cell types. One can imagine that elongate, narrow cells might move water more quickly with fewer walls to cross and formation of capillary space within the cell. I can't even imagine an advantage for the irregular wall shapes in *Racomitrium* (Figure 156). Bill Buck once asked me what I thought was the significance of the elongate cells in many pleurocarpous mosses. I couldn't give a good answer then, and now, several decades later, I still can't.

Papillae

Many theories have been proposed for papillae, but little is available as experimental evidence to support them. The papillae have a number of shapes and forms (Figure 157-Figure 159), while varying in size and density. Based on this variability, it seems to me that their functions may not be the same in all species or under all conditions.

Figure 157. *Tortula muralis* leaf cells with C-shaped papillae. Photo by Walter Obermayer, with permission.

Figure 158. *Tortula muralis* SEM of branched papillae. It is easy to see how these papillae could scatter light and protect the chlorophyll during dry periods. Photo from Botany Department website, University of British Columbia, BC, Canada, with permission.

Figure 159. *Chrysoblastella chilensis* leaf cross section showing papillae and capillary spaces between them. Photo by Juan Larrain, with permission.

When lamina papillae are dense, they give the leaf a waxy, often succulent look (Figure 160). The dull surface most likely does the same to the sunlight as it does to our eyes – it bends the light rays, preventing them from making straight entry into the leaf cells and thereby reducing damage to the chlorophyll when the leaf is dry. When the leaf is wet, the capillary spaces fill with water and the leaf surface behaves more like a uniform translucent surface (Figure 161). At least that is how some of us have interpreted the behavior. In experiments in my lab with papillose leaves under the microscope, we found that wet leaves transmitted about twice as much light as dry leaves, supporting that hypothesis.

Figure 160. *Encalypta streptocarpa* illustrating the waxy appearance when dry caused by numerous papillae. Photo by Michael Lüth, with permission.

Figure 161. *Encalypta streptocarpa* showing translucent appearance of the leaf when wet. Photo by Jan-Peter Frahm, with permission.

In some, perhaps all, the papillae facilitate water uptake by providing capillary spaces (Proctor 1979; Longton 1988; Pressel *et al.* 2010; see Chapter 7-4), but they can also facilitate water loss (Pressel *et al.* 2010). The uptake is usually accomplished by the small channels between the papillae, but in *Andreaeobryum macrosporum* (Figure 162), a small capillary channel goes through the papillae toward the cell and facilitates the rapid uptake of water during rehydration (Crandall-Stotler & Bozzola 1990, 1991).

Figure 162. *Andreaeobryum macrosporum*, a moss for which papillae are known to aid in uptake of water. Photo from Botany website, University of British Columbia, Canada, with permission.

An Alternative to Papillae?

In the moss *Rhacocarpus purpurascens*, the leaf cell wall has an unusual structure. The wall has three layers that Pressel *et al.* (2010) interpret as "a supreme adaptation to exposed habitats." This moss lives where there are frequent alternations between drought and heavy precipitation. We know that *Sphagnum* experiences water logging that prevents photosynthesis, and Pressel *et al.* reasoned that this special wall structure in *R. purpurascens* prevents water logging. Its outer cell wall layer is porous, ensuring rapid water uptake and retention. The hydrophobic cuticle-like layer simultaneously prevents water logging. The middle layer serves to extend the period of cell hydration, permitting active metabolism under drying conditions. The *R. purpurascens* cell wall

differs in function from cells with papillae in that papillae not only accelerate water uptake, but also accelerate water loss. Pressel *et al.* surmise that unlike the alternating conditions experienced by *R. purpurascens*, constantly flowing aerated water or underhangs where water logging can depress gas exchange select for mosses that are protected from water logging by surface waxes – a condition seemingly quite different from that seen in tracheophytes.

Stomata

True stomata do not exist in the gametophytes of bryophytes. However, as in tracheophytes, they do occur in many sporophytes. These are well-documented in the sporophytes of hornworts, but are not universal in mosses. They seem to be absent in leafy liverwort capsules, but evidence of potential evolutionary precursors is present in capsules of the genus *Haplomitrium* (Figure 163-Figure 164) (Duckett & Pressel 2019).

Figure 163. *Haplomitrium hookeri*, in a genus that exhibits precursors to stomata in the capsule. Photo by Janice Glime.

Figure 164. *Haplomitrium hookeri* with capsules. Photo by Norbert Schnyder, with permission.

Egunyomi (1982) reported sporophyte stomata in 29 tropical African moss species, distributed in 12 families. These mostly have round pores with two guard cells. Capsules he examined ranged in number of stomata from 2 to >200 (*Wijkia trichocoleoides* - Figure 165). Some stomata are raised above the level of the capsule epidermis [*Wijkia trichocoleoides*, *Trichosteleum microcalyx* (Figure 166), *Stereophyllum radiculosum* (Figure 167-Figure 168), and *Stereophyllum reclinatum*]. Others are sunken [*Brachymenium leptophyllum* (Figure 169) and *Bryum coronatum* (Figure 170)]. He found interesting correlations between stomata number and seta length, and between stoma size and epidermal cell size.

Figure 165. *Wijkia trichocoleoides*, a species with more than 200 stomata in its capsule. Photo by John C. Brinda, through Creative Commons.

Figure 166. *Trichosteleum* sp. with capsules, a species with stomata raised above the capsule epidermis. Photo by Jan-Peter Frahm, with permission.

Figure 167. *Stereophyllum radiculosum* leaves, a species with stomata raised above the capsule epidermis. Photo by Juan David Parra, through Creative Commons.

Figure 168. *Stereophyllum radiculosum* capsule with raised stomata creating visible bumps in the lower part of the capsule. Photo by Juan David Parra, through Creative Commons.

Figure 169. *Brachymenium leptophyllum* with capsules that have sunken stomata. Photo from Earth.com, with permission.

Figure 170. *Bryum coronatum* with capsules that have sunken stomata. Photo by Aruna Balasubrahmanya, through Creative Commons.

Their function, however, seems to differ from that of tracheophyte stomata, playing a role in dispersal by permitting the capsule to dehydrate and contract. Their function has been the subject of recent research and will be updated soon.

Fluorescence

Fluorescence is seldom mentioned in bryophyte studies. I can remember the excitement of Gisela Nordhorn-Richter when she relayed to me the use of a fluorescent microscope to see propagula in *Pohlia*. It became a great tool for detecting these often obscure structures with UV light.

Following her enthusiasm, I had the opportunity to examine *Fontinalis antipyretica* with a fluorescent microscope and was surprised to find beautiful yellow cell walls and glowing red chloroplasts (Figure 171) – well, the chloroplasts didn't really surprise me, but they certainly made a beautiful image.

Figure 171. *Fontinalis antipyretica* wall fluorescence. Photo by Janice Glime.

Kroken *et al.* (1996) found that both charophytes and bryophytes have fluorescent cell walls. They suggested that the bryophytes inherited this fluorescence ability from the charophytes, citing evidence from time of production and location. A number of charophytes produce these resistant cell walls in response to desiccation stress. Furthermore, *Coleochaete* (Figure 172) is the only charophyte known to produce fluorescent tissues at the placental junction in hydrated tissues, induced by sexual reproduction. However, this characteristic is true of all bryophytes tested. Furthermore, in *Sphagnum*, the maternal tissue in the apical portion of the **pseudopodium** (Figure 173) has fluorescent compounds similar to those in *Coleochaete* zygotes. Other known sites of autofluorescence in bryophytes include the sporangial epidermis, spiral thickenings of elaters, rhizoids, and leaves. Kroken and coworkers suggested that this fluorescence represents repeated exaptation. The regulation of deposition has been modified through time, "resulting in a sequence of functions: desiccation resistance and/or microbial resistance in lower charophytes, a role in embryogenesis in *Coleochaete* and embryophytes, and finally, decay resistance in innovative structures that characterize bryophytes, such as rhizoids, sporangial epidermis, and elaters.

Fluorescence is discussed in more detail in Chapter 9-5 of this volume.

Thallus

Liverworts are of two types – thalloid and leafy. The thallus brings its own set of adaptations, with its thickness making possibilities that are not available to the leafy taxa with their one-cell-thick leaves. Among the **xerophytic** (of dry habitats) adaptations are the ability to roll up, shrivel, or fold the thalli, exposing the normally ventral side where red pigments (**anthocyanin**) or hyaline ventral scales (Figure 174-Figure 175) serve to protect the photosynthetic tissue from damage due to exposure to sunlight while dry (Kürschner 2004). The hyaline scales such as those in many *Mannia* (Figure 174-Figure 175), *Riccia* (Figure 176), and *Oxymitra* (Figure 177) species undoubtedly serve to reduce desiccation and provide capillary spaces to facilitate water uptake upon wetting.

Figure 174. *Mannia androgyna* in hydrated condition with reddish edges that characterize the color of anthocyanins on the ventral side. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission from Russ Kleinman & Karen Blisard.

Figure 177. *Oxymitra incrassata* showing marginal scales. Photo by Chris Cargill, with permission.

The raised cells of the epidermis and the chimney-like hyaline air chambers of some species in *Exormotheca* (Figure 178) may likewise serve as protection from solar radiation and protection from desiccation. Thalli of some species have "windows" (**Fensterthallus**), for example the chimney-like, hyaline air-chambers of *Exormotheca* (Figure 178-Figure 179), like those in the flowering plant family Aizoaceae (for example *Lithops*). These windows provide a covering that helps to reduce the light intensities that reach the photosynthetic layer (Kürschner 2004). The liverwort thallus is thick and nearly semi-circular in cross section. Internally, it has dense assimilatory columns in its air chambers. The column thickness in the liverworts frequently correlates with the degree of insolation.

Figure 178. *Exormotheca welwitschii* in southern Portugal, showing "windows" in the thalli. Photo by Michael Lüth, with permission.

Figure 179. *Exormotheca* sp. thallus showing columnar cells that form the windows to the photosynthetic tissue of the thallus. Photo © Wilhelm Barthlott <lotus-salvinia.de>, with permission.

Liverworts such as *Plagiochasma rupestre* (Figure 180) have hydrophobic wax globules on the thallus surface, making them unwettable. Such waxes keep xerophytic members of the **Marchantiales** from taking up water through the thallus surface, using their pegged rhizoids instead.

Figure 180. *Plagiochasma rupestre*, a thallose liverwort with hydrophobic wax on its surface. Photo by Jan-Peter Frahm, with permission.

Thallus pores could serve as a site of water entry, but a ring of wax around the inner margin of the pore in species like *Marchantia polymorpha* (Figure 139-Figure 142, Figure 181) serves both to repel water and to make the

opening smaller, making it difficult for cohesive water droplets to enter the air chambers of the thallus. Many thalloid species have hydrophobic cuticular ledges around these pores (Ziegler 1987). These waxes protect the air chambers from becoming water-logged (Schonherr & Ziegler 1975; Kürschner 2004).

Figure 181. *Marchantia polymorpha* thallus pore opening with ridge that is heavily endowed with wax. Photo © Wilhelm Barthlott, with permission.

Once inside the thallus, we must look for adaptations to obtain sufficient CO₂ and to maintain moisture. For the thallose liverworts this problem seems to be solved in a manner similar to that of most flowering plants – a ventilated photosynthetic tissue that has stacks of cells one cell wide interspersed within air chambers (Figure 140-Figure 142) (Proctor 2010). See **Air Chambers** above

Pigmentation

In physiological studies on animals, it is clear that environmentally induced variation is often adaptive. More arachidonic acid makes membranes more pliable. Non-nucleating proteins prevent ice crystallization. Changes from glucose to glycogen prepare an animal for dormancy. Even physical changes, such as color of fur or feathers, can prepare an animal for a change in seasons. Development of red pigment in *Sphagnum* (Figure 182) and *Fontinalis* (Figure 183-Figure 184) may protect the chlorophyll from high light intensity.

Figure 182. *Sphagnum* showing the red colors that develop in some species when they grow in the sun. Photo by Janice Glime.

Figure 183. *Fontinalis antipyretica* with red pigments responding to cold spring water and full sun. Photo by Janice Glime.

Figure 184. *Fontinalis antipyretica* with red pigments, responding to being out of water, but moist, in bright light. Photo by Janice Glime.

Red pigments in high elevations and alpine regions might serve dual purposes. The red color can protect the chlorophyll and DNA from UV damage, but it could also cause the mosses to absorb heat in their cool climate. The images of *Grimmia elongata* (Figure 185-Figure 186) illustrate the green and red color expressions in this species.

Figure 185. *Grimmia elongata* showing its green form. Photo by Michael Lüth, with permission.

Figure 186. *Grimmia elongata* in Norway, exhibiting its red pigments in the high UV light of the high elevation. Photo by Michael Lüth, with permission.

Some pigmentation may just come along for the ride. For example, phenolic compounds are typically colored, but their primary function can be support or antiherbivory. Such support functions are most likely for structures like the costa (Figure 187) or stem rigidity (Figure 188), but they also occur in many leaf borders (Figure 68).

Figure 187. *Syntrichia inermis* leaf showing dark color in costa. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 188. *Fontinalis dalecarlica* stem section showing dense coloration in the cell walls. Photo by Janice Glime.

Seta Colors

David Long (Bryonet 24 March 2023) asked why some moss setae are red. Questions like this bring out some of the lurkers because there is no known right answer. In fact, Jack Sharp used to respond to such questions with the admonishment that not all things are adaptive – they simply must not be maladaptive to persist.

This question can be divided into two parts: what biochemistry makes it red, and does it have an adaptive persistence.

Let's first examine possible adaptive significance. Here are my potential hypotheses:

1. In species like *Ceratodon purpureus* where the capsule is likewise red-purple, the pigmentation pathway starts early in development of the sporophyte.
2. Red is a warning color to animals, so the red color could deter herbivory.
3. Red absorbs heat, thus warming the developing sporophyte if that occurs in spring or autumn, possibly speeding up development.
4. Red protects against UV damage and could therefore be helpful in preventing damage to young sporophyte tissues.
5. Lignin-like compounds might provide structural support, and these can be red in color.

Gender

Zander (Bryonet 8 May 2012) suggested that the presence of only males in a population would have the adaptive advantage of conserving photosynthate by the lack of necessity for producing sporophytes. Thus dioecy in dry habitats might be an adaptation to conserve photosynthate. But Stark has reported that in many desert populations the males are absent. Nevertheless, this principle would operate whether the population was male or female. On the other hand, monoecy provides advantages in a moist or otherwise less stressful habitat where there is sufficient energy for producing sporophytes.

Adaptive value of gender expression was discussed in detail in Chapters 3 and will not be discussed further here.

Wound Response

If you are a plant, what you do when you get damaged may have important effects on the future of your species. And if you live in fast-flowing water (Figure 189), that damage is a certainty. Some species are adapted to take advantage of the wounds; others merely protect themselves; some (perhaps most bryophytes) do both. The advantage for bryophytes – a means for dispersing and making new colonies.

We have limited understanding of the means of protection. One study on the biochemical response is that for *Marchantia polymorpha*. When wounded, *Marchantia polymorpha* (Figure 190) produces highly volatile 8-carbon compounds including (R)-1-octen-3-ol and octan-3-one (Kihara *et al.* 2014). These emissions occurred within 40 minutes of the wounding. The importance of arachidonic acid and/or eicosapentaenoic acid was demonstrated by the weak or absent response of the volatiles. In completely disrupted thalli, only minimal amounts of octan-3-one were produced, whereas the greatest amounts were produced in

partially disrupted thalli, compared to undisturbed thalli. This suggests signalling from the disrupted cells that initiates the production of octan-3-one in the undisturbed cells.

Figure 189. *Cinclidotus danubicus* habitat, illustrating the power of the water. Damage to leaves can be significant during high-water events. Photo by Michael Lüth, with permission.

Figure 190. *Marchantia polymorpha* with an isopod – a potential herbivore. Herbivory and other wounds can stimulate production of highly volatile compounds in this liverwort. Photo by Walter Obermayer, with permission.

