only a light condensation on the upper half of the walls of the container. When you discover, probably in a few weeks, that there is no longer any morning dew, it is time to add water, but not much.

Figure 110. Terrarium with moss, showing severe condensation that must be removed by drying the walls or keeping the container open until it is gone. Photo by J. Paul Moore, with permission.

After all this care, Schenk (1997) warns that the terrarium will most likely last only three weeks! (I have had better success than that with larger aquaria.) That can be extended by providing fluorescent lights to avoid the etiolated growth so noticeable in low light. Nevertheless, a mold garden is most likely to ensue within this short time,

and great care and luck are needed to find the right wetting and drying cycle.

Within those first few weeks, a moss garden terrarium can be full of surprises, with mushrooms appearing, capsules extending, and the somewhat rapid but unnatural elongation of the moss stems in low light.

One of the contributors to the demise of the moss terrarium indoors is the warm temperatures night and day indoors. If there is a cool location for the terrarium, it might survive a longer display, and surely in the refrigerator it would last, but would be of little use, not to mention suffering from lack of light.

One last caution I would insert is that lichens are to be avoided if one wishes to maintain a moss terrarium for any length of time. In the moist conditions of confinement, they will soon spread their fungi broadly and overtake the moss, albeit no longer as lichens, but nevertheless encroaching rapidly upon the surfaces of green. If lichens are to be enjoyed in this terrarium, it must by all means be kept open and the mosses provided with water occasionally as needed, perhaps with dry periods, but not too frequently.

I was relieved to read this moss gardener's treatment of the terrarium. If such an expert as Schenk was able to maintain such a terrarium garden for only three weeks, I felt elated that I, too, had succeeded on occasion to maintain one for so long! In short, if you wish to maintain a terrarium of bryophytes for a lengthy period of time, my best advice to you is Good Luck!

Echoing the comments above, David Wagner (Bryonet 23 June 2013) suggested that the problem with terraria is that they are usually closed containers. He has observed mosses doing well for several years in an open water table where water flowed across the water table. This depends on water that is low in dissolved minerals and may require a filtering system on tap water. One danger in closed terraria, especially small ones, is that the enclosed humidity and lack of air movement encourages the growth of fungi and soon they take over.

Alison Downing (Bryonet 23 June 2013) reported success in growing bryophytes for display by using fish tanks for the mesic species. She attributed the success to using water from a garden pond, citing high levels of chlorine in tap water as a possible source of bryophyte collapse. Nevertheless, these bryophytes in the aquaria also have a limited life.

Ben Tan (Bryonet 23 June 2013) found that bryophytes transplanted to a closed terrarium usually survived from 6-18 months. Even on moss walls, the bryophytes needed complete replacement every two years to maintain aesthetic appeal. This is with no fertilizer, watered with tap water, in a fully air-conditioned room. Even *Bryum* (Figure 93) and *Hyophila* (Figure 111) last only about one year in a self-contained environment indoors with proper light and high humidity.

Alison Dibble (Bryonet June 2013) reports better success. She grows bryophytes on the windowsill all winter in small bonsai dishes. Others are in clear plastic boxes or a clear glass container with a loose-fitting lid. If the container is open, Dibble soaks the mosses in the sink once a week. In the summer she puts them outside under the overhang of a north-facing boulder and lets nature do the watering, but if there is a dry spell she waters them.

Using this method, she has kept one bottle of mosses, including *Sphagnum* (Figure 1), for more than three years. And even in a terrarium there is competition. Her *Saelania glaucescens* (Figure 112) had been growing well for five years, but *Mnium* (Figure 113) began to overtake it.

Figure 111, *Hyophila involuta*, in a genus that lasts about one year in a terrarium. Photo by Michael Lüth, with permission.

Figure 112. *Saelania glaucescens*, a moss that has survived a terrarium for five years, but that is being overtaken by *Mnium*. Photo by Janice Glime.

Figure 113. *Mnium marginatum* overgrowing other mosses, a problem it can cause in a terrarium. Photo by Jan-Peter Frahm, with permission.

Appropriate moisture levels are clearly a problem. Yoest (2011) suggests that if mosses and flowering plants or other tracheophytes are to co-exist, one must periodically remove the covering to water the tracheophytes. Keep the cover off for a day or two to allow excess water to escape. When you return the lid, check for condensation and vent the container until you achieve the right balance. In a dish garden or terrarium, proper drainage is needed, so putting pebbles on the bottom can help. Contrary to what most people might expect, the humidity level must be kept low. This condition can often be achieved by using a cover with a small opening at the top.

As an alternative, David Spain (in Yoest 2011) suggests removing the cover in the daytime and covering it at night. He has created a terrarium with a tall cover over a dish, using this routine. The terrarium has the fern ebony spleenwort (*Asplenium platyneuron*; Figure 114) and the mosses *Dicranum scoparium* (Figure 4), *Leucobryum glaucum* (Figure 27), *Hypnum imponens* (Figure 15-Figure 16), and *Campylopus introflexus* (Figure 71). (Be careful with the latter – it is an invasive species, so don't just throw it outside when you no longer want it.) Another of Spain's favorites is the moss *Climacium americanum* (Figure 115). Spain concludes that "mosses do not make ideal terrarium plants."

Figure 114. *Asplenium platyneuron*, a fern that survives in a terrarium that is opened daily and closed at night. Photo by F. B. Matos, through Creative Commons.

Figure 115. *Climacium americanum* with capsules in moss garden, a species that looks good in a terrarium. Photo by Janice Glime.

I have a large (40-gallon) terrarium with begonias, ferns, *Tillandsia*, and a few mosses (Figure 106). Like Spain and Yoest, when I water it, I leave the cover partially open for a few days until the excess water evaporates. Then I cover it and it will last about six months before it needs to be watered again. I have limited success with the mosses because they seem to produce weak stems and to become infected with fungi. Extra aeration helps to avoid fungi, but then more frequent watering is needed, at least for the tracheophytes.

Bryophytes as Pests

Sadly, bryophytes can even be considered to be pests in gardens and flower pots (e.g. Newby *et al.* 2007). Greenhouse managers are often dismayed at having the invasion of *Marchantia polymorpha* (Figure 116) in many of their flower pots. But it is their method of watering that distributes this liverwort everywhere. The heavy force of water from a hose propels the gemmae out of their cups and onto bare soil nearby. These liverworts often arrive in the greenhouse initially as free-loading passengers in flower pots of new flowers or ferns, either as plants or as gemmae. And the greenhouse satisfies their growing needs.

Figure 116. *Marchantia polymorpha* with gemmae cups. Gemmae are splashed about in greenhouses when plants are watered. Photo by David T. Holyoak, with permission.

Another species known throughout most of North America only in greenhouses is the thallose liverwort *Lunularia cruciata* (Figure 117). Like species of *Marchantia* (Figure 116), it produces gemma in cups, in this case crescent-shaped cups, and these likewise are easily dispersed by typical greenhouse watering methods.

Figure 117. *Lunularia cruciata* with gemmae cups and gemmae that are distributed with rain or watering in a greenhouse. Photo by Des Callaghan, with permission.

Other volunteers that I have observed include *Bryum* spp. (Figure 64, Figure 93), *Leptobryum pyriforme* (Figure 72), and *Ceratodon purpureus* (Figure 105). These are all mosses, with the latter two frequently producing numerous capsules and thus most likely spreading by spores. *Bryum argenteum* (Figure 64) has detachable terminal buds that will grow new plants. It is likely that it benefits in the same way as the gemmae of the two liverwort species.

A final caution is appropriate. Some bryophytes are invasive, although much less so than their flowering plant counterparts. Nevertheless, they can disrupt ecosystems, changing the success of seed germination, affecting the invertebrates that live there, and changing the hydrology. In addition to the ones that like to travel among flower pots, the most invasive and widespread of these are *Campylopus introflexus* (Figure 71), *Eurhynchium praelongum* (Figure 118), *Lunularia cruciata* (Figure 117), *Orthodontium lineare* (Figure 119), *Pseudoscleropodium purum* (Figure 120), and *Lophocolea semiteres* (Figure 121) (Essl *et al.* 2013; Mateo *et al.* 2015). Some of these have spread due to their use as packing material, especially for shipping plants in the horticultural industry.

Summary

Peat mosses have been widely used in horticulture as soil additives, and for bedding, as well as forming the foundation for topiary, wreaths, and hanging baskets. Their ability to add moisture makes them ideal as a shipping medium for plants.

Peat mosses are used as soil conditioners, providing a holding medium for nutrients, releasing them slowly following drying. They provide good compost, especially when mixed with such waste products as fish offal or sewage. Some peat mosses provide additional fixed nitrogen through their **Cyanobacteria** flora. Their antibiotic properties discourage damping-off fungal growth while maintaining moisture. These same properties make them good for air layering. All of these properties make peat mosses good culture media and potting mixes, but other relatively dense mosses work well also.

Peat mosses have been used in forestry to culture young seedlings and in the food industry to culture mushrooms and morels.

Small mosses work well in container gardens such as bonsai and bonkei, where various species are used to simulate different aspects of miniature landscapes. Terraria are more difficult, with mold being a frequent problem. Aeration is important, as is the choice of mosses.

Some species are pests in greenhouses, sometimes being dispersed as gemmae. The watering techniques make gemmae and other detachable parts airborne.

Acknowledgments

Thank you to Michael Richardson for sending the story on fire in a flower pot to Bryonet.

CHAPTER 7-2

GARDENING: JAPANESE MOSS GARDENS

Figure 1. Kyoto Gold Temple moss garden in fall. Photo courtesy of Leng Yang.

Moss Gardens

It is the end of a hectic week and your mind is racing between projects nagging to be finished before another set entreats you. The afternoon hour is late and Friday traffic winds about you in the fury to be somewhere else. Children shout and horns warn of impending danger, or just impatience. You turn the corner and park in the only remaining spot next to the shrouded garden. The Japanese have taught us how to construct a fence that deflects the city's clamor, creating a refuge from the turmoil that bombards our daily lives. But within that fence, in the midst of the city, is a garden – a moss garden. Barely 50 meters on a side, the garden is a far away and peaceful world. Here all seems to melt away as the soft mountains in the distance, created by gentle hills of moss, blend into the quiet fields of green before us. At last we can relax. In such a setting, we can reflect on all that is beautiful and calm.

For the caretaker of this garden, be it large or small, it certainly requires an understanding of mosses in all their ecological and physiological glory. Although the Japanese have been successful for centuries, moss gardening is no small challenge.

Japanese Moss Gardens

Perhaps originating in their present usage during Japan's feudal era (12th-19th centuries), mosses have become a part of Japanese tradition (Schenk 1997). In Japanese, *koke* means moss and *dera* means temple, hence the name of the moss temple *kokedera* (Figure 1). However, as far back as a thousand years ago the Zen Buddhist monks wrote of the mosses in their temple gardens. Yet the rest of the world is just beginning to understand and copy the tranquility of the moss garden.

Bryophytes have always been greatly appreciated as a precious attribute in Japanese gardens (Figure 1). Some of the Japanese gardens are known from as early as the 7th

century A.D. (Seike *et al.* 1980). The earliest of these were based on the T'ang China gardens, but they soon developed their own character, resembling the Japanese landscape. The theme generally reflects the Japanese religion of Shinto, wherein the world is viewed as "infused with the primeval forces of creation" (Seike *et al.* 1980).

By the fifteenth and sixteenth centuries, the scale of the gardens was smaller, opening the way for miniature plants such as bryophytes to provide the feeling of expanse. Natural features such as ponds and waterfalls were represented by stone and gravel (Figure 2). Unlike gardens throughout most of the world, the Japanese garden is ruled by simplicity. Following this theme of tranquility, the garden must not appear manicured, but rather must maintain a natural look, as in Figure 3. For this reason, as the gardens became the setting for the tea ceremony, they also continued this tradition of a natural look. To avoid the austerity of too much care, the Tea Masters considered the most appropriate caretakers to be old men (Figure 4) and boys who would not be too painstaking in their care to sweep and clean the garden. Having leaves tucked among the rocks or at the bases of trees provides interest (A. L. Sadler in Seike *et al.* 1980).

Figure 2. This moss is interrupted by a sand garden at Ginkakuji, Kyoto, Japan. This sand resembles a river and the rock an island. Photo by Janice Glime.

Figure 3. Ginkakuji Silver Temple Moss Garden with *Polytrichum* in Kyoto, Japan. Stones give the sense of boulders, giving the feeling of mountain crags, adding focus and depth. Photo by Janice Glime.

Public gardens often have a gate at the entrance. Even these offer serenity and often have bryophytes growing on the roof of the gate (Figure 5). The gate gives one the impression of shutting out the world of work, noise, and traffic.

Figure 4. Ginkakuji moss gardener using a broom to clean leaves from the moss garden. Photo by Janice Glime.

Figure 5. Kyoto gold temple with mosses growing on the entrance gate. Photo courtesy of Leng Yang.

Courtyard gardens (Figure 6-Figure 7) are small and provide a relaxing view from a window or doorway. Generally only a few plants provide highlights to an arrangement of gravel and rocks. Mosses may be used here to make a green layer on the ground, or may be islands in a bed of gravel (Figure 8) that simulates the sea or a pond (Seike *et al.* 1980). In even larger courtyards and many moss gardens, the pond may be real, with koi swimming about (Figure 9).

Figure 9. Shrine and pond with koi in Kyoto, Japan. Photo by Janice Glime.

Sand is used in many of the gardens. It is always well kept, often raked with the ridges of raking forming various designs (Figure 10-Figure 12). Some of these simulate a lake with islands and mountains (Figure 10). In other cases, the mosses surround a gravel bed shaped to resemble a lake (Figure 11). The mosses are not arranged in rectangular plots so common to western gardens, but rather typically follow a circular theme. Species of *Polytrichum* (Figure 12) are often used for these islands to break up the bright appearance of the sand (Saito 1980).

Figure 10. Tofukuji Garden bordered with mosses. The raked sand and moss islands give the illusion of a lake with mountains. Photo from Wikimedia Commons.

Figure 11. Rosan-ji garden, Kyoto, Japan, showing gravel with islands of mosses. Photo from Wikimedia Commons.

Figure 12. Tofuku-ji hojyo, a sand garden surrounded with *Polytrichum*. Photo from Wikimedia Commons.

A path of stones may meander (Figure 13) through the gravel or across the moss bed and is often not straight or even direct. Even the straight paths give a sense of meander by mixing large and small stones (Figure 14) or making sure 4 corners never meet (Seike *et al.* 1980). Small stone or wooden bridges (Figure 15) may cross the gravel bed in somewhat larger courtyards, and generally a stone or iron lamp such as the one seen in Figure 16-Figure 17 provides the soft light of a candle or merely a point of interest. Other common objects in the moss and temple gardens are a small pagoda, often made of stone (Figure

18) or a basin for washing one's hands (Figure 19-Figure 20). A small garden, such as most courtyard gardens, will typically have a single plant or one of the above objects as its point of focus.

Figure 20. Kenroku-en garden stone water basin in a moss garden in Japan. Note the natural appearance of the basin. It is likely that the leaf was added as a touch of nature and to add a spot of color. Photo from Wikimedia Commons.

Among the larger gardens, one may see, instead of mosses mimicking the mountains, that shrubs mimic the mosses (Figure 21). In these gardens, the shrubs are cut into rounded forms that look like moss-covered rocks, cascading down a hillside, and sometimes with a small stream or waterfall in their midst. Waterfalls are common in the larger gardens, but occasionally even in very small ones (Figure 22-Figure 24).

Figure 24. Even this tiny restaurant garden in Nagoya, Japan has a waterfall. This is a restful view outside your window while you eat. Photo by Janice Glime.

Many attractive moss gardens are seen in Kyoto, the ancient capital city of Japan, where the surrounding mountains ensure constant humidity, and prolonged summer rainy seasons favor growth and survival of the mosses. Perhaps the most popular Kokedera, or Moss Temple, is the Koinzan Saihoji Temple (Figure 21) located at the foot of Mt. Koinzan in the west of Kyoto City. There are 92 different species there, each with its own required environmental conditions (Figure 25).

Figure 25. Hill and pond garden in Koinzan Saihoji Temple garden in Kyoto, Japan, with *Polytrichum* in the foreground and several other bryophyte species. Photo by Janice Glime.

Types of Japanese Moss Gardens

Generally there are three types of Japanese moss gardens: the flat garden (Figure 26) "for contemplation and meditation," the Tea Ceremony garden (Figure 27-Figure 28) that must convey the feeling of simplicity and seclusion, and both the oldest and most widely appreciated – the hill and pond garden (Figure 29-Figure 31). A roofed courtyard or indoor garden may provide a tea table and cushions for a tea ceremony. The hill and pond gardens resemble the natural landscapes of Japan in simplified form (Avery 1966). They may have bridges, often not straight (Figure 32), forcing the visitor to walk slowly and enjoy the garden. The use of rocks to portray mountains or add a focus point (Figure 33), ponds as oceans or lakes (Figure 25), and bryophytes as the foliage are the essence of traditional Japanese gardens where flowers, *per se*, are of lesser importance; a green garden, unlike ephemeral flowers, symbolizes long life and offers a place for relaxation and contemplation. In sharp contrast to the myriad of colors and shapes in a traditional American or European garden, the moss garden allures with its subtle shades of green, accented here and there with a rock or group of rocks (Figure 34), a bamboo fountain (Figure 35), a lamp (Figure 36), or an occasional small flowering shrub (Figure 37).

Imagine yourself sitting alone in a Japanese spa perched near the top of a mountainside overlooking a green valley untouched by habitation. On every side of the valley are mountains and boulders – as far as you can see. All is peaceful and you are able to relax your eyes and your body. Thousands of Japanese seek just such retreats every year to take them away from the stresses of daily life. Among the most ancient uses of mosses that has persisted into modern life is the design of moss gardens to create that same feeling of distance, lack of commercial clutter, and tranquility of spirit. By using rocks and tiny plants such as mosses, the Japanese create in miniature those scenes that they crave in nature. Even in the space of a few feet in a dooryard or window garden in a city, they often create such an illusion of distant mountains, dry stream beds, and green forests (Figure 38). The Japanese Zen scholars have philosophical ideas about landscapes, and about simplicity and repose, which they try to express in their traditional gardens (Fletcher 1991). While the space in the gardens is usually small, they may try to create an atmosphere of being deep within the mountains and provide a feeling of tranquility. Japanese gardening is not a mere imitation of nature; perhaps "borrowed scenery" is a more appropriate description (Avery 1966) for the attempt to alleviate the drabness of city life. Contemporary Zen scholars contend that many such gardens represent the best in abstract art (Avery 1966).

Figure 38. This tiny moss garden with a waterfall can be seen through a guest window in a restaurant in Nagoya, Japan. *Platyhypnidium riparioides* is in the water and *Philonotis falcata* is at the edge. Photo by Janice Glime.

Even bowls (Figure 39) and other objects in the gardens are likely to be covered in mosses, softening the lines and giving a quiet, cool appearance.

Figure 39. This moss-bearing basin is in a city park in Nagoya, Japan. Photo by Janice Glime.

Dangers to Gardens

These ancient gardens suffer new dangers in our modern society. Kyoto is the city of moss gardens (Figure 40-Figure 56), especially temple gardens. But even restaurants and private residences share in the serenity with their own small gardens. Aside from the effects of trampling from the ever-increasing population of visitors, the fumes of cars and busses have taken their toll. The pollution from these visitor vehicles has forced the closing of Saihoji in Kyoto to the casual visitor, requiring reservations in advance and forcing visitors to park at the bottom of the hill and walk up to avoid further damage from air pollution.

Figure 40. This moss garden in Kyoto, Japan, has a single species to emphasize its tranquility. Photo by Janice Glime.

Figure 50. This moss garden at Ginkakuji (Silver Temple) garden in Kyoto, Japan, maintains a natural look. Photo by Janice Glime.

Educational Gardens

One unusual feature at the Ginkakuji (Silver Temple) garden in Kyoto is that it attempts to teach the public about the mosses. In Japan, each species has a Japanese name, and like birds and flowering plants, mosses are known by these names. However, the bryologists know both the scientific names and Japanese names of the mosses. The displays of mosses provide an explanation of their utility to the gardens, showing the most important species (Figure 51, Figure 52). The "interrupter" mosses are "undesirable" mosses that must be weeded out (Figure 53). Among these are non-weedy things, but nevertheless undesirable ones, often for aesthetic reasons. To our surprise, this included *Andreaea* (Figure 54) because of its nearly black (and undesirable) color. Heinjo During, with the help of his students, attempted to interpret the Japanese names into their proper Latin ones, giving us a list of important temple garden species (Figure 55).

Figure 51. This educational display is labelled VIP mosses. Each is labelled with its Japanese name. These VIP mosses are among the most important ones in the moss garden at the Ginkakuji Temple in Kyoto. Photo courtesy of Onno Muller.

Figure 52. These mosses, also on educational display at the Ginkakuji Temple, are normal inhabitants of the Ginkakuji garden. Photo courtesy of Onno Muller.

Figure 53. This educational display is labelled "the Interrupter Mosses." These are weedy mosses that must be pulled from the gardens to permit the others to survive. Apparently they "interrupt" the tranquility. Photo courtesy of Onno Muller.

Variations

We must not forget that the Japanese are also creative. While they appreciate the calm of a garden, they do not restrict themselves to the purity of the three garden types mentioned above. The following images illustrate some of that diversity (Figure 57-Figure 63).

Figure 57. Tōfuku-ji, Kyoto, Japan. This formal pattern looks like a mix of western and Japanese design. Photo from Wikimedia Commons.

Figure 63. The mosses in this Japanese garden near Columbus, Ohio, USA, do not quite reach the restful landscape achieved in most of the Japanese gardens. This may be partly due to the lack of a rainy season and the land-bound location. Photo by Janice Glime.

Charcoal Gardens

Nancy Church provided me with images of the charcoal gardens (Figure 64-Figure 66) in which moss gardeners used charcoal, providing highlights. The small black pieces with lines are charcoal, a feature that Nancy considered to be beautiful and amazing.

Figure 65. Japanese charcoal and moss garden. Photo by Amy Laudenslager, through Nancy Church.

Figure 66. Japanese charcoal and moss gardens. Photo by Amy Laudenslager, through Nancy Church.

Dominant Species

Although many species are used, a few dominate the gardens, especially the private gardens. One of the most common is *Polytrichum* (Figure 67-Figure 71). This is most likely because it does well in the conditions of the garden and is easier to transplant than most (personal experience). *Leucobryum* (Figure 72-Figure 74) is used frequently, despite its narrower requirements (it seems to be a problem to cultivate in the USA according to my friends and my own experience). Perhaps the Japanese species are easier to grow than ours. But its endearing quality is its beautiful, pale cushions. It creates a restful landscape.

Figure 73. *Leucobryum juniperoideum* at moss temple in Kyoto, Japan. Photo courtesy of Zen Iwatsuki.

Figure 74. *Leucobryum* in a temple garden in Japan. Photo by Janice Glime.

At a plantation preparing for the sale of bryophytes for gardens, the thallose liverwort *Riccia* (Figure 75) was cultured. It has the advantage of being able to withstand dry conditions for long periods, then wake up during the rainy season. But I must admit to finding none of it in the gardens I saw. It does not give the restful look of the two mosses mentioned above.

Summary

Moss gardens are known for their serenity, emphasizing simple shades of green with only occasional color from shrubs or other flowers. Mosses are used to miniaturize the landscape, giving the feeling of distance. They have been a part of Japanese tradition since the feudal era.

There are three basic types of Japanese moss gardens: flat gardens, Tea Ceremony gardens, and pool and mountain gardens. In addition, sand gardens are often combined with moss gardens, often simulating lakes or streams. A number of variants exist, including the charcoal garden.

Even private homes, restaurants, and other shopkeepers maintain small moss gardens, especially where they can be viewed from within the building. The greatest number of moss gardens is in the city of Kyoto. The primary mosses used are species of *Polytrichum* and *Leucobryum*, but some gardens have nearly 100 species.

Acknowledgments

Heinjo During kindly sent me the pictures and gained the permission for me to use the educational pictures taken by his student, Onno Muller, illustrating the educational displays at the gardens at Ginkakuji, Kyoto, Japan. He and his students translated the Japanese names into the Latin names.

CHAPTER 7-3

GARDENING: PRIVATE MOSS GARDENS

Figure 1. This is a large private moss garden in Nagoya, Japan, using boulders to add interest. Photo by Janice Glime.

Private Gardens

Private gardens are gaining popularity in the USA (Dunn 2008; Martin 2008; Cullina 2009). You know moss gardens are coming of age when an article appears in the *New York Times* (see Tortorella 2014). Garden journals give advice on establishment and care of moss gardens. But what works in one part of the world may not work in another, and that is true within countries as well. Watering instructions and species choice must be in tune with local climate, light, available bryophytes, and competing species.

In Japan, even tiny spaces a meter wide by three meters long are used for a garden. It may be a vegetable garden, but often it is a moss garden with a few tracheophyte highlights (Figure 1). Such private gardens give their owners a sense of space and tranquility (Figure 2). Mosses are particularly enjoyed because they miniaturize the landscape and give a feeling of looking into the distance (Figure 3-Figure 9). Cushions of *Leucobryum* (Figure 10) can resemble distant mountains. *Polytrichum* (Figure 11) can simulate a forest. *Hypnum imponens* (Figure 12), a common "sheet moss" sold for decorative purposes, is used to "fill nooks and crannies" (Cullina

2008). Small mosses in the foreground provide the open fields. Pebbles become boulders.

Smith *et al.* (2010) summarized the role of residential gardens in preserving biodiversity in urban areas. But bryophytes are typically neglected in such studies. In their studies of 61 domestic gardens in Sheffield, UK, they found 67 bryophyte taxa and 77 lichen taxa. The individual gardens supported growth of 3 to 24 bryophyte species each, with a mean richness of 11.3 species. Of these, 14 species occurred in lawns. About one quarter of the species occurred in only one garden. Only 10% of the species occurred in more than half the gardens. The richness of species correlated with garden area (correlated with substrate richness) and altitude. Species present in 20 or more of the 61 gardens were *Amblystegium serpens* (Figure 13; 31 spp), *Barbula convoluta* (Figure 14; 30 spp), *Barbula unguiculata* (Figure 63; 22), *Brachythecium rutabulum* (Figure 15; 55 spp), *Bryum argenteum* (Figure 16; 21 spp), *Ceratodon purpureus* (Figure 45-Figure 46; 42 spp), *Didymodon insulanus* (Figure 17; 27 spp), *Funaria hygrometrica* (Figure 18; 23 spp), *Kindbergia praelonga* (Figure 19; 56 spp), *Ptychostomum capillare* (Figure 20; 37 spp), *Rhynchostegium confertum* (Figure 21; 32 spp), *Rhytidiadelphus squarrosus* (Figure 22; 23 spp), and *Tortula muralis* (Figure 23; 35 spp).

Making Your Garden

Private moss gardens are common in Japan (Pullar 1966/1967; Inoue 1980), but elsewhere they are rare. In Chatsworth, Great Britain, there is a moss and lichen garden of 33 moss and 4 liverwort species, including such common taxa as *Dicranella heteromalla* (Figure 24-Figure 25), *Dicranum scoparium* (Figure 26), *Hylocomium splendens* (Figure 27), *Neckera crispa* (Figure 28), *Plagiomnium undulatum* (Figure 29), *Polytrichum commune* (Figure 30), *P. piliferum* (Figure 31-Figure 32), *Rhizomnium punctatum* (Figure 33-Figure 34), and *Thamnobryum alopecurum* (Figure 35) (Ando 1972). And where else but at the home of a poet – we find cushions of *Polytrichum commune* adorning the gardens of Poet Laureate W. Wordsworth.

In the Netherlands, a Japanese garden at the estate of Clingendael has become a moss garden. It sports several locally rare species [the leafy liverworts *Odontoschisma denudatum* (Figure 36) and *Plagiochila asplenoides* (Figure 37)] among its 57 taxa. Schoenmakers (1985) speculates that several of the species that are restricted to paths are the inadvertent contributions of visitors.

Mossery

In the 19th Century, a number of British and Americans joined the fad of moss collecting (Wikipedia 2017). This interest led to the establishment of mosseries in a number of both British and American gardens. Mosseries are typically made with slatted wood, with a flat roof. They are open to the north, permitting the entrance of light while maintaining shade. Moss samples were installed in the cracks between the wooden slats. Regular moistening of the entire structure helped to maintain growth.

Garden Variety

In the United States, mosses are being used as a means of exploring new garden themes (Massie 1996). A number of web sites give instructions for planting moss gardens, often supplying pictures of very small ones to the large ones of Japan. Even in the highly settled New Jersey, one anthropologist maintains an entire acre of moss (Whiteside 1987). And the prestigious journal *Horticulture* sports one article titled "Even a rolling stone could get some moss here" (Atkinson 1990).

In spite of the presence of moss gardens in the United States at least as early as the 1930's (at Cutting Estate, Great River, Long Island, N.Y.; Grout 1931), few suppliers provide a selection of mosses. Atkinson (1990) complained that when inquiring of the editor of a horticulture magazine where one could obtain mosses for gardens he was referred to Carolina Biological Supply! Nevertheless, more recently a quick search on the web revealed several sources for *Atrichum* (Figure 38), *Callicladium* (Figure 39), *Dicranum scoparium* (Figure 26), *Campylopus* (Figure 40), *Hypnum imponens* (Figure 12), *Thuidium delicatulum* (Figure 41), *Leucobryum* (Figure 10), *Climacium dendroides* (Figure 42), *Dicranella heteromalla* (Figure 24-Figure 25), and *Plagiomnium cuspidatum* (Figure 43). One site sold sheet moss that had been cleaned, spread on a backing, glued down, and dyed green! No, thank you! Another source offers a complete garden, including 400 sq feet of moss, for \$US 399.99.

Seasons

To maintain variations in color through the growing season, one needs to pay attention to the phenological

changes among the mosses, just as in planting a flower garden. This can provide highlights in different places as the garden changes through the growing season.

Mosses have life cycles that change their appearance. Spring is a typical season for the production of antheridial splash cups. In some species these are reddish (Figure 31); in others, especially splash platforms, they are green, but look like green flowers (Figure 44). Others have colorful setae (Figure 45, Figure 47) and capsules (Figure 46-Figure 48), and these can appear throughout the summer and autumn, depending on the species.

Figure 44. *Rhizomnium punctatum* males showing splash platforms that look like green flowers. Photo by Michael Lüth, with permission.

Figure 47. Moss with ice on capsules, showing colorful setae even in early winter. Photo by J. Paul Moore, with permission.

Figure 48. *Pottia lanceolata* with contrasting capsule color. Photo by Michael Lüth, with permission.

Water Gardens

Many bryophytes like a damp habitat (Figure 49). And some of these habitats are very poor in nutrients. Hence, the bryophytes are naturals for water gardens (Figure 50- Figure 51) (Freiland 2017).

Among the many aquatic species, one of the best for a garden is *Philonotis fontana* (Figure 52). It has a fresh, pale green color and tolerates partial submersion or soggy ground.

Figure 49. Water garden and moss where a pipe has been repurposed for creating a garden. Photo from pxhere, through Creative Commons.

Figure 51. Water garden with mosses on rocks. Photo from pxhere, through Creative Commons.

Figure 52. *Philonotis fontana* with capsules, a suitable moss for water gardens. Photo by Michael Lüth, with permission.

Bog Garden

Gardeners such as Case (1994) have found *Sphagnum* (Figure 53) bog gardens to be a viable alternative in the Great Lakes area, avoiding high maintenance problems of woodland species unsuited for residential living. These require special conditions devoid of limestone rock and chlorine.

The RaisingRarities website <<http://raisingrarities.com/bog-garden/>> provides instructions for preparing a bog garden. The pond is excavated and a pond liner is used to cover the shape (Figure 54). It can have a pool attached, as in the diagram, but will require a shallow section for the bog (Figure 55). The lining at the lip of the bog area keeps sand from entering the deeper pool and should go up the bog side of the stones and under them (Figure 56). The bog shelf should be filled 2.5-5 cm deep with pure silica sand. Plant *Sphagnum* (Figure 53) on the bog shelf and fill the entire shelf with it. Pitcher plants and sundews can be added for

interest, planted among the *Sphagnum*. Collect rainwater and use it to keep the pond and bog at a constant level.

My Personal Garden

For my own moss garden, I managed to rescue *Marchantia polymorpha* (Figure 57; with gemmae cups) that was being overtaken by lawn grass on the university campus. It started as a small clump, but one day only a few weeks later I found tiny grey-green specks all over my bare soil (I was just starting the garden). On closer inspection, I found these to be germinating gemmae – the liverwort had spread all over the bare surface and was invading my dying *Leucobryum* (Figure 10) cushion as well. By the second year, I had several forests of archegoniophores (Figure 58), but it seems I didn't get any males.

Figure 57. My moss garden initially had a small patch of *Marchantia polymorpha*, about 10 cm in diameter. Within a month, it spread by gemmae, extending about a half meter in each direction. Photo by Michael Lüth, with permission.

Figure 58. The second year these *Marchantia* plants produced archegoniophores in abundance. After a few years, I had to remove some of the *Marchantia* to provide space for mosses. Photo by Janice Glime.

Added to that were *Fissidens* (Figure 59), *Brachythecium* (Figure 60), *Climacium dendroides* (Figure 42), *Dicranum scoparium* (Figure 26)), *Leucobryum glaucum* (Figure 10), *Plagiomnium cuspidatum* (Figure 43), *Polytrichum juniperinum* (Figure 61), *Rhytidiadelphus triquetris* (Figure 62), *Barbula* (Figure 63), *Thuidium delicatulum* (Figure 41), and *Ceratodon purpureus* (Figure 45-Figure 46) that I was able to collect locally, mostly in places where they were doomed to be overgrown or destroyed by traffic. Of these, *Fissidens*, *Plagiomnium cuspidatum*, and *Thuidium delicatulum* (Figure 41) were the most successful.

Figure 59. *Fissidens taxifolius* with capsules; some species of *Fissidens* grow easily in moss gardens in North America. Photo by Keith Bowman, with permission.

Figure 60. *Brachythecium salebrosum*, a species that can occur in large mats usable for moss gardens. Photo by Michael Lüth, with permission.

Figure 61. *Polytrichum juniperinum* with capsules in moss garden in Michigan, USA. Photo by Janice Glime.

Figure 62. *Rhytidiadelphus triquetrus*, a species that often grows well in moss gardens in North America. Photo by Janice Glime.

Figure 63. *Barbula unguiculata*, a hardy species that adds a contrasting color in the moss garden, preferring a sunny site. Photo by Michael Lüth, with permission.

The *Leucobryum glaucum* (Figure 10) was a gift from a friend, and it fared well the first year. It looked bad when winter ended and stains of tannic acid from leaf litter discolored it. It survived, but not well, so the next year I made sure it was not covered with litter for the winter, but it did not make it. I replaced it with a really nice hummock of *L. glaucum*. This time I put it on a bed of pine needles, a substrate it often has in nature. But it wasn't long before the chipmunks decided that made a nice entrance to their tunnel.

Some night-active animal also tore up all the *Dicranum scoparium* (Figure 26) and *Thuidium delicatulum* (Figure 41) the first night, and once dismembered from their normal growth habit, both failed to thrive. However, later introductions have survived winter and both have produced new growth, so there is hope. Some rodent decided that the *Thuidium* patch was the best place to enter its underground passage, but I seem to have thwarted that hole by stepping on it and filling it in. Alas, now there is a hole in the *Polytrichum* patch.

Most of the *Polytrichum juniperinum* (Figure 61) is doing fine (Figure 64). It is only the large patch that didn't have good structural integrity that looks like a fallen forest. But even there a few die-hards are putting up new shoots.

Figure 64. My personal moss garden, when it was about three years old, in Houghton, Michigan, USA. Photo by Janice Glime.

The real winners [*Marchantia* (Figure 57-Figure 58) aside] are *Fissidens* (Figure 59) and *Plagiomnium cuspidatum* (Figure 43), with the latter looking a luscious bright green. To my surprise, the *Rhytidiadelphus triquetrus* (Figure 62) did well, whereas *Hylocomium splendens* (Figure 27) didn't like its transplant at all. One patch of *Climacium dendroides* (Figure 42) had mostly brown plants with a few new green shoots arising, but the second patch eventually sprang to life, producing a solid cushion of plants of a most vital green. The old, weedy *Ceratodon purpureus* (Figure 45) seems not to like my gardens much and disappears rather rapidly.

A new patch of the liverwort *Conocephalum conicum* (Figure 65) seems to be doing well. It, and *Fissidens* (Figure 59), also fared well in my indoor garden. That is, they fared well until the birds ate the *Conocephalum*. I found it with triangular cuts around the edge. Each day it grew smaller until it disappeared. The *Fissidens* diminished and ultimately disappeared after the box turtle died. Apparently the turtle had been an effective dispersal agent for both species because they kept appearing in new places until after the turtle died.

Figure 65. *Conocephalum conicum*, a rock and soil dweller that adds interesting texture to a moss garden. Photo by Robert Klips, with permission.

I attribute my success, after several failures, to the installation of a sprinkling system. It comes on about 4 am for 20 minutes each night. (We usually don't get much rain in spring or summer.) That makes it hydrated and ready to

take advantage of the cool morning sun. It seems to have made all the difference.

I have learned that leaf litter apparently creates more problems than just deprivation of light during the growing season. The tannic acid seems detrimental to several species, because even when I remove the litter the day the snow retreats from its surface, the mosses that were covered with it seem to have suffered. When I removed most of the leaves before winter, the mosses seemed to fare much better.

Mountain Moss Enterprises

The Mountain Moss Enterprises is located near Revard, North Carolina, USA, and is owned by Annie Martin. Known as Mossin' Annie, this entrepreneur has dedicated her life to rescuing bryophytes that are in the path of destruction due to construction or other human activities. These mosses she either plants in one of her many projects, both public and private, or in her own garden where she cares for them until they meet their destiny in a moss garden somewhere.

One of the frequent sources of her bryophytes is from overgrown blacktop. This seemingly unlikely habitat can be a good source for large patches of bryophytes that come in large sheets. Others come from roofs where the owners are convinced they are harmful.

Martin lives in an area of the Appalachians that receives 150-200 cm rainfall per year (Tortorella 2014). Nevertheless, she waters her moss gardens three times each day. She claims that with 3-4 minutes of supplemental water per day the mosses will grow year-round in "nearly any temperature." (I can't imagine that watering when they are under snow is helpful. It would most likely create ice that could actually dry them out more.)

Mosses can dry out or freeze, and easily survive, green up when once again getting wet, but during that dry period they don't look nice. This ability to dry makes them easy to ship, so the distance to a moss supplier is not a real problem. But obtaining mosses from elsewhere does present ecological problems. In addition to the raping of the landscape by some moss collectors, it introduces non-native species.

Martin makes a variety of designs in her gardens, sometimes using differences in colors of leaves to create designs (Figure 66). In other cases, she may use colorful lichens (Figure 67) or furniture to create highlights (Figure 68).

Figure 66. Moss garden at Mountain Moss Enterprises, Pisgah Forest, North Carolina, USA, August 2009. Photo by Annie Martin.

Figure 67. MountainMoss Enterprises moss arrangement with red cap lichens, *Cladonia* sp. Photo courtesy of Annie Martin.

Figure 68. Mossin' Annie garden in snow, showing the green of the mosses, even in winter. Photo courtesy of Annie Martin.

Annie Martin (pers. comm. 31 January 2010) received a grant to explore the cultivation of mosses as a cash crop to replace declining tobacco farms. This study involved a partnership of NC Cooperative Extension, Rural Advancement foundation International-USA, and the NC Tobacco Trust Fund Commission which provided the funding. Martin was able to explore various propagation techniques.

Martin points out that moss cultivation requires far less time, labor, and equipment for both maintenance and harvesting compared to tobacco farming. Start-up money is likewise far less for establishing mosses. Maintenance costs are limited to labor and watering, requiring no chemicals, no fertilizers, no pesticides, and no herbicides. This eliminates the pollution of groundwater that is typical of agriculture. On the other hand, the mosses in the Southeast can be harvested any time of year, with their productivity measured in square feet.

Moss and Stone Gardens

David Spain is the owner of Moss and Stone Gardens in Raleigh, North Carolina, USA (Tortorella 2014). Spain presented moss gardening on the Martha Stewart Show, reporting that "she was a big moss fanatic." Spain recounts his early attempts to grow mosses, bemoaning the lack of teachers or sources appropriate for the area. One of these early attempts, following online advice, was to make a mix of mosses in a blender with buttermilk. This slurry was

painted onto rocks or soil. Instead of a moss garden, he got a mold garden. His garden designs tend to mimic nature (Figure 96-Figure 98).

Dale Sievert's Garden

Dale Sievert is a landscape gardener in Wisconsin. He became enamored with mosses and now his property is adorned with 60 species of bryophytes. Some of these species arrived by themselves. Among the more common ones in the garden are *Bryum caespitium* (a widespread species; Figure 70), *Thuidium delicatulum* (a species that spreads rapidly; Figure 71), *Rhodobryum ontariense* (an interesting species that resembles miniature palm trees; Figure 72), *Plagiomnium cuspidatum* (a species that commonly volunteers; Figure 73), *Leucobryum glaucum* (a cushion moss that prefers acidic soil; Figure 75), and *Anomodon rostratus* (a very common species locally and in his garden; Figure 87).

Figure 70. *Bryum caespitium* forming intriguing hummocks among the rocks. Photo courtesy of Dale Sievert.

Figure 71. *Thuidium delicatulum*, a moss that spreads easily and usually survives well in the Sievert and other gardens. Photo courtesy of Dale Sievert.

Figure 72. *Rhodobryum ontariense*, a moss shaped like a palm tree that adds interest to any garden. Photo courtesy of Dale Sievert.

Figure 73. *Plagiomnium cuspidatum* in snow. This is a common volunteer in Dale Sievert's garden and in mine, where it doesn't mind being buried in snow. Photo courtesy of Dale Sievert.

Sometimes Sievert lets the mosses determine their own successional pathway. As is typical, pleurocarpous mosses often overrun the acrocarpous mosses (Figure 74). But acrocarpous mosses can invade tight acrocarpous moss cushions as well, as is a common event in which *Polytrichum* invades a *Leucobryum* cushion (Figure 75). A series of pictures demonstrates some of the changes through time, 2011-2015 (Figure 76-Figure 78).

Figure 74. Nature has her own ideas about what belongs where. Here *Atrichum* is being invaded by pleurocarpous mosses. Photo courtesy of Dale Sievert.

Figure 76. Moss and cat statues in 2011 showing well-established but still thin mat of mosses. Photo courtesy of Dale Sievert.

Sievert has a number of special features to highlight the various areas of his garden. A bamboo fountain pours into a small pool surrounded by mosses (Figure 79). A bird bath is adorned by colorful rocks and moss-covered rocks (Figure 80). As in many gardens, including my own, a Japanese lantern adds interest (Figure 81). Small to large boulders can add diversity to the scene and may add their own beauty (Figure 82-Figure 83). Stumps provide flat platforms for miniature gardens (Figure 84-Figure 85) or depressions that have their own interest and are great bryophyte substrates (Figure 86). Statuary peers at the visitors or poses playfully among mosses (Figure 85-Figure 86). Ferns provide changes in texture (Figure 87). Pools can attract frogs (Figure 88).

Figure 79. Bamboo fountain in mossy garden, creating a refreshing pool that raises the humidity for the nearby mosses. Photo courtesy of Dale Sievert.

Figure 82. Rocks and a bit of wood enhance this scene with mostly *Anomodon rostratus*, a common moss in Dale Sievert's garden. Photo courtesy of Dale Sievert.

Figure 88. Pools can provide habitat and a welcome drink for wildlife. Here the Green Frog *Rana clamitans* sits on a mossy rock. Photo courtesy of Dale Sievert.

Fungi (Figure 89-Figure 90) are willing participants in Dale Sievert's garden. The mosses help to keep the soil moist longer, permitting the fungal threads to thrive. In the right conditions, the fruiting bodies emerge, adding color to the garden.

Figure 89. The pore fungus *Boletus* sp. and moss. Photo courtesy of Dale Sievert.

Figure 90. *Coprinus* with the moss *Anomodon rostratus*. Photo courtesy of Dale Sievert.

Dale has been fortunate to have some of his mosses exhibit prolific "fruiting." The setae and capsules often add brilliant colors to the landscape.

New Methods in Moss Gardening

Rick Smith (2009) has written one of the North American guides to moss gardening, *New Methods in Moss Gardening*. Smith provides his personal experiences around the world where he has created moss gardens or been a consultant. He provides instructions for growing twelve of the most common mosses, accompanied by pictures (Figure 96-Figure 98).

Figure 96. Moss garden designed by Rick Smith. Photo courtesy of Rick Smith.

Figure 98. Moss garden designed by Rick Smith. Photo courtesy of Rick Smith.

Indoor Moss Garden

As my aging body prevents me from maintaining my outdoor moss garden, I am now attempting an indoor moss garden. So far, I am able to do the required bending, but at least once planted it is essentially maintenance-free – no weeds! I was pleased to have a supplier who rescues the bryophytes she sells by removing them from roofs or construction sites where they are slated for destruction, then cultivates them. Several other suppliers state that they grow their own mosses. I avoid the "grab bags" after trying one and concluding they were ravaged from the forest.

My previous attempts at introducing mosses inside were unsuccessful, with the town's water quality being incompatible despite a filter on the garden room watering system. I was successful with *Conocephalum* cf. *salebrosum*. And it also appeared that my turtle was successful in dispersing it.

My new adventure in the indoor moss garden is still quite young, but I do have some success stories. My first introduction was again *Conocephalum* cf. *salebrosum* (Figure 99-Figure 104), and it has been highly successful. The *Conocephalum* cf. *salebrosum* is doing especially well at the base of the waterfall and the stream margins (Figure 99-Figure 101). My *Marchantia polymorpha* got dried out, but it is trying to come back, perhaps from gemmae.

Figure 99. Newly planted *Conocephalum salebrosum* along stream, with some bare fake rock at edge. on 16 December 2022. Photo by Janice Glime.

Figure 100. *Conocephalum salebrosum* growing successfully at the very moist base of the waterfall on 19 February 2023. The green rock and its surrounding liverworts can be seen at the middle left of Figure 99 from two months earlier. Photo by Janice Glime.

Figure 104. *Conocephalum salebrosum* showing the bright green of new branches on the thallus after two months in the garden room. Photo by Janice Glime.

My next adventure was a small patch of *Thuidium delicatulum* (Figure 105). To my surprise, this was also quite successful (Figure 106). Both of these bryophytes have produced new branches and have a wonderful, fresh color.

Figure 105. *Thuidium delicatulum* in garden room on 19 Feb 2023. Photo by Janice Glime.

Figure 106. *Thuidium delicatulum* in garden room on 19 Feb 2023; it was planted ~25 November 2022. Photo by Janice Glime.

Two other bryophytes seem to be doing very well – *Rhytidiadelphus squarrosus* and *Rhytidiadelphus triquetris*. I wasn't surprised at the latter because it had also been successful in my outdoor garden. *Leucobryum glaucum* is surviving, appears healthy, but so far no expansion. Of course it is winter here, so the room is cool, but not freezing. It gets watered at least 3 times a week and has a small, two-meter high waterfall to maintain moisture.

Figure 107. *Rhytidiadelphus squarrosus* in garden room 19 Feb 2023 after nearly three months. Photo by Janice Glime.

Figure 108. *Rhytidiadelphus triquetris* in garden room 19 Feb 2023 after nearly three months there. Photo by Janice Glime.

Figure 109. *Leucobryum glaucum* in garden room 19 Feb 2023 after ~3 months. The color is darker than normal and many apical pieces are scattered loose on it. Photo by Janice Glime.