Croisier *et al.* (2010) found a variety of responses in the bryophytes they surveyed. Instead of the predominant C8 volatiles, they found a variety of C5, C6, C8, and C9 volatiles in 23 mosses tested. These are **oxylipins** – metabolites derived from oxidative fragmentation of polyunsaturated fatty acids. Both C18 and C20 fatty acids serve as the precursors for the volatile oxylipins that respond to mechanical wounding of mosses. These oxylipins are important hormonal regulators and defense compounds in plants. In liverworts and hornworts, oxylipin production was less pronounced than in the mosses.

This still leaves us with the ecological question of how these volatiles protect the species. Do they deter herbivores, as do many volatiles in tracheophytes? The *Marchantia* story suggests they are inducible. Do they protect against fungal attack? (Fungal attack will be covered later in a chapter on fungal interactions.) Do they play any role in dedifferentiation and regrowth? Do they stimulate the production of rhizoids or protonemata often seen at wound sites? This would seem to be a fertile area

of research for understanding hormonal interaction and control of development in bryophytes.

Summary

Bryophytes have a simple structure. That does not mean they have not advanced morphologically. Their stems may have conducting cells, have various phenolic compounds in the cell walls, or be covered with paraphyllia, rhizoids, or tomentum. The leaves may have borders, marginal teeth, lobes, hair tips, costae, lamellae, or keels. The leaf cells may be short and nearly isodiametric (often with thick walls), larger hexagonal cells with thin walls, or elongate narrow cells. These cells may have waxes, papillae, or be swollen. These structures seem to be adaptations to habitats ranging from aquatic to desert.

Aquatic bryophytes that do not spend much time out of water generally lack papillae, have elongate narrow cells, and lack conducting cells in the stems. They may have strong stems with colored cell walls from phenolic compounds, protecting them against moving water and suspended solids. At the other extreme, xerophytic bryophytes are often papillate, have thicker waxes, are reduced in size, and have mechanisms of curling up while dry and expanding when wet. Specialized cell walls, lamellae, and marginal teeth may provide mechanisms to increase photosynthesis while preventing water logging. Hair tips can scatter high light, absorb water, or reduce drying. Pigments can protect bryophytes from high light intensities, especially when low temperatures slow photosynthesis or the plant is dormant due to high temperatures.

Leafy liverworts may be able to hold water droplets with their lobes and teeth. These structures could also serve to deter herbivores. The thallus can have windows to direct light and protect the photosynthetic cells, be protected by waxes and scales, have thallus pores that open and close, permitting gas exchange while preventing internal water logging.

These adaptive value of bryophyte structures are largely speculation, hypotheses waiting to be tested.

Acknowledgments

This chapter is largely the product of discussions with other bryologists, especially on Bryonet. Thank you to Louis Anderson for his constant reminders that things do not always have an adaptive function. My appreciation always goes to the many people who have given me permission to use their images, including those who make them available online through Creative Commons. And thank you to Bryonetters who contributed to the discussion on seta colors.

CHAPTER 5-1

ECOPHYSIOLOGY OF DEVELOPMENT: HORMONES

Figure 1. *Funaria hygrometrica* demonstrating the doughnut-shaped growth typical of cultures. Photo by Janice Glime.

Introduction

Although the field of development usually attracts scientists with very different interests from those of the ecologist, the two fields nevertheless have important overlaps that define the niche of the organism. It is the development and life cycle that permit the organism to time its life so that it can survive, from having water to grow, to dispersing its sperm and spores, to being dormant when the going is rough. Thus, it is appropriate for the ecologist to have some rudimentary understanding of the environmental controls on the physiological aspects of development and to understand the sorts of responses that might occur.

Bryophytes are limited in their occupancy of the world by a lack of lignin. This compound, providing strength and structure for the mighty sequoia, permits tracheophytes to attain heights unimaginable for the unlignified bryophyte. Height for most mosses standing alone is but a few centimeters, achieving greater heights when supported by their neighbors, the power of the clone! Yet some mosses, like *Dawsonia* (Figure 2), achieve heights exceeding 2 dm, with enough strength to maintain it alone.

Figure 2. *Dawsonia superba*, the tallest stand-alone moss. Photo by Janice Glime.

In some cases, lignin-like compounds may add strength to the cellulose walls of the cells. But perhaps a new discovery may help in understanding how bryophytes maintain their strength. **Extensins**, previously known from tracheophytes, have just been found in mosses for the first time, in what else – *Physcomitrella patens* (Figure 3; Schipper *et al.* 2002). These glycoproteins, rich with hydroxyproline, comprise about 5-10% of the dry weight of most primary cell walls and serve to strengthen the walls (Taiz & Zieger 1991). Taiz and Zieger (1991) claim that tracheophyte fibers with a tensile strength similar to that of steel wire may gain their strength from the combination of both lignin and extensin. The importance of extensin to bryophyte strength remains to be demonstrated.

Figure 3. *Physcomitrella patens* in its natural habitat. Photo by Michael Lüth, with permission.

Bryophytes, with a very thin cuticle, if any, and leaves only one cell thick, easily lose water. Yet, there are about 15,000 species, more than any other group of plants besides flowering plants. How is it that they are able to survive in such harsh environments where they might completely dry out for months at a time? How do they live in places that **never** get any rainfall?

Then there is the problem of sexual reproduction, of transferring gametes from a male organ to a female organ when the male gamete, the sperm, requires water in order to swim! It seems that one of the best solutions was to produce gametes only when water was available, but that requires developing the gametangia well in advance of the fertilization event in order to be ready on time. Something has to trigger the plants to stop using all their energy for growth and put some of it into making gametangia. A method of receiving and responding to environmental signals was necessary.

Finally, these plants needed ways to get to new homes when theirs were being destroyed, whether by erosion, fire, or other unpredictable events. They needed reproductive structures that could travel in a medium of air and survive without water for a long period of time. Hence, they needed spores that did not swim and these needed a thick cover to prevent total desiccation.

All of these events had to be carefully controlled, timed to take advantage of seasons when water was available for fertilization and when dry air was available for spore dispersal. These "primitive" bryophytes have been successful at organizing their morphology, their

biochemistry, and their life cycles in a way best suited to their individual environments.

For these organisms to complete their life cycles, a coordinated set of developmental stages and environmental signals must exist. If this coordination is lacking, the plant may find itself in a life cycle stage that has requirements the environment is unable to supply. Unlike animals, the plant cannot move to a new habitat when the going gets rough. When the spore lands and germinates, a bryophyte must be able to develop its protonema, produce a leafy gametophore, develop archegonia and antheridia, achieve fertilization, develop a sporophyte with a capsule, and disperse its spores without changing its location.

As we have studied the taxonomy of bryophytes during the last two centuries, numerous examples of life cycle adaptations have become apparent through our descriptions of the genera and species that grow in a variety of habitats. It is obvious that many strategies exist, from the **neotenous** (having juvenile traits retained in adults) habit of *Buxbaumia* (Figure 4) to produce sporophytes without developing an upright gametophyte, to the highly developed gametophyte of *Fissidens obscurus*, where sporophytes are generally unknown. Some mosses readily form gametophores on nutrient-poor soil, such as the pioneer *Funaria hygrometrica* (Figure 1), whereas others such as *Pylaisiella* (Figure 25) seem to benefit from products of associated organisms (Spiess *et al.* 1971, 1972). Some rely predominantly on spores for dispersal, whereas others depend on abundant gemmae. Control of these life cycle differences depends on a complex evolutionary interaction with the environment to select the strategy that best adapts the bryophyte to its particular set of circumstances.

Figure 4. *Buxbaumia aphylla*, demonstrating the neotenous development of reproductive structures and ultimately a sporophyte without the development of a leafy gametophyte. Photo by Janice Glime.

While our understanding of development has been progressing since the early descriptive work of Goebel (1930) and Lorch (1931), so has our understanding of moss ecology. During (1979) began to bridge the fields of development and ecology by his presentation of life cycle strategies. He has suggested that the ability to occupy a habitat is dependent upon life span, type of reproduction, time required for maturity, spore size, spore longevity, and growth form. Based on the review presented by Bopp (1981) and knowledge of the importance of growth hormones in regulating development in higher plants, it is

possible now for us to consider the role of hormones during all stages of the life cycle. Reviews on developmental physiology by Bopp (1981), on biochemical constituents by Suire and Asakawa (1981), and recently the review on control of development by Christianson (2000a) begin to make it possible to evaluate environmental signals as they relate to known physiological responses that determine development.

Developmental Adjustments

Like some of the insects that can adjust their life cycle mid course, changing their developmental rates, at least some bryophytes likewise adjust their developmental periods based on seasonal and temperature effects. For example, *Fontinalis squamosa* (Figure 5) cultured in early May at 14° and 20°C required 18 days to germinate from tiny (10 µm), early season green spores. Capsules collected at the same time and stored at 10°C until late May provided spores that were larger (25 µm) and germinated under the same conditions in as few as 5 days (Glime & Knoop 1986). Capsules stored at 3°C until late May provided spores that generally failed to germinate, and those that did required a minimum of 15 days, failing to develop further.

In this case, spores shed prematurely apparently developed externally and took longer to germinate. Such adjustments suggest that under natural conditions at different latitudes the moss would have different responses, with the ones at colder temperatures being able to germinate more quickly when the critical temperature was reached, but at very cold temperatures, germination would generally not occur, thus protecting the protonema from potential freezing.

Figure 5. *Fontinalis squamosa* spore germinating. Photo by Janice Glime.

In a latitudinal study on *Meesia triquetra* (Figure 6), Montagnes and Vitt (1991) found that morphology varied in a linear way with latitude, with variances in characters decreasing with increasing latitude. Among the characters that decreased were annual growth increment, number of leaves produced each year, and leaf length. As leaf length decreased, leaf width increased with increasing latitude, and the tip was less acute, making a shorter, broader, more ovate leaf. However, unlike the insect larvae that are able to adjust their life cycles "on the fly," these morphological changes persisted in a **common garden** (where different populations are grown together with the same conditions),

therefore suggesting that they are genetically controlled (Montagnes 1990) and most likely a product of natural selection.

Figure 6. *Meesia triquetra*. Photo by Michael Lüth, with permission.

Polytrichum strictum (Figure 7) (Longton 1974) likewise had decreased leaf length as it grew farther north, and as expected, less annual growth in length and weight, and fewer leaves per annual growth increment (Figure 8). These factors seemed to be under both external and genetic control.

Figure 7. *Polytrichum strictum* from the temperate zone. Photo by Jan-Peter Frahm, with permission.

Figure 8. *Polytrichum strictum* from Alaska, USA, showing shorter plants and smaller leaves. Photo by Andres Baron Lopez, with permission.

Hylocomium splendens (Figure 9) varies so much that subspecies and varieties have been named. On the west coast of Canada, it grows in **wefts** (loosely interwoven, often ascending growth form), earning it the subspecies designation ***giganteum***, and has the typical stair-step frond (Figure 10; Montagnes & Vitt 1991). North of the tree line, where it is designated var. ***obtusifolia***, it lacks the stair-step character. The variety ***splendens*** is intermediate to these two taxa.

Figure 9. *Hylocomium splendens* in its typical weft form. Photo by Michael Lüth, with permission.

Figure 10. *Hylocomium splendens* showing stair-step growth form typical of the north temperate and boreal region. Photo by Janice Glime.

In summary, as demonstrated in *Meesia*, *Polytrichum*, and *Hylocomium*, increasing latitudes can select for mosses with **shorter leaves**, cause **reduced annual growth**, **reduce the number of leaves** produced per year, and **change growth form and branching patterns**. These differences can be under environmental or genetic control, or both.

Life Cycle Importance

Bryophyte life cycles have stimulated the curiosity of botanists for centuries. Their simple representation of two clearly visible generations makes them choice organisms for introducing the concept of a life cycle to students. Because of their ease of expressing genetic effects, bryophytes have provided the laboratory material for pioneering breakthrough research in several areas of genetics and molecular biology, permitting us to understand not only bryophyte development, but paving the way for understanding tracheophyte development as well (Reski 1998; Schumaker & Dietrich 1998; Christianson 2000b). The first sex (X & Y) chromosomes were found in

bryophytes, in *Sphaerocarpos* (Figure 11). The continuity of chromosomes during mitosis was elucidated in bryophytes. Discovery of non-Mendelian inheritance was first found in bryophytes. Furthermore, the haploid generation permits us to isolate gene mutations in order to determine their developmental roles.

Figure 11. *Sphaerocarpos michelii*. Photo by Michael Lüth, with permission.

The moss *Physcomitrella patens* (Figure 3) has become the experimental rival of *Arabidopsis*, *Nicotiana*, and *Brassica*. Its most recent advantage is in **reverse genetics** (genotype-driven technique in which genes are either knocked out or added to see the effect on phenotypic expression), enabling geneticists and physiologists to understand gene function by targeting specific genes. Because the moss is haploid, it is much easier to isolate a mutant gene and determine its function. As this new information becomes available, understanding the role of the environment in regulating gene function, and ultimately in influencing development, will become much clearer.

We should expect a variety of geographic differences in the life cycle as well as differences influenced by the weather in a given year in one location. To understand and predict these differences, we must first understand the developmental ecophysiology. This requires that we understand the functions of hormones.

Growth Regulators

Hormones, or growth regulators, were originally defined for animals as substances that are produced in one part of the organism and move to another where they carry out their action, in very small quantities. This definition works less well for plants, wherein ethylene always and others sometimes are produced in their final step at the site of action. But plant hormones differ from those of animals in other major ways as well. They have a much wider array of actions than the limited action ability of most animal hormones (Christianson 2000a). (Or do those animal folks just not understand their hormones as well as the botanists understand theirs?) Rather, in plants the hormones usually act in combinations that present a wide array of possible outcomes. In plants, as in animals, every aspect of development involves hormones.

If hormones are within the organism, why should an ecologist even care to understand their nature and action? Hormones are often leaked into the environment by other

organisms and those external sources may even be necessary to the development of the plants. Plants both excrete hormones and are affected by external hormones (Beutelmann & Bauer 1977). Bryophytes are no exception to these external regulators. This makes the role of the environment of far more importance than for most animal hormone functions (human contributions notwithstanding). While the number of hormones known in plants is small (Table 1), the importance of external hormones is poorly known, especially in bryophytes.

Consider for a moment what the bryophytes have been doing for their 400-million-year history. Limited in structure by their lack of lignin, they were not limited in any discernible way regarding their biochemical evolution. This has afforded them three times as long to perfect their development and biochemical adaptations compared to the Magnoliophyta (flowering plants) (Christianson 2000a). In fact, the very absence of large morphological adaptations has increased the selection pressures for cellular level biochemical ones (Christianson 2000a). Here we will examine what we do know about the hormones found in bryophytes.

Auxins

Auxins have long been known as plant growth hormones, and were conclusively demonstrated in bryophytes in 1985 (Law *et al.* 1985), but their mode of action is still not clearly understood. They are amino-acid based hormones, and through studies with Venus flytrap (*Dionaea muscipula*), we have discovered that they have a role in cell extension. This extension seems to be mediated by an efflux of H⁺ that accumulates between the cells, breakage of the calcium pectate bonds that glue cell walls together, and appearance of Ca⁺⁺ inside the cells in the area of rapid growth. Concomitant with these events, the auxin **IAA** (indole-3-acetic acid) increases in the region of growth (in this case, the lower side of the midrib). Using the moss *Funaria hygrometrica* (Figure 12), Kapoor and Bhatla (1998) suggest that the influx of Ca⁺⁺ to the cells may be induced by the IAA, although in this case it is in callose (complex, branched polysaccharide) synthesis that precedes the differentiation of chloronema (youngest part of protonema) to caulonema (part of protonema giving rise to leafy plants). IAA has a known role in this chloronema to caulonema transformation (Decker *et al.* 2006).

Table 1. Classes of growth regulators affecting bryophytes, their known presence in mosses and liverworts, and their known functions in that group.