Sun-loving mosses usually die within the same growing season. Likewise, xerophytes don't do well in the high level of moisture.

After 45 years, there are at last volunteers in the garden. These are mostly on pumice that I put there just for that purpose. The mosses are thin and I don't recognize them, but they are healthy.

Figure 110. Volunteer moss on pumice beside the garden room waterfall – after more than 40 years of opportunity! Photo by Janice Glime.

Harvesting Ban

In 2006, a moratorium was declared on moss harvesting in the national forests around Asheville, North Carolina, USA (Tortorella 2014). This ban was based on a study of the moss trade. Local collectors would sell sheet moss for as little as \$.50 per pound to members of the floral trade. But stripping a log of all its moss requires 20 years for a new crop, despite all the local rainfall. Gary Kauffman, an ecologist and researcher on the study, determined that if a third of the moss was left on the log, the mosses would grow back in ten years. One of the dangers of collecting the mosses is what fishermen call "bycatch." Unintended species come along with the desired ones, and some of these are rare and endangered. Including these bycatch species, studies indicate that more than 70 species are harvested in the Appalachian moss industry.

Because of these conservation concerns, it is best to do as Annie Martin has done – rescue mosses and liverworts that are scheduled for destruction. In many of these locations, the moss "invaders" are hardy species and ones likely to survive in a garden.

Summary

Private moss gardens tend to serve the same purpose as the larger moss gardens. Rocks, pebble paths, lamps, and other items add interest, and the limited color gives them a peaceful appeal. Outside of Japan, fewer moss gardens exist, in part because the climate is often not suitable. Another difference seems to be the love of color in other parts of the world.

Mosseries are an older form of growing mosses. The moss gardens themselves have a wide variety, using artistic designs, Japanese styles, natural styles, and mixed with flowering plants. They vary by season, changing colors when producing reproductive structures and between wet and dry states. Water gardens require different species, but running water can add sound to the landscape. Bog gardens can be used to grow insectivorous plants and other bog plants.

Worldwide, mosses such as *Polytrichum* and *Leucobryum* seem to be popular choices for these gardens. Species like *Thuidium delicatulum*, *Fissidens* sp., and *Plagiomnium cuspidatum* spread easily and may overtake acrocarpous mosses nearby. *Plagiomnium cuspidatum* can often arrive by itself.

Conocephalum salebrosum, *Thuidium delicatulum*, *Rhytidiadelphus triquetrus*, and *R. squarrosus* do well in indoor gardens.

Harvesting mosses should only be done on your own property or other private property where you have permission. The best way to get plants is to rescue them where they are scheduled for destruction.

Acknowledgments

I appreciate the email discussions with Nancy Church, Annie Martin, Rick Smith, and David Spain. Most recently, I spent an afternoon discussing mosses and moss gardening with Dale Sievert, leading me to include additional topics in an attempt to answer his questions.

CHAPTER 7-4

GARDENING: MOSS GARDEN DEVELOPMENT AND MAINTENANCE

Figure 1. This moss garden in Kyoto, Japan, takes advantage of a stream to add to its peaceful nature. Photo by Janice Glime.

Choice of Bryophytes

Careful selection of bryophytes will greatly increase the chances for success. These plants often have niches that are not provided by the typical garden spot, so care should be taken to select species with habitat requirements similar to that available in the garden.

When you collect different species of mosses and then plant them together, the needs of the different species may differ. There are many species and it's often difficult to discern differences without using a hand lens or consulting a bryologist. If requirements differ, the one most suited can more easily overgrow the other. I suggest that you learn to distinguish the acrocarpous from pleurocarpous species and keep these two separated. The horizontal growth form of pleurocarpous species easily overtakes the upright acrocarpous species.

Most acrocarpous mosses do not like constant moisture whereas most pleurocarpous ones do. One way to deal with this is to maintain a regular watering schedule and allow the mosses that are flourishing to take over the ones that are not. Dead or dying mosses of one species can make a welcoming surface for other mosses to invade or provide suitable substrate for spores to germinate. You can speed up the process by fragmenting some of the flourishing mosses directly on top of the ones that are failing.

In some cases large areas might be transplanted with a moss that is not appropriate for the new conditions and all of the new transplants die. If the area continues to be watered as if the moss is still alive, after several months the spores of another species might germinate on top of the decaying moss and a more appropriate species will develop.

This bed of dead moss retains moisture, controls erosion, and reduces weed invasion. It permits spores of other mosses to have places to land and establish without blowing away. Developing a moss area will eventually lead to some of the species performing better than others and the faster-growing species will subsequently dominate the area.

Spain (2012a) advises that you can "let mother nature decide what species to introduce by clearing the area down to bare earth and then begin watering just as though there was moss already present... If you build it, they will come!"

One might learn from the mosses that are often considered weeds. Charlie Campbell (Bryonet 17 April 2014) found that his parents' lawn in northern England had *Rhytidiadelphus squarrosus* (Figure 2) as a co-dominant with the grass. *Atrichum undulatum* (Figure 3) and *Plagiommium undulatum* (Figure 4) also occurred in small patches. In Berkshire, his flats were surrounded by grasslands and were on dry, sandy, open lawn. On the shady side of the flats the *Rhytidiadelphus squarrosus* grew, but on the sunny areas two different communities developed. On the west-facing slope the community was rich in bryophytes, including *Riccia glauca* (Figure 5), *Sphaerocarpos* sp. (Figure 6), *Didymodon vinealis* (Figure 7), and others. On the east-facing side, an abundant *Polytrichum juniperinum* (Figure 8) cover developed. After several days of rain, *Lophocolea bidentata* (Figure 9) became extremely frequent on both sunny sites.

Figure 9. *Lophocolea bidentata*, a moss that seems to suddenly appear in sunny spots after a rainfall. Photo by Michael Lüth, with permission.

Few published studies have taken an experimental approach to moss gardening, although I'm sure many gardeners have used trial and error to determine the best bryophytes for their gardens. Radu *et al.* (2016), however, were interested in bryophytes for a variety of applications and set out to determine the most suitable species. They used six species of mosses in hydroponic experiments:

Syntrichia ruralis (Figure 10), *Homalothecium sericeum* (Figure 11), *Ceratodon purpureus* (Figure 12), *Grimmia pulvinata* (Figure 13), *Racomitrium aciculare* (Figure 14), and *Bryum capillare* (Figure 15). These species were tested at different light intensities and water dosing regimes. The researchers concluded that *Grimmia pulvinata* and *Ceratodon purpureus* adapted the best to the controlled environment. They thus considered them to be suitable for use in landscape design. But lab conditions are not field conditions, and constant conditions are quite different from constantly varying conditions. The chapter on Phenology in Volume 1 can suggest a few.

Thallose Liverworts

One seldom thinks of liverworts in the context of a "moss" garden, but several thallose liverworts are suitable for "moss" gardens. These can be pressed into soft soil so that they have good contact with the substrate (Fletcher

1991). Among the known successful ones are *Marchantia polymorpha* (Figure 16) and *Lunularia cruciata* (Figure 17) on garden paths and damp soil, *Conocephalum conicum* (moist soil; Figure 18), and *Riccia sorocarpa* (Figure 19) and *Riccia glauca* (Figure 5) in damp fields and garden beds (but small and easily overgrown).

Figure 19. *Riccia sorocarpa*, a common thallose liverwort. Photo by Michael Lüth, with permission.

Sphagnum – peat mosses

Most *Sphagnum* (Figure 20) taxa require a wet, acidic habitat, and most have a somewhat narrow range for both of these. Their habitat should be mimicked, and that means that they need to be supplied water from below (Fletcher 1991). This can be accomplished by placing them in flower pots in a shallow tray of standing water. *Sphagnum* is well constructed to soak up and transport the water externally through all the capillary spaces surrounding its stem. The proper pH can be maintained by growing the plants on their own peat. Tap water can easily kill them. If it has many minerals in it, they will accumulate on the surface and eventually kill them. Calcium is particularly lethal to *Sphagnum*. To solve this dilemma, distilled water or rainwater is the best watering medium. No fertilizer is needed, and in fact should be avoided.

Figure 20. *Sphagnum fuscum*, a species that lives on tops of hummocks. Photo by Michael Lüth, with permission.

Sphagnum comes in a wide range of colors (Figure 21), and a bouquet of colors and hues can be arranged in the same garden by using some care in choices of species. Some of these may be maintained by placing them at greater distance from the water source, such as *Sphagnum fuscum* (Figure 20) (Fletcher 1991).

Figure 21. *Sphagnum magellanicum* and other species of *Sphagnum* showing some of the range of colors that occur together naturally. Photo by Janice Glime.

Although many *Sphagnum* (Figure 20) species are sun-loving, too much can fry them. Fletcher (1991) reports losing many of his plants during a hot summer when he forgot to move the plants into the shade. The problem is that sun will quickly dry out the plants, and most of the taxa are not drought tolerant. Furthermore, most lack protection against bright sun that can destroy the chlorophyll.

Birds can be a problem in a moss garden. The conditions that favor growth of *Sphagnum* (Figure 20-Figure 21) also favor the presence of a number of invertebrates. Hungry birds, especially early in spring, can be quite disruptive as they rummage for dinner. And nesting can be an even bigger problem, especially if your garden provides lots of mosses in a city area where few other mosses exist. In my indoor garden, mosses and zebra finches simply cannot co-exist. The birds win every time, carrying off every bit of moss for nesting material. Fletcher (1991) suggests covering the mosses with netting to minimize the disturbance. Wire netting must be avoided because it is likely to release zinc or other metal that is toxic to the bryophytes.

Fletcher (1991) suggests *Sphagnum quinquefarium* (Figure 22) for well-drained slopes in wet woods. *Sphagnum cuspidatum* (Figure 23) does well in pools, where it looks like a wet kitten. Fletcher has even kept it in a jam jar for a year. On a bed of peat, *Sphagnum compactum* (Figure 24) can tolerate drying, prefers shade, and does not like being water-logged.

Figure 22. *Sphagnum quinquefarium*, a moss of well-drained slopes in forests. Photo by Michael Lüth, with permission.

Figure 24. *Sphagnum compactum*, a species that grows on wet sand or rocks in shaded areas where it tolerates drying. Photo by Michael Lüth, with permission.

Polytrichum – hairy cap mosses

The most common of the mosses in Japanese gardens (Figure 1) of all kinds is the common hairy cap moss, *Polytrichum* (Figure 25). This group of mosses is common in both temple gardens and private gardens. *Polytrichum* is difficult to transplant because the clump easily becomes disturbed in the process. For that reason, smaller, young clumps work best. But don't despair if those larger clumps collapse and turn brown. I have learned to trust the resilience of moss stems, and *Polytrichum* stems are a good example to support this trust. I transplanted one year after they had collapsed from their original orientation. They looked pretty bad when they went into the garden, and they didn't improve much. The next spring I was nearly ready to remove them, but didn't get the energy to do it. Then small green tips began to appear. Most of the sprawling clump still looks rather sad. They might have come back, but a chipmunk decided to occupy that part of the garden, building an entrance to its underground runway. Nevertheless, life is there, and perhaps with time the clump will fill in through stems.

Figure 25. *Polytrichum commune* var *commune*, a common species used in moss gardens. Photo by David Holyoak, with permission.

Members of the genus *Polytrichum* can resist disturbance by the broom or bamboo rake used to remove fallen leaves and other debris (Ando 1987), and they are unusual among mosses for their resistance to drought and ability to withstand direct sunlight as well as shade (Steere 1968). *Polytrichum juniperinum* (Figure 8) and *P. piliferum* (Figure 26-Figure 27) do well if the clump integrity is maintained, again making small, young clumps easier to transplant.

Figure 26. *Polytrichum piliferum* males, adding a bit of color to moss gardens in spring. Photo from Proyecto Musgo, through Creative Commons.

Figure 27. *Polytrichum piliferum* with young sporophytes. Photo by Janice Glime.

As with *Sphagnum* (Figure 22-Figure 24), lime in some tap water can form crusts on the leaves (Fletcher 1991). One reason for this is that water for *Sphagnum* in nature must generally come from above. Although many mosses have good capillary action to move water externally, *Polytrichum* (Figure 25-Figure 27) species have large, waxy leaves that tend to repel water and do not move it well externally. Although they have one of the best developed internal conducting systems, they still take in most, if not all, of their water through the tip of the plant. Thus, water must be supplied from above and needs to be almost completely free from minerals. Even so, dust splashing from the soil can easily reach the leaves and contribute to their mineral accumulation.

Fletcher (1991) contends that the most easily grown mosses are those that have strong rhizoids, because they are least damaged by lime. For the remaining majority, one can use peat as a substrate, but that is often too moist. Another alternative is to use a sand substrate or in some cases organic soil free of lime, and water only with distilled water. Rain water is also a good choice, but may be contaminated with lime in areas with alkaline soil or limestone rocks. Nevertheless, as Fletcher points out, the impact of rainfall helps to wash off the minerals. A good spraying system is essential in areas where rainfall is infrequent. Fletcher advises to wash the mosses off with a spray of rainwater when they have accumulated minerals on their leaves.

Fletcher has succeeded in keeping *Polytrichum* (Figure 8) alive for 20 years, but he finds it necessary to transplant them every 1-2 years onto fresh peat. Once done, this permits old, dying shoots to produce new sprouts that emerge from the peat. On the other hand, I have had a bed of *Polytrichum juniperinum* (Figure 8) for seven years without disturbing it, and it is still doing well. It looks awful in the spring, but it recovers.

Polytrichum commune (Figure 25) and *P. strictum* (Figure 28) grow mostly in bogs and fens. *Polytrichum strictum* is aided in its quest for water by a white tomentum on the lower part of the stem.

Figure 28. *Polytrichum strictum* with capsules, a bog/fen species that is suitable for moss gardens. Photo by Michael Lüth, with permission.

Atrichum

Atrichum (Figure 3) is a relative in the same family as *Polytrichum* (Figure 25-Figure 27). But its needs are

somewhat different. Whereas *Polytrichum* has stiff, waxy leaves with lamellae across most of the surface, *Atrichum* has thin leaves (Figure 29) with lamellae only in the middle over the more narrow costa (Figure 30). This genus does best on soil, not peat (Fletcher 1991). Some species can be an invasive moss along paths (Figure 31) and can easily regrow from fragments. These provide a nice yellowish green.

Figure 29. *Atrichum altecrisatum* leaf portion showing lamellae over costa down center. Photo by Bob Klips, with permission.

Figure 30. *Atrichum altecrisatum* showing lamellae over costa in leaf cross section. Photo by Bob Klips, with permission.

Figure 31. *Atrichum altecrisatum* along a path in the forest in Houghton, Michigan, USA. Photo by Janice Glime.

When *Atrichum* dries, the leaves curl (Figure 32) and often turn brown (Figure 33). In this form it is not very attractive. It will look nice in a well-watered or humid garden.

Figure 32. *Atrichum altecristatum* drying and curling. Photo courtesy of Eric Schneider.

Figure 33. *Atrichum angustatum* with dry, brown leaves and capsules. Photo by Janice Glime.

Leucobryum

Leucobryum glaucum (Figure 34) was a favorite moss of many of my students. A common moss, it is easily recognizable by its whitish color and pincushion appearance. Its whiteness is emphasized in its name, with *bryum* meaning moss, *leuco* meaning white, and *glaucum* meaning whitish like wax. It goes by the common names of cushion, pincushion, or white moss. It likes acid soil, frequently occurring in conifer forests. Although it typically occurs in the shade, it can tolerate sun exposures. And the genus is common on many continents.

Leucobryum (Figure 34) is an **acrocarpous** moss, or upright type, producing stalks and capsules at the tips of the upright stems. Its mound form (Figure 34) makes a striking element in garden designs and borders, providing both a break in the topography and a striking contrast in color. This color contrast is due to hyaline cells that mask the green color of the leaves. As the moss dries, the hyaline cells lose water, the optics change, and the moss appears whiter.

Figure 34. *Leucobryum glaucum* at tree base, a common species in moss gardens. Photo by Janice Glime.

The texture of *Leucobryum* (Figure 34) cushions is somewhat coarse, due to the leaves that are more than one cell thick and relatively large. Cushion size can become quite large (Figure 35), and these will be very compact.

Figure 35. *Leucobryum glaucum* demonstrating the large cushions in an undisturbed forest in Copper Harbor, Michigan, USA. Photo by Janice Glime.

Annie Martin (Mountain Moss Newsletter winter 2010) relayed her experience relocating *Leucobryum glaucum* (Figure 34) from a gravel road where it was growing in full sun. It was dehydrated and white. She placed it among other *Leucobryum* plants in her garden and watered it three different times that evening. By morning it looked as fresh and alive as the established *Leucobryum* plants.

I have attempted cultivating *Leucobryum glaucum* (Figure 34) several times with only short-lived success. This moss seems especially susceptible to destruction by the leachates of leaf litter, even if the litter is cleared as soon as the snow melts.

Another habit of this plant might lead to dismay if one isn't familiar with its behavior. When it is reproducing

asexually, the leaves at the tip break off, providing a white covering of fragments on the colony (Martin 2010). This gives it a "cruddy" appearance for a while, but the plants are fine – just reproducing and dispersing. You can sweep these off with a soft brush to improve the appearance and at the same time disperse your *Leucobryum* (Figure 34) to additional locations in your garden.

If your *Leucobryum glaucum* (Figure 34) turns black, you do have a problem. This indicates that it is being kept too wet (Martin 2010). Perhaps this explains its sickly look in my garden when it emerged from the snow in spring. The slow melt in spring may have kept it too wet too long with little light and no opportunity to get dry. This discoloration can also be caused by fungal attack – an event further promoted by moisture. Martin advises to let the moss dry out for a while to see if it will recover.

On the other side of the coin, *Leucobryum* (Figure 34) has some remarkable recovery techniques. If it gets turned upside down, it will begin growing from the exposed side (Martin 2010), sometimes making a ball!

Martin (2010) finds this moss to be easy to pick up. The pincushion sits on the soil surface and grows on its own dead base (Figure 36). There is usually no soil attached. I have been advised to plant it on a bed of pine needles, but my one attempt at that was undone by a chipmunk that chose it for making the entrance to a burrow. It seems to like sandy soil and to avoid rich soil. As always, Martin warns us not to take bryophytes from parks or forests and to ask permission before collecting on private land.

Figure 36. *Leucobryum glaucum* showing dead lower parts that sit on the soil surface. Photo courtesy of Diane Lucas.

Leucobryum bowringii (Figure 37), *L. juniperoideum* (Figure 38) grow in mounds or cushions, creating a gentle, rolling landscape resembling miniature hills (like Figure 36). *Leucobryum* (Figure 39) is abundant and highly praised for its huge whitish cushions that provide beautiful contrast.

Figure 39. *Leucobryum* "spills" down the hill in a moss garden in Kyoto, Japan. Photo by Janice Glime.

Dicranum

Dicranum is an acrocarpous genus that prefers shade. The most widespread and common species, *Dicranum scoparium* (Figure 40), forms cushions. The leaves curve and typically they all curve in one direction (Figure 41), creating the temptation to pet it. It provides a dark green contrast to *Leucobryum* (Figure 34) species and is found in

many parts of the world, permitting its use in the moss gardens of Japan.

Figure 40. *Dicranum scoparium* on forest floor, a common moss of forests that adds a dark green to the garden. Photo by Janice Glime.

Figure 41. *Dicranum scoparium* showing leaves curved in one direction. Photo by Janice Glime.

Mniaceae

Mniaceae can be similarly propagated, preferring damp, shaded places. *Plagiomnium cuspidatum* (Figure 42) has been quite successful in my garden and thrived as an invader among the shrubs around the campus library. Several members of **Mniaceae** are known and used for their big, lush leaves (Figure 42).

Figure 42. *Plagiomnium cuspidatum* is easily grown if it can be transplanted without disturbing its connections to the soil and each other. Photo by Michael Lüth, with permission.

I have found this species as a well-developed moss among my flagstones on a path, where it was totally a volunteer.

Thuidium delicatulum

Thuidium delicatulum (Figure 43) is one of the fast-growing mosses (Martin 2010) and can take over a moss garden (Dale Sievert, pers. Comm. 13 October 2017). Despite the disturbances by chipmunks, I have found it to be persistent in my garden, showing up in new locations.

Figure 43. *Thuidium delicatulum* when it is wet and fresh. Photo by Jan-Peter Frahm, with permission.

Martin (2010) finds this moss to be a strong grower in winter in North Carolina – in her words, growing "by leaps and bounds during the winter months." She found that it quickly spread over mosses like *Leucobryum* (Figure 34) and *Dicranum* (Figure 40), invading and sometimes covering these mounds.

Thuidium is papillose (Figure 44), crunchy when dry (Figure 45), but soft when wet (Figure 43). It looks like a miniature fern and is often known as "fern moss." It will grow in open areas among grasses, but its need for some shade makes it a more likely candidate for shady portions of a garden.

Figure 44. *Thuidium delicatulum* branch showing the projecting papillae on the leaves. Photo by Bob Klips, with permission.

Figure 45. *Thuidium delicatulum* dry (and crunchy). Photo by Janice Glime.

Pseudoscleropodium purum

Pseudoscleropodium purum (Figure 46) is a large, pleurocarpous moss that tends to grow on acidic soil. It seems to like acidic grasslands, roadsides, and maintained lawns. It has attractive branches that look rope-like due to the concave leaves that end in a sudden, short, narrow tip. Like *Thuidium* (Figure 43), it is a rapidly growing species (Martin 2010). But be careful – it is also an invasive species, sometimes getting introduced when it is used as a packing material.

Figure 46. *Pseudoscleropodium purum*, a common moss in Europe, but invasive in parts of the USA. Photo by Janice Glime.

Rhodobryum

Rhodobryum (Figure 47) is a special genus that has very attractive individual plants. The leaves are crowded at the tips of the stems, making these look like a colony of miniature palm trees. The genus can grow in deep shade and seems to like it somewhat damp. Hilty (2017) describes its habitats in Illinois as moist ground in woodlands, wooded hillsides, ground at the base of trees in woods, swampy woodlands, shaded clay banks of ravines, moist decaying logs, limestone rocks along streams, moist limestone cliffs, shaded limestone ledges, limestone blocks in woods, thin soil over sandstone rocks in wooded areas, shaded ground in hanging fens, and sandy clay banks along creeks. Although it is a relatively uncommon moss, this presents a wide range of habitats where you can grow them.

Figure 47. *Rhodobryum ontariense*, an attractive moss for gardens. It prefers alkaline habitats but also grows over sandstone rocks. Photo by Janice Glime.

The *Fissidens* (Figure 48) in my moss garden has spread to other gardens in my yard. It can be aggressive, as seen in Figure 49 where it is overgrowing *Marchantia polymorpha*.

Fissidens

Fissidens (Figure 48) is not often mentioned as a genus for moss gardens. However, my experience with it is that it is an excellent choice. It holds up well and stays green when it is dry. But the best news is that it grows well when propagated and spreads by itself, perhaps with the help of the chipmunks.

Figure 48. *Fissidens adianthoides* is a moss easily cultivated by transplant or fragments. Photo by Michael L  th, with permission.

Others

In the shade in Japan, common species include *Pyrrhobryum dozymanum* (Figure 50), and *Trachycystis microphylla* (Figure 51). Like *Leucobryum*, these latter taxa grow in mounds or cushions, creating a gentle, rolling landscape resembling miniature hills. *Hypnum* (Figure 52) and *Racomitrium* (Figure 53) are common in drier places and *Fissidens* (Figure 48) and *Atrichum* (Figure 3) in wet places (Steere 1968). Both *Hypnum plumaeforme* (Figure 54) and *Racomitrium canescens* (Figure 53) are able to grow without deep shade, but require frequent watering and weeding (Ueta & Deguchi 1980). In his webpage, Svenson (2000) recommended *Racomitrium canescens* as a moss for both sun and shade. It is quite drought tolerant, and it can form large, thick mats that have a broad tolerance, even to trampling. Other mosses suitable for gardens include *Eurhynchium praelongum* (Figure 55), *Rhynchostegium confertum* (Figure 56), *Brachythecium rutabulum* (Figure 57), and *Rhytidiadelphus squarrosus* (Figure 2) (Fletcher 1991).

Some mosses are especially adept at being transplanted and seem to survive despite drought or rainy season. Among these, I have been most successful with the medium-sized species of *Fissidens* such as *F. adianthoides* (Figure 48). It helps considerably if the shape of the original colony can be maintained, preventing exposure of longer stems by maintaining the shorter outer members of the cushion. This is especially true for cushion-formers like *Leucobryum* (Figure 39) and *Dicranum* (Figure 40). If this is not possible, pushing a rock against the exposed broken parts of the cushion helps to maintain the moisture there.

Hylocomium splendens (Figure 58) and *Pleurozium schreberi* (Figure 59) likewise do not transplant well. I have to wonder if a symbiotic fungus is involved. I was surprised that *Rhytidiadelphus triquetrus* (Figure 60), a species in the same family as *Pleurozium* and *Hylocomium*, does well. *Thuidium delicatulum* (Figure 43-Figure 45) is somewhat successful, but mine was disturbed badly by a chipmunk that seemed to think that was the best place to enter its burrow. Followed by a very dry summer, *T. delicatulum* did not seem to be doing well. Nevertheless, it now occupies spots shaded by flowering plants and rocks, having dispersed there without my help.

Moss gardening is a growing industry, even in the United States and other parts of the world outside Japan. However, not all plants touted as mosses are truly mosses. Spanish moss (*Tillandsia usneoides*; Figure 61), a bromeliad, hence a flowering plant, is included among the types available from at least one moss seller. Rock mosses (*Selaginella*; Figure 62) and club mosses (Figure 63) (both Lycopodiaceae) are both cryptogamic tracheophytes, not bryophytes. Sheet moss, *Sphagnum* (Figure 20-Figure 24), and "bun" moss (growing in clumps) are other types listed and are true mosses. Sheet mosses include such mosses as *Hypnum* (Figure 52) and *Thuidium* (Figure 43-Figure 45) (Nelson & Carpenter 1965).

Figure 61. *Tillandsia usneoides*, Spanish moss, but not a real moss. Photo by George Shepherd, through Creative Commons.

Figure 63. *Lycopodium annotinum*, a club moss, but not a true moss. Photo by Janice Glime.

Annie Martin has *Climacium americanum* in her moss garden (Figure 64). This attractive moss looks like miniature trees. It is especially interesting when it produces capsules because it looks like a miniature Christmas tree with candles (Figure 66). This same moss grows in abundance along the path to the Frank Lloyd Wright house, Falling Waters, Pennsylvania, USA (Figure 65).

Sources

Few sellers are available for purchasing live mosses. And even where these sources are available, the mosses are usually expensive. Even when people have the sources and the money for purchase, gathering one's own is always a temptation. There are advantages to the latter – it shows the gatherer how and where the moss grows in nature and makes it easier to create the right microclimate for it.

BUT good stewardship is of paramount importance. And good stewardship precludes removing mosses from nature, whether it is a national forest or private land. Annie Martin, in response to criticism from Bryonettters, explained her method of developing moss mats for sale. She obtains her mosses in two ways – rescuing those that are about to be destroyed by development or because they are presumed to be a nuisance (roofs, parking lots, cracks in the sidewalk) or by obtaining permission from owners on private land. Judicious harvesting on private land can permit the mosses to grow back. On her own property, she cultivates these for sale. Martin expressed dismay that she could not get a permit to remove mosses in an area to be logged. Logging permits are permitted, but saving mosses beforehand is prohibited! They can't even be rescued to prevent destruction by trucks fighting fires. On the other hand, Martin has had good experience with private owners and business owners who give her permission to remove mosses. People in the area know her and call her before destroying unwanted mosses.

It also helps to know the relative growth rates of mosses. Annie Martin suggests that log mosses tend to fall in the faster growing category. I can add *Plagiomnium cuspidatum* (Figure 42), *Fissidens adianthoides* (Figure 48), and *Marchantia polymorpha* (Figure 16) as species that spread quickly.

Lawns

One typical push lawn mower running for one hour equals 43 new automobiles running for the same time (Martin 2010)! Go green with moss!

David Benner developed a moss lawn so he would never have to mow again (Dunn 2008). He hasn't watered or mowed his lawn since the Kennedy Administration, and it's doing just fine, reports Jancee Dundee (2008) in her "In the Garden" column. Benner, a retired professor of horticulture, is a long-time moss lawn advocate. He is delighted that this approach is gaining momentum. But to visitors of his mossy lawn, he forbids high heels. (I wonder if it isn't more dangerous for the wearer than it is for the moss!)

Tim Currier, owner of Sticks and Stones Farm, Newtown, CT, USA, had been selling mosses for gardening for ten years, but in 2007 his sales increased by 30% (Dunn 2008). Celeste Kennedy, owner of Rolling Hill Farm in Green Bay, VA, USA, reports a 40% increase in the same time frame. Both homeowners and businesses have contributed to this rise in sales.

Dunn (2008) touts the advantages of mosses, including erosion prevention, density that repels weeds, no need for fertilizer, lack of herbivory by deer, and tolerates at least some trampling (e.g. Figure 67). It thrives in poor soil and only requires shade and occasional water.

Figure 67. Moss lawn near Minisink Lake, Bushkill, PA, USA. Photo by Janice Glime.

The American Society of Landscape Architects predicted that native drought-resistant plants such as mosses would be a trendy change in 2008, providing a sustainable substitute for grass in lawns (Dunn 2008). Nancy Somerville, the executive vice president, states that the organization is seeing more creative plantings, with moss being "a great one." It satisfies needs for both better environmentalism and concerns about water. The EPA estimates that nearly one third of residential water use is for landscaping, a condition our diminishing water supply cannot sustain. The condition will only get worse with global warming, although in some areas more rain will fall.

Christine Cook, owner of Mossaics in Easton, CT, USA, contends that a moss lawn needs only one percent or less of the amount of water needed to maintain a suburban grass lawn (Dunn 2008). Benner's philosophy (Dunn 2008) is even better – he doesn't water; "things have to tough it out."

In 1962, when Benner first began his moss lawn, the only book he could find on the subject was written in Japanese (Dunn 2008). But he knew that moss thrives in acidic soil, whereas some people spread lime on a grassy lawn to eliminate moss. Therefore, he covered his lawn with a mix of sulfur powder and aluminum sulfate to acidify it. Three months later he removed the dead leaves, exposing the soil. Winter was the wait and see period, but in the spring mosses began to sprout everywhere. "It was like magic" he remembers. He didn't even have to plant – he just waited for spores to blow in. He now has 25 different kinds, and he didn't plant any of them! He has found fern moss (*Thuidium* sp.; Figure 43-Figure 45), hair cap moss (*Polytrichum*; Figure 8, Figure 25-Figure 28), rock cap moss (*Dicranum*; Figure 40), and cushion moss (*Leucobryum*; Figure 34, Figure 37-Figure 39) to be the easiest to grow. These four taxa are now sold by his son, Al Benner, through Moss Acres, a commercial establishment in the Poconos of Pennsylvania, USA. This business has actually increased about 30% each year, with such customers as the New York Times' headquarters for its atrium garden.

Benner senior claims that "some sort of magical invigorating energy goes through you when you stand on a thick patch of wet moss" (Dunn 2008).

It seems that moss enthusiasts are lurking everywhere. T. J. Turgeon, an executive vice president of a private bank for wealthy people, began his moss growing in 2004 (Dunn 2008). He says, "I'm having an absolute blast with it. I'm great at a dinner party, because I can talk about moss and no one's ever heard it before. People at work think I'm out of my mind. I don't know if other people do this, but wherever I go, I take moss."

Sallie Baldwin is a graphic designer from Greenwich, CT, USA, who has been turning her front yard into a moss lawn for 18 years (Dunn 2008). She sometimes amuses her neighbors by swapping a bit of "weedy" grass in her lawn for the "weedy" moss in theirs.

Special Use Species

You may choose to place some of your bryophytes in special locations that are more restrictive. These could include boulders, rock or concrete walls, or even paths. Some mosses are suitable for transplanting to these special situations.

If it is not too dry, *Marchantia polymorpha* (Figure 16) does well on disturbed soil. My *Marchantia polymorpha* (Figure 16) sported a bevy of children in a 25-cm circle around the parent plants, products of gemmae (Figure 68) splashed by the rain or the sprinkler system, and the parents had only been in the garden about three weeks! These young thalli were not only on the bare ground, but had become established on the cushions of *Leucobryum* (Figure 34) within reach. The following year the original clump was a forest of **archegoniophores** (structure where female gametes and ultimately capsules are produced; Figure 16).

My *Marchantia polymorpha* (Figure 16) sported a bevy of children in a 25-cm circle around the parent plants, products of gemmae splashed by the rain or the sprinkler system, and the parents had only been in the garden about three weeks! These young thalli were not only on the bare

ground, but had become established on the cushions of *Leucobryum* (Figure 34) within reach.

Figure 68. *Marchantia polymorpha* gemmae cups with gemmae. Photo by Dick Haaksma, with permission.

Lawn Species

For substitute lawns and gardens, *Eurhynchium praelongum* (Figure 55), *Calliergonella cuspidata* (Figure 69), and *Polytrichum juniperinum* (Figure 8) serve well, although I doubt the North American populations of *C. cuspidata* would do so well in most terrestrial areas. In Europe this moss is found on dry hillsides, but in North America it behaves as an aquatic, at least anywhere I have seen it.

Figure 69. *Calliergonella cuspidata*, a species that does well in lawns and gardens in Europe, but not in North America. Photo by Michael Becker through creative Commons.

One of the most common lawn mosses is the pleurocarpous species *Brachythecium rutabulum* (Figure 57) (Fletcher 1991). It is among the largest of the *Brachythecium* species, has the typical plicate leaves, and can be distinguished from the others by its papillose seta (Figure 70-Figure 71). Its ability to grow in more sunny areas makes it also a good candidate for gardens as well as paths. It has invaded between the stones of the path along the side of my house. The moss *Eurhynchium*

praelongum (Figure 55) will grow in similar areas, but is a smaller plant.

Figure 70. *Brachythecium rutabulum* showing setae that support the capsules. Photo by David Holyoak, with permission.

Figure 71. *Brachythecium rutabulum* papillose seta. The papillae are best seen along the lower sides of the seta in this picture. Photo by Janice Glime.

Another lawn species in Europe is *Rhytidiadelphus squarrosus* (Figure 2). Well manicured and fertilized lawns are deprived of this species, but grassy meadows mowed by livestock may have it abundantly (Fletcher 1991).

Since mosses barely penetrate the soil with their rhizoids, only shallow soil of 1-2 cm is needed. Texture determines ability to attach but also determines moisture retention. Thus species that typically grow on sand are not likely to do well on humus or clay. Fletcher (1991) suggests bringing back a small plastic bag of soil that can be placed on top of a peat substrate. He contends that the soil type is more important for small moss plants than for large ones. Large plants most likely provide their own substrate after a few years of growth (Figure 72).

Figure 72. *Campylopus flexuosus* showing senesced lower parts of plants upon which the active parts are able to grow. Photo by Michael Lüth, with permission.

Sun Species

Bryum argenteum (Figure 73) and *Ceratodon purpureus* (Figure 12) are good sun species. *Bryum argenteum* changes little in appearance between wet and dry. It reproduces largely by fragmentation of the tips and typically does well in locations where there is a fair amount of foot traffic.

Figure 73. *Bryum argenteum*, a common lawn species that propagates from fragments from the tips. Photo by Michael Lüth, with permission.

Ceratodon purpureus (Figure 12; Figure 74-Figure 84) is the moss my students nicknamed "tricky moss." It can take on many forms, depending on its microclimatic conditions. In spring, it is usually well hydrated and bright green (Figure 74-Figure 75). In summer, and often in autumn, it is usually dry and becomes crispy, brittle, and dark green or brownish (Figure 80-Figure 82). Its carpets can be somewhat loose (Figure 75) or quite tight (Figure 77). It is an early invader of roofs, areas on the ground receiving roof runoff, rock ledges, road sides, parking lots, and sparsely vegetated fields. It even grows in Antarctic pools (Figure 84). Nevertheless, it often does not respond well to transplantation.

Wall Species

The common European moss *Tortula muralis* (Figure 85) easily establishes itself on cement, bricks, or other walls (Fletcher 1991). Although it may be found on soil, this is not its best habitat. For rooftops (the clay tile kind), concrete, and rock walls, Svenson (2000) recommends *Tortula muralis* and *Didymodon vinealis* (Figure 7).

Figure 85. The moss *Tortula muralis* is often found on rooftops, concrete, and rock walls; *muralis* means "of the wall." Photo by Michael Lüth, with permission.

Path Species

The most famous of the species growing on paths is *Bryum argenteum* (Figure 73), silver moss. It is easily dispersed by its deciduous tips whenever something walks across it. Hence, it is common in cemeteries and other soil areas with light foot traffic.

In addition to the ubiquitous silver moss, *Barbula* [*B. unguiculata* (Figure 86), *B. convoluta* (Figure 87), *B. cylindrica* (Figure 88), and *B. fallax* (Figure 89)] is common, especially between bricks or stones (Figure 90) (Fletcher 1991). Species of *Barbula* add a fresh green color to the garden (Figure 91).

Figure 91. *Barbula unguiculata* in the center, flanked by *Conocephalum conicum* at the top right, and *Polytrichum juniperinum* below it. Photo by Janice Glime.

Based on invasion of a newly cut ski trail, I would recommend *Atrichum altecristatum* (Figure 92). This moss invaded quickly about 10 years ago and is still present today. The plants provide a yellow-green color when fresh. However, when they dry out they are not nice to look out. If a watering system is present, they will benefit.

Figure 92. *Atrichum altecristatum* drying, a species tolerant of living on paths. Photo courtesy of Eric Schneider.

Annie Martin includes *Ceratodon purpureus* (Figure 93-Figure 94) among her plantings between stones of paths. If you are willing to wait, this species will probably arrive by itself.

Figure 93. Stone path planting, showing Annie Martin pushing mosses, including *Ceratodon purpureus*, into cracks between the stones. Photo courtesy of Annie Martin <www.mountainmoss.com>.

Figure 94. *Ceratodon purpureus* with capsules in stone path in March 2017. These were planted here in December 2016. Photo courtesy of Annie Martin <www.mountainmoss.com>.

I was surprised to find *Hedwigia ciliata* (Figure 95) covering paths in our local cemetery (Figure 96). The paths were covered in gravel and could be identified by the yellow-green color of the wet moss. The moss all but disappeared from a distance when it dried and became whitened. I would not ordinarily think of this as a path moss, but it was certainly doing well in parts of the cemetery.

Erosion Control

The use of mosses to control erosion has probably been known for many centuries. Shana Gross (Bryonet 23 January 2009) reported her experiments on establishing moss growths for this purpose. She examined effects of fragment size, substrate, fragment location along the shoot, watering methods, hormone application, and nutrient application on *Bryum argenteum* (Figure 73), *Ceratodon purpureus* (Figure 12; Figure 74-Figure 84), and *Polytrichum juniperinum* (Figure 8). The responses depended on the species. She strongly supports the use of mosses for erosion control, but this adventure is not without its problems. The mosses grew well in the greenhouse, but responded poorly in the field. Fragments planted in the field required some means to affix them until

they became established. Transplanting clumps from field populations was more successful, but that is not feasible for larger areas. She suggested using methodology from cryptogamic crusts (see Belnap 1993), where inoculum of the species improved colonization over letting nature do the propagating.

Shaw (1986) developed experimental propagation methods. He was successful in propagation when he dried the gametophytes (leafy plants), ground them into a fine powder, and sowed them on native soil. His purpose was to develop a laboratory protocol for evolutionary studies, but it could be applied to getting starter biomass for stopping erosion. He found that the plants presented normal morphology.

Cultivation

Fletcher (1991) has found that mosses can be grown in a variety of containers, including Perspex sandwich boxes, Tupperware, plastic ice cream boxes, glass jars, and aquaria. However, bryophytes kept in this way typically do not survive for more than a few months. He replaced this method with a seed tray, covered with a sheet of glass or sheet of acrylic plastic. These must be kept in cool, open air and shaded. But even this improved method does not work as one might hope; bryophytes fare well for only a few weeks to months. Fletcher even tried peat beds or other means to maintain moisture, but this made matters worse. Clearly there was a need for a better method.

Johannes Enroth related to Bryonet (5 March 2010) his experience growing *Racomitrium canescens* (Figure 53) experimentally in a cemetery. The study group took advantage of the fragmentation growth capabilities of mosses and cut the shoots into small pieces (see also Figure 97). They spread these on sand and kept them moist until they became established. "The moss grew fast and formed a dense, beautiful cover that changed color along with changing air moisture" (Figure 105). This moss is a good suggestion for sunny areas.

Figure 97. *Climacium americanum* clipping to propagate. Photo by J. Paul Moore, with permission.

In Australia, Alison Downing (Bryonet 23 January 2009) and her coworkers experimented with calcareous and

acid soils to look for the success of dormant propagules. They collected soil in the field and carried it back to the lab in cotton bags to prevent mold in the humidity of plastic bags. They collected only the top 10 mm of soil, avoiding the collection of plants. In the lab, they sieved the soil in a clean environment. The sand foundation was steam-sterilized to avoid contamination from the sand. Dry heat is not effective for the resistant bryophytes unless it is at extremely high temperatures. Using the sterilized sand, they filled a 10-cm-diameter plastic horticultural pot to about 1 cm below the top. The collected soil was placed in a 5 mm layer on top of the sand. The soil propagules were cultured in a greenhouse, watered carefully with demineralized water, and the pots covered with sheets of glass to prevent contamination. The pots were checked daily and kept moist by misting with demineralized water when needed. After 8 weeks the calcareous and arid soils exhibited 100% bryophyte cover. The propagules in the non-calcareous soil required a few more weeks. Even rare species can show up using this method.

Annie Martin (Bryonet 6 August 2010) prepares the ground to prevent the invasion of rooted plants. She has used five different substrates (Figure 98-Figure 99) in her gardens, including 0.3 cm synthetic felt, 0.6 cm felt with adhesive plastic backing (used for installing carpets), basic landscape fabric (paper thin), black landscape fabric 0.5 cm thick (perforated and similar to felt; Figure 98), and coco fiber mat (to control erosion; Figure 98-Figure 99). For *Bryum* (Figure 73), *Ceratodon* (Figure 12; Figure 74-Figure 84), and *Hedwigia* (Figure 95), she uses asphalt shingles for a substrate.

Figure 98. Mats for planting mosses. The black layer is a synthetic felt with adhesive plastic backing. Photo by Annie Martin <www.mountainmoss.com>, with permission.

Figure 99. Close view of coco fiber mat and black felt for planting mosses. Photo by Annie Martin <www.mountainmoss.com>, with permission.

These substrates are not eco-friendly or natural. When installing a moss garden for her clients, Martin (Bryonet 6 August 2010) plants the mosses directly on the ground. In the nursery, the felt substrates help in retaining moisture and make it easier to lift the mosses into flats or boxes for shipping.

As Annie Martin (Bryonet 8 March 2012) gained experience, experimenting with various substrates, she developed a preference for Geo-Tex fabric as the primary substrate for field production. This retains moisture and provides a weed barrier. Martin (Bryonet 8 March 2012) plants large areas by transplanting hand-sized colonies and spreading fragments in between (Figure 100). Watering for the next few weeks is critical, but make it gentle.

Figure 100. Planting of bryophytes on mat of coco fibers. Annie Martin disperses fragments between the clumps. Photo by Annie Martin <www.mountainmoss.com>, with permission.

Katherine Frego (pers. comm. to Nancy Church 6 April 2010) reported on her success in growing *Pleurozium schreberi* (Figure 59), *Dicranum polysetum* (Figure 101), *D. scoparium* (Figure 40), *Ptilium crista-castrensis* (Figure 102), and *Ptilidium ciliare* (Figure 103). She found she could collect them at any time. She then dried them in the shade and chopped them with scissors. These fragments were stored in paper bags for months. When she was ready to culture them, she put them on a humus-y soil and covered them with a hairnet to keep them in place. She sprayed them thoroughly to wet them and they sprouted new shoots very soon afterwards. Fragments about 1 cm long formed new shoots directly. Smaller shoots formed protonemata first, and these were more fragile and vulnerable.

Johannes Enroth (Bryonet 6 August 2010) became the curator of a stone and moss garden in the courtyard of the Ministry of Education in downtown Helsinki, Finland. The original garden, planted by Timo Koponen in the 1980's, had only three species: *Racomitrium canescens* (Figure 104-Figure 105), *Plagiomnium cuspidatum* (Figure 42), and *Climacium dendroides* (Figure 106). In 2007, the number of species had expanded to 15, dominated by *Encalypta streptocarpa* (Figure 107). The latter forms a pure mat of several square meters on the sand in the middle of the yard.

Figure 104. *Racomitrium canescens* exhibiting dry appearance. The tips look frosted and add interesting contrast to other shades of green in the garden. Photo by Michael Lüth, with permission.

Figure 107. *Encalypta streptocarpa* with capsules, a species that arrived in a Finnish moss garden by itself. Photo by Michael Lüth, with permission.

I have experimented in my own garden, using various substrates and cultivation methods. One of my early attempts was to use burlap (Figure 108-Figure 109), placing it on top of visqueen plastic to prevent seeds in the soil from germinating and penetrating into the moss carpet (Figure 109). It also meant that seeds germinating on top would be unable to drive their roots into soil. Netting over the mosses helped to hold them in place when chipmunks

and squirrels ran over them (Figure 110). But apparently the soil helps in the retention of moisture because these mosses dried out more quickly than those directly on soil.

Figure 108. *Bryum* sp. on burlap. Photo by Janice Glime.

Figure 109. *Ceratodon purpureus* and *Bryum* sp. on burlap. Photo by Janice Glime.

Figure 110. *Ceratodon purpureus* and *Bryum* sp. with partial netting on burlap. Photo by Janice Glime.

Next I tried cutting the bryophytes into fragments (Figure 111) and spreading them on brown felt (Figure

112-Figure 113). This met with similar problems. The felt dried quickly, became stiff, and the moss fragments likewise dried out.

Figure 111. Fragments of bryophytes on cutting board, ready to plant. Photo by Janice Glime.

To understand the best way to keep bryophytes, we must understand how they normally grow. Rather than

being the moisture-loving plants portrayed in most popular literature, they actually prefer places with good air circulation and only a small percentage of species grow in the damp, enclosed places most people think of. Rather, many taxa grow on dry rocks, sand, or in open sun. Some prefer acid rocks and some prefer limestone. Most cannot grow where leaf litter will cover them in the fall and remain there for the winter. Some do well in pine forests where they can grow over or between the needle litter.

Johannes Enroth, Bryonet 9 March 2010, recalls covering a surface with *Racomitrium canescens* (Figure 104-Figure 105) shoot fragments. Within a matter of months, the moss formed a "nice mat." Two *Polytrichum* (Figure 8, Figure 25-Figure 28) species from spores and individual shoots planted in the soil were not very successful. Growth was slow and the planted shoots often died. *Plagiomnium* sp. (Figure 42) was more successful.

Nancy Church (pers. comm. 27 July 2010), formerly from Moss Acres, told me that they used a product called Terra Blend70/30 with Ultra Grow. The 70/30 ratio refers to the wood fiber/paper fiber content. The Moss Acre folks believe the "Ultra Grow," the ingredients of which are kept a close secret of the manufacturer, is part of what makes this so effective with mosses. Keith Bowman, one of Dr. Kimmerer's graduate students, worked with Moss Acres on experiments with the Ultra Grow cellulose, and Church was curious to see if the fertilizer helped the vascular plants (weeds) or the moss more. It has certainly helped the moss in all of the "amateur" experiments they've done at Moss Acres.