Class	Specific Regulator	Presence	Function
auxins	IAA	mosses, liverworts	membrane transport (esp. Ca), cell elongation, protonema differentiation, stem elongation (promote at low, inhibit at high), rhizoid initiation, seta elongation, tropisms, apical dominance
cytokinins	zeatin	mosses	cell division, aging, bud initiation, archegonium initiation,
	isopentenyladenine	mosses	gametophore production
	Factor H?	mosses	inhibition of caulonema growth, bud initiation, gemma formation
	analogs	mosses, liverworts	promote thallus growth, slow aging, increase Ca in cell
gibberellins	gibberellin-like	?	development, promote growth, enhance antheridial development, decrease archegonial production
dormancy hormones	lunularic acid (LA)	liverworts	growth regulator, dormancy, drought tolerance, antiherbivory?
	abscisic acid (ABA)	mosses, hornworts?	drought tolerance, growth form, capsule stomatal closure, gametophore bud inhibition; controls cytokinin response
ethylene	ethylene	mosses, liverworts	development, leaf morphology, epinasty, cell elongation, color changes, response to substrate, senescence, suppression of 3rd row of leaves in liverworts, increased number of antheridia, chloronema to caulonema, inhibits seta elongation, may control gametophore bud development
acetylcholine		mosses, liverworts?	light response?; antiherbivory?; cellular regulation?
cryptochromes		mosses, liverworts?	protonema branching, gametophore induction, development, auxin control, photoperiodic responses

While the Venus flytrap provides the advantages of knowing where and when the growth response will occur, the number of responses of a single plant is limited, and the response is extremely rapid, making it difficult to obtain large amounts of data. The moss system provides a slower response that can be controlled by the researcher through externally applied auxin. As a single-cell-thick response system (leaf or protonema, Figure 12), the moss offers strong advantages over leaves or buds of tracheophytes, where any externally applied auxin must slowly penetrate

the epidermis or other protective cells and substances. Because of these advantages, we are beginning to understand the role of IAA and calcium through the use of moss models.

Auxin activity seems to be an ancient character present when liverworts first emerged on land (Ishizaki *et al.* 2012). Ishizaki and coworkers demonstrated auxin activity at the bottom of gemma cups and junction of gametophyte and sporophyte in *Marchantia polymorpha* (Figure 13), suggesting its importance in actively dividing cells.

Figure 12. *Funaria hygrometrica* protonema with differentiation into chloronema (perpendicular cross walls) and caulonema (diagonal cross walls). Photo by Janice Glime.

Figure 13. *Marchantia polymorpha* vegetative thallus with gemma cups. IAA moves basipetally (away from the tips) in this species. Photo by Janice Glime.

Our knowledge of the role of IAA in moss gametophores is still limited. We do know that the maximum concentrations are at the stem apex and base (Decker *et al.* 2006). The IAA seems to respond to changes in light quality, with red light retarding growth of protonemata but causing elongation of the gametophores, nevertheless making leaves shorter and narrower. Far red light enhances these responses (Bierfreund *et al.* 2003).

Thomas *et al.* (1983) demonstrated that IAA controlled seta elongation in the liverwort *Pellia epiphylla* (Figure 14). Although this and other studies provided indications of the presence of IAA in bryophytes, the first definitive HPLC (high-performance liquid chromatography) demonstration of its presence was published in 1985 by Law and coworkers in sterile culture of the liverwort *Plagiochila asplenoides* (Figure 15) subsp. *arctica*. The natural auxin is **indole-3-acetic acid** (IAA), which is produced in the stem and branch tips of higher plants, and among bryophytes the same apical production is indicated in *Marchantia* (Maravolo 1976; Gaal *et al.* 1982). Due to its polarity, IAA moves **basipetally** (toward the base), as demonstrated in *Marchantia polymorpha* (Figure 13) by Maravolo (1976, 1980), where it travels in the midrib. Its transport is inhibited by aging and ethylene.

Figure 14. *Pellia epiphylla*, a species in which IAA controls seta elongation. Photo by Malcolm Storey, through Creative Commons.

Figure 15. *Plagiochila asplenoides*, a liverwort in which the presence of IAA has been demonstrated. Photo by Dick Haaksma, with permission.

In mosses, we know that early development is triggered by the auxin IAA working with **cytokinin** (another hormone) and requiring light that acts through the mediation of **phytochrome** (pigment sensitive to photoperiod) and a blue light receptor (Reski 1998), possibly **cryptochromes**. Auxins respond to light and gravity and thus provide a means for plants to grow in the right direction relative to the Earth. Their mode of action is still controversial, despite extensive research into their movements within plants and plant responses.

IAA seems to be essential for normal stem elongation (Bidwell 1979). When researchers removed the tips of actively growing tracheophytes, growth stopped. If they applied IAA, growth continued. On the other hand, at least in flowering plants, removal of the stem apex can promote growth of the branches, which were heretofore inhibited by the IAA during its downward movement. Similar reactions seem to occur in at least some mosses, as exhibited by the **innovations** (new ascendant branches near the shoot tip; Figure 16) of mosses following **gametangial senescence** (*i.e.* loss of gametangial function with aging), but experimental evidence of the IAA connection in bryophytes seems to be lacking.

Figure 16. Innovation (arrow) beneath senescing antheridial head of *Philonotis caespitosa*. Photo by Michael Lüth, with permission.

Auxins play major metabolic roles. IAA, in particular, seems to play a role in membrane transport; Lüttge and coworkers (1972) demonstrated that IAA can enhance leaf uptake of potassium by *Mnium* from both KCl and K₂SO₄. Inhibition of IAA by TIBA (2,3,5-triiodobenzoic acid; polar auxin transport inhibitor) reduces starch accumulation at night and disrupts meristem polarity in the thallose liverwort *Riella helicophylla* (Figure 17) (Stange 1985). The role of IAA in cell extension is still unclear, but perhaps it again plays a metabolic role in the transport of substances across the cell membrane, particularly calcium, thus increasing the osmotic potential of the cell.

Figure 17. *Riella helicophylla*, a liverwort where polar auxin transport causes reduction in nighttime starch accumulation and disruption of meristem polarity. Photo from NACICCA, through Creative Commons.

Auxins promote stem elongation at low concentrations and inhibit it at high ones, presumably due to induction of

ethylene (Goodwin & Mercer 1983), and concentrations that promote growth in one part of a plant may inhibit it in another. In reviewing the body of literature on auxins in both non-tracheophytes and tracheophytes, Cooke and coworkers (2002) were surprised to find bryophytes exhibited most of the same physiological mechanisms for regulating IAA and for IAA-mediated responses as did the tracheophytes. These responses include **tropisms**, **apical dominance**, and **rhizoid initiation**. Both charophytes (the likely progenitors of bryophytes) and liverworts synthesize IAA via the tryptophan-independent pathway, regulating IAA levels through a balance between the rates of IAA biosynthesis and IAA degradation. All other land plants use the same pathway, but seem to have more precise spatial and temporal control through additional hydrolysis reactions. Although charophyte tips are apparently not sensitive to polar IAA transport inhibitors, both moss and liverwort gametophytes and moss sporophytes carry out polar transport, but sensitivity to the transport inhibitors differs within these groups.

The small quantities in which auxins are present in plants, combined with the small size of bryophytes, have made detection difficult. Their presence was indicated at least as early as 1963 when Cox and Westing demonstrated it in peat extracts. Despite its nanoconcentrations, Bhatla and Dhingra-Babbar (1990) report the presence of IAA in the protonemata of *Funaria hygrometrica* (Figure 12), *Physcomitrella patens* (Figure 3), and *Polytrichastrum formosum* (Figure 18), where it seems to be involved in differentiation. Many researchers (Cove *et al.* 2006; Von Schwartzberg 2009) consider *Physcomitrella patens* to be a potential model system for study of this and other hormones because we now know its genome and can use gene knockout to determine the functions of the genes and ultimately the functions of the hormones.

Figure 18. *Polytrichastrum formosum*, a moss in which IAA seems to be important in differentiation. Photo by David T. Holyoak, with permission.

Cytokinins

Cytokinins are important in bud formation. Using *Physcomitrella patens* (Figure 3) as a model, we can observe that the apical cell of the protonema divides (Reutter *et al.* 1998). When bud development begins, some of the subapical cells produce three-faced apical cells. These are the buds that will develop into the **gametophores**

(leafy shoots). Application of cytokinin enhances bud formation, but the buds often do not develop further. The moss *P. patens* produced isopentenyl-type cytokinins, whereas the zeatin-types produced by **tracheophytes** (non-bryophyte plants) were absent.

Cytokinins in bryophytes remained elusive until very recently because of their low concentrations. Cytokinins form another class of hormones that generally cause cell division (mitosis). Higher plants contain various **endogenous** cytokinins (produced within plant), such as zeatin, and scientists have identified many other compounds that act as cytokinins, such as kinetin and benzyl adenine. Unlike IAA, cytokinins travel to the tip of the protonema and accumulate there. Only two cytokinins (zeatin, isopentenyladenine) had been identified in bryophytes by 1979, both from protonemata (Cove *et al.* 1979, Gerhauser unpubl.). By 1990, there were indications that a third exists (Bhatla & Dhingra-Babbar 1990). Now we know that at least 20 of the 40 known cytokinins exist in the moss *Physcomitrella patens* (Figure 3), the most abundant of which are cis-Zeatin-riboside-O-glucoside, N6-(Δ^2 -isopentenyl)adenosine-5'-monophosphate (iPRMP), and trans-zeatin-riboside-O-glucoside as intracellular hormones (von Schwartzberg *et al.* 2007).

The ability of cytokinins to affect Developmental changes in gametophores has been demonstrated experimentally. Chopra and Sood (1973) have shown that the cytokinin analog **kinetin** promotes growth of thalli in *Riccia crystallina* (Figure 27), but it also enhances archegonial formation. Vashistha (1987) likewise found that three different cytokinins applied to the liverwort *Riccia frostii* (Figure 19) stimulated vegetative growth and archegonial induction. Besides cell division, this hormone group can prevent or slow aging and cause changes in sex expression in higher plants (Kahn 1971). Cytokinins seem to cause the increase of calcium in the cell and together with calcium may cause an increase in ethylene. Magnesium ions seem to antagonize this calcium transport.

Figure 19. *Riccia frostii*, a liverwort that responds to cytokinin in the medium. Photo by Rosemary Taylor, with permission.

Mosses respond differently to different concentration levels of cytokinins (Reski & Abel 1985). Among protonemata, only the chloronemata respond to low cytokinin concentrations, At high concentrations, only the caulonemata responded by increased bud formation.

Hence, there is a specificity among cells in the concentrations to which they respond.

Reutter *et al.* (1998) were able to connect specific genes with their functions by using transgenic *Physcomitrella patens* (Figure 3). Using mutants that were unable to accomplish specific developmental tasks, they showed that cytokinins were able to supply the necessary signals for these events to occur (Figure 20).

In some cases, an outside source is needed to catalyze the production of cytokinins. For example, *Agrobacterium tumefaciens* (Figure 21) has the isopentenyl transferase gene that is needed to catalyze the first step in the biosynthesis of cytokinin (Decker *et al.* 2006). For some mosses, this bacterium is needed for development to go from the protonema to gametophore stage. Reutter *et al.* (1998) found that the moss *Physcomitrella patens* (Figure 3) responds differently to the same cytokinin when it is internal (**endogenous**) vs external (**exogenous**), and that most of both cytokinin and auxin is outside the moss (Reutter *et al.* 1998; Ralf Reski, pers. comm. 19 September 2013). Reutter *et al.* (1998) suggest that this external presence may permit translocation of the hormones in the bryophytes.

Figure 20. *Physcomitrella patens* hormonal contents. WT=wild type, PC22 = mutant defective in gametophore development and plastid division, P24=mutant that does not produce buds, *ipt*=gene of respective transgenic plant. Y axis is the immunoreactive IP, IPA, and IAA equivalent [pmol (gFW)⁻¹] in 9-day-old plants in liquid culture. Note that hormone levels are elevated in all the *ipt* transgenics. Redrawn from Reutter *et al.* 1998.

Figure 21. *Agrobacterium tumefaciens* on a carrot, a species known to provide hormones to mosses in nature. Photo through Creative Commons.

External application of cytokinins cause *Physcomitrella patens* (Figure 3) to develop abnormally, causing bud production without leafy gametophore development and becoming necrotic (Reutter *et al.* 1998). On the other hand, transgenic mutant mosses with the added bacterial ipt gene were able to develop normally with the internal production of cytokinins.

Cytokinins may have important roles in responding to the environment (Lorenz *et al.* 2003). For example, it seems to have a role in the change from juvenile tissue growth to sexual reproduction under high-energy conditions (exogenous carbohydrates or bright light). Thelander *et al.* (2005) found that high-energy conditions resulted in pronounced caulonema formation. Low energy conditions, resulting from low light, short days, or low temperatures, stimulate development of gametangia and subsequent development of sporophytes (Hohe *et al.* 2002).

The limited number of cell types, ability to regenerate from small fragments, and ease of cultivation of the entire life cycle in the laboratory makes bryophytes good experimental organisms for study of the functioning of cytokinins (von Schwartzberg 2006). And the fully mapped genotype of *Physcomitrella patens* (Figure 3) provides us with an ideal study organism. Von Schwartzberg *et al.* (2007) found that the nucleotide iPRMP is the most abundant extracellular cytokinin in *Physcomitrella patens*. By using cytokinin oxidase/dehydrogenase (CKX)-overexpressing plants, von Schwartzberg and coworkers observed reduced and retarded budding, absence of sexual reproduction, and abnormal protonema cells. Extracellular IP and IPR seem to be the primary cytokinins responsible for inducing buds in *P. patens*. Control of levels is undoubtedly important.

¹⁴C-labelled adenine has also shown up in cytokinin in the culture medium of *Physcomitrella patens* (Figure 3), indicating a similar role of adenine in production of cytokinin (Bhatla & Dhingra-Babbar 1990). A similar, perhaps same, substance in *Bryum klinggraeffii* (Figure 22) inhibits growth and stimulates gemma formation. Because it leaks into the medium, this substance could have interactive effects on other species of mosses and even control its own population size. More recently, Proust *et al.* (2011) found that **strigolactones** regulate the branching of protonemata in *Physcomitrella patens* and act as **quorum sensors** – a way of signalling that no more bryophytes should be added there. Hence, the strigolactones inhibit the growth of both that protonema and that of neighboring colonies.

Figure 22. *Bryum klinggraeffii*, a moss in which a cytokinin-like substance leaks into the environment and inhibits growth while promoting gemma formation. Photo by Michael Lüth, with permission.

Based on the work of Bopp (1963, 1968), Watson (1981) suggested that it could be the inhibitory properties of a hormone (Factor H – see below) that caused differing aggressive patterns among juvenile *Polytrichum s.l.* (Figure 7-Figure 8; Figure 18) species, thus affecting ultimate community structure. Perhaps more important is the effect of controlling simultaneous production of buds in the population so that they develop together and conserve moisture by creating a smooth surface. This same control would prevent them from over-shadowing one another, avoiding intra-specific light competition.

It seems that the moss need not produce its own cytokinin. Rather, it may serve as host to bacteria that produce this hormone. In *Funaria hygrometrica* (Figure 1), the bacterium *Methylobacterium* (Figure 23) is epiphytic on the moss, inhabiting leaf surfaces, especially in the grooves between adjacent leaf **lamina** cells (cells of the blade portion of the leaf, exclusive of costa) (Hornschuh *et al.* 2002). In the presence of these bacteria on agar cultures, the protonema produces buds just as it would in the presence of cytokinin, and the exudate also stimulates the growth of the protonemal filaments. Glime and Knoop (1986) suggested a similar relationship in *Fontinalis squamosa* (Figure 24), wherein the only protonemata cultures that produced buds on a mineral nutrient medium were the ones that became contaminated with bacteria and fungi.

Figure 24. *Fontinalis squamosa* protonema. Photo by Janice Glime.