Sandrine Hogue-Hugron (Bryonet 31 May 2011) experimented with growing bryophytes to restore sand pits. Although there was colonization on the bare sand, colonization was optimal when the sand was mixed with peat. Peat is also a good substrate for making a bog garden. Industrial peat is a good choice because it is usually free of propagules. The peat can be further sterilized by heating to 60°C for an hour and a half.

Winter Culture

Martin (2010) finds that winter is a good time to harvest and plant mosses in western North Carolina, USA. But if you live in the Keweenaw Peninsula of Michigan, USA, the mosses are under a meter or more of snow. In Japan, the best time to plant is just before the rainy season, reducing the need for frequent watering. Martin reports that her mosses emerge from short snowfall events looking green, whereas when mine emerge after 4-5 months of snow burial, they often look brown, becoming green when new growth appears.

Freezing doesn't harm the mosses (Figure 114), with some photosynthesizing at temperatures below 0°C (Liu *et al.* 2001). Snow insulates them, and I am guessing that some photosynthesis is able to occur in the light filtering through shallow snow in spring and fall. Martin (2010) has been successful in planting mosses on frozen ground, but the moss itself should be thawed first. She warns that on warmer days when the temperatures are above freezing, the garden should be watered, especially during the first few weeks after planting. (And don't forget to empty the hose so it won't freeze and burst.)

Figure 114. *Hylocomium splendens* in snow. Photo by Michael Lüth, with permission.

When there is no snow cover, winter is a season of growth, along with spring and autumn when the air is cool. Bryophytes tend to be dormant in the heat of summer, especially if they are dry.

Moss Plantations

When visiting a commercial moss plantation in Japan near Nagoya, I found the ground planted in several species of *Polytrichum* (Figure 8, Figure 25-Figure 28) and its relatives *Pogonatum* (Figure 115) and *Atrichum* (Figure 3, Figure 92). The landscape was dotted with small pine and fig trees, providing light shade for the mosses beneath (Figure 116). Other growers cover the mosses with straw or bamboo screens to provide shade. The proprietor proceeded to show me, with hand motions and occasional translations by N. Takaki (for whom *Takakia* is named), how the mosses were dried, then pulverized between the hands, and sown like grass seed in wooden flats. These flats were kept well watered in full shade until the mosses were well established. Then they were transplanted outside under the shade of the pines and figs until they formed a carpet (Figure 116).

Figure 115. *Pogonatum japonicum*, a moss in a genus used in moss gardens in Japan. Photo from Digital Museum, Hiroshima University, with permission.

Figure 116. This plantation in Nagoya, Japan, uses pine trees to provide shade for growing mosses. Photo by Janice Glime.

When they were harvested for a buyer, they were removed in squares about 20x20 cm and stacked to dry (Figure 117). Their new owner would then plant them, checkerboard fashion, in a dooryard garden or along a small backyard path, trampling them into the ground and once again breaking off small fragments of moss. A small board can be used to press and spread the mosses instead of trampling, but pressing them into the ground is important. It is the ability of mosses to regenerate from fragments that makes this process work so well. The fragments and new growth eventually fill in the empty squares of the checkerboard, providing a continuous carpet for the moss garden, although Schenk (1997) advises us that it can take 2-3 years for a *Polytrichum* (Figure 8, Figure 25-Figure 28) carpet to fill the gap. Mosses such as *Brachythecium* (Figure 57), with their horizontal growth form, may fill the gap within a year.

Figure 117. Stacks of *Polytrichum* are ready for delivery to a private garden near Nagoya, Japan. Photo by Janice Glime.

This ancient art of planting mosses by pulverizing them has been adopted by the American Horticulturist Society. In their Fact Sheet for Moss Gardening, they recommend grinding dried moss and spreading it as powder, cautioning the gardener never to buy moss from a grower unless you are certain that the moss has been propagated by the seller and not taken from the wild – good conservation advice.

Experimental studies support this pulverizing method as well. Miles and Longton (1990) found that fragmentation was superior to spores in the development of upright shoots in such common garden mosses as *Atrichum*

undulatum (Figure 3) and *Bryum argenteum* (Figure 73). In fact, Shaw (1986) contends that whether in an industrial setting or in the laboratory, starting cultures from spores is impractical for many species. He found, using the pulverizing method, that within a month, new gametophores were evident in most species, and within three months regenerated plants filled his pots. He had the best results when the plants were misted for six seconds every thirty minutes. Svenson (2000), on his moss gardening website, recommended filling in the bare spots between patches of moss by using the pulverizing method. This can be done by putting pieces of moss in a blender with a small quantity of water for two minutes, then spreading them between the transplanted mosses.

A mixture of 50% coarse sand, 30% vermiculite, and 20% peat provides a good substrate, and the optimum growth temperature for temperate zone mosses is believed to be around 10°C (Iwatsuki 1979). In the laboratory, Petri plates with layers of filter paper saturated in tap water have been successfully used to regenerate *Atrichum undulatum* (Figure 3) leaf fragments (Gemmell 1953); in nature, the soil will do just fine if kept moist. [Note that not all tap water is created equal; it may kill some species and be worse in some areas.]

My students at Michigan Technological University successfully grew protonemata from fragments of five North American taxa in genera commonly used in moss gardens [*Atrichum oerstedianum* (Figure 118), *Dicranum scoparium* (Figure 40), *Fissidens adianthoides* (Figure 48), *Leucobryum glaucum* (Figure 34), *Plagiomnium affine* (Figure 119)] in a dish garden, using this method and a modified version with a strip of cheesecloth over the fragments to retain moisture (Plante *et al.* unpublished data 1993; pers. obs.). Protonemata developed in 2-3 weeks. Fragments placed on sand alone failed to produce any growth during the experiment. In addition to the fragments, whole plants were planted, and at least a few plants of *Atrichum oerstedianum*, *Fissidens adianthoides*, and *Plagiomnium affine* produced new branches, although the original branches became brown and wilted. Subdued light (900 lux for 8 hr d⁻¹) and moderate temperatures (ca. 20°C) seemed more favorable than a higher light intensity and temperatures of 38°C.

Figure 118. *Atrichum oerstedianum*, a species that can be grown from fragments. Photo by Karen Renzaglia, with permission.

Figure 119. *Plagiomnium affine*, a species that can be grown from fragments. Photo by Janice Glime.

It is during the critical early establishment stage that moisture is very important, and the Japanese often time their planting to coincide with the rainy season so that the mosses get natural watering daily. Yet, the entire first year and often the second require careful attention to water requirements. As discussed in the chapter on "Water Relations: Rehydration and Repair," frequent wetting and drying is quite detrimental to a moss because each time it is dried and rewet it must repair damaged membranes, often requiring a full day before there is any net energy gain. Transplanting brings with it its own share of damage and adjustment that makes the mosses less tolerant of natural stresses.

It is interesting that Schenk (1997), with his long-time experience as a moss gardener, reports that few mosses will grow successfully from fragments. He touts *Leucobryum* (Figure 34; Figure 120-Figure 121), *Racomitrium* (Figure 53), and *Dicranoweisia* (Figure 122) with this ability, but finds others to be reticent to yield to the gardener's wishes. Nevertheless, as he acknowledges, all mosses share this ability to regenerate from fragments, and I have observed in nature young shoots of *Scapania undulata* (Figure 123) (Glime 1970) and *Atrichum* (Figure 3, Figure 92) (Glime 1982) developing from leaf fragments to which they were still attached. *Fissidens* (Figure 48) species are especially adept at this, and I soon found new colonies all over my garden room, presumably transported about as fragments by my box turtle – they had never produced any capsules. In the lab, Plante *et al.* (unpub. data 1993) were successful with both whole plants and fragments of *Fissidens*.

One of the most luxurious growths of moss I have seen outside of nature was on a discarded piece of carpet that was able to soak up and maintain moisture over long periods of time (see, for example, Figure 124). This is

reminiscent of the technique of using cheesecloth on flats to grow mosses that are to be draped over rocks or uneven landscapes. The cheesecloth method takes advantage of fragments, although spores can be used as well (McDowell 1968). Partially dried moss fragments must be spread over cheesecloth that overlies a sand-peat moss or sawdust mix in a flat. The pH can be lowered by soaking the mix in a solution of 1 part skim milk or prepared powdered milk to 7 parts water (McDowell 1972). These are covered with a second piece of cheesecloth and kept moist by misting.

Figure 124. This rug has a luxurious growth of *Ceratodon purpureus*. Photo by Michael Lüth, with permission.

When the plants are well established (about 4 ½ months), it is easy to transplant them by lifting the soil/cheesecloth layer. The cheesecloth can be cut to shape as needed. Some gardeners have been successful in growing rock-dwelling taxa this way as well. The cheesecloth can easily be draped over rocks. The mosses grow through the cheesecloth, and eventually the cloth will rot away. If the white color of the cheesecloth is bothersome, coffee (soak in 3 teaspoons instant coffee per cup boiling water for 10 minutes) can be used to stain the cloth (McDowell 1972). Crum (1973) has found that *Brachythecium salebrosum* (Figure 125) and *Plagiommium cuspidatum* (Figure 42) are relatively easy to grow in this way, emphasizing that regeneration works better than transplantation.

Figure 125. *Brachythecium salebrosum* with capsules, a moss that will develop well on cheesecloth. Photo by Michael Lüth, with permission.

Even when mosses are transplanted or sewn directly on the garden soil, it is often necessary to spread a cover of cheesecloth to prevent damage from birds that would destroy the tender plants before they could gain sufficient establishment. If the moss is to be transplanted, the cheesecloth serves the double purpose of keeping the moss from breaking apart as it is handled.

Planting on rocks can be a challenge, as the moss may buckle up on the dry substrate, or simply get blown away. One solution to this is to glue them there with a good epoxy such as Araldite, a very strong two component epoxy resin (Paul King, pers. comm.).

Transplanting

For those preferring the transplant method, the best place to gather moss is rich woodland areas (Pullar 1966/1967) and the best time of year to collect is from autumn into the winter months (Iwatsuki 1979), depending on where you live. But mosses should not be gathered without permission of the owner, and on public lands a collecting permit is usually required (and should only be done if the area is scheduled for destruction). Furthermore, bryophytes should not be imported from other countries for one's personal gardens, and when such importation is necessary for an institution, proper permission must be gained from both the country of origin and the one of import.

Mosses can be transported in a variety of ways fitting your own convenience. Annie Martin uses plastic sleds (Figure 126) and plastic flats (Figure 127). Paul More uses cardboard boxes (Figure 128). I have used deeper boxes, putting layers of newspaper between the layers of mosses to separate them. The newspaper can be omitted, but it is easier to separate the mosses later when the layers are distinct. I have also used ice cream buckets on short excursions when I had no transportation (Figure 129).

Figure 126. Sleds of mosses, in this case being transported for planting. Photo by Annie Martin <www.mountainmoss.com>, with permission.

Although bryophytes lack roots, their rhizoids are often connected to symbiotic fungi (e.g. Davey & Currah 2006; Renzaglia *et al.* 2007; Pressel *et al.* 2010). Therefore, they should not simply be plucked from their substrate. It is preferable to bring the top layer of soil with them. This is important for several reasons. It will help to maintain fungal connections and provide an inoculum for new associations to establish; it will help hold cushion growth forms together; and it will retain the suitable nutrient and pH conditions of its original substrate, at least initially.

For some species, removal from their forest habitat might mean removal from a necessary host plant. Some bryophytes, in particular *Cryptothallus mirabilis* (Figure 130), require a photosynthetic partner to provide carbohydrates. This partnership can be mediated by the mycelial threads of a fungus that is also linked to a shrub or tree that reaches closer to the canopy. Or it might be linked to decaying leaves or logs. This is a recent area of research, so we know little about these partnerships, but they may explain the failure of some transplants.

Figure 130. *Cryptothallus mirabilis*, a thallose liverwort that requires a fungal partner to obtain carbohydrates. Photo by David Holyoak, with permission.

Pinning the bryophytes to the substrate with wooden toothpicks angled through the mat (Figure 131), a technique I learned from Jon Shaw, helps to maintain contact with the substrate during dry periods, and of course keeps them where you put them. Special moss clips (Figure 132) are available for anchoring the mosses, but toothpicks work and are less conspicuous.

Figure 131. Toothpicks holding transplanted mosses onto a clay bank. Photo courtesy of Annie Martin <www.mountainmoss.com>.

Figure 132. Moss pins from Moss and Stone Garden. Photo with permission from David Spain.

In this regard, Schenk (1997) advises maintaining as much soil depth as possible when gathering the clump of moss, whereas Bland (1971) advises one to remove as much as possible to prevent curling up at the edges (Figure 133), turning the moss upside down and washing away the soil to prevent shrinkage. I recommend the former because it causes the least disruption of rhizoids and one doesn't have to worry about destroying possible mycorrhizal connections, which may be more common than we realize. It does require keeping the moss and soil wet until the soil has blended with the underlying substrate.

Figure 133. *Bryum* sp. in moss garden. These mosses were touching tightly together when they were planted, but when they dried they shrank, creating spaces around the edges. Photo by Janice Glime.

Signs of death occur rapidly in transplants, but those clumps that remain green will become stabilized within a few weeks. Once they do, Ando (1971) suggests that regular watering can be discontinued. Seike *et al.* (1980), on the other hand, recommend daily watering.

Maintenance of the integrity of the clump is of utmost importance. If it is necessary to expose the lower part of the stems around the edge of the clump (Figure 134) due to using only part of a clump or other disruption, these lower parts should be protected either by building up soil around them or pressing a rock next to them (Figure 135). If some of the stems are taller than the other stems, they can be cut to avoid having them dry out. For many bryophytes, a new branch will form and continue growing.

Figure 134. *Bryum* sp. with exposed edge in the forefront. The moss will dry out here and die back from the edge. Rocks placed against such edges, or other moss clumps, will reduce the drying, but frequent watering after transplanting is important. Photo by Janice Glime.

Figure 135. *Ceratodon purpureus* and *Bryum* sp. with stones to protect edges. Photo by Janice Glime.

If you are trying to establish a lawn, you might be able to purchase a ready-to-go mat (Figure 136). These can be rolled up much as the sod purchased for grass lawns. With a landscaping mat under them, they are easy to handle (Figure 137) and to cut to fit any area (Figure 138-Figure 140).

Weeding of the imported moss is important so that competition is not planted with the mosses. Leaf, stick, and seed litter should be removed, but caution must be used to prevent disruption of the clump.

Some gardeners recommend making a depression, laying a bed of gravel, then putting the mosses on top, but still within the depression. Exposure of the lower parts of the moss seems to be a prescription for disaster due to excessive drying.

It is to our benefit in gardening that the mosses respond quickly to the stresses of sun, showing bleaching or browning of leaves in only a day (Schenk 1997). This quick forewarning tells us to try a different location, a different moss, or provide more care and maintenance.

Substrate Conditioning

Successful moss gardening requires at least a modicum of knowledge of the ecology of mosses, and a student of their ecology has much to learn from the successful moss gardener. Aside from the expectation that they will require a moist, shaded habitat, most non-bryologists have little understanding of bryophyte requirements. Most mosses seem to prefer a pH of about 5.5, attainable by spreading powdered sulfur over the soil (about 1.1 kg per 9 m²) (Schenk 1997). Alternatives include powdered skimmed milk, aluminum sulfate, or rhododendron fertilizer. A light misting from the sprinkler will help to affix these to the ground. However, Alison Downing reminded us on Bryonet (20 April 2005) to be careful using milk (or any lime) on sandstone because the calcium in milk can completely change the nature of a sandstone habitat. Instead of *Campylopus* (Figure 141), *Lophocolea* (Figure 9), *Sclerodontium* (Figure 142), and other typical sandstone taxa, you will find instead introduced or cosmopolitan taxa such as *Funaria* (Figure 143) or *Bryum* (Figure 73).

Maintenance

Martin (2016) advises using the three W's in caring for a moss garden: Water, Walk, Weed. Although mosses will survive extended drought, they won't look nice. And when you are first propagating them, whether by spores, fragments, or transplants, they need constant hydration, often requiring watering. Walking on more mature plants helps to spread them through fragmentation (Figure 144). Weeding needs no explanation – the tracheophytes can quickly outgrow them.

Figure 144. Annie Martin demonstrates walking on mosses to help in fragmentation and dispersal. Photo by Annie Martin, with permission <www.mountainmoss.com>.

No Fertilizers?

Fertilizers must be applied to mosses with great caution. An "elixir" of manure seems to be a suitable supplement (Schenk 1997). Svenson's (2000) website suggested steeping cow manure in a burlap or cheesecloth bag in a bucket of water for 3 weeks (outside, I hope!) before applying it. An alternative is using 1 part of skim milk or buttermilk to 7 parts of water and applying twice per day for two weeks in spring to acidify the soil. Most other fertilizers, especially if applied dry, can kill the moss.

David H. Wagner (Bryonet 8 May 1998) told us that the egg albumen mixed with buttermilk would polymerize and act as a protein binder, creating an adhesive. As the mosses grow and become established, the mix becomes a source of nitrogen for them.

Iwatsuki and Kodama (1961) caution that fertilizer should never be used for mosses. Contrasting to the powdered sulfur acidifier recommendation of Schenk (1997), Stubbs (1973) recommends the use of fertilizer based on iron sulfate as a means of killing moss fast. In fact, fertilizer is a commonly suggested means for getting rid of unwanted mosses. On these one-cell-thick leaves, the dry powder soon goes into solution when water becomes available, greatly altering the osmotic relationship between outside and in and introducing the potential of membrane damage. Furthermore, dry fertilizers tend to be hygroscopic and draw water from the delicate and unprotected moss leaves. The effect is much like the desiccation seen among the mosses on Mount Rainier shortly after the eruption of nearby Mt. St. Helen's (Figure 145). However, if applied in liquid form followed by frequent watering, fertilizer can benefit the moss. Lime fertilizers, however, should be avoided due to their alteration of the pH. The seeming contradiction to the advice of Schenk is that he suggests applying the acidifiers to the soil and wetting them down **before** the moss is planted there.

Horticultural magazines and texts extol the advantages of a wide variety of human foods as starters for mosses. Gillis (1991) describes making moss beds by mixing a

handful of moss, a can of beer, and a half teaspoon of sugar in a blender, then spreading the mix 5 mm thick on the ground. She found that the mosses grew within five weeks. In addition to beer, egg whites, and buttermilk, others have successfully used rice water, carrot water, potato water, and just water as the medium. Ellis (1992) claims that such mixtures, even the water, are particularly helpful in adhering the moss fragments to rocks. My own experience is that these food additions serve best to feed fungi and pillbugs, thus being detrimental to the mosses.

Figure 145. This *Grimmia* on Mt. Rainier, Washington, USA, is covered with ash from the eruption of nearby Mt. St. Helen's. The moss is badly desiccated by the ash that is like some fertilizers. Photo by Janice Glime.

Annie Martin (Bryonet 22 June 2013) raised the issue of fertilizing the mosses. First, fertilizers should be applied in very dilute watering additions. Fertilizers on dry mosses can further desiccate them. As in all other issues regarding bryophytes, bryophyte species differ in their responses. Annie Martin (Bryonet 22 June 2013) reported that in her early days of moss gardening experimentation, she watered with Miracle-Gro acid mix. However, when she learned of the dangers of fertilizers she switched to straight tap water only.

One additional problem with applying fertilizers is that flowering plants will benefit more than the mosses, thus introducing a greater weed problem.

Watering

The subject of watering is an interesting one. Some people are adamant that only distilled, demineralized, or rainwater can be used. Others have no problem using tap water (Figure 146). This argument does not surprise me. Tap water can differ greatly between locations. I was amazed to find *Fontinalis* (Figure 147) growing happily for years in a tap water aquarium in Japan. But when I tried to grow several species in tap water in New Hampshire, USA, the copper in the water from the pipes turned the plants yellow overnight. After that failure, we used only stream water.

Figure 146. Sprinkling system used by Paul Moore on his moss lawn. Photo courtesy of J. Paul Moore.

Figure 147. *Fontinalis antipyretica*, an aquatic moss that is sensitive to heat. Photo by Bernd Haynold, through Wikimedia Commons.

City water is much more likely to kill bryophytes than spring water. City water usually has chlorine added and suffers from the solution of metals from water pipes. It also matters if the tap water is the exclusive source of water. Minerals can accumulate on the surface on the bryophytes; intermittent rainfall can remove some of that accumulation. *pH* can make a difference because it is less likely to carry calcium that forms crusts on the mosses. Annie Martin (Bryonet 22 June 2013) has had no problems using tap water (Figure 148) for at least 10 years, but her water is acidic. Martin considers adequate watering to be the most important factor in moss garden success.

For my own garden, I used collected distilled water or rainwater for several years (Figure 149). Other years I used only misting with a sprinkling system that used tap water (Figure 150). However, that tap water went through a filtering system that removed some of the minerals, and spraying it in the air helped to dissipate the chlorine.

Figure 148. Furman-Moss-Watering at Mountain Moss. Photo courtesy of Annie Martin <www.mountainmoss.com>.

Figure 149. Distilled water and collected rainwater are both good sources of water if your tap water is detrimental to your bryophyte garden. Since the garden is outdoors, the bryophytes collect dust and get their nutrients from that dust when they are watered. Photo by Janice Glime.

Figure 150. Sprinkler in my own moss garden. When the water comes on, the sprinkler head rises to about 15 cm and sends water in all direction.

One gardener in Raleigh, NC, USA, has been very successful growing *Mniaceae*, including *Plagiomnium* (Figure 42) (reported by Annie Martin, Bryonet 6 August

2010). He, like Martin, uses three layers of felt with plastic underneath and netting on top. Martin believes his success is due to watering six times each day for 4 minutes per watering session. He uses creek water in his misting system. Watering in unplanted areas also resulted in a carpet of thriving *Plagiommium* that arrived by itself.

Annie Martin (Bryonet 6 August 2010) warns that not all mosses have the same nutrient or watering requirements. She finds that *Bryum* species (Figure 73) need to dry out sometimes; likewise, *Dicranum scoparium* (Figure 40) will not tolerate being wet all the time.

I have never tested it because my own garden is too small to replicate, but I have assumed that watering the mosses on a sunny, hot afternoon is not wise. They can't close guard cells like flowering plants, and they are C₃ plants that respire more than they photosynthesize at higher temperatures, often starting above 20°C. I have assumed that it is best to let them shut down on hot, sunny afternoons. I do know that *Fontinalis* species (Figure 147) cannot sustain vitality if kept in water at 20°C for more than 3 weeks (Glime 1987), presumably due to the high respiratory ratio. In my own moss garden, I have an automatic sprinkling system that comes on at 6 am, giving the plants sufficient moisture to photosynthesize in the cool hours of the morning. This regime seemed to work well. In hotter locations, an earlier watering time might be preferable.

One dealer recommends daily misting as opposed to intermittent watering to avoid drying or water logging. But one must exercise caution here. Bryophytes that suffer frequent wetting and drying (to the point of damage) will not have sufficient time for repair during the intermittent moist periods. Consider a sprinkling system to keep things moist, preferably on a timer to water at night, permitting the bryophytes to photosynthesize in the cool morning.

I have found that advice I get on moss gardening from another part of the country often does not work for me, and I end up going back to my original methods. Alkaline soils or clay soils will require different watering regimes from those of humus, and ease of transplanting and growing will be much better in humid or rainy climates. For example, I found that mosses stay wet longer for me if I do NOT put them on layers of felt, but can understand that downstate where Rick Smith gardens, limestone soils may serve as a desiccant and dry the mosses more quickly and the felt would protect against that. The felt and plastic do help reduce weed invasion.

Weeding

Mashuri Waite (Bryonet 2 February 2011) expressed his surprise when visiting the Cibodas Botanical Garden in West Java, Indonesia. He found that a species of *Marchantia* (Figure 16) was a problem weed in that garden. This was in contrast to his experience in Hawaii. This is yet another example of differences in the success of a species of bryophyte under different growing conditions.

Weeds are also a matter of personal choice. To one person it is a weed; to another it is a cherished plant to be encouraged.

Weeding bryophyte gardens requires different methodology from gardens of flowers and ferns. The surface-growing bryophytes are easily dislodged as the weeds are pulled up. It is best to pull the weeds, especially

tracheophytes, as soon as they appear and before they grow large roots. This will create the least disruption. When pulling them, especially if they have penetrated the ground very far, hold the plant to be pulled close to the ground and place the middle and index fingers of the opposite hand so that one is on each side of the base of the stem to hold the bryophyte in place as the rooted plant is pulled. Weeding should be done as often as necessary to keep the garden weed free.

Weeding is not as big a job as it may seem if it is done frequently. Young plants are easy to pull. And usually kneeling or stepping on the bryophytes does not harm the bryophytes and may even help to propagate them.

Herbicides

There actually are a number of publications on the effects of herbicides on bryophytes (e.g. Stjernquist 1981; Balcerkiewicz & Rusinska 1987).

Of course mosses are slow growing and soon succumb to the encroachment of tracheophytes, so it is no wonder that herbicide applications can result in luxurious moss carpets. Schenk (1997) has witnessed the ready success of *Polytrichum* (Figure 8, Figure 25-Figure 28), *Pohlia* (Figure 151), and *Atrichum* (Figure 3, Figure 92) following such applications, and Ella Campbell, at a bryological meeting, once commented that the hornworts were ready colonizers following herbicide applications. Likewise, Balcerkiewicz and Rusinska (1987) found that bryophytes expanded on areas treated with herbicides.

Figure 151. *Pohlia nutans*, a species that seems to benefit from herbicide applications. Photo by Michael Lüth, with permission.

Herbicides such as Paraquat, Simazine (Bond 1976), 2, 4-D, Atrazine (D. H. Wagner, pers. comm.), and Roundup (Schenk 1997) will encourage moss growth by eliminating invading tracheophytes (Bond 1976). Weeding is of course a safer option, but be sure to hold the mosses down as you pull each weed to avoid disrupting the rhizoids too badly.

Ben Tan (Bryonet 15 April 2014) reported that experiments using herbicides and pesticides, conducted by his students, did not result in an easy kill of the mosses except at very high concentrations. He cautioned that if one does eliminate the mosses, aggressive flowering plants (weeds) will readily establish themselves.

But this is not the experience of all researchers. Rowntree *et al.* (2003) found that the herbicide Asulox inhibits moss growth. When they cut plants to a standard length and expose them to Asulox for 24 hours, they found

that all 18 species tested exhibited reduced elongation. The amount varied among species and at different concentrations. The effective concentrations were the same as those effective on fern gametophytes. Rowntree and coworkers suggested that the ability to produce secondary branches might confer tolerance to single exposures of Asulox in some species.

In a different study, Rowntree *et al.* (2005) exposed cultures of *Bryum rubens* (Figure 152-Figure 153), *Campylopus introflexus* (Figure 141), and *Polytrichastrum formosum* (Figure 154) to Asulam in the culture medium. This study used protonemata that were exposed for 24 hours to Asulam, then transferred to herbicide-free media. A second trial maintained the protonemata on the herbicide medium for three weeks. In this case, the 24-hour exposure at concentrations of 0.001 g active ingredient L⁻¹ had no effect on growth or development of the mosses. However, all three species experienced reduced growth and developmental anomalies in continuous of exposure at 0.01 g L⁻¹. *Campylopus introflexus* was the least sensitive; *Polytrichastrum formosum* was the most sensitive, with a 10-fold difference in response.

Figure 154. *Polytrichastrum formosum*, a species for which development is affected by the herbicide Asulam. Photo by Michael Lüth, with permission.

Karunen *et al.* (1976) exposed germinating *Polytrichum commune* (Figure 25) spores to S-ethyl dipropylthiocarbamate. Surprisingly, at low concentrations (2 ppm by weight), the herbicide actually stimulated the growth of the young protonemata compared to the controls. They had a higher chloroplast pigment content as well. When the concentration was increased to 100 ppm, however, the development was slowed and there was a 30% reduction of chlorophylls and carotenoids. Nevertheless, the dry weight did not differ significantly from that of the controls. At 200 ppm, the spores either did not germinate, stopped germinating at an early stage, or formed deformed sporelings with few tightly-packed short cells. A number of unusual morphological changes occurred. A concentration of 300 ppm the spores rarely germinated.

Dichlorophen (2, 2'-methylene-bis(4 chlorophenol)) is a commercial product used to eliminate bryophytes (Brown *et al.* 1986). Brown and coworkers experimented with the pleurocarpous moss *Rhytidiadelphus squarrosus* (Figure 2) and the thallose liverwort *Marchantia polymorpha* (Figure 16). Dichlorophen induces loss of intracellular potassium and magnesium, inhibits photosynthesis, and depending on concentrations either stimulates or depresses CO₂ production in the dark. These symptoms suggest membrane damage. Tissue age affects the sensitivity, but light does not.

Rod Seppelt (Bryonet 17 April 2011) reported that an Australian student had studied the effects of herbicides on mosses. The student concluded that it was the surfactants in some herbicides that provided the damaging factor. But he concluded that bryophyte response to herbicides was complex.

Using 115 plots in a randomized design, Newmaster *et al.* (1999) compared the effects of two silvicultural herbicides (Vision®, Release®) on bryophytes and lichens in a harvested boreal mixed woodland. Concentration gradients of 0.71-6.72 kg active ingredient ha⁻¹ caused a decrease in species richness and abundance in both groups. Only a few species of colonizers remained. Bryophytes and lichens could be sorted into herbicide-tolerant colonizers, semi tolerant long-term stayers from dry open forest, and sensitive forest mesophytes.

Bryophyte "Predators"

Bryophytes are not without their share of enemies – playing roles with impacts that few ecologists have begun to imagine. I couldn't keep mosses in my garden room – even when I brought in vast quantities; my finches soon spread them about the room in their efforts to carry them to their nests, but even the dispersed mosses were soon removed by the birds. Newly established protonemata are soon disrupted and destroyed by birds gathering new plants or scratching for grit. In my terrarium, the pillbugs (*Porcellio scaber*; Figure 155) eradicated them from the rocks completely in just a few weeks, and the beautiful carpet I draped on a rock outside was transformed literally overnight into the look of Swiss cheese. Picking up the moss carpet to understand the problem resulted in hundreds of pillbugs falling to the ground! As mentioned earlier, those wanting to use moss they collect are often encouraged to spray a 50% mix of buttermilk and water on the desired surface and then presumably spread a moss carpet over it, but I tried a similar recommendation of raw eggs to little avail. It was that patch of moss that became devoured by pillbugs and I suspect the egg helped make it so.

Figure 155. *Porcellio* cf. *scaber* on *Marchantia polymorpha*, a common herbivore on bryophytes. Photo by Walter Obermayer, with permission.

To keep your bryophyte garden healthy and green, Mizutani (1975, 1976) and Fukushima (1979a, b, 1980) advise eliminating potential destroyers such as moles (Figure 156), slugs (Figure 157), crickets (Figure 158), and ants (Figure 159). Good luck!

Figure 156. Mole, sometimes a pest in moss gardens. Photo by Michael David Hill, through Creative Commons.

Figure 158. *Gryllus rubens*, southeastern field cricket. Crickets can be a pest in moss gardens. Photo by Jeffrey Reed, through Creative Commons.

Figure 159. Ant on moss, sometimes a pest in moss gardens. Photo through Creative Commons.

A second concern may be introducing pests from other locations, especially outside the country. Bryonettors discussed this several years ago, but many of the reports covered what didn't work. Among these, Eva Krab (Bryonet 3 February 2012) reported using 100% CO₂ for 12 hours in a closed chamber, then leaving the cores of moss out at room temperature for 24 hours to allow eggs to hatch, then freezing them at -20°C. After three rounds of those treatments, she had no success with *Sphagnum fuscum* (Figure 20) and only limited success with *Hylocomium splendens* (Figure 58).

Other Pests

Rick Smith, on Bryonet 9 February 2011, claimed that "birds have so much time on their hands they relentlessly attack moss gardens and unless the botanic garden has lots of moss then the birds concentrate their damage on the small poor moss garden." My own experience is that chipmunks can be just as destructive. They need only run across the bryophytes and their feet kick them up. And they seem to have a special attraction for *Thuidium delicatulum* (Figure 43-Figure 45) as the entrance to their tunnels. Mine never lasted for more than a few days before it had a bare spot and a tunnel entrance in the middle of it! I'm fairly certain that was a chipmunk, but some of those torn up patches may have been the work of birds instead of chipmunks. The fresh patches of mosses seem to attract the most attention. Perhaps it is due to birds looking for food among the fauna. Rick Smith also warned that "other obstacles are rodent damage (vole, squirrel, raccoon) and leaf removal."

Rick Smith has written a small book, *New Methods in Moss Gardening*. In that book he explains using an invisible mat system to reduce the unwanted interaction. He places felt (Figure 162) on the bottom – 2-3 layers, to block the competing vascular plants from emerging and to keep the soil from wicking the water away. On that he grows the mosses with a net on top to keep the birds and

rodents from tearing it up. I have not had much success with the felt, but I think the problem is that I start with clumps of moss and Rick starts with tiny pieces that he broadcasts on the felt, then grows them in controlled conditions until they are large enough to put in the garden. I did try that once, but mine dried out too quickly. His method is much like grabbing that discarded carpet that has accumulated bits of soil and a healthy growth of mosses. But for thicker mats where tree seeds can lodge, seeds still germinate and succeed.

Overwatering can have some interesting invertebrate consequences. Too much water encourages earthworms to live closer to the surface, resulting in castings (Spain 2012b). If this is a moss garden with thin mats, the castings are deposited on the moss (Figure 160). When these are numerous, as they can be, they become unsightly. The prevention is to decrease the watering.

Figure 160. Earthworm castings on a moss mat. Photo by Ken Gergle for Moss and Stone Gardens.

Earthworm castings can be removed by letting them dry and removing them with a knife or crumbling them (Spain 2012b). The remaining hard portion can be removed by using a pump sprayer to soften them and gently wash them away. Using a hose or other high-power sprayer should be avoided because it will make the moss and soil wet again, once again encouraging movement of the worms to near the surface.

Netting

The netting is another story. One recommendation is to use a fine net with a mesh of about 0.8 mm such as a bridal veil, a material known as **tulle**, to keep rodents and birds from disrupting the bryophytes. But bridal veil is unsightly. Instead, I started with a fine mesh like one might find on a wedding veil, but instead of the soft cloth of wedding veils, I chose nylon window screening because it was not so conspicuous. That protected the mosses from rodents and birds, but for some of the mosses it kept them from getting wet unless it was a downpour. The water would bead up on top of the screen (Figure 161-Figure 162) and its cohesion kept it from penetrating. Sometimes cohesion and adhesion work to disadvantage!

Figure 161. *Bryum* sp. on burlap with wet net in lower half of image. Upper mosses in image have no netting. Photo by Janice Glime.

Figure 163. *Polytrichum juniperinum* under netting, showing how they have grown sideways due to the restriction of the netting. Photo by Janice Glime.

Figure 162. Wet netting on *Polytrichum commune* that is planted on brown felt, showing the water beading on the net and not penetrating to the moss. Photo by Janice Glime.

Polytrichum (Figure 8) had particular problems with the nylon window screening. It often bent over instead of growing through the mesh (Figure 163-Figure 165), and the water beaded up on top of the net. In the morning when dew was on the net, the mosses were invisible. The next growing season some of the narrower young shoots grew through the net, but setae from the previous autumn were trapped under the net (Figure 166). Finally, all the growing tips were above the netting that spring (Figure 167). But even then, water movement was not normal because of the constricting threads at the point where the moss penetrated the net. And if the mosses grow through the net, the netting can never be removed. Now, seven years later, the net is hidden and the mosses appear to be normal (Figure 168).

Figure 164. *Polytrichum* and fragments on felt under nylon window screening. Rocks hold the edges of the screening in place. Photo by Janice Glime.

Figure 165. *Polytrichum juniperinum* under netting after stems became more upright. Photo by Janice Glime.

Figure 166. *Polytrichum juniperinum* emergence through netting with sporophytes produced the previous growing season trapped beneath the netting. Photo by Janice Glime.

Figure 167. *Polytrichum juniperinum* emergence through netting after several years of growth. Note how it keeps the plants separated, reducing their ability to help each other transport and retain water. Photo by Janice Glime.

Figure 168. *Polytrichum juniperinum* in moss garden, November 2017. They are continuing growth above the netting, with netting completely hidden. Photo by Janice Glime.

Rick Smith (Bryonet 30 August 2010) solved the constriction problem by placing the net over moss

fragments so that they grew through it while they were still small and thin. Young (small) plants will grow through the bird netting, but so do some young weeds, and they are pretty impossible to pull out by the roots and to get out of the netting.

One solution to this problem is to put bird mist netting over the bryophytes instead. Susan Moyle Studlar (Bryonet 6 February 2012) considers netting to be essential to keep birds out. In her West Virginia, USA, garden, the birds toss the mosses about "with abandon" in search of the invertebrates beneath them. She found that the Berlin Botanic Garden used bird netting to protect the bryophytes from birds (Figure 169).

Figure 169. Moss garden in Berlin Botanic Garden, showing bird netting. Photo courtesy of Susan Moyle Studlar.

I finally solved the problem by ordering bird mist netting. It has a mesh about 5-6 mm and is made of fine black plastic. I hold it in place and help it conform to the uneven surface by pinning it down with bobbi pins. Once it is firmly attached, it is invisible unless you are looking for it or are up close. This type of netting is less conspicuous and doesn't interfere with growth (Figure 170-Figure 171). It must be firmly attached at its edges or the mosses will still be susceptible to disturbance and the netting can come off. Some birds may even try to remove it for nesting material.

Figure 170. *Leucobryum glaucum* moss garden with bird netting. Note the clumps that have been broken up – damage done before the netting was applied. Photo by Janice Glime.

Figure 171. *Leucobryum glaucum* with bird netting in moss garden. Photo by Janice Glime.

Removing Autumn Leaves

Most of the bryophytes will need partial shade. But in a relatively small space, the best shade is likely to come from one or two deciduous trees. And these dump enough leaves in the fall to bury the bryophytes. The leaves do not decay rapidly enough to expose the bryophytes the next spring, and some seem to suffer from the tannic acids during the winter under the snow. Hence, removal is necessary.

Famous gardens such as Saihoji in Kyoto require constant maintenance to encourage the mosses against the competing tracheophytes. Leaf litter and weeds must be removed lest the mosses be crowded out, but care must be taken to maintain the natural, unmanicured look. Wire or bamboo rakes or soft brooms (Figure 172) are used for such maintenance; brooms should be firm but not harsh to reduce damage to the delicate moss leaves. There is a Japanese saying that only old men and little boys can tend the moss gardens because anyone else would be too careful and the gardens would lose their natural look (Takaki, pers. comm.; Figure 173).

Figure 172. This broom is used for tending a private moss garden in Japan. Photo by Janice Glime.

Figure 173. This "old man" tends moss in Ginkakuji temple garden in Kyoto, Japan. Photo by Janice Glime.

Benner avoids raking leaves by covering the mosses with netting (Dunn 2008). He then collects the leaves and puts them in his compost heap.

Modern technology offers other solutions. One can vacuum the leaves or blow them onto a pile or onto flower gardens where they serve as a mulch (Figure 174). Annie Martin

<<https://www.youtube.com/watch?v=nh9S1IDfXzE&t=3s>> suggests watering the moss garden first when blowing them. The mosses will stay put, but the leaves will still blow. Use an up and down jerky motion to dislodge the leaves.

Figure 174. Blowing leaves off the mosses. Photo by Annie Martin, with permission.

The modern methods of vacuuming the leaves have their limitations. Vacuuming is best done when the leaves are dry, and in some areas there are few dry days at that time of year or in some years. One must be careful not to blow or suck up dry mosses that are not well-connected yet. But then, even raking or brushing the leaves away is best done with dry leaves to protect the bryophytes from being removed.

Overwintering

Generally the predominantly perennial mosses will come through winter just fine. And in most cases, they will look bright green as soon as the snow recedes, being the earliest of the green plants to appear (Figure 175).

Figure 175. *Dicranella heteromalla* and *Atrichum* sp. demonstrate the fresh condition exhibited by many kinds of mosses that have just been uncovered from winter snow. Photo by Michael Lüth, with permission.

But don't despair if your moss garden comes out from under the snow the next spring looking like soon-to-be fossils. With a few warm (not hot) days and plenty of water, new shoots arise above the pathetic remnants of last year. My *Leucobryum* (Figure 34), *Polytrichum* (Figure 8, Figure 176), and *Fissidens* (Figure 48) did just that. The *Racomitrium* (Figure 53) remained brown and dead-looking for a long time, and I was ready to replace it with something more friendly when tiny green tips began to appear. There is nothing like a personal garden to teach you about the trials and tribulations of the bryophytes and their ways of solving these problems. And *Marchantia polymorpha* thalli are green and healthy when the snow recedes in the spring. It will be interesting to see how the competition plays out. I think *Marchantia* (Figure 16) is going to win.

Figure 176. *Polytrichum* sp. in snow. Photo by Annie Martin <www.mountainmoss.com>, with permission.

Arranging the Garden

Give some thought to the arrangement of the mosses and other plants. For the mosses to offer their peaceful

appeal, flowering plants must be kept at a minimum. One long-blooming highlight is enough for a garden of 4m², and it should be set off to the side or back to avoid detracting from the mosses (Figure 177). Be sure the plant won't crowd the ground, lie on top of the moss, or prevent light and/or water from reaching the moss. And avoid things that lose lots of leaves, requiring raking. As an alternative, lamps or statues can serve as highlights (Figure 178).

Figure 177. Moss garden with geranium accent. In early spring the irises on the right will bloom and be the accent. Photo by Janice Glime.

Figure 178. A small painted clay lantern provides a highlight in this garden when the flowers have stopped blooming. Netting over some of the mosses has water beads on the netting. Photo by Janice Glime.

Most mosses will need light shade, especially in the afternoon. A small tree, large shrub, building, or fence can provide this (Figure 179).

Figure 179. A neighbor's garage, a cedar fence, lilac bushes, and a Japanese maple tree provide shade for this moss garden in the morning, with the garage and my house shading it in the afternoon. Photo by Janice Glime.

The benefit of mosses in the garden can extend beyond their aesthetic value to that of enhancing the quality of other garden plants. Schenk (1997) reports that his friend, Gordon Emerson of Ohio, finds that bulbs, tubers, and corms increase more readily under moss cover than when planted in bare ground. Presumably the increased moisture permits them to produce and store more energy.

Environmental Benefits

I have already noted the decrease in water usage need by a moss garden vs a grass lawn. The bryophytes can often provide other solutions to environmental issues, such as collecting and preventing water run-off from storms. They also require no pesticides, herbicides, or fertilizers, therefore avoiding the contamination of the water that filters through them.

Figure 180. *Fontinalis antipyretica*, an aquatic moss that is sensitive to heat. Photo by Bernd Haynold, through Wikimedia Commons.

Summary

Among the most common "moss" garden plants are thallose liverworts, especially *Marchantia polymorpha*, peat mosses (*Sphagnum*), *Polytrichum*, *Atrichum*, members of the *Mniaceae*, *Leucobryum* (but it is somewhat difficult), *Rhizogonium* in Asia, *Rhytidiadelphus triquetris*, *Eurhynchium* (*sensu lato*), and *Bryum argenteum*. *Fissidens* species seem to be particularly easy to grow in temperate North America.

Special habitats may support only a few species, including *Rhytidiadelphus squarrosus* and *Brachythecium rutabulum* for lawns, *Bryum argenteum* and *Barbula* for paths, and *Tortula muralis* for walls.

Mosses cultivated in containers will need plenty of ventilation. Flats are good starter containers, with the mosses later transplanted to a "plantation" with light shade. Both can be planted by pulverizing the plants and spreading them like grass seed. A sprinkling system may be needed in a climate without a rainy season, and one should take advantage of the rainy season, where it exists, by planting just before it so the young plants or transplanted ones get plenty of water.

When transplanting mosses from the wild, the integrity of the clump or mat must be maintained. Of course one must have permission, and care should be taken not to decimate the population.

The substrate may be amended with a variety of substances to lower the pH, but liming and fertilizers are detrimental to bryophyte health. Herbicides may eliminate tracheophyte competition, but hand care by pulling weeds and clearing away litter is most likely a safer choice. Avoid giving the garden a manicured look and use only a light broom or wooden rake to clear away litter. Winter care need be no more than removing deciduous litter.

Once established, the bryophytes will require less water than a lawn or flower garden, require no fertilizers or pesticides, and prevent erosion. They are more environmentally friendly than most kinds of gardens.

Acknowledgments

I must acknowledge many Japanese friends for their tours of Japanese gardens and explanations of the establishment and care. In particular, Zen Iwatsuki and Norio Takaki gave me wonderful tours of both public and private gardens, indoors and out, and explained to me in English what the Japanese gardeners were telling us about the care of the gardens and plantation.

Thank you Ken Kellmann and Steve Soldan for calling our attention to the delightful New York Times article on moss lawns.

CHAPTER 7-5

GARDENING: PUBLIC GARDENS

Figure 1. Jassy moss house. This unusual garden transports you into another world. Photo courtesy of Ben Tan.

Botanical Gardens

Botanical gardens often have a bryophyte section, sometimes mimicking a Japanese garden. Some use mosses around indoor or outdoor waterfalls. And some actually label the bryophytes for teaching purposes. As you might guess, Japan is one of the places to see this latter practice.

Bryophyte gardening has been somewhat limited in North America, but there are notable exceptions. Annie Martin rescues bryophytes that are slated for destruction in North Carolina, USA.

Rick Smith teaches moss gardening by offering workshops. As a result of his workshops, Smith was invited to establish a moss garden at the Luthy Botanic Garden in Peoria, Illinois, USA, and a second at the Illinois Central College Arboretum in East Peoria. Both of these gardens have *Dicranum scoparium* (a dark green moss forming cushions; Figure 2), *Polytrichum commune* (Figure 3), *Bryoandersonia illecebra* (Figure 4), *Leucobryum glaucum* (Figure 5), *Hypnum* spp. (Figure 6),

Thuidium delicatulum (a species that spreads easily; Figure 7), *Anomodon attenuatus* (Figure 8), and *Plagiomnium cuspidatum* (Figure 9).

Figure 2. *Dicranum scoparium* with capsules, a common species in moss gardens, public or private. Photo by Janice Glime.

Figure 9. *Plagiommium cuspidatum*, a frequent volunteer in moss gardens. Photo by Hermann Schachner, through Creative Commons.

Rick Smith (Bryonet) reports that he uses the mat system in both his own private garden and in public gardens. He uses a thin synthetic mat that stores rainwater similar to the storage by a sponge. As the moisture evaporates from the mosses, they draw more water from the underlying mat. He does not water his gardens, but in many climates watering is necessary, especially when the bryophytes are first getting established. He recommends only rainwater if watering is necessary, but occasional watering with other sources such as distilled water usually won't harm the garden if it is interspersed with frequent natural watering.

George Schenk has moss gardens in Seattle, Washington, USA, New Zealand, and the Philippines, all areas that receive considerable annual rainfall. His book on *Moss Gardening* received the 1997 Horticultural Society of America's book of the Year Award. Amazon says of the book "A delightful book that encourages gardeners to pay closer attention to the subtle beauty of miniature landscapes and introduces one of the glories of Japanese gardens into American designs. The author writes entertainingly of mosses on rocks and walls, in containers, and as a lush ground cover, and he presents a gallery of his favorite moss species."

Problems in Public Gardens

Rick Smith (Bryonet 9 February 2010) admonished that the challenge in most public gardens is growing bryophytes in urban areas vs. their natural woodland setting. Traditional moss gardens require a staff to weed the garden of the tracheophyte seedlings.

In public gardens, the gardeners are also the problems. They want to treat the bryophytes like "small vascular plants" that need to be watered and fertilized, but these are just what one must avoid. Care is primarily that of removing unwanted plants and leaf litter.