One aspect of the life cycle that will be discussed in other chapters is the production of asexual structures, a feature that is rare among **tracheophytes** (non-bryophyte plants). One example of this unique phenomenon is the discovery of protonemal gemmae in the aquatic moss *Fontinalis antipyretica* (Ares *et al.* 2014). In this species, where capsule production is relatively rare, vegetative shoots are important dispersal units. These dispersal units can come from detached cortical cells, margins and abaxial (away from the stem) surfaces of leaves, leaf laminae, and stems with leaves removed. Likewise, the protonema can continue growth from the filament or its rhizoids. But the discovery by Ares *et al.* is that these protonemata can also produce filamentous gemmae and spherical brood cells. These occur as the cultures age or dry out. Thus in nature they are produced as streams dry and water levels drop, providing a means of surviving these unfavorable periods. It is interesting that bacteria and fungi in the cultures (and in nature) seem to play a role in this development. but at this point in time we do not know what that biochemical interaction may be or how the drying of the environment may trigger the formation of propagules on the protonema.

One of the cytokinins that is effective on bryophytes is produced by the bacterium *Agrobacterium* (Figure 21). It appears that flowering plants lack the gene for this cytokinin, but evidence suggests that mosses may in fact possess it, and furthermore, *Agrobacterium* in the environment may supply it to some mosses. Addition of *Agrobacterium tumefaciens* (Figure 21) to the medium can stimulate the production of gametophores in *Pylaisiella selwynii* (Figure 25; Spiess *et al.* 1971), an epiphyte. The presence of this bacterium with the moss on tree bark suggests its possible role in the development of *Pylaisiella selwynii* in that habitat.

Figure 25. *Pylaisiella selwynii* growing on bark where it encounters the bacterium *Agrobacterium tumefaciens*, which most likely contributes to its production of gametophores there. Photo by Janice Glime.

Factor H

A possible cytokinin known as **Factor H**, an adenine derivative (Bhatla & Dhingra-Babbar 1990), has been known for much longer as a stimulant for increasing the number of gametophore buds (Klein 1967; Brandes & Kende 1968). **Factor H** has been isolated from the culture medium of *Funaria hygrometrica* (Figure 1) and from

tissue extracts of several other mosses (Bhatla & Dhingra-Babbar 1990). Its roles in inhibiting caulonema growth and promoting bud formation are clear, thus resembling the behavior of a cytokinin. Christianson (1998b) discovered that not all mosses have the same "Factor H."

Although the experiments mentioned above suggest that mosses respond to this hormone from other species, *Ceratodon purpureus* (Figure 26) is not affected by this substance from *Funaria hygrometrica* (Figure 1), nor is it able to affect the development of *Funaria hygrometrica*, but *Ceratodon* does exhibit interspecific regulation. Its growth substance does not pass through a dialysis membrane, whereas factor H does.

Figure 26. *Ceratodon purpureus*, a species that is not affected by "factor H" from neighboring species. Photo by Michael Lüth, with permission.

In 1980, Bopp determined that Factor H not only is not a cytokinin, it is not a cytokinin-like substance. But in 2013, Ralf Reski assured me it is most likely a cytokinin. Its identity seems still to be unknown. It does seem to carry out some of the functions we might attribute to a cytokinin.

The Factor H that has made medical news lately (Büttner-Mainik *et al.* 2011) should not be confused with the natural Factor H produced by bryophytes. The moss *Physcomitrella patens* (Figure 3), through recombinant DNA, is able to make the human complement regulatory serum protein Factor H – a substance that can assist in treatment of human diseases, including severe kidney and retinal disorders. It is a cheaper solution that does not involve the need for animals to manufacture the compound.

Gibberellins

Gibberellins (GA) are terpenoid-based hormones (Harborne 1982) that can stimulate stem elongation as well as cell division, depending on the species involved (Bidwell 1979). Gibberellins, unlike auxins, are non-polar and free to move about all over the plant. In studying *Marchantia polymorpha* (Figure 13) Melstrom and co-workers (1974) isolated three gibberellin-like substances from the thalli. Chopra and Sood (1973) found that gibberellins could enhance antheridial formation while promoting normal growth in the thallose liverwort *Riccia crystallina* (Figure 27). Chopra and Kumra (1986) later found that GA₃ not only enhanced normal growth of *Riccia gangetica*, but also increased the production of antheridia while causing a decrease in archegonial production.

Figure 27. *Riccia crystallina*, a species in which gibberellins can enhance antheridial formation while promoting normal thallus growth. Photo by David T. Holyoak, with permission.

However, Bhatla & Dhingra-Babbar (1990) reported that gibberellins still are not confirmed in mosses, although GA-like substances are known in both mosses and liverworts (Chopra & Kumar 1988). Even recent studies have failed to confirm the presence of GA in bryophytes, with the "lab rat" *Physcomitrella patens* (Figure 3) failing to respond to gibberellic acid (Hiranoa *et al.* 2007). It appears that GID1/DELLA-mediated GA signaling arose in tracheophytes after they diverged from the bryophyte lineage (Hiranoa *et al.* 2007; Yasamura *et al.* 2007). On the other hand, Ergün *et al.* (2002) demonstrated that at least some bryophytes can produce not only IAA, ABA and zeatin, but also GA₃. Furthermore, the production of GA in mosses should be expected, since its presence is known in algae (Radley 1961; Mowat 1965; Tietz & Kasprik 1986; Tietz *et al.* 1989; Hirsch *et al.* 1989).

Gibberellic acid is the hormone responsible for giant growth. I can remember that in my high school years Burpee was experimenting with it on horticultural flowers and encouraged seed buyers to try it and report the results. It didn't do much for my poor flowers in terrible soil. Could the absence of this hormone be part of the reason bryophytes have remained small?

Even if GA is absent in bryophytes, that does not necessarily mean that mosses cannot respond to it. Indeed, the fungi could deliver GA to the mosses and thus facilitate or interfere with development, perhaps accounting for bryophyte specificity to certain habitats. Certainly the presence and use of gibberellins in bryophytes is worthy of further exploration.

Abscisic Acid

Abscisic acid (ABA) is known not only in plants, but also in bacteria, animals, and elsewhere (Hartung 2010; Takezawa *et al.* 2011). It is therefore an important hormone to understand. The moss *Physcomitrella patens* (Figure 3) once again provides a suitable organism in which to study its functions. In this, and other bryophytes, it is known to respond to stress, including desiccation (Mayaba *et al.* 2001) and cold tolerance (Minami *et al.* 2003, 2005). In *Atrichum androgynum* (Figure 29) this desiccation tolerance seems to be accomplished by increasing the concentration of soluble sugars. In

Physcomitrella patens (Figure 3), 22 genes are activated by ABA, and part of its role appears to be in the period of recovery from desiccation (Khandelwal *et al.* 2010).

The role of ABA in development seems to be ambiguous (Hartung 2010). Nevertheless, high levels of ABA seem to be present in organs of bryophytes that produce sporophytes.

Abscisic acid (ABA) is a sesquiterpenoid (15-C compound) that is partially produced via the mevalonic pathway in chloroplasts and other plastids. Therefore, synthesis occurs primarily in the leaves. It appears to be an indirect product in the synthesis of **carotenoids** (yellow to red lipid-soluble pigments). It has a variety of roles in both tracheophytes and bryophytes. In tracheophytes, it is important in regulating transpiration, stress responses, germination of seeds, and embryogenesis. Its most widespread function is in signalling water stress and regulating water loss. Interaction with other hormones gives it a role in most plant developmental processes.

ABA has been confirmed relatively recently in bryophytes, in the protonema of *Funaria hygrometrica* (Figure 12) (Bhatla & Dhingra-Babbar 1990; Werner *et al.* 1991). Its presence was unknown in liverworts (Gorham 1990) until 1994 (Hartung *et al.* 1994). However, there are indications that it is present in all bryophytes – at least all that have been tested (Hartung *et al.* 1994). It is known to inhibit the cytokinin-stimulated response of bud induction in the moss *Funaria hygrometrica* (Figure 1), making cytokinin a useful bioassay tool for detecting not only the presence but also the concentration of **ABA** (another hormone), since the inhibition is concentration dependent (Christianson 2000b).

The highest concentrations in bryophytes occur in species adapted to dry environments, and conversely, the lowest concentrations in aquatic species, suggesting it had a role in drought tolerance (Hartung *et al.* 1994). For example, in *Funaria hygrometrica* (Figure 12), it makes the protonema drought resistant and in the Marchantiales it induces drought tolerance in the thallus. Burch and Wilkinson (2002) used it to ensure drought tolerance for long-term storage of *Ditrichum cornubicum* (Figure 28) protonemata, reducing membrane damage suffered during dehydration and freezing, and providing 100% recovery upon rehydration.

Figure 28. *Ditrichum cornubicum*, a moss in which ABA has been used to ensure drought tolerance for long-term storage, apparently through accumulation of sugars. Photo by David T. Holyoak, with permission.

The use of ABA for cryopreservation reduces both labor and loss of plant material in *Ceratodon purpureus* (Figure 26), *Funaria hygrometrica* (Figure 1), *Physcomitrella patens* (Figure 3), and *Sphagnum* spp. (Christianson 1998a). There are likewise genetic implications for its presence, with 11 expressed sequence tags matching up with tracheophyte stress response genes, "including responses which may involve ABA" (Machuka *et al.* 1999). In *Atrichum androgynum* (Figure 29), application of ABA prior to desiccation reduces membrane leakage (Beckett 1999). It appears that this drought tolerance mechanism may be similar to that in higher plants under stress, with ABA reducing membrane damage by reducing the changes in membrane lipids (Guschina *et al.* 2002). On the other hand, ABA does not endow all bryophytes with desiccation tolerance. *Plagiochila* (Figure 15) shows no response, and *Marchantia polymorpha* (Figure 13) requires both ABA and encapsulation in alginate (sticky gum) beads for successful cryopreservation (Pence 1998). Furthermore, in the desiccation-tolerant *Syntrichia* (Figure 30), desiccation tolerance is not under ABA control, despite a large number of desiccation-response genes (Oliver 1996).

But what is the role of ABA in development? Decker *et al.* (2006) found that under the influence of ABA the protonematal subapical cells differentiate into round, short cells (**brachycytes**) or **tnema** cells (short-lived abscission cells), the latter being nearly free of cytoplasm (Figure 31). Thus, ABA has a role in asexual reproduction of the protonema. We know that in *Funaria hygrometrica* (Figure 1), when the ABA is removed, these short, round cells (**brachycytes**) germinate and form new protonemata (Schnepf & Reinhard 1997). The role of ABA is at least in part that of restructuring the cell walls of the protonema (Schipper *et al.* 2002; Decker *et al.* 2006).

Figure 29 *Atrichum androgynum*, a moss in which membrane leakage is reduced by ABA application. Photo by Tom Thekathyl, with permission.

One interesting role of ABA is its ability to convert the aquatic (floating) forms of *Riccia fluitans* (Figure 32) and *Ricciocarpos natans* (Figure 34) into their terrestrial forms (Figure 33, Figure 35; Hartung *et al.* 1994). In *Riccia fluitans*, ABA causes changes in the gene expression that cause the nearly filamentous floating form to become the

broadly thallose soil form (Hellwege *et al.* 1996). This mechanism may be similar to that seen in the aquatic fern *Marsilea quadrifolia* in which ABA induces changes from aquatic to aerial leaf forms (Hsu *et al.* 2001).

Figure 33. *Riccia fluitans* soil form. Photo by Michael Lüth, with permission.

Figure 34. *Ricciocarpus natans* floating form. Photo by Jan-Peter Frahm, with permission.

One more important role of ABA in tracheophytes is the movement of K^+ out of guard cells of leaves, causing them to close, and suggesting that it might control membrane permeability. It is interesting that it likewise induces the closure of stomata in capsules of mosses and in Anthocerotophyta (hornwort) sporophytes (Hartung *et al.* 1994). ABA also seems to play a role in regulation of extracellular protein secretion (Decker *et al.* 2006).

Figure 35. *Ricciocarpus natans* soil form. Photo by Janice Glime.

It is not unusual for desiccation-tolerant species to also be cold/freezing tolerant. Nagao *et al.* (2005) found that The transformation from starch to sugar in chloroplasts is associated with ABA-induced freezing tolerance in protonemata of *Physcomitrella patens* (Figure 36), changing the LT50 from -2°C to -10°C . Compared to untreated cells, ABA-treated cells had more slender chloroplasts and a reduced starch grain content. Instead of one central vacuole, the treated cells often had multiple segmented vacuoles. At -4°C the untreated cells had lesions in the cell membranes; the treated cells did not. Osmotic concentration increased as sugars accumulated.

Figure 36. *Physcomitrella patens* protonema, a common research organism for hormone studies. Photo from Ralf Reski Lab, through Creative Commons.

Wang *et al.* (2011) found 65 proteins that responded to ABA in *Physcomitrella patens* (Figure 3; Figure 36). This involved down regulation of 13 proteins and upregulation of 52 proteins, 4 of which were newly induced. The roles of these proteins included material and energy metabolism, defense, protein destination and storage, transcription, signal transduction, cell growth/division, transport, and cytoskeleton. Most of the up-regulated proteins functioned as molecular chaperones, transcriptional regulators, and defense proteins. Thus the ABA was able to trigger responses that served in defense and protection from oxidative damage. They also learned that *Physcomitrella patens* responds to exogenous (applied externally) ABA. This latter response permits them to respond to other organisms in the environment. They found that ABA could inhibit photosynthesis, a phenomenon that suggests we should look at the ability of other organisms to compete with them with this hormone. Such an inhibition may prevent spores from germinating on leaf litter that is leaking ABA. This would seem like an interesting field for ecological research.

Lunularic acid

We know that a hormone similar to ABA, **lunularic acid** (LA), first discovered in *Lunularia cruciata* (Figure 37; Schwabe & Nachmony-Bascomb 1963), is present in at least the 47 genera (80 species) of liverworts examined by Gorham (1975, 1990) and is important in dormancy and growth regulation (Schwabe 1990). More recently it has been identified in *Plagiochila spinulosa* (Figure 38) (Connolly *et al.* 1999), *Ricciocarpus natans* (Figure 34-

Figure 35) (Kunz & Becker 1992), *Frullania convoluta* (Flegel *et al.* 1999), and *Marchantia polymorpha* (Figure 13) (Friederich *et al.* 1999).

Figure 37. *Lunularia cruciata* with gemmae pockets. Photo by Martin Hutten, with permission.

Figure 38. *Plagiochila spinulosa*, a leafy liverwort known to produce lunularic acid. Photo by Michael Lüth, with permission.

Although reputedly unique to liverworts, this hormone has recently been found in *Hydrangea macrophylla*, a flowering plant (Eckermann *et al.* 2003). In liverworts, the largest amounts of LA occur in dormant and desiccation-resistant thalli (Chopra & Kumar 1988) and its presence confers drought resistance (Schwabe & Nachmony-Bascomb 1963; Schwabe 1972), reminiscent of ABA. Part of this resistance is the initiation of dormancy, an effect that is greater at higher temperatures (Schwabe 1990). Nevertheless, Gorham (1990) found that lunularic acid does not affect stomatal conductance, suggesting that its effect on cells is different from that of abscisic acid.

Lunularic acid is compartmentalized (localized) within cells, hence restricting its function (Gorham 1977), although Imoto and Ohta (1985) found that it is equally distributed between vacuoles and cytoplasm in *Marchantia polymorpha* (Figure 13), and that it does not accumulate in chloroplasts, mitochondria, or peroxisomes. Gorham (1977) found it in all organs of *Marchantia* and *Preissia* (Figure 39), in sporophytes of *Pellia epiphylla* (Figure 14), and in the greatest concentration (more than 600 µg/g fresh weight) in young thallus tips of *Conocephalum conicum*

(Figure 40) grown in continuous light. Higher light intensities increased its concentration; age decreased it. Continuous light caused a greater production of both growth and lunularic acid in thallose liverworts than in any photoperiod interrupted by darkness, creating a condition in which lunularic acid was not inhibitory. Leafy liverworts of the Jungermanniales contained smaller quantities (1-50 µg/g fresh weight) than did the thallose species tested.