One additional problem in public gardens is human traffic. Although Annie Martin frequently points out that you should walk on your bryophytes to help in their dispersal, they are not equipped to withstand the parade of an army of people or small children playing tag. This presents the need for paths. These can be presented in a variety of ways, as you will see in the images in this chapter. Sand paths are common, but stone paths can be works of art themselves, with bryophytes filling the spaces

between the stones. Wooden steps, including logs, provide niches for additional bryophytes. Care must be taken that there is no smooth wood that might invite algae, hence becoming slippery and a safety hazard.

Moss Gardens of the World

Dale Sievert has visited many gardens, large and small, and has kindly contributed his images for this chapter. This is but a small sampling of moss gardens in the world.

Bloedel Reserve, Washington, USA

The Bloedel Reserve is a 60.7-hectare (150-acre) forest garden on Bainbridge Island in the state of Washington, USA, first opened to the public in 1988. There one can find beautiful mossy landscapes. It includes a Japanese garden with a sand, moss, and rock garden, but many of the bryophyte landscapes in the reserve have a more natural look (Figure 10-Figure 11).

Figure 10. A large moss lawn at Bloedel Reserve, Washington, USA. Photo courtesy of Dale Sievert.

Figure 11. Interesting mossy topography at Bloedel Reserve, Washington, USA. Photo courtesy of Dale Sievert.

Seattle Japanese Garden, Seattle, Washington, USA

The Seattle Japanese Garden occupies 1.4 hectares (3.5 acres) in the Madison Park neighborhood of Seattle. It was designed under the supervision of the Japanese gardener Juki Iida in 1960. It features pools, streams, bridges, lamps, and the beautiful autumn color of Japanese maples, along with bryophytes (Figure 12-Figure 13).

Figure 12. Mosses offset by fall colors of Japanese maples in the Seattle Japanese Garden, Seattle, Washington, USA. Photo courtesy of Dale Sievert.

Figure 15. Moss lawn at the Portland Japanese Garden, Portland, Oregon, USA. Photo courtesy of Dale Sievert.

Figure 13. Moss-covered lantern in Seattle Japanese Garden. Photo courtesy of Dale Sievert.

Figure 16. Path through the Portland Japanese Garden, Portland, Oregon, USA. Photo courtesy of Dale Sievert.

Portland Japanese Garden, Portland, Oregon, USA

This garden is considered to be the most authentic Japanese garden outside of Japan. It occupies 2.2 hectares (5.5 acres) in the scenic west hills of Portland. The garden was designed by Professor Takuma Tono. One can see crooked paths, waterfalls, arched bridges, moss-covered lanterns, pools with koi, and other features often found in the gardens in Japan. Bryophytes are a prominent feature (Figure 14-Figure 16).

Figure 14. Sand and moss garden at the Portland Japanese Garden, Portland, Oregon, USA. Photo courtesy of Dale Sievert.

Anderson Japanese Garden, Rockford, IL, USA

These gardens are considered to be premiere among American Japanese gardens (Figure 17-Figure 19). They were established in 1978 when John Anderson, a Rockford businessman, was inspired by his visit to the Portland Japanese Garden. The design was assisted by Hoichi Kurisu, using the Anderson's swampy backyard. With 12 acres of gardens and koi-filled pools, this setting is often used for both peaceful reprise and weddings.

Figure 17. A blend of rocks, moss, and sand in the Anderson Japanese Garden, Rockford, IL, USA. Photo courtesy of Dale Sievert.

Figure 18. A mixture of round and rectangular steps at the Anderson Japanese Garden, Rockford, IL, USA. Photo courtesy of Dale Sievert.

Figure 19. Water feature with a large, moss-covered rock at the Anderson Japanese Garden, Rockford, IL, USA. Photo courtesy of Dale Sievert.

Golden Gate Park, San Francisco, California, USA

Starting with sand dunes, William Hammond Hall (a park engineer) and master gardener John McLaren created a restful place to escape the bustle of the city. The Golden Gate Park is a large urban park of 411.6 hectares (1,017 acres). In addition to its conservatory of flowers, it presents a Japanese tea garden, an oak forest, a botanical garden that began in 1890, and two Dutch windmills that pump the water to irrigate the garden (Figure 20-Figure 21). More than 8000 varieties of plants occupy the gardens.

Figure 20. Mosses and trees in garden of Golden Gate Park, San Francisco, California, USA. Photo by courtesy of Dale Sievert.

Figure 21. Golden Gate Park, San Francisco, California, USA showing a walking path and a moss lawn. Photo courtesy of Dale Sievert.

Zion National Park, Utah, USA

Zion National Park covers 593 km² (229.1 mi²) and is characterized by rivers in deep canyons, colorful stone cliffs, waterfalls, and fantastic views. Despite the xeric nature of most of the park, one can still find bryophytes there (Figure 22). In 1909, the area was established as a National Monument by President William Henry Taft. But its name of Mukuntuweap National Monument drew criticism because it was difficult to pronounce. In 1918 it was renamed to Zion, the name that had been used by the Mormons who settled there. In 1919 it was established by The United States Congress as a national park.

Figure 22. Moss along walk in Zion National Park, Utah. Photo courtesy of Dale Sievert.

Missouri Botanical Garden, St. Louis, Missouri, USA

The Missouri Botanical Garden was founded in 1859 and is the oldest botanical garden in the USA. The garden is comprised of 32 hectares (79 acres) and includes a Japanese strolling garden (Seiwa-en) of 5.7 hectares (14 acres). Designed by Koichi Kawana, this is the largest Japanese garden in North America (Figure 23).

Figure 23. Moss lawn in the Missouri Botanic Garden, St. Louis, Missouri. Photo courtesy of Dale Sievert.

Rotary Botanical Garden, Janesville, Wisconsin, USA

The Rotary Botanical Garden in Janesville is an 81 hectare (20-acre) reprise. Bryophytes can be seen along some of the paths and in the Japanese garden, and some have managed to establish themselves between the stones of the paths (Figure 24). Of interest to the bryologists is the fern and moss garden.

Figure 24. Path and balls of mosses at the Rotary Botanic Garden, Janesville, Wisconsin, USA. Photo courtesy of Dale Sievert.

Sarah Duke Gardens, Durham, North Carolina, USA

The Sarah Duke Gardens comprise approximately 22 hectares (55 acres) of landscaped and wooded areas at Duke University. There are 5 miles of allées, walks, and pathways throughout the gardens. The official beginning of the gardens was 1934, when Dr. Frederick Moir Hanes, a faculty member at the Duke Medical School, persuaded Sarah P. Duke to provide \$20,000 toward planting flowers in a debris-filled ravine. But alas, the gardens were destroyed in 1935 by a flood. Sarah Duke's daughter provided funds to rebuild the gardens above the flooding zone as a memorial to her mother, who died in 1936. In parts of the gardens, the ground is covered by a restful green mat of bryophytes (Figure 25).

Figure 25. Path in moss and shrub garden at Sarah Duke Gardens, Durham, NC, USA. Photo courtesy of Dale Sievert.

Limahuli Gardens, Kauai, Hawaii, USA

The Limahuli Gardens are part of the Limahuli Preserve and occupy 6.9 hectares (17 acres) among the 399 hectares (985 acres) of the preserve. The gardens were built to "honor the connection between nature and humanity." This is in one of the last easily-accessible valleys where native forest, pristine streams, and archaeological complexes remain. The descendants of its original inhabitants are its caretakers. In 1967, after Hawaii became a state, Juliet Rice Wichman, a member of the Hui, was assigned to develop the new park. She immediately began to plan and plant. She bequeathed the gardens to one of her grandsons. Since its beginnings it has been awarded "Best Natural Botanical Garden" from the American Horticultural Society for demonstrating the "best environmental practices of water, soil, and rare plant conservation in an overall garden design" and the Koa Award for dedication to the perpetuation of the Hawaiian culture. Bryophytes contribute to the luscious natural landscape (Figure 26).

Figure 26. Mosses and tropical vegetation in the Limahuli Gardens, Kauai, Hawaii, USA. Photo courtesy of Dale Sievert.

Sikkim, India

In Sikkim, one can find many walls with mounds of mosses growing on the sides and tops. Waterfalls are green with bryophytes. And bryophytes adorn the forest floor and branches (Figure 27-Figure 28).

Figure 27. Moss epiphytes in Sikkim, India. Photo courtesy of Dale Sievert.

Figure 28. Mosses at Sikkim, India. Photo courtesy of Dale Sievert.

Floriade, Venlo, Holland

This garden at Floriade represents modern architecture that utilizes bryophytes in the design (Figure 29).

Figure 29. Moss garden at Floriade, Venlo, Holland. Photo courtesy of Dale Sievert.

Villa d'Este, Tivoli, Italy

The Villa d'Este is near Rome, Italy. It is adorned with numerous fountains, some of which are covered with bryophytes (Figure 30).

Figure 30. Villa d'Este fountain with mosses. Photo courtesy of Dale Sievert.

Herculaneum, Italy

Herculaneum rests in the shadow of Mount Vesuvius. It was an ancient Roman town destroyed in 79 AD by volcanic pyroclastic flows. Only ruins remain of the ancient town, and ruins often provide suitable substrates for bryophytes (Figure 31). But more recent statues may be covered with bryophytes (Figure 32).

Figure 31. Herculaneum, Italy, ruins with mossy surfaces. Photo by Xtreambar, through Creative Commons.

Figure 32. Mossy statuery fountain at Herculaneum, Italy. Photo courtesy of Dale Sievert.

Cibodas Botanical Garden, Java, Indonesia

Gradstein (2006) reported that personnel created a small river and pond to grow *Plagiomnium* (Figure 9) in the Cibodas Botanical Garden, Java, Indonesia (Figure 77). The area was sprayed with water, particularly during the dry season. This permitted successful cultivation of *Marchantia* (Figure 34), *Dumortiera* (Figure 35), *Trichocolea tomentella* (Figure 36), and *Plagiochila tjibodensis*. Other bryophytes that did not require special treatment were *Hypopterygium* (Figure 37), *Pyrrhobryum* (Figure 38), *Fissidens* (Figure 39), *Thuidium* (Figure 7), *Leucobryum* (Figure 5), and *Hypnodendron* (Figure 40). *Pogonatum* (Figure 41) grew on sand and *Rhodobryum* (Figure 42) grew on a mix of sand and humus. The garden was successful in growing epiphytes on soil covered with bark chips.

Bryophytes Occurring in Public Gardens

This chapter has only a small sampling of public gardens and parks with mosses, including some that have attempted to mimic the Japanese gardens. Some are natural and others are planted with horticultural varieties, but the non-"moss gardens" included here have bryophytes that have arrived and survived without deliberate human intervention.

Chris Preston (Bryonet 2 February 2022) reported 97 moss species and 14 liverwort species from the Cambridge University Botanic Garden (Figure 43) in the winter/spring season. These were volunteer species, not planted ones. Preston was unable to relocate at least 25 of the species that had been recorded there by past bryologists.

Figure 43. Cambridge Botanic Garden lake, illustrating the variety of habitats that support 97 moss and 14 liverwort species. Photo by C. M. Glee, through Creative Commons.

Morgan *et al.* (2008) reported 52 species of mosses and 15 of liverworts at the 31-hectare Bartlett Arboretum Forest (Figure 44) in Stamford, Connecticut, USA. This multiuse forest provides multiple opportunities for species to arrive on shoes and boots and perhaps even clothing.

Figure 44. Bartlett, Arboretum, Stamford, Connecticut, where 52 moss and 15 liverworts are reported. Photo through Creative Commons.

Eckstein and Burghardt (2008) found 139 bryophyte species in the Old Botanical Garden in Göttingen (Figure 45), Germany. These were comprised of 123 mosses and

16 liverworts, making it one of the richest botanical gardens investigated in Germany and the one with the greatest density of bryophytes. One of these is *Didymodon umbrosus* (Figure 46), a rare introduced species. Furthermore, 23 of these species are on the Lower Saxony Red List.

Odgaard (Bryonet 5 February 2022) has investigated the mosses in the botanical garden of Aarhus, Denmark (Figure 47). In the 1970's, only *Dicranoweisia cirrata* (Figure 48) grew there as an epiphyte. In 2022 he reported that the epiphyte flora had expanded considerably, including the new inhabitants *Orthotrichum affine* (Figure 49), *O. diaphanum* (Figure 50), *O. lyellii* (Figure 51-Figure 52), *O. pulchellum* (Figure 53), *Ulota phyllantha* (Figure 54), *Syntrichia laevipila* (Figure 55-Figure 56), *S. latifolia* (Figure 57-Figure 59), and *Zygodon conoideus* (Figure 60-Figure 62). He attributed this increase in diversity to the improved air quality, especially the reduction of sulfur. Like many researchers, he noted the importance of bryophytes in botanical gardens as a means of monitoring changes in air quality.

Common Species in Public Places

Fukarek (2006) notes that the bryophyte survey of the Botanic Garden Rombergpark (Figure 65) in Dortmund, Germany, is the first survey of bryophytes in that area. The bryophytes that occurred in 5 or more of the 14 sampling plots are *Amblystegium serpens* (Figure 66), *Atrichum undulatum* (Figure 67), *Brachythecium rutabulum* (Figure 68), *Ceratodon purpureus* (Figure 69-Figure 70), *Eurhynchium praelongum* (Figure 71), *Grimmia pulvinata* (Figure 72), *Hypnum cupressiforme* (Figure 73), *Orthotrichum affine* (Figure 49), *Rhynchostegium confertum* (Figure 74), and *Tortula muralis* (Figure 75). Smith *et al.* (2010) examined bryophyte species in 61 domestic gardens in the city of Sheffield, UK. They similarly found that only 10% of the bryophyte species occurred in more than half of the gardens. In the Bartlett Arboretum Forest (Figure 44) in Stamford, Connecticut, the mix of bryophytes was different, but there was no quantification in the study (Morgan *et al.* 2008). Only *Atrichum undulatum* (Figure 67), *Brachythecium rutabulum* (Figure 68), and *Ceratodon purpureus* (Figure 69-Figure 70) occurred here in common with those in 5 or more plots at the Botanic Garden Rombergpark.

Lunularia cruciata (Figure 76) is the only liverwort to appear in as many as 5 plots at the Botanic Garden Rombergpark, Germany (Figure 65). Interestingly, *Lunularia cruciata* is the only one of these species listed by Essl and Lambdon (2009) as alien species in Europe.

Among the 90 species of bryophytes in the tropical Cibodas Botanical Garden, Indonesia (Figure 77) (Nadhifah *et al.* 2018), there were no species in common with temperate Bartlett Arboretum Forest (Figure 44) in Stamford, Connecticut (Morgan *et al.* 2008) or the Botanic Garden Rombergpark, Germany (Figure 65) (Fukarek 2006), but several genera seem to be common in such gardens in widespread regions, boreal to tropical and both hemispheres. These include the thallose liverworts *Marchantia* (Figure 34) and *Riccia* (Figure 78), the leafy liverwort *Frullania* (Figure 79), and the mosses *Barbula* (Figure 80), *Bryum* (Figure 81), *Campylopus* (Figure 82), *Fissidens* (Figure 83), *Leucobryum* (Figure 5), *Plagiomnium* (Figure 9), and *Sphagnum* (Figure 84).

Fastanti and Wulanasari (2021) found 30 species (27 moss species, 3 liverwort species) of bryophytes in the 189 ha of Cibinong Science Center-Botanical Garden, Indonesia. There were no hornworts. In sharp contrast, the 4.3 ha of the Szent István University Gödöllő Botanical Garden in Hungary had 69 bryophyte species with 3 liverwort and 66 moss species (Fintha *et al.* 2021). Most of these were common in Hungary and many also occur in other Hungarian botanical gardens, including *Amblystegium serpens* (Figure 66), *Barbula unguiculata* (Figure 80), *Brachythecium rutabulum* (Figure 68), *Brachythecium salebrosum* (Figure 1), *Bryum argenteum* (Figure 81), *Calliergonella cuspidata* (Figure 86), *Ceratodon purpureus* (Figure 69-Figure 70), *Fissidens taxifolius* (Figure 83), *Grimmia pulvinata* (Figure 72), *Homalothecium lutescens* (Figure 87), *Homalothecium sericeum* (Figure 88), *Hypnum cupressiforme* (Figure 73), *Leskea polycarpa* (Figure 89), *Orthotrichum affine* (Figure 49), *Orthotrichum diaphanum* (Figure 50), *Eurhynchium hians* (= *Oxyrrhynchium hians*; Figure 90), *Plagiomnium cuspidatum* (Figure 9), *Syntrichia ruralis* (Figure 91), *Tortula muralis* (Figure 92).

On the other hand, five species [*Brachythecium glareosum* (Figure 93), *Dicranella varia* (as *Dicranella howei*; Figure 94), *Didymodon insulanus* (Figure 95, *Fissidens bryoides* (as *Fissidens viridulus*; Figure 96), *Orthotrichum obtusifolium* (as *Nyholmia obtusifolia*; Figure 97)] were listed as near threatened on the Hungarian Red Data List (Fintha *et al.* 2021). However, since three have been reclassified into widely distributed species, it is possible they were not legitimately red-listed.

Figure 93. *Brachythecium glareosum*, a near threatened species found at the Szent István University Gödöllő Botanical Garden in Hungary. Photo by Sharon Pilkington, with permission.

In the preparation of this chapter, I compiled a total species list for 30 studies of bryophytes in parks, cemeteries, and botanical gardens to provide an estimate of the most frequent species. This is a crude list because of the huge variation in size and the worldwide distribution of the gardens. Nevertheless, some species seem to be everywhere.

Hornworts are notably absent in most gardens, with only *Anthoceros agrestis* (Figure 99) present in as many as three. Liverworts varied widely in number of species with some gardens lacking them entirely [e.g. 1500 ha forest park at Hôrka, Slovakia (Figure 98) (Mišíková *et al.* 2007)] and others having numbers of liverwort species exceeding those of the mosses [e.g. 1480 ha in restinga in Setiba State Park, Espírito Santo State, Brazil, has 25 liverworts and 9 mosses (Visnadi & Vital 1995)].

Figure 98. Forest path above the tunnel, Malkovská Hôrka location, Prešov forest park, Slovakia, a park devoid of liverworts. Photo by Jozef Kotu, through Creative Commons.

In Serra da Canastra National Park (Figure 100), Minas Gerais, Brazil, with more than 71,000 hectares, Marchi do Carmo and Peralta (2016) found the hornwort *Phaeoceros laevis* (Figure 101). Among the liverworts, there were 53 species of the *Lejeuneaceae* (Figure 102). The park supported 289 species of bryophytes, most of which are widely distributed in Brazil.

In the park of Mátrai Gyógyintézet Sanatorium, NE Hungary, Szűcs *et al.* (2018) found 65 bryophytes, of which only 3 were liverworts. Red-listed species for the territory, but found in the park, included ***Brachythecium glareosum*** (Figure 93), ***Cirriphyllum piliferum*** (Figure 103), ***Orthotrichum pumilum*** (Figure 104), ***Rhynchostegiella tenella*** (Figure 105), and ***Syntrichia latifolia*** (Figure 57-Figure 59).

Figure 103. ***Cirriphyllum piliferum***, a red-listed species found in the park of Mátrai Gyógyintézet Sanatorium, NE Hungary. Photo by Claire Halpin, with permission.

Figure 104. ***Orthotrichum pumilum*** with capsules, a red-listed species found in the park of Mátrai Gyógyintézet Sanatorium, NE Hungary. Photo by Hugues Tinguy, with permission.

Figure 105. ***Rhynchostegiella tenella*** with capsules, a red-listed species found in the park of Mátrai Gyógyintézet Sanatorium, NE Hungary. Photo by Hugues Tinguy, with permission.

Szűcs and Fintha (2019) reported 54 bryophyte species from the Erdőtelek Arboretum in Hungary. It is interesting that among these were the red-listed ***Brachythecium glareosum*** (Figure 93), ***Cirriphyllum piliferum*** (Figure 103), and ***Orthotrichum obtusifolium*** (Figure 97), also present in the park of Mátrai Gyógyintézet Sanatorium, NE Hungary (Szűcs *et al.* 2018) or Szent István University Gödöllő Botanical Garden in Hungary (Fintha *et al.* 2021). Based on this and other studies, the common species in these parks and botanical gardens are ***Amblystegium serpens*** (Figure 66), ***Barbula unguiculata*** (Figure 80), ***Brachythecium rutabulum*** (Figure 68), ***Bryum argenteum*** (Figure 81), ***Ceratodon purpureus*** (Figure 69-Figure 70), ***Hypnum cupressiforme*** (Figure 73), ***Leskea polycarpa*** (Figure 89), ***Orthotrichum anomalum*** (Figure 106), ***Orthotrichum diaphanum*** (Figure 50), ***Eurhynchium hians*** (= ***Oxyrrhynchium hians***; Figure 90), ***Radula complanata*** (Figure 107), ***Syntrichia ruralis*** (Figure 91), and ***Tortula muralis*** (Figure 75).

Europe

Numbers of species vary widely among the parks in Europe. Nevertheless, they provide a glimpse of the abundance of mosses vs liverworts vs hornworts, the substrate distribution, and the effects of urban vs suburban vs natural habitats.

In the Azorean parks and gardens of the Reserva Florestal de Recreio do Pinhal da Paz on São Miguel Island (Figure 108), an Island of Portugal, Polaino-Martin *et al.* (2020) identified 43 bryophyte species, of which 19 were liverworts and 1 hornwort. These represented 17 sites about 100 m apart on rocks, soil, and tree bark, but concentrated on the "most striking" species. Three of these are endemic to Macaronesia. Others are endemic to Europe. This compares with 279 taxa known from the Serra de Sintra in Portugal (Figure 109) (Cacciatori *et al.* 2015).

Figure 108. Pinhal da Paz, Ponta Delgada, São Miguel, Açores, site of 43 bryophyte species. Photo by José Luís Ávila Silveira & Pedro Noronha e Costa through public domain.

Figure 109. Serra de Sintra, Portugal, home of 279 bryophyte taxa. Photo by Vitor Oliveira, through Creative Commons.

Segarra Moragues *et al.* (2021) investigated the bryophytes in 94 sampling sites in the city of Valencia, Spain. They identified 96 moss and 6 liverwort species. The greatest taxon richness occurred in locations with a variety of natural and relatively undisturbed substrates such as those found at the Botanical Garden (Figure 110), Viveros Garden (Figure 111), and the Turia River Garden (Figure 112).

Figure 110. Valencia Botanical Garden, Spain, where natural substrates favor bryophyte richness. Photo by Pablo Enzo, through Creative Commons.

Figure 112. Turia River Garden, a park with a variety of natural substrates that support bryophytes. Photo by through Creative Commons 1 Stefan Majewski, through Creative Commons.

In Germany, Stech (1996) found 80 species (9 liverworts, 80 mosses) in the outdoor area of the Botanical Gardens of the University of Bonn (Figure 113). The greenhouses (Figure 114) had 11 liverworts and 41 mosses. In the UNESCO Heritage Park Sanssouci in Potsdam, Germany (Figure 115), Müller (2014) found 118 species of bryophytes. Of these, 25 were red-listed as threatened. This was in part due to a large re-colonization of epiphytes following the reduced air pollution. (See also Müller 2015).

Giordano *et al.* (2004) examined the biodiversity of epiphytic bryophytes in urban and nearby sites in southern Italy. Their interest was in the use of these as indicators through their bioaccumulations. As indicated by Segarra Moragues *et al.* (2021) they showed clearly that the number of species was lower in more urban areas. They also found that acrocarpous mosses and vegetative reproduction occur more frequently in more urban areas.

In Wroclaw, Poland, Fudali (2001, 2005) found only 81 bryophyte species in 22 town parks and 6 cemeteries. These were more specialized in their substrates, with more

than 40% occurring on only one type. Epiphytes were rare, but did seem to occur at the bases and first 30 cm of the tree trunks. Only the outer locations had forest species. In cemeteries, a higher number of species correlated with the age of monuments and dimensions of the object areas. In a wider study, Fudali (2006) found 125 species on 145 sites in 94 parks and 51 cemeteries in Poland. These were comprised of 11 liverwort and 114 moss taxa. The number of taxa was not significantly correlated with area of the study site, emphasizing the importance of even small parks in maintaining diversity of bryophytes. Parks on the outskirts typically had more diversity than did those in the city center. Frequent mosses were similar to those found in other studies of parks, including *Amblystegium serpens* (Figure 66), *Bryum argenteum* (Figure 81), *B. caespitium* (Figure 116), *Ceratodon purpureus* (Figure 69-Figure 70), and *Funaria hygrometrica* (Figure 117). As in many other locations, epilithic species included *Barbula unguiculata* (Figure 80), *Grimmia pulvinata* (Figure 72), *Orthotrichum diaphanum* (Figure 50), *Ptychostomum capillare* (= *Bryum capillare*; Figure 118), *Schistidium apocarpum* (Figure 119), and *Tortula muralis* (Figure 75); frequent terrestrial species included *Barbula convoluta* (= *Streblotrichum convolutum*; Figure 120), *Brachythecium rutabulum* (Figure 68), and *Eurhynchium hians* (= *Oxyrrhynchium hians* Figure 90). *Marchantia polymorpha* (Figure 34) was the only liverwort found in the city interiors. Fudali *et al.* (2015) reported 171 bryophyte taxa from the 8483 ha Roztocze National Park in Poland (Figure 121). These included 43 species protected by law in Poland, 20 of which are strictly protected and 13 as threatened in Poland. Furthermore, 36 species were new for the region.

In an experimental and teaching garden at the University of Lodz, Poland, Wolski *et al.* (2012) found 41 species of mosses and only 1 liverwort. These represented the epigeic, epilithic, epiphytic, epixylic, and aquatic habitats. The epigeic (soil) habitat had the most species (34), whereas the aquatic habitat had the least (1). These urban parks, nevertheless, exhibit a large diversity of species of bryophytes, especially species not found elsewhere in the city.

In Slovakia, Godovičová *et al.* (2020) found 12 liverwort and 92 moss species in 14 historical parks and gardens. Among these, *Amblystegium serpens* (Figure 66), *Brachythecium rutabulum* (Figure 68), *Bryum argenteum* (Figure 81) and *Tortula muralis* (Figure 75) were present in all 14 study sites. Small urban parks had fewer bryophyte species than did rural areas, with the most species on soil and least on wood. As in some other studies, a rare species (*Ptychostomum bornholmensis* – see Figure 122) used the parks as a refuge.

Figure 122. *Ptychostomum creberrimum*; *Ptychostomum bornholmensis* is a rare species occurring in historical parks and gardens in Slovakia. Photo by Wayne Lampa, through Creative Commons.

In the forest park of Hôrka (Figure 98), located in the center of the town Veľký Krtíš, Slovakia, Mišíková *et al.* (2007) found 37 bryophyte species, but no liverworts or hornworts. In a broader study, Mišíková *et al.* (2015) found 81 bryophyte species in ten villages in Slovakia. These were not parks, where the bryophytes are afforded some degree of protection. Nevertheless, with the 81 species in total, species richness of individual localities ranged 17 to 57 species. They suggested that the cooler, more humid climate in the northern part of central Slovakia favored a greater species richness there. They also found that cemeteries and parks contributed to higher diversity. The highest numbers of species occurred on bare damp soil or on concrete and stony walls.

Godovičová (2019) explored the bryophytes in the Horský Park protected area (Figure 123) in the urban Bratislava, Slovakia. This forest park had 57 bryophytes, with 6 liverworts and no hornworts. Two red-listed species [*Fissidens exilis* (Figure 124) and *Rhynchostegium rotundifolium* (Figure 125)] occurred there. As in many other studies, the greatest number of species (19) occurred on exposed soil and the least along streams (6).

In the Central Park Archbishop's Garden in Eger, Hungary (Figure 126), Szűcs *et al.* (2020) found 55 moss and 4 liverwort taxa. Of these, 49% were from only three families (**Orthotrichaceae**, **Pottiaceae**, and **Brachytheciaceae**). The species composition and life strategies of bryophytes in this park differed remarkably from that of other Central and Eastern European parks.

Figure 126. Central Park Archbishop's Garden in Eger, Hungary, home to 55 moss and 4 liverwort species, with nearly half in only three families. Photo by Zolchew, through Creative Commons.

In eastern Serbia, Sabovljević (2006) found 82 bryophyte species, including 11 liverworts, in the Djerdap National Park (Figure 127). Although this seems like a large number, the park occupies 63,786 ha with a wide range of habitats.

Figure 127. Djerdap National Park on the Danube. Photo by Milan Paunović, with permission.

In the Vrana Park (<40 ha), Sofia city, Bulgaria, Gospodinov *et al.* (2018) found 68 bryophyte species, four of which are of conservation importance. In Loven Park, in the same city, only 31 species of mosses and 5 of liverworts were found, despite the larger size (243 ha) of the park (Natcheva & Gospodinov 2020). The researchers considered the lack of habitat diversity and microrelief, a dense understory of shrubs and saplings, and invasion of ivy (*Hedera helix*) on soil and tree trunks to be the reasons for the low diversity.

In 2018, Mamchur *et al.* found 143 moss species in the Pohulyanka forest park, Ukraine (Figure 128). They compared the bryophytes in this study to earlier records in the last 50-100 years and found that 34 species could no longer be located. On the other hand, 72 species in this study were not found in those earlier studies. Among the current species, 25 are rare for the **nemoral** (pertaining to groves or woodlands) and forest steppe zones. The number of epiphytic species has increased, a fact that the researchers attribute to anthropogenic activity.

Asia

Lu and Jing (2019) reported on the ground bryophytes of 11 parks in Nanjing, China. They found only 51 bryophyte species, with 35% of them in only three families (**Pottiaceae**, **Bryaceae**, **Brachytheciaceae**). The most common ones were *Barbula unguiculata* (Figure 80), *Brachythecium rutabulum* (Figure 68), *Haplocladium angustifolium* (Figure 129), *Haplocladium microphyllum* (Figure 130), *Physcomitrium sphaericum* (Figure 131), and *Taxiphyllum taxirameum* (Figure 132). The first two of these are widespread and common in various parks and gardens. The number of species per park ranged from 3 to 20, with turfs as the main life form. They found an interesting correlation of environmental factors with diversity. Humidity, human disturbance, canopy density, and distance to main roads were the important factors. The latter variable is one that seems not to be considered in most studies.

Liu *et al.* (2015) found 83 species in saxicolous communities in urban habitats in Chongqing, China. Soil communities supported only 46 species, contrasting with European studies cited above. Surprisingly to me, diversity indices of both of these communities were higher on campuses than in parks, natural scenic resorts, or the Jinyunshan National Nature Reserve (Figure 133). The environmental parameters differed in importance, with canopy density being most important for saxicolous communities in parks and campuses. In natural science scenic resorts and the nature reserve, altitude, relative humidity, and human disturbance were most important. In the soil communities, pH, canopy density, and human disturbance were of major importance in parks and campuses. In the natural scenic resorts and nature reserve, altitude, relative humidity and water content of the soil were the most important determinants of the soil bryophyte communities.

Figure 133. Jinyunshan Nature Reserve with karst topography in Chongqing, China, an area with lower bryophyte diversity than urban areas in the province. Photo by Bernt Rostad, through Creative Commons.

The Japanese are famous for their moss gardens, which are discussed elsewhere in this chapter. Nakamura and Suga (1997) instead studied the bryophytes in various urban and natural environments, including a nature park, agricultural area, urban park, street residential district, housing complex district, commercial district, and industrial district. These study sites had 83 bryophyte species in 1975, but in 1995, only 78 were located (Figure 134). Nevertheless, the number of species at individual sites increased for most sites. Only the agricultural site experienced a decrease in species. **Erect** forms increased at all sites, whereas **prostrate** forms decreased in both the nature park and the agricultural district. On the other hand, **thalloid** forms increased in the nature park site. In the industrial site, **erect** forms were the only remaining type. Like several sites in Europe, soil was the most common substrate, followed by tree trunks and then concrete. The number of bryophyte species was positively correlated with the woody vegetation cover, indicating a dependence on shade and perhaps moisture.

Figure 134. Changes in moss, liverwort, and hornwort species from 1975 to 1995 in Chiba City and Yotsukaidou City, Japan. Image slightly modified from Nakamura & Suga 1997.

Tropics

In the Chapada Diamantina National Park, Brazil (Figure 135), Bastos *et al.* (1998) found only 27 species of

mosses and 4 species of liverworts. Most of these species were restricted to this high altitude complex. Later, Sierra *et al.* (2018) studied the bryophyte flora of the Jaú National Park (Figure 136) in Brazil. In their extensive collecting of 712 collections, they found 150 species. Of these, 20 were rarely collected Amazonian endemics.

In the more tropical Panama, Gradstein and Salazar Allen (1992) sampled the bryophytes along an elevational gradient in the Darién National Park (Figure 137). The inundated lowland, hillside-lowland, submontane, and montane elfin forest had distinctly different species assemblages. They found the largest number of exclusive species as well as the greatest bryophyte biomass in the montane forest. The submontane forest, however, has the greatest overall species richness. The lowland forest had the lowest diversity. Forty liverwort taxa in the park were reported as new to Panama.

North America

In the Taum Sauk Mountain State Park, Missouri, USA (Figure 138), Holmberg and Atwood (2014) documented 123 bryophytes, with 103 mosses, 18 liverworts, and 2 hornworts in 3035 ha.

Figure 138. Taum Sauk Mountain State Park, Slippery Rock, Missouri, a temperate park with 103 mosses, 18 liverworts, and 2 hornworts. Photo by Yinan Chen, through Creative Commons.

Australia

In Mungo National Park in arid Australia (Figure 139), Downing and Selkirk (1993) found that the number of species did not differ significantly between sites representing differences in soils, topography, and tracheophytes. Bryophytes were well represented in soil crusts. Ephemerals were censused by soil cultures. Factors influencing the bryophyte vegetation included soil texture, pH, conductivity, nutrient status, vascular plant vegetation, light level, leaf litter, and fire frequency. The species are typical of calcareous substrates throughout the desert area.

Ramsay *et al.* (1990) found more than 90 species in the Mount Tomah Botanic Garden in Australia (Figure 140), a 30 ha park. In the Royal Botanic Gardens, Sydney (Figure 141), Ramsay *et al.* (1993) found 70 moss, 24 liverwort, and 1 hornwort species. These included many species and genera noted in other parks and gardens around the world, including *Amblystegium serpens* (Figure 66), *Barbula* (2 spp.; Figure 80), *Brachythecium rutabulum* (Figure 68), *Bryum argenteum* (+ 9 other *Bryum* spp., Figure 81), *Campylopus* (6 species; Figure 82), *Ceratodon purpureus*

(Figure 69-Figure 70), *Eurhynchium praelongum* (Figure 71), *Fissidens* (8 spp.; Figure 83), *Leucobryum* (1 sp.; Figure 5), *Ptychostomum capillare* (= *Bryum capillare*; Figure 118), *Syntrichia laevipila*, (+ 1 other *Syntrichia* sp.; Figure 55-Figure 56). *Tortula muralis* (Figure 75), and the liverworts *Frullania* (3 spp.; Figure 79), *Lunularia cruciata* (Figure 76), *Marchantia polymorpha* (Figure 34), and *Riccia* (4 spp.; Figure 78). Some of these species may have arrived from other parts of the world.

Other botanical garden investigations include those of Nohl (1977), Menzel (1984), Al Araj and Klotz (1989), Ziegler (1996), Kiessling & Stetzka (1997), De Bruyn & Homm (2009), and Teutsch (2021).

Value

Public gardens cover a wide range of purposes. This translates into a variety of sources for any bryophytes found there. Bryophytes can serve as aesthetic enhancement, but they can also provide protected places where experimentation is possible. Since gardens are likely to be encouraged by use of fertilizers, response of bryophytes can be studied by providing invisible (hidden) markers and following the responses of the bryophytes to the fertilizers. This might be complicated, however, when one tries to create a suitable control.

Among the 90 species of bryophytes in the Cibodas Botanical Garden, Indonesia (Figure 77), Nadhifah *et al.* (2018) found 42 species with potential use and 42 species with potential use in medicine, ornamental purposes, agriculture, and environmental services.

Perhaps one of the most valuable uses would be to track dispersal and its mechanisms. Plants in botanical gardens often come from all over the world, or at least from some place else. Hence, these gardens can have species that arrived as hitchhikers with the tracheophytes that were planted there. This provides an opportunity to see what survives in both the short and long term. But, of course, these hitchhikers are a problem beyond the confines of the garden. They can become invasive species, as seen for *Pseudoscleropodium purum* (Figure 142) and others.

Figure 142. *Pseudoscleropodium purum*, an invasive species. Photo by Claire Halpin, with permission.

Bryophyte Volunteers in Personal Gardens

Smith *et al.* (2010) studied the bryophytes in 61 domestic gardens in Sheffield, UK. They recorded 67 bryophytes, with individual gardens having 3-24 species. The mean richness was 11.3. Slightly over 20% of the bryophyte species occurred in grass lawns, and these species were the most widespread compared to those of

other habitats. Only 10% occurred in more than half the gardens. Area, substrate richness, and altitude explained 39.1% of the bryophyte richness.

Dick Lister (Bryonet 5 February 2022) provided us with a species list from the Royal Horticultural Society's garden tour at Wisley, Surrey, England. Of the 8 categories of gardens, the most common bryophyte taxa, occurring in at least 4 of the 8 are *Brachythecium rutabulum* (Figure 68), *Bryum dichotomum* (Figure 143), *Campylopus introflexus* (Figure 82), *Ceratodon purpureus* (Figure 69-Figure 70), *Cratoneuron filicinum* (Figure 144), *Eurhynchium praelongum* (as *Kindbergia praelonga*; Figure 71), *Funaria hygrometrica* (Figure 117), *Hypnum cupressiforme* (Figure 73), *Zygodon viridissimus* (Figure 145). Of these, all are common elsewhere in gardens except *Cratoneuron filicinum* and *Zygodon viridissimus*. In addition to these frequent species, these gardens had many additional species and genera that are frequent in the public parks and gardens elsewhere, including the liverworts *Lunularia cruciata* (Figure 76), *Marchantia polymorpha* (Figure 34), and *Riccia sorocarpa* (Figure 78), the hornwort *Anthoceros* (Figure 99), and the mosses *Amblystegium serpens* (Figure 66), *Atrichum undulatum* (Figure 67), *Barbula convoluta* (Figure 120), *Barbula unguiculata* (Figure 80), *Bryum argenteum* (Figure 81), *Ptychostomum capillare* (as *Bryum capillare*; Figure 118), *Eurhynchium hians* (as *Oxyrrhynchium hians*; Figure 90), *Fissidens* (Figure 83), *Grimmia pulvinata* (Figure 72), *Homalothecium sericeum* (Figure 88), *Orthotrichum affine* (Figure 49), *Orthotrichum anomalum* (Figure 106), *Orthotrichum diaphanum* (Figure 50), *Orthotrichum lyellii* (Figure 51-Figure 52), *Rhynchostegium confertum* (Figure 74), *Syntrichia laevipila* (Figure 55-Figure 56), *Syntrichia latifolia* (Figure 57-Figure 59), *Syntrichia ruralis* (Figure 91), *Tortula muralis* (Figure 75), and *Ulota phyllantha* (Figure 54).

Alien Species

It would appear that bryophytes should be able to invade new areas such as gardens more easily than most tracheophytes (Essl & Lambdon 2009). Their dispersal by spores is easier than that by seeds, making colonization easier. On the other hand, their very limited cultivation use results in few deliberate introductions. Their impacts, due to their small size, are small. Nevertheless, we have almost no understanding of the long-term effects of invasive bryophytes.

Essl and Lambdon (2009) noted that we have little information regarding the invasion history of bryophytes. Their spore dispersal is efficient, giving them a greater colonizing ability than that of tracheophytes. Deliberate introductions are rare because they are seldom used in gardens. Because of their small size, we assume that they have little measurable impact on the ecosystems they invade. This is an area that needs to be considered by the scientific community, particularly as their use in green technology and gardening is increasing and their availability through internet orders is increasing.

In Europe, Essl and Lambdon (2009) identified 45 species that seem to be alien in at least parts of Europe (Table 1). These include at least 21 mosses and 11 liverworts, but no hornworts. Of these, *Campylopus introflexus* (Figure 82) and *Orthodontium lineare* (Figure 146) have become widespread mosses and the Mediterranean liverwort *Lunularia cruciata* (Figure 76) has exhibited great northward expansion. A number of tropical species were present only in glasshouses, including *Marchantia pappeana* (Figure 147), *Vesicularia reticulata* (Figure 148), and *Zoopsis liukuensis* (Figure 149). Glasshouses seem to be the only places outside California to find *Lunularia cruciata* in North America (Schuster 1992).

Table 1. Alien bryophytes in Europe, ranked by decreasing number of invaded countries/regions. Only species invading >3 countries/regions are shown. From Essl and Lambdon 2009.

<i>Campylopus introflexus</i>	21
<i>Orthodontium lineare</i>	15
<i>Didymodon australasiae</i>	11
<i>Ricciocarpos natans</i>	8
<i>Leptophascum leptophyllum</i>	6
<i>Hennediella stanfordensis</i>	4
<i>Tortula bolanderi</i>	4
<i>Lunularia cruciata</i>	12
<i>Riccia rhenana</i>	12
<i>Scopelophila cataractae</i>	7
<i>Dicranoweisia cirrata</i>	4

Although most of the alien bryophytes remain rare in their new locations, several have become rather widespread and have the potential to impact their ecosystems (Essl & Lambdon 2009). At present, these are *Campylopus introflexus* (Figure 82) and *Orthodontium lineare* (Figure 146). The thallose liverwort *Lunularia cruciata* (Figure 76) continues to spread, but it seems to be rather restricted in its habitat, mostly surviving in glass houses outside its normal range. Essl and Lambdon concluded that the alien bryophyte species in Europe tend to occur in disturbed habitats where humans have played a major role, including gardens, roadsides, and walls.

We must first ask ourselves what impacts invasive bryophyte species **might** have. Essl and Lambdon (2009) suggest that they could compete with native bryophytes and lichens or even with germinating seedlings by blocking light, sequestering nutrients, or occupying space. It appears that the only documented strong impact by an invasive bryophyte is that of *Campylopus introflexus* (Figure 82). Its dense mats significantly reduce the diversity of both bryophytes and lichens (Hahn 2006). In other cases, this species has colonized thatched roofs in southern England

where they could replace the diminishing populations of *Leptodontium gemmascens* (pers. comm. by Ron Porley, in Essl & Lambdon 2009).

As interest has grown regarding invasive species, Essl *et al.* (2013) have provided us with a glimpse of the forces behind invasive bryophytes. Of the 139 bryophytes considered to be alien in Europe, they consider 34 to be hitch-hikers (34 species) or companions (27 species) with ornamental plants, constituting the most important means of introduction. Fortunately, most of these seem to be successful only in habitats created by humans and seem unable to become established in natural ecosystems.

Impacts of alien bryophytes on biodiversity and socio-economy are a recent phenomenon, with >85 % of impacts on biodiversity, and 80 % of impacts on socio-economy recorded since 1990 (Essl *et al.* 2014). On average, 40 years (impacts on biodiversity) and 25 years (impacts on socio-economy) elapsed between the year a bryophyte species was first recorded as alien in a region and the year impacts were first recorded. They found that since the first reported invasion occurred, the number of records has increased rapidly. Based on this trend, they concluded that the impacts of these invaders will continue to increase.

Essl *et al.* (2015) began to explore the macroecology of bryophyte invasions. Most naturalizations occurred in complementary regions of the opposite hemisphere (Essl *et al.* 2015). And the Southern Hemisphere has experienced more invasions with naturalizations than has the Northern Hemisphere. Hence, naturalizations are most likely to occur in biogeographically separated regions that exhibit climates similar to that of the location of origin.

Bryophytes in Glass Houses

France (2019) interviewed the horticultural staff at the Ferns and Fossils House at the Royal Botanic Garden Edinburgh (Figure 150). He recommended raising the status of bryophytes in botanic gardens and increasing the diversity of living collections.

Figure 150. Greenhouse, Royal Botanic Garden of Edinburgh, an opportunity to include more bryophytes in a public place. Photo by Eldubhe, through Creative Commons.

Botanical gardens and greenhouses often import and cultivate non-native species. Essl and Lambdon (2009) assessed the reasons for studying bryophyte invasions. They considered them to be poorly recorded and thus provide little information upon which to assess their

invasion history. They have efficient dispersal by spores and have a greater ability to naturalize than other major taxonomic groups. They are seldom cultivated, so deliberate introductions are few. Their small size makes their impact on the environment small. On the other hand, the possibility that these invasions have long-term effects has never been explored.

For whatever reason, *Lunularia cruciata* (Figure 76) is particularly common in glass houses (Sabovljević & Marka 2009), often in parts of the world where it is unknown outside these structures.

Educational Displays

A number of gardens serve educational needs. This may be the entire garden, or only small portions. This education is usually accomplished by signs. Some gardens include a feel garden, especially pitched toward the blind, but can also be attractive to children. Mosses offer a wide range of textures that can be a delight to those meeting them for the first time. Additional information can be provided in Braille.

The Moss House (Figure 151-Figure 152) in India is designed for teaching. The bryophytes are planted and the species patch is outlined with white rocks (Figure 153-Figure 154). A label is placed on a stake in the patch. A simpler design without the feel of a garden is to plant bryophytes in pots and provide them with a label (Figure 155).

Indoor gardens like the Moss House require watering. This is best done with an automatic misting system (Figure 156), but care must be taken to create the appropriate regime. A filtering system might be needed to remove chlorine and unwanted minerals from the water. A fan may be needed to prevent mold.

Labelling

In an arboretum labels (Figure 153-Figure 155) help us to learn the names of the trees. Few gardens exist where a similar education is available for bryophytes. I quickly learned one of the problems of providing such labels for bryophytes. I learned that the field trip I had been asked to lead would have 60 participants. I went armed with a stack of pink computer cards. At each bryophyte, I placed a card with the name of the species. But the bryophytes were small and the cards were large. Many of the cards touched several species. That is only part of the problem in a bryophyte garden. As time passes, the species that is labelled can expand or get overgrown by other bryophytes. Furthermore, to most people, all bryophytes look pretty much the same. One Botanical Garden has attempted to solve the problem by locating a large patch of the bryophyte and attaching a label, then posting information explaining the characters used to identify the bryophyte and providing other useful information about it (Figure 157).

Summary

Public gardens occur all over the world, and many have sections with bryophytes, especially in Japanese gardens. These bryophytes require caretakers who understand the differences in the needs of bryophytes, avoiding fertilizers and maintaining boundaries between species. Watering may also be necessary.

Moss gardens are best known from Japan, but a number have mimicked the Japanese style of moss gardens in other countries.

Local species can be preserved in parks that serve as refuges in city landscapes. The number of species depends on the size of the park, the number of habitat types, and degree of human disturbance. Climate affects the parks in the same way it does non-park areas.

Bryophytes may enter the country or local area in pots of other plants that become a part of these gardens, whether public or private. These tend to be more successful in the human disturbance areas like parks and gardens than they do in nature. These aliens are most likely to arrive from the opposite hemisphere from areas with similar climates. *Campylopus introflexus* and *Orthodontium lineare*, in particular, have become well established in many areas as invasive species. Glass houses may have bryophytes that arrive in pots from all over the world. *Lunularia cruciata* exists in many locations only in glass houses.

Teaching gardens are often enhanced for learning by having labels. These need to be carefully monitored to be sure the same species remains with its label.

Acknowledgments

Dale Sievert made this chapter possible with his images of gardens with mosses from all over the world, and especially from North America. Virendra Nath contributed images from the Moss House that formed the basis of the Educational Displays section.