Figure 39. *Preissia quadrata*, a liverwort known to have lunularic acid in all its organs. Photo by Jan-Peter Frahm, with permission.

Figure 40. *Conocephalum conicum* showing growing tips where concentration of lunularic acid. Photo by Jan-Peter Frahm, with permission.

Because of its dormancy effect, lunularic acid could act as a growth inhibitor. However, compared to its analogs, this hormone is less effective in inhibiting growth of the liverwort *Marchantia polymorpha* (Figure 13) and the flowering plants *Nasturtium officinale* (water cress) and *Phleum pratense* (timothy grass) (Nakayama *et al.* 1996), but is known to inhibit growth in *Lunularia cruciata* (Figure 37) (Yoshikawa *et al.* 2002).

Lunularic acid forms a variety of conjugates (Kunz & Becker 1992). Among these are glycosides, suggesting an antiherbivory role as well. This suggestion is supported by Wurzel and coworkers (1990) who found, in *Ricciocarpus natans* (Figure 34-Figure 35), molluscicidal behavior against *Biomphalaria glabrata*, a snail that carries schistosomiasis (parasitic disease caused by blood fluke).

Research on lunularic acid in this century is scarce, but we still have much to learn about its role in liverworts.

Ethylene

Ethylene (C_2H_4) is important in every step of the developmental process of higher plants (Abeles 1973), and has been demonstrated in both liverworts (Fredericq *et al.* 1977; Thomas *et al.* 1983) and mosses (Rohwer & Bopp 1985). It is known from the sporophyte of *Pellia* (Figure 14), especially during rapid seta elongation (Thomas *et al.* 1983) and from the thallus of *Marchantia* (Figure 13) (DeGreef *et al.* 1981). However, Stange and Osborne (1989) found that the liverwort *Riella* (Figure 17) appears to have a different pathway for ethylene synthesis from that of higher plants.

Ethylene is an unsaturated hydrocarbon synthesized in tracheophytes via the following pathway:

IAA is possibly the catalyst for the conversion of SAM (S-adenosylmethionine) to ACC (1-aminocyclopropane-1-carboxylic acid) (Bradford & Yang 1980a), as suggested by the 10-fold increase in ethylene obtained when 10^{-6} IAA is supplied in the medium (Bhatla & Dhingra-Babbar 1990). O_2 is required for the conversion of ACC to C_2H_4 (Bradford & Yang 1980b), suggesting that there might be interesting environmental responses for mosses that live part of their lives in water.

Although ethylene is a gaseous substance, it has been termed a growth hormone. It is important in **senescence** (aging) and its presence can cause **epinasty** (leaf and stem curling). In the aquatic moss *Fontinalis squamosa*, treatment with its precursor ACC causes color changes, wavy leaves, and curled tips (Figure 41), as well as inhibiting growth at high concentrations (Glime & Rohwer 1983). It is likely that these responses are actually to ethylene produced in response to the ACC application.

Figure 41. **Left:** *Fontinalis squamosa* grown with ACC, the precursor of ethylene, demonstrating the contorted leaves and curved tips. **Right:** *Neckera pennata* exhibiting undulate leaves that could prove to be the result of genetically controlled ethylene behavior. Photos by Janice Glime.

Ethylene production coincides with that of the change from chloronema to caulonema and is probably tied to the increase in auxins (Rohwer & Bopp 1985). We know that ethylene and IAA can work together in both bryophytes and higher plants (Mignone & Basile 2000). In bryophytes,

we know that an additive effect exists in at least some, for example *Riella helicophylla* (Figure 17), causing "super" cell elongation (Stange & Osborne 1988). Chopra and Sood (1973) demonstrated that ethrel, which produces ethylene in water, causes the production of more antheridia in *Riccia crystallina* (Figure 27).

IAA and ethylene often work in tandem, controlling each other's concentrations. For example, in *Pellia epiphylla* (Figure 14), IAA results in seta elongation, whereas ethylene inhibits it (Thomas *et al.* 1983). In the leafy liverworts, ethylene works together with auxin and certain arabinogalactan-proteins to suppress the third row of leaves by suppressing development of every third leaf primordium (Basile & Basile 1984; Mignone & Basile 2000). Mignone and Basile considered that ethylene played a suppression role in three processes. It is able to cause reductive development by causing failure in development of primordia to mature organs. It modulates the size and shapes of leaves. And it facilitates the change from diffuse growth to polar/apical growth. Nevertheless, ethylene remains largely a mystery.

The ACC pathway seems to work somewhat differently in bryophytes (Osborne *et al.* 1996). Lower plants seem unable to convert ACC to ethylene, nevertheless producing ethylene continuously. Although the *Riella helicophylla* (Figure 17) they studied seemed to take up the ACC easily, no ethylene gas was released. Nevertheless, in *Fontinalis* (Figure 41) ACC causes symptoms consistent with those expected from ethylene (Rohwer & Bopp 1985).

Acetylcholine

Acetylcholine – a compound better known for its role in nerve cells, has been conclusively shown in bacteria, protists, and mosses (Hartmann & Kilbinger 1974; Wessler *et al.* 1999), and more recently, in corn (Momonoki 1992). Interestingly, the original report (Hartmann & Kilbinger 1974) found it only in a hybrid of *Funaria hygrometrica* (Figure 1) and *Physcomitrium pyriforme* (Figure 3), whereas its hydrolyzing enzyme cholinesterase was not found in either (Fluck & Jaffe 1974). Later, however, Gupta *et al.* (2001) found cholinesterase in 30 out of 39 species of bryophytes tested, including five liverworts, with the highest activity in the moss *Anoetangium bicolor*.

In non-animal organisms, the production of acetylcholine (ACh) is always accompanied by cholinesterase activity, thus preventing it from behaving as a hormone (Wessler *et al.* 1999). Nevertheless, its activity and the activation of acetylcholine receptors can interfere with ion channels and key enzymes – the cellular signalling pathways. In this role, it appears to play a part in regulating such cellular functions as mitosis, cell differentiation, organization of the cytoskeleton, cell-to-cell contact, secretion, and absorption. Furthermore, it appears to contribute to the regulation of immune functions.

But the role of acetylcholine in bryophytes is still unclear (Bhatla & Dhingra-Babbar 1990). Light quality certainly affects its production in at least some bryophytes, with 56 times as much produced in red light as in red/far-red (Bhatla & Dhingra-Babbar 1990). The red/far-red response is indicative of regulation by phytochrome (pigment that measures day length), but researchers disagree on the mechanism. As a growth regulator, it could

have an important role in habitat response and spore germination as a means of interpreting light quality.

In lactic acid bacteria, acetylcholine can be produced in response to osmotic stress (Kets *et al.* 1997). In a moss that is often desiccated by dust and other solutes on the surface, as well as being subjected to frequent desiccation due to weather, perhaps the acetylcholine might respond similarly.

Cryptochromes

Cryptochromes – This almost colorless yellow plant pigment has both enlightened and dumbfounded the plant physiologists since its discovery. Although we know that it responds to light and somehow signals to IAA in a way that affects plant development, its mechanism has remained elusive. Then entered the moss, of course the lab rat of all mosses, *Physcomitrella patens* (Figure 3). In 1999, Imaizumi and coworkers posted the identification of a cryptochrome homologue from this moss. *Physcomitrella patens* is more than just a convenient, small organism for testing things. It is unique. It is the only plant found thus far in which gene replacement is predictably reliable due to the high frequency of homologous recombination. In plain English, that means that instead of one chance in a million for a transplanted gene entering the genome, it is a predictable certainty.

Hence, to discover how cryptochromes function in plants, researchers (Imaizumi *et al.* 2002) created a moss [a strain of *Physcomitrella patens* (Figure 3)] with a defective genome, one that had disruptants for the two known genes for cryptochromes (CRY1 & CRY2). The moss could not make its cryptochromes. The results were rather astounding. They revealed that cryptochrome signals regulate induction of side branching of the protonema, gametophore induction, and development. Furthermore, disruption of these cryptochromes altered the induction of the auxin-inducible genes. Since these modified mosses were more sensitive to external auxin than their unmodified relatives in blue-light responses, it appears that the cryptochromes provide the signal to repress auxin signals that control plant development. This breakthrough in discovering the utility of *Physcomitrella patens* in delineating gene function could have astounding contributions to the entire field of plant physiology! In fact, it already does.

Summary

All aspects of development are influenced not only by the internal environment, but also by the external environment. These signals trigger responses in the bryophytes that permit them to survive and take advantage of the ever-changing conditions of their environment, from growth forms to drought resistance to dormancy.

These responses are typically mediated by hormones. Known bryophyte hormones include **auxins** (IAA) that regulate growth and gametangial production, **cytokinins** (**isopentenyladenine**, **zeatin**, and most likely **Factor H**) that regulate protonemal bud formation and branching, **gibberellin**-like compounds that inhibit cytokinin responses, **lunularic acid** and

ABA (abscisic acid) that regulate dormancy and drought resistance, and **ethylene** that controls antheridial production and triggers **senescence**; **acetylcholine** and **cryptochromes** (photo-receptive pigments) also play a role in controlling bryophyte growth and development. The modes of control of these growth regulators are poorly understood in bryophytes, although in most cases they seem to act similarly to their mode of action in tracheophytes.

Some hormones may be supplied **exogenously**, that is, supplied by other organisms in the environment such as bacteria and fungi. And some of the hormones may be moved from place to place in the bryophyte by external conduction.

Acknowledgments

Inspiration for these chapters on development evolved from discussions with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen. Several of the experiments were conducted at the Botanisches Institut, Universität Heidelberg, Germany. I appreciate the many suggestions from a student's perspective by Medora Burke-Scoll. Linda Luster checked the literature citations, proofread, and checked for needed glossary entries. KT McConnell helped with clarity and suggested the minisummaries after some of the topics. Ralf Reski helped me sort out the two kinds of Factor H and provided me with references.

CHAPTER 5-2

ECOPHYSIOLOGY OF DEVELOPMENT: SPORE GERMINATION

TABLE OF CONTENTS

Spore Maturation.....	5-2-2
Maturation Seasons	5-2-3
Does Dormancy Exist in Bryophytes?	5-2-3
Definition of Spore Germination.....	5-2-2
Germination Process	5-2-7
Water Needs.....	5-2-7
Energy Needs	5-2-8
Light Needs	5-2-10
Environmental Control over Germination.....	5-2-12
pH.....	5-2-13
Nutrients.....	5-2-13
Temperature	5-2-14
Vernalization.....	5-2-15
Germination Inhibitors	5-2-16
Hormonal Regulation.....	5-2-17
Inter- and Intraspecific Interactions	5-2-20
Interspecific Competition.....	5-2-22
External Growth Promoters.....	5-2-23
Pollutants.....	5-2-25
Spore Size	5-2-25

CHAPTER 5-2

ECOPHYSIOLOGY OF DEVELOPMENT: SPORE GERMINATION

Figure 1. Maturing capsules of *Oligotrichum hercynicum*. Photo by Michael Lüth, with permission.

Spore Maturation

Following meiosis, the spore must mature into the decorated unit that gets dispersed. The spore originally has only one plastid, but this number increases by fission (Mueller 1974). The typical spore wall in bryophytes is composed of three distinct layers: **intine**, **exine** and **perine** (Diego Knop Henriques, Bryonet 28 September 2011). The innermost is the **intine**, basically composed of fibrillar material, mainly pectin, and it plays a pivotal role in spore germination. The **exine** is a thin layer right outside the intine and has **sporopollenin** in its composition. Colpitts *et al.* (2011) demonstrated that spores of *Physcomitrella patens* (Figure 2) have the genetic information to produce sporopollenin in their spore walls, a gene that is expressed in the sporophyte generation. Sporopollenin is present in the intine of the spore and confers a great resistance to chemical and environmental factors, as it does in pollen. The **perine** is the outermost layer, also contains sporopollenin, and, in the majority of moss species, is the layer responsible for the spore ornamentation.

Figure 2. *Physcomitrella patens* with capsules. Photo by Michael Lüth, with permission.

Mueller (1974) described the formation of the spore wall in the moss *Fissidens crispus* (Figure 3). First the exine forms around the protoplast after meiosis. When the spore is fully enlarged, it is coated by the perine. Then the intine forms. Both the intine and exine originate from within the spore, but the perine comes from material within the capsule, but outside the spore. It is this deposited perine that forms the ornamentation on the spore wall.

Figure 3. *Fissidens crispus* capsule that has lost its spores. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Brown and Lemmon (1980) added to this wall description by using ultrastructural analysis of sporogenesis in the moss *Ditrichum pallidum* (Figure 4) to describe the internal events of the spore. They found that following meiosis, an extensive system of microtubules is present, underlying the entire distal spore surface where the exine deposition initiates. Following this, the lamellate exine thickens, extending to the proximal surface. The plastid and nucleus migrate to the proximal surface and an elaborate system of microtubules facilitates aperture development. Brown and Lemmon added a fourth layer to the description, a separating layer between the exine and intine. The developed aperture results from a modification of the proximal surface of the spore with a pore that contains fibrillar material surrounded by a thin ring (annulus).

Maturation Seasons

Spore maturation tendencies differ with latitudes and climate. They also differ by families, at least in pleurocarpous mosses. Hedenäs (2007) summarized spore maturation seasons for a number of pleurocarpous families:

Winter:

Brachytheciaceae
Ctenidiaceae
Heterocladioideae
Hylocomiaceae

Summer:

Plagiotheciaceae
Amblystegiaceae
Thuidiaceae

temperate

Hypnaceae
Rhytidiaceae

Does Dormancy Exist in Bryophytes?

Heinjo During, on Bryonet 4 March 2016, suggested that we know very little about dormancy in bryophytes. If it exists, it might require a trigger to initiate it. During suggested that low or fluctuating temperatures could be involved. I could also postulate that darkness within the capsule might initiate dormancy before the spores are dispersed. Once dormant, many studies suggest that light and moisture are needed for germination. But During points out that most papers suggest that dormancy of moss spores is rare or absent. Others argue that it may be less rare – lacking investigation.

The behavior of spores in *Archidium alternifolium* (Figure 5-Figure 6) suggest that it may experience some sort of dormancy (see Miles & Longton 1992). This species requires an unpredictable but long time to germinate. Could it be that, like some seeds, its spores are immature at the time of shedding and require certain conditions to complete maturation before germinating? This immaturity might be physiological without any morphological indication. Or might there be some inhibitor that must be washed away before it germinates, like some of the desert seeds?

Figure 5. *Archidium alternifolium* with capsule. Michael Lüth, with permission.

Figure 6. *Archidium alternifolium* capsule showing the large spores inside. Photo by Norbert Stapper, with permission.

Some indications of dormancy do exist. McLetchie (1999) examined dormancy/nondormancy cycles in the liverwort *Sphaerocarpos texanus* (Figure 39). He found the loss of dormancy increased as the length of time that spores were kept at the various incubation periods from 1-91 weeks. Furthermore, warmer temperatures aided in breaking dormancy. On the other hand, spores held at each of the three thermoperiods germinated best when transferred to 16/10°C and failed to germinate when transferred to the warmer combinations of 35/20 and 30/15°C (see below under Temperature). Thus, warmer temperatures both maintained dormancy and accelerated germination when that temperature dropped. Seasonal changes followed by low temperatures induced these spores to return to a secondary dormancy.

Hock *et al.* (2013) suggested that the spores of *Phascum cuspidatum* (Figure 7) in grassland exhibited dormancy. Watson (1983) suggested that chemical inhibition occurs among juvenile members of *Polytrichum s.l.* (Figure 8).

Definition of Spore Germination

Successful germination is prerequisite to establishment in a new location, yet its consideration is lacking in nearly every ecological study. If we are to retain our rare and endangered species, we must understand the germination and establishment requirements that will permit them to become established in our conserved areas.

Bryophyte spores begin their life following meiosis in the capsule (Figure 1). There they wait and develop to maturity before dispersal. Generally, they do not germinate within the capsule.

There is no general agreement on the definition of spore germination. **Swelling** is the result of the uptake of water by the spore; **distension** occurs when the cell wall ruptures and the germ tube is formed. Some authors consider swollen spores as germinated (Bauer & Mohr 1959, Mogensen 1978a). But swelling of the spore is a passive process and therefore it does not fully satisfy a definition of germination. From the physiological standpoint, a spore has germinated when the spore wall has ruptured and when the germ tube has been formed, since these involve active processes. A more precise definition is given by Valanne (1966) who states that the "distension phase is the least ambiguous and most useful practical criterion for spore germination." In some species, among others *Polytrichum commune* (Figure 8), there is an intermediate phase between the swelling and the distension in which the germ tube is formed and the spore wall is stretched – the **protrusion phase** (Figure 22) (Karunen 1972).

Figure 8. *Polytrichum commune* with capsules. Photo by Kristian Peters, through Creative Commons.

Some species don't wait for environmental conditions become suitable. Rather, they germinate while still in the capsule (D'Rozario & Bera 2006). This is known for *Marchantia palmata* as well as a few other liverworts and some mosses. Two forms of germination occur among the bryophytes: **endosporic** and **exosporic**. **Endosporic** development is that development in which the spore cell divides within the cell wall, creating a multicellular structure before a protonemal thread emerges from the spore wall. In these cases, the spore wall stretches as the internal structure expands. This endosporic phase often coincides with **precocious germination**, that is,

development that occurs while the spore is still within the capsule (Nehira 1983). Such a developmental pattern occurs in *Pellia epiphylla* (Figure 9-Figure 10) and *P. neesiana* (Figure 11) (Bartholomew-Began 1996), distinguishing these taxa from other members of the **Metzgeriales** and from most bryophytes. Such a strategy would be an adaptive device for such taxa as *Gymnostomum* (Figure 12; pers. obs.) and others that live in dry habitats where a head start could permit them to reach sufficient size to survive before becoming dry. Nehira (1987) found that the endosporous habit was common among **epiphytic** (tree-dwelling) and **saxicolous** (rock-dwelling) liverworts and mosses. Other taxa, including the mosses *Andreaea* (Figure 13), *Glyphomitrium* (Figure 14), and *Pylaisiella* (Figure 15), and the liverworts *Cavicularia* (Figure 16), *Radula* (Figure 17), and *Trichocoleopsis* (Figure 18), may be endosporous, but do not become multicellular and stretched until after capsule dehiscence (Nehira 1983).

Exosporic development, occurring in most mosses and liverworts, has its first and only development outside the spore wall (Figure 22), a strategy more appropriate for wetter habitats than those used by species with endosporic development. Many sporeling types are known among the **Bryophyta** (Figure 12-Figure 15), **Marchantiophyta** (Figure 9-Figure 11, Figure 16-Figure 18), and

Anthocerotophyta (Figure 19-Figure 20); (see Nehira 1983 for illustrations and a review). These are influenced not only genetically, but may also be modified environmentally (Alcalde *et al.* 1996). Even wavelength of light can affect germination patterns, as in *Anthoceros miyabeanus*, where in red light it is exosporic, but in white light it is endosporic (Wada *et al.* 1984). Could such a difference in wavelength effect precocious development for those receiving mostly red light in the green capsule, but then stimulate exosporic development once the spore has left the capsule and become exposed to white light?

Germination Process

The germination process is one in which cell wall thicknesses change (Olesen & Mogensen 1978). For *Polytrichum commune* (Figure 8), *Ceratodon purpureus* (Figure 112), *Funaria hygrometrica* (Figure 23), and *Macromitrium sulcatum* (Figure 21), and probably most if not all species, this process involves a thickening of the intine in the region of the aperture, a decrease in the thickness of the exine there, presence of a lamellate structure next to the thin part of the exine, and accumulation of electron-dense material into the thin layer separating the intine and exine. In *P. commune*, a knob-like structure forms in association with the thickened part of the intine. Water is absorbed through the aperture region, followed by swelling, rupture of the spore wall, protrusion, and recovery followed by spore distension. Spore swelling involves both symmetrical and asymmetrical swelling. The asymmetrical swelling results from swelling of the asymmetrical intine which protrudes beyond the exine and perine of the spore. The symmetrical swelling is not actually a part of the germination, but rather is the result of remoistening.

The swelling stage of spore germination requires water, whereas the distention phase requires light (Bhatla 1994). These requirements exhibit a certain amount of control over the timing of germination and help to prevent the needless loss of resources. These requirements are critical to the maintenance of spores in soil spore banks by preventing germination when the soil is wet but the spore is buried. Additional factors involved in germination are pH, calcium ions, and auxins (Bhatla 1994).

Water Needs

Based on studies conducted so far, all bryophytes require water for germination of the spore. The swelling phase of germination seems only to require the physical process of water absorption, resulting in rehydration (Bhatla 1994). Lack of sufficient water may in fact be the means that prevents germination of most spores within the capsule. On the other hand, mechanisms for rapid water uptake to seize upon germination opportunities could be important for some species.

Neidhart (1979) reports that spores of *Funaria hygrometrica* (Figure 23) withstand desiccation better in the capsule than when isolated. This seems reasonable since the capsule itself should prevent excessive drying on the interior. However, Neidhart used "young" spores and capsules but did not indicate whether the spores were swollen. Since one problem with desiccation is the leakage of nutrients through damaged membranes upon rewetting, it might be possible that spores in the capsule withstand desiccation better if the capsule can serve as a reservoir of nutrients after rewetting. Little evidence is available to tell us if the moss spores are able to draw upon nutritional sources of the moss as they continue their development in the capsule. Mogensen (1978a, 1981) has indicated that the columella serves as a reservoir of liquid, and that the smallest spores die first as that reservoir dries, permitting the larger spores to continue their growth. A similar series

of abortions of smaller spores occurs in *Fontinalis squamosa* (Figure 24; Glime & Knoop 1986). It would be interesting to examine this reservoir to determine if it in fact may be a source of sucrose or other nutritional substances as well.

Note dark gray areas in the photo on right are those areas lacking chlorophyll, and smaller spores tend to disappear in UV light. Photo by Janice Glime.

Once the spores leave the capsule, it is the structure of the spore itself that must serve to prevent desiccation. Bryophyte spores have an innermost layer called the **intine**, consisting of complex polysaccharides such as pectin and callose. The outer wall, the **exine**, is lamellated with plates believed to be **sporopollenin** (phenol-containing polymer known to impart high chemical resistance to exine of pollen), as in higher plants. In some species an opaque zone, termed the **separating layer**, may be seen between the intine and the exine.

Mosses have a further, poorly understood layer, the **perine**, which forms on the outside of the exine in some taxa. The **perine** often forms a pattern characteristic of the species. It is unusual in that it is formed by the sporophyte as an add-on to the outer wall of the spore (Mogensen 1983). It is made from old tissue of the columella and the mother spore wall (Crum 2001). Thus, such a layer is absent in liverworts, which lack a columella. Mogensen

(1981) hypothesizes that the perine plays a role in avoiding germination during periods with too little water to survive, such as that provided by dew, and that it is of particular importance as a survival mechanism for the annual shuttle life strategy (living only one or few years in one location). However, we do not know how strongly the perine is bound(?) to the exine layer, or even how. It would be worthwhile to investigate SEM (scanning electron microscope) pictures of the perine of different moss species to see whether certain perine patterns are correlated with habitats liable to desiccation. Furthermore, it is possible that it plays an important role by providing capillary spaces that permit rapid uptake of water during precipitation events, or, as Mogensen suggests, its variation in thickness may provide "significant protection against desiccation of the spore."

Mogensen (1983) hypothesizes that the **exine**, or outer layer of the spore, serves to protect the spore from mechanical damage from the external environment. He bases this hypothesis on its loss of **tensibility** (strength when pulled end-to-end) at maturity, a phenomenon that seems to be common to all bryophytes. On the other hand, a thicker exine might also help to protect the spore from UV, permitting it to take advantage of those long-distance excursions by wind and updrafts.

The **intine** seems also to have a role in rapid uptake of water, through the aperture, facilitating distribution of water to all parts of the cell membrane (Mogensen 1983). The intine might also differ among species in its ability to facilitate this uptake and distribution. Since the thin part of the intine corresponds with the thick part of the exine and vice versa, perhaps water can move from one end of the cell to the other between the layers and thus need only to traverse the thin parts of each layer.

Energy Needs

The presence of water is a necessary prerequisite for the conversion of stored food reserves into glucose for the production of ATP. Any growth following swelling will necessarily require energy, so it is necessary to understand energy storage and requirements for conversion in order to interpret control over successful germination.

The requirement of light for spores to germinate permits them to remain where they have landed until conditions suitable for further development are present. Therefore, energy is not wasted by germination underground, under leaves, or under snow cover. However, even light-requiring moss spores can be induced to germinate by the addition of sucrose in dark conditions, indicating that the need for light is a need for energy. Sood (1975) found that 1.5% sucrose was optimum for germination, but that 4.8% was inhibitory for *Pogonatum aloides* (Figure 25), which does not germinate in the dark. Moss spores are green and chloroplast **grana** (stack of chlorophyll packets within the chloroplast where light reactions of photosynthesis take place) are already present before germination. Furthermore, when sufficient starch is present, the spores are able to make chloroplasts in the dark (Bhatla 1994). Therefore, the most obvious hypothesis to explain the need for light is that light causes photosynthesis, which produces glucose and the glucose is converted to sucrose that provides energy and contributes to swelling by causing osmosis.

Figure 25. *Pogonatum aloides* with persistent protonemata. Photo by Janice Glime.

A second hypothesis is that stored carbohydrates break down into sucrose. We know that α -amylase, the enzyme that breaks starch down to glucose, increases its activity in short days and decreases it in long days in *Marchantia polymorpha* (Figure 26). Likewise, GA_3 (a gibberellin) can mimic this photoperiod response (Maravolo 1980). We also know that gibberellin antagonists prevent starch disappearance (*i.e.* prevent metabolism to sugars). Gibberellins, therefore, seem to play a role in starch metabolism leading to germination. However, since gibberellins themselves are not light sensitive, we must look for a photoreceptor. Hahn and Miller (1966) demonstrated that increase in size of chloroplasts in *Polytrichum commune* (Figure 8) germinating spores was due to presence of starch. The reaction was red/far-red reversible (*i.e.*, interchanging these two light qualities would reverse the reaction), and only red and white light produced germination and chloroplast replication. Spores of the species would germinate only in light or in darkness + sucrose. The red/far-red reversibility is evidence of **phytochrome** activity, and the coupling of starch degradation with the multiplication of chloroplasts suggests that light is necessary for this starch to sugar conversion, thus supporting the second hypothesis.

Figure 26. *Marchantia polymorpha* spores & elaters (stained) as they would appear in the capsule. Photo from Michigan State University teaching collection, with permission.

The response to short days is likewise consistent with phytochrome activity and would permit the spores to germinate in spring at the beginning of the growing season when most areas in the temperate zone have adequate rain

and sufficiently cool temperatures for these C_3 mosses and liverworts to succeed. On the other hand, decreased germination in long days would prevent precocious germination of spring-produced spores that would most likely not succeed in the hotter, drier days of summer.

The decrease in stored carbohydrate (mostly as starch) over time may account for the inability of older spores, especially small ones, to germinate. It would be interesting to correlate stored carbohydrate with spore longevity. Our lack of field data on time of spore germination greatly inhibits our interpretation of the ecological implications of these physiological characteristics.

A third way to obtain sugars is breakdown of fatty acids through the glyoxylic acid cycle. This pathway has been described for germinating seeds, rich in fatty acids. Bryophytes also have fatty acids (Jamieson & Reid 1976; Suire & Asakawa 1981), and these are known in moss spores (Karunen & Liljenberg 1978). They play a role in spore germination of *Polytrichum commune* (Figure 8) (Karunen 1972), where, at the end of the protrusion phase, fatty acid degradation gives energy for development of chloroplasts.

It is clear that an energy source is necessary for many (probably all) spores. However, there is no rule that says the method must be the same for all, nor that only one of these could be in effect. Multiple sources of sugars and a variety of options would permit greater success in a wider variety of conditions. Perhaps having multiple possible sources of energy for spore germination is one factor that permits ubiquitous species of bryophytes to be ubiquitous. But what are the relative roles of photosynthesis, glyoxylate cycle, and breakdown of starch in production of sugars and energy during germination of the spore?

In very immature brown spores (lacking chlorophyll) we often see small lipid bodies. Chloroplasts are not yet formed and photosynthesis does not take place. It is reasonable that the first way to obtain sugars in such spores is through breakdown of lipids in the glyoxylate cycle, and lipid catabolism may occur prior to chloroplast formation.

In addition to gibberellins, IAA can have a stimulating effect on germination of spores in light but not in dark (Valanne 1966). How can we explain this? We know light has a stimulating effect on production of sugars. As a result of the change in osmotic potential of the cell, there is uptake of water. IAA makes the cell wall more elastic so that the spore can swell. In the dark there is no sugar production and exogenously supplied IAA has no effect. However, in the same experiment, Valanne noticed a decrease in percent of spores germinated when compared to control cultures with no growth substances. It might be possible that supplied IAA increased the IAA concentration above normal levels. High levels can induce the formation of IAA oxidase, resulting in the catabolism of IAA, and induce the production of ethylene, both of which could explain the lower percent germination of spores in IAA culture media compared with the control medium. This scenario would support hypothesis 1, that light is necessary because photosynthesis is necessary to provide sugars.

IAA probably has its main effect during the swelling of the spore. The inactivation of IAA by IAA oxidase is often correlated with an increase in GA content (Maravolo 1980). We know from tracheophyte studies that GA is sometimes formed in the day and used at night and that it

can cause the same response as a long day in long-day plants (Salisbury & Ross 1978). GA has a stimulating effect on α -amylase, and the resulting breakdown of starch provides material for cell wall formation. GA may thus play a role in the distension phase.

One might propose the following sequence: breakdown of lipid bodies prior to formation of chloroplasts; effect of IAA and photosynthetically derived sugars during the swelling phase; formation of gibberellic acid and breakdown of starch leading to the distension phase. This, however, is the reverse of the process known for tracheophytes. The position of lipid breakdown is the most tenuous, with Karunen's (1972) work showing degradation of fatty acids at the end of the protrusion phase, giving energy for chloroplast development.

It is clear that germination requires **energy**. Three potential pathways could provide that energy: 1) stimulation of **phytochrome** that initiates the **starch to sugar** conversion that precedes production of **chlorophyll**, possibly under control of **GA**; 2) conversion of **fatty acids** to sugars, providing energy for production of chlorophyll; 3) photosynthesis of green spores in the light. The requirement for light insures that spores will not germinate under soil or elsewhere where they will never get light. Small spores and older spores have poor germination success, most likely because of diminished energy stores. **IAA** provides the **elasticity** needed, sugar provides **energy** and the **osmotic potential** that brings in water, and **GA** stimulates the **α -amylase** production that precedes **distension**.

Light Needs

Most moss spores have chlorophyll at maturity, and that most likely helps to provide their energy as they germinate, through photosynthesis, as demonstrated in *Funaria hygrometrica* (Figure 23) (Krupa 1965).

Light is not required for swelling in most spores (Valanne 1966), but it is for germination. Even in species where swelling (germination) occurs in the dark, some individual spores require light. In *Ceratodon purpureus* (Figure 112), starch grains increase at the onset of darkness (Valanne 1971) but disappear from chloroplasts of those that swell in darkness, and the lipid bodies change shape (Valanne 1966). Since these changes do not occur in those species requiring light, it suggests that lack of germination may be due to the inability to mobilize food reserves. We have discussed the ability of **gibberellic acid** to mobilize starch in the presence of light, but what accounts for dark mobilization? Do spores differ in their content of **α -amylase**, with those rich in α -amylase waiting only for sufficient water to carry out their reactions? Is this mechanism purely a random distribution of materials at **sporogenesis** (spore production), or is it a genetically engineered device that conserves resources in some spores while permitting others to germinate early?

The clandestine *Cryptothallus mirabilis* (Figure 27), a liverwort that lives **within** a bed of *Sphagnum*, lacks chlorophyll in the entire plant, including spores (Hill 1969) and has no requirement for light to germinate. It would be helpful to know if it has a ready supply of α -amylase.

Figure 27. *Cryptothallus mirabilis* with young sporophytes. Photo by Michael Lüth, with permission.

Although it seems that light intensity is the most important factor in germination of bryophyte spores, Kinugawa and Nakao (1965) found that photoperiod affected the termination of *Bryum pseudotriquetrum* (Figure 28). Most spores required more than a 5-hour photoperiod for germination, whereas more than about 12 hours seemed to make little difference, even though only about 75% of the spores were germinating (Figure 29).

Figure 28. *Bryum pseudotriquetrum* with capsules. Photo by Michael Lüth, with permission.

Figure 29. Effect of day length on germination of spores of *Bryum pseudotriquetrum*. Redrawn from Kinugawa & Nakao 1965.

We know almost nothing about light intensities needed in the field for germination of spores. In the lab, we often add substances that could replace the need for photosynthetic activity. For example, *Bartramidula bartramioides* germinated best at 3500-4000 lux of continuous light in the lab, but the addition of a 1% sucrose solution may have had overriding effects to counter the low light and continuous illumination (Chopra & Rahbar 1982).

During (1979) assumes that lack of light and water in the capsule might restrain the germination of spores within the capsule, but it is questionable whether the capsule keeps all the light out. Spores can germinate under very low light intensities, e.g.: (1) Spores of *Schistostega pennata* (cave moss; Figure 30) germinate in the dark (Nehira 1967). (2) Geissler (1982) found that moss spores germinate under snow, thus under a greater far-red/red light ratio than sunlight (Winchester pers. comm.). (3) Spores of *Dicranum scoparium* (Figure 50) and *Ceratodon purpureus* (Figure 112) germinate at a light intensity of only 1 lux (Valanne 1966). (4) *Cryptothallus mirabilis* (Figure 27), which lives under a thick *Sphagnum* layer, is able to germinate in the dark, or under a very low light intensity. These examples show that low light intensity may not be a decisive factor to inhibit the germination of at least some kinds of spores within the capsule, or at least might not be the only factor involved.

Figure 30. *Schistostega pennata* spores, a species where spores germinate in the dark and under snow. Photo by Misha Ignatov, with permission.

On the other hand, the wavelength of light inside the capsule may play a significant role. The capsule wall changes its color during maturation and the color of the capsule at the time of spore maturation could have an effect on the germination of spores. We know that spores of different species germinate under different wavelengths (Valanne 1966). For example, *Funaria hygrometrica* spores (Figure 23) will germinate at long wavelengths (580-700 nm) at low light intensities, but require high intensities at short wavelengths (362-500 nm) (Krupa 1967). Since short wavelengths are likely to be filtered out most easily, this could be an effective inhibitory mechanism. Valanne (1966) reported that far red and blue

light inhibit swelling of *F. hygrometrica* spores and that blue-green light reduces distention in *Funaria* and *Ceratodon* (Figure 112) to lower than that in the dark. On the other hand, she found that *Ceratodon* and *Dicranum* (Figure 50) are indifferent to far red light. Bauer and Mohr (1959) showed that the ratio of red to far-red light is important in the germination of *Funaria*.

In a later study on *Ceratodon purpureus* (Figure 112), Valanne (1971) found that illumination with blue light resulted in sporelings with chloroplasts that were richer in starch, had denser stroma, and had more mitochondria than those in red light. The sporelings in red light made more effective use of reserve lipids.

Bauer and Mohr (1959) found that the initiation of germination in *Funaria* (Figure 23) depends on phytochrome. The involvement of phytochrome could explain why Krupa (1967) found retarded germination in green light, but after 18 hours at 680 nm (optimum wavelength), followed by 24 hours at 544 nm (green), germination was greater than when 680 nm illumination was followed by dark. In working with *Octoblepharum albidum* (Figure 31) spores, Egunyomi (1979) also found that wavelength was important in the onset of germination. Red, cyan, green, mimcro-7, and orange light resulted in germination, but blue, mercury green, deep yellow, and deep red inhibited it. White light resulted in germination and reversed the effects of the inhibitory light, except for the inhibition by mercury green. It might be worthwhile to follow the germination capabilities of the spores of different species during ripening of the capsule, and to relate the spore maturation stages with the changes of color of the capsule. Such color changes in the capsule might be important in preparing the spores for germination at their maturity while preventing it if they are dispersed while still immature.

Figure 31. The epiphytic moss *Octoblepharum albidum* with capsules. Photo by Janice Glime.

Not only does the capsule wall change color during the maturation process, but ambient light will change considerably between early spring and summer. As the snow melts and the trees still lack leaves, white light is able to reach the ground. But in a few weeks to months, depending on the latitude, canopy leaves filter out the red light and transmit light high in green and far-red (Bjorkman 1981). These light quality changes could likewise serve as signals to spore germination, and, in combination with

capsule color, could be effective inhibitors for mature spores still inside the capsule.

In some species, such as *Mnium hornum* (Figure 32), instead of depending directly on its environment, the spore has an endogenous development cycle that results in the immediate germination of the spore (Newton 1972a, b). Nevertheless, although the germination is independent of both light and temperature, light is still important in maintaining the internal clock; a slight delay of the development caused by short days helps to maintain an annual rhythm in spore maturation (*i.e.*, it resets the clock) and subsequent germination. It is possible that temperature plays a similar role.

Figure 32. *Mnium hornum* with capsules. Photo by Jan-Peter Frahm, with permission.

Whereas most bryophytes require light to germinate, a few that live in very low light do not and others require as little as 1 lux. In culture, sugar can substitute for the presence of light and its presence may explain the germination of some species in the dark in nature. Furthermore, the presence of α -amylase could permit spores to convert stored starch to sugar for germination without light. The wave length of light seems to be important for some mosses and could safeguard spores against germinating in the wrong habitat. There are insufficient studies on requirements for spore germination to draw any generalizations about light requirements and habitat, but we can hypothesize that most sun-loving species are more likely to require red light than those that grow in the forest and other low-light habitats. Nevertheless, as mentioned above, *Ceratodon purpureus*, often found in high light situations, can germinate at only 1 lux. Clearly something more than light intensity and photosynthesis is involved.

Environmental Control over Germination

The three requirements already named – water, energy, and light – obviously will exercise primary control over the germination of spores. However, specific requirements of individual species will further narrow the window of germination. These controls can include pH, nutrients, temperature, photoperiod, and exogenous substances, all interacting with internal substances that respond to these environmental cues.

Delay until the right weather (temperature, moisture) occurs is easily perpetuated genetically, but what selects for genes to prevent germination on the wrong substrate? Unless the spore can be re-dispersed, there is no selective advantage that would favor inhibition of germination. Yet there are species where the nature of the substrate does control germination and further development. For example, calcium enhances germination success in the **calciphile** (calcium loving) *Orthotrichum cupulatum* (Figure 33), but germination of *Dicranella cerviculata* (Figure 34) is depressed by calcium (Vaarama & Tarén 1963). In *Stereophyllum radiculosum* (Figure 35), control cultures and those at 22 ppm Ca produced one protonema per spore, whereas those at 50-150 ppm each produced two (Olarinmoye *et al.* 1981). When the leafy liverwort *Cheilolejeunea clypeata* was grown on a Ca-free medium, the spores became distended, but the protonema failed to develop during the next five months of culture, whereas in the normal medium young plants had developed (Geldreich 1948).

Are these alternatives in protonemal production adaptive, suggesting that more calcium should be able to support more gametophores? A species loses nothing by germinating in an unsuitable habitat, as opposed to no germination at all. Yet it seems that many spores hang on tenaciously to life for years, awaiting the right set of conditions for germination. And sometimes those needed changes may actually occur.

pH

Apinis (1939) contended that most moss spores are almost indifferent to pH range. The spores germinate in a wide pH range, the protonema range is more restricted, and the pH range of the leafy plant in culture corresponds closely to its range in nature. Philippi (1969), on the other hand, found that species from acid or raw humus reacted uniformly, preferring acid, whereas species from wood had a strong divergence of pH range. Armentano and Caponetti (1972) felt that pH may be the factor that limits the habitat for *Funaria hygrometrica* (Figure 23) and *Tetraplodon mnioides* (Figure 36), both of which germinate better at a basic pH. Vishvakarma and Kaul (1988) found that in culture two liverworts, *Plagiochasma appendiculatum* (Figure 37) and *Reboulia hemisphaerica* (Figure 38), had an optimum pH for germination and thallus growth of 6.0.

Figure 36. Capsules of the dung moss *Tetraplodon mnioides*. Photo by Zen Iwatsuki, with permission.

But how does pH affect spore germination? Does each species have a spore wall requiring a characteristic pH, such as that found on tree bark? What is the effect of pH on the cation exchange between spores and the substrate? A change in the pH can affect enzymatic activities, but it can also affect the solubility and release of certain ions in the substrate and cause, indirectly, a toxic effect. Could it be that pH is simply an indicator of needed ions that are

associated with the higher or lower pH? Vishvakarma and coworkers (1987) found that calcium enhanced spore germination in *Plagiochasma* (Figure 37) and magnesium did likewise in *Reboulia* (Figure 38); both of these ions are generally associated with high pH. Furthermore, as we have seen above, calcium is involved in germination of some species, and its transport may be affected by pH.

Nutrients

Although only water and light are generally considered necessary for germination, Arnaudow (1925) was unable to get spores of *Dicranum scoparium* (Figure 50) to germinate in water for four weeks, but when particles of earth were added to the water, they germinated in two days.

The cosmopolitan *Funaria hygrometrica* (Figure 23) seems to have some precise requirement that is elusive. Its

germination occurs over a wide range of temperature, light intensity, and chemical conditions. According to Hoffman (1966), the soils where it grows have no consistently high or low nutrients and pH is neither high nor low. Yet, Hoffman's efforts to grow the moss on soils with various nutrient conditions failed, but soil from burned areas supported growth. In experiments with heated soils, Hoffman found that it grows well on C horizon soils (inorganic parent rock material) heated to 200-300°C, but grows poorly or not at all if the soil has been heated to over 300°C. However, if N and P are added to soils heated to 600°C, it grows well. This suggests that loss of N and P at high temperatures account for its inability to grow. On the other hand, Southorn (1977) relates the presence of *Funaria hygrometrica* to the change of source of N and P in the soil. He found that ammonia-N inhibits germination, and that replacement of *Funaria hygrometrica* by other bryophytes was correlated with a decrease of phosphate-P. The decrease in abundance may also partly be a result of changing nutrient concentration due to leaching by rain water. Yet Chevallier (1975) demonstrated the requirement of manganese as a **micronutrient** (those required in small quantities) for germination. The restriction of *F. hygrometrica* to relatively open areas is consistent with its requirement for light for germination.

But what do other bryophytes require? Most bryophytes have been grown from tissue cultures (see Sargent 1988) using one of several standard media. No comprehensive study in the lab or the field has provided any information on the nutrient requirements, if any, for germination success. Most likely the requirements are few, if any, until after germination and the protonema requires them for growth.

Temperature

One might conjecture that temperature could control when and where species germinate and thus limit distribution. For example, Longton and Greene (1969) found that germination rate steadily increased within a temperature range between 5° and 20°C in *Pleurozium schreberi* (Figure 98), a normal temperature range for spring and autumn. One advantage to this ability to germinate over a wide range of temperatures, with an optimum adjusted to the climate, is that it would permit multiple chances to take advantage of changeable weather in a given season without forfeiting an entire year's crop of spores due to an inopportune germination time. Certainly such strategies exist, as in this *Pleurozium* example.

In *Sphaerocarpos texanus* (Figure 39), as discussed above, loss of spore dormancy increases as length of time at a suitable temperature increases (McLetchie 1999). Spores kept at 35/20°C lost dormancy faster than those at 30/15°C or 25/15°C. However, the best germination occurred when these spores were subsequently placed at 16/10°C (typical temperate spring or fall temperatures) and it failed at 35/20°C and 30/15°C (late spring and summer temperatures).

At first, McLetchie and Johnson (1997) found that the size of the *Sphaerocarpos texanus* (Figure 39) spore tetrad affected the male:female ratio; spores were normally dispersed in tetrads of 2 males and 2 females. However, if the tetrad was less than 90 µm, the sex ratio was female biased. Then McLetchie (2001) found that spores of

Sphaerocarpos texanus behave like eggs of alligators, wherein gender is determined by temperature of the eggs! In this dioicous liverwort the sex ratio is affected by the temperature at which the spore loses its dormancy! At 25/15°C, the population became female biased, whereas at higher temperatures (35/20, 30/15°C) it was not, suggesting a differential survivorship at the spore stage.

The development of physiological races for germination temperature optima in different localities is probably a widespread phenomenon. Dietert (1977) tested *Funaria hygrometrica* (Figure 23) and *Weissia controversa* spores (see Figure 40) and found optimum temperatures that differed among populations of one species. Populations from colder habitats showed lower germination optima than populations from warmer habitats, thus suggesting that survival of the sporeling did not require the greater temperature. At first, this seems intuitively to be backwards. This temperature relationship is the reverse of McNaughton's (1966) results for *Typha* (cattail) seeds, where a higher temperature requirement for germination of northern seeds protected the seedlings from late freezing that was not a problem for southern populations. On the other hand, this system of cold-adapted species germinating at a lower temperature than those from warm areas provides a longer growing season for individuals in colder climates than would be possible if they had a higher temperature optimum. Since bryophytes are less susceptible to damage by cold and its accompanying desiccation than most tracheophytes, germination early in the season may not be a problem.

Figure 40. *Weissia longifolia* spores, a species that differs among populations in optimum germination temperatures. Photo by Kristian Peters, with permission.

The lack of need for warmer temperatures for sporeling survival is supported by Dietert's later work (1980) that showed optimum germination temperatures for

Funaria hygrometrica (Figure 23) of 30°C, protonema growth at 25°C, and a requirement for cooler temperatures for gametangial formation. In this case, requirements seem to agree with McNaughton's (1966) conclusions that a high germination temperature is necessary to protect the organism from late freezing conditions, but once germination has occurred, sufficiently warm temperatures are assured so there is no selection pressure for the higher temperature optimum. In other words, there is a strong selection pressure against those individuals that germinate at lower temperatures and then experience sub-zero temperatures, but once the temperature has reached 30°C, it is not likely to be sub-zero again, thus permitting those individuals to survive; there is apparently no selection pressure for high or low temperature for development in this case, unless this positions the moss to germinate in the fall and develop over winter.

One problem for spores that germinate and must overwinter as protonema is desiccation. Frost and ice crystals are hygroscopic and draw the water from the delicate filaments. But if water is available, at least some species can overwinter safely, as can be seen for *Dicranella heteromalla* that live through winter in acid mine water (Figure 41).

Figure 41. *Dicranella heteromalla* protonemata that survived winter in an acid mine lake. Photo by Jan Fott, with permission.

Chopra and Sood (1973) experimented with vernalization and temperature in the thallose liverwort *Riccia crystallina* (Figure 42). After 3-4 months only a few spores germinated, and those were in only 4-5% of the cultures. However, a cold treatment of 8-15°C not only increased the percentage of germination but also shortened the dormancy period to 15 days.

In summary, a requirement for a minimum temperature would prevent early germination and the increasing number of spores germinating as the temperature rises protects the population against loss of all germlings at one time in a bad weather event. Populations from colder climates may adapt by having a lower requirement for germination, thus providing them with a longer growing season. In some species, the temperature at which the spores lose their dormancy affects the gender and thus the sex ratio of the colony.

Vernalization

We must distinguish between the ability of spores to withstand low temperatures and the necessity for chilling (**vernalization**) for germination. For example, Van Zanten (1976, 1978a, b) froze spores in order to study **freezing tolerance** to demonstrate the possible long-range dispersal of mosses. Some spores kept their ability to germinate after 36 months of freezing.

But withstanding freezing is quite different from the need for cold temperatures for germination. Geissler (1982) illustrated the possible necessity for freezing in some taxa, mentioning that some bryophytes have a hibernation period of two winters, most likely requiring cold, but perhaps merely exhibiting immature spores, as found in seeds of some flowering plants. In *Orthotrichum anomalum* (Figure 45) and *Leucodon sciurioides* (Figure 43), freezing is favorable for the germination of the spores (During 1979), although it may not be a necessity, whereas *Splachnum vasculosum* (Figure 44) does require freezing (-5°C) (During 1979). However, survivorship is greater if spores are frozen in the capsule than if they are fully hydrated (in distilled water). It is likely that water activates the spores before freezing is accomplished and then freezes them in an active rather than a dormant state.

Figure 43. *Leucodon sciurioides* with capsules. Photo by Michael Lüth, with permission.

Figure 44. *Splachnum vasculosum* with capsules. Photo by Dick Haaksma, with permission.

Membrane damage can occur during freezing of an active cell, causing leakage of necessary nutrients, and a recently activated cell is more likely to have used up the energy resources for repair of membrane damage caused by desiccation (Bewley 1979). Furthermore, leaching of nutrients from a cell with a damaged membrane would be greater in distilled water than in almost any natural medium. This short period of hydration before freezing could leave insufficient nutrients and energy for repair when the cell is reactivated after freezing, and energy could, therefore, be insufficient for normal germination processes.

The achlorophyllous *Cryptothallus mirabilis* (Figure 27) actually germinates sooner if exposed to temperatures of -18°C (Benson-Evans & Hughes 1960 in Schuster 1966). This is perhaps not surprising since it grows among *Sphagnum* species, thus being more frequent in northern habitats.

Cold, but not freezing, temperatures could be important for some species to facilitate the conversion of starch to sucrose. Glier and Caruso (1974) found that the activity of starch degradative enzymes of cold-requiring plants increased after a long exposure at 4°C . It is thus possible that cold-requiring bryophyte species use this exposure to metabolize their starch. Species that do freeze and survive could also be cold-requiring, passing through the cold, but above-freezing, temperatures as the temperature warms in spring.

Such aquatic species as *Fontinalis* (Figure 22, Figure 24) might require other inhibitory mechanisms to block conversion and subsequent germination in winter since they will seldom experience temperatures below 1°C in the water, or perhaps they are adapted to winter germination, which would coincide with capsule maturation and dispersal.

Germination Inhibitors

Under favorable conditions, most dispersed spores germinate fairly rapidly. Spores of *Campylopus* (Figure 46), *Microdus* (Figure 47), and *Hymenostylium* (Figure 48) germinate in 2, 3, and 4 days respectively (Mehta 1988). *Funaria hygrometrica* (Figure 23) spores germinate in 3-5 days. Although some spores have specific temperature requirements, most spores germinate when shed, provided they have suitable light and water,

suggesting that they lack dormancy in the form of germination inhibitors and must depend on the sporophyte to permit major dispersal only at a suitable time. Van Zanten (1976, 1978a, b) has demonstrated long-term survivorship for spores of a number of species, suggesting that dryness effectively maintains dormancy. Others survive burial in soil, where darkness maintains dormancy.

Nevertheless, some spores are shed under what would seem to be suitable germination conditions. What makes them wait? Why don't spores simply germinate on leaves of their parents where most of them land? Certainly avoidance of such a tactic is desirable because they would deprive the parent plant of light, but what is it that prevents such an occurrence? It seems that at least some leafy mosses [e.g. *Syntrichia* (Figure 49) & *Dicranum* (Figure 50)] can provide a diffusible substance, not yet named or characterized, that inhibits the germination of the spores (Mishler & Newton 1988). Such inhibition has been known for a long time in *Marchantia polymorpha* (Figure 26), where the gemmae remain dormant on the parent, but begin growing immediately when dispersed from that parent onto a suitable substrate. In fact, it appears that mature plants may inhibit successful germination of both spores and asexual structures in at least some mosses (Newton & Mishler 1996).

Figure 49. *Syntrichia ruralis* with capsules & water drops. This genus inhibits germination of its own spores. Photo by Peggy Edwards, with permission.

For desert mosses, brief periods of moisture could cause germination, but subsequent drying would be lethal. Therefore, it would be beneficial for spores to have an inhibitor that prevented germination until sufficient water was present. In some desert seeds, an inhibitor is leached

out of the seed by rain water (Fitter & Hay 1981). When rain continues, the concentration of the inhibitor in the seeds decreases below a critical level and germination occurs. When rain stops before this critical level is reached, the inhibitor is resynthesized and germination is postponed until a later rain period.

The same scenario might apply to mosses. We know that mosses can contain high concentrations of phenolic compounds (often serving as inhibitors), especially in some of the capsules that house the spores. These compounds, known to prevent germination in seeds, are likely mechanisms for preventing germination of spores within the capsule. This mechanism may also be important for inhibiting germination of spores that fall onto humic substrata or older moss parts where phenolic compounds are present. Some of the compounds could travel with the spores as they disperse, perhaps inhibiting some individuals more than others, and thus spreading the water requirements and period of dormancy over a wider range that might take advantage of unpredictable conditions.

ABA and ethylene are both known inhibitors of seed germination and could serve as well to inhibit bryophyte germination, with lunularic acid as a possible inhibitor in liverworts. Ethylene could be an effective inhibitor of spores buried in soil, building up in the small spaces there, but is a spore large enough to produce sufficient quantities on a predictable scale to inhibit germination? We don't know if this ever occurs, or even if these substances are present in bryophyte spores. These ideas are conjecture since experimental studies on the effects of either internal or external inhibitors on moss spores are lacking.

Hormonal Regulation

Like phenolic compounds, hormones may intervene in germination of spores. Shukla and Kaul (1991) found that low concentrations of five kinds of auxins, ascorbic acid, benzoic acid, and gibberellic acid all stimulated germination in the liverwort *Plagiochasma appendiculatum* (Figure 37), but at concentrations greater than 5 ppm, growth was inhibited. High concentrations could accumulate within the capsule, diminishing after operculum dehiscence. Could hormones from decomposing leaf litter possibly inhibit spore germination? Or could it be that newly dispersed spores have high concentrations that get leached from them by water?

Experiments by Arnaudow (1925) suggest that the gametophyte could exercise control over the germination of spores within the capsule. When embryos of *Dicranum scoparium* (Figure 50) were transplanted to *Atrichum undulatum* (Figure 53) archegonia (and that was without the help of a computer to guide his hands!), normal development ensued, producing larger capsules than in controls, but remarkably many *D. scoparium* spores germinated in the capsules of transplanted sporophytes, producing 3-4-celled protonemata.

Such a phenomenon of germination within the capsule is rare in mosses, occurring for example in *Dicnemon* (Figure 51) and *Eucamptodon* (Figure 52) (Goebel 1930). Arnaudow found no germinated spores in *Dicranum scoparium* (Figure 50) or *Atrichum undulatum* (Figure 53) controls, and suggested that nutrition could account for the difference. Could it be absence of an appropriate inhibitor? Or possibly a hormonal stimulant (Table 1)?

Figure 50. *Dicranum scoparium*, a moss used by Arnaudow (1925) for embryo transplant studies. Photo by Michael Lüth, with permission.

Figure 52. *Eucamptodon perichaetiale* with capsules. In this genus, spores germinate within the capsule. Photo by Jan-Peter Frahm, with permission.

There is reason to suppose that gibberellin might be involved; GA stimulates breakdown of starch and causes subsequent swelling of spores. If this is true, under natural conditions one should expect swollen spores in *Atrichum undulatum* (Figure 53) and not in *Dicranum scoparium* (Figure 50) capsules. Nehira (1963) found ripe spores of *Dicranum caesium* (Figure 54) to be 20 μm in diameter and greenish brown. On germination the spores stretched slightly. This suggests that spores of at least this *Dicranum* species do not swell in the capsule. On the

other hand, Longton and Miles (1982) found 66-81% of *Atrichum* spores to be green and round, dependent on habitat. An obvious experiment to test our hypothesis for explaining Arnaudow's observations would be to supply fruiting *D. scoparium* plants with GA. Germination of spores within the capsule will support the hypothesis.

Figure 53. *Atrichum undulatum*, a species of moss used by Arnaudow (1925) for embryo transplant studies. Photo by Michael Lüth, with permission.

Figure 54. *Dicranum caesium*, a species for which spores do no swell in the capsule. Photo from Digital Museum, University of Hiroshima, with permission.

Table 1. Theorized hormonal control of spore dormancy in *Dicranum scoparium*, based on experiments of Arnaudow (1925), where embryos of *D. scoparium* were transplanted into the archegonium of *Atrichum undulatum*, causing *D. scoparium* spores to germinate within the resulting transplanted capsule. (Z and X are hypothesized substances.)

	Control		Experimental
gametophyte	<i>D. scoparium</i>	<i>A. undulatum</i>	<i>A. undulatum</i>
	-	Z	X
sporophyte	<i>D. scoparium</i>	<i>A. undulatum</i>	<i>D. scoparium</i>
	-	Z	-
germination	no	no	yes

Suppose, then, that the sporophyte of *Atrichum* (Figure 53) might produce abscisic acid, which reduces the

effect of GA (Goodwin & Mercer 1983). In this respect, Oppenheimer (1922) and Buch (1920) mention formation of chemical substances that emanate from the capsule wall and inhibit germination. Such an inhibitor, **lunularic acid**, is known to inhibit germination of gemmae in the liverwort *Lunularia cruciata* (Figure 55) while they are retained by the parent thallus (Schwabe 1976). In mosses, where lunularic acid is unknown, abscisic acid could have a similar role (Pryce 1972). This hypothesis is further supported by the fact that operculum dehiscence is usually correlated with spore maturation in mosses (Hancock & Brassard 1974), and abscisic acid could promote this dehiscence, a role similar to that of autumn leaf dehiscence. On the other hand, if abscisic acid does not cause dehiscence of cells, we may find that drying of the capsule is the major factor in determining time of dehiscence, and that the ring of weak cells that facilitates this is under enzymic control or perhaps ethylene control at an earlier stage of development.

Figure 55. *Lunularia cruciata* with gemmae in cups and on the thallus. The thallus inhibits their germination. Photo by Martin Hutten, with permission.

In any event, it appears that we should also look closely at the gametophyte as a potential controlling generation for spore dormancy. Hughes (1954) found that control of sporangium production in *Pogonatum aloides* (Figure 25) and *Polytrichum piliferum* (Figure 56) is photoperiodic, sensed by the gametophyte, and communicated to the sporophyte. Another explanation then is that in transplanted *Dicranum scoparium* (Figure 50) sporophytes, communication for spore dormancy was not sent at the proper time by its *Atrichum undulatum* (Figure 53) gametophyte.

Another hormonal effect may intervene in dispersal of the entire capsule in such desert mosses as *Goniomitrium* (Figure 57) and *Bryobartramia* (Scott 1982). Both mosses have a short seta, a **cleistocarpous** (lacking regular mechanism for opening such as operculum or lines of dehiscence), globose capsule, and a calyptra that covers the capsule completely until dispersal (Scott & Stone 1976). Ethylene produced by the sporophyte could accumulate and cause release of capsules. Ethylene inhibits cell elongation, perhaps accounting for the short setae. The autocatalytic ability of ethylene, if captured in enclosed space under the calyptra, may cause **abscission** (breaking away) and **senescence** (aging). In higher plants abscission is the result of synthesis and secretion of a wall-degrading enzyme.

Ethylene also softens the cell wall (Salisbury & Ross 1978), and its presence increases production of abscisic acid (ABA).

Figure 56. *Polytrichum piliferum* with capsules. Spores in this species respond to photoperiod to germinate. Photo by Michael Lüth, with permission.

Figure 57. *Goniomitrium enerve* with capsules. In this genus, the entire capsule disperses. Photo by David Tng, with permission.

Few species experience the germination of spores within the capsule. This inhibition could be caused by insufficient light or by the presence of an inhibitor. Such an inhibitor could be produced by either the gametophyte or sporophyte. We know that high concentrations of auxins, GA, and other hormones can inhibit germination, and the sealed capsule could accumulate such substances to inhibitory levels. Ethylene remains an unexplored possibility in this inhibition and may also play a role in the abscission of the capsule to release the operculum.

The role of hormones in germination of bryophyte spores is poorly understood. It appears that the gibberellins, growth hormones, are involved in at least some cases (Anterola *et al.* 2009). By inhibiting the production of gibberellins in *Physcomitrella patens* (Figure 2), Anterola and coworkers demonstrated a reduction in spore germination rate.

Inter- and Intraspecific Interactions

Exogenous inhibitors are those substances produced by other organisms that inhibit spore germination. Some species get downright nasty in their competition. For example, species of the lichen *Cladonia* can produce chemical inhibitors that prevent or reduce moss spore germination (Lawrey 1977). For *Funaria hygrometrica* (Figure 23), *Weissia controversa* (Figure 58-Figure 59), *Plagiomnium cuspidatum* (Figure 60), and *Physcomitrium pyriforme* (Figure 111), inhibition by *Cladonia subcariosa* (Figure 61), *C. cristatella* (Figure 62), and *Cladonia squamosa* (Figure 63) in acetone extract was complete, whereas germination was 90% or greater in acetone controls in all except *Physcomitrium pyriforme*. The ubiquitous pollution-tolerant *Pohlia nutans* (Figure 64) exhibited only 34% germination in controls, but maintained from 0.8 to 5.6% germination in the three lichen extracts. The least affected species was *Amblystegium serpens* (Figure 64), with 91% germination in controls, and 15-71% germination with lichen extracts. However, such concentrations of lichen extracts may never exist in nature where adhesion onto soil **colloids** (substances having particles that remain dispersed in solution) may render them ineffective, or they may not leave the lichen in sufficient quantity to have any effect (unless bryophytes leach the acids out with acetone!). On the other hand, dead or damaged thalli could indeed leach out lichen acids. Such inhibition can account for some of the moss to lichen successional patterns observed in nature.

Gardner and Mueller (1981) found that the effectiveness of lichen acids in inhibiting germination of *Funaria hygrometrica* (Figure 66-Figure 67) spores was dependent upon pH. At pH 7, none of eight lichen acids tested had any effect on germination at concentrations of 2.7×10^{-5} M, but at lower and higher pH levels many became increasingly more toxic, whereas others resulted in better germination at pH values other than 7. These differences could account for the success or failure of bryophyte species in soils of various pH levels where lichens are also growing.

Based on the ease of growing *Funaria hygrometrica* (Figure 66-Figure 67) in the laboratory (Bopp 1980), one would expect to find germlings of this species everywhere in nature. Yet this simply is not the case. Longton (pers. comm.) has found he could not grow *Funaria* on soil in nature where he had collected it, yet he could grow it there on a Petri plate. If one considers the fact that *Funaria* remains only 1-2 years in burned areas (Hoffman 1966), and seldom remains longer than that where it invades other disturbed areas, it appears that the moss must suffer from either self-inhibition, **allelopathy** (influence of plant metabolites on other plants – i.e., chemical warfare), or competition. In fact, Klein (1967) showed that *F. hygrometrica* protonemata release Factor H (probably a cytokinin) to the substrate and that it greatly reduces protonemal differentiation. Furthermore, old cultures of *Funaria* exhibit senility after about one year (Bopp & Knoop, pers. comm.), suggesting that a diffusible substance might accumulate in the substrate.

To test this theory of inhibition by older protonemata, I (Glime unpubl.) grew spores of *Funaria hygrometrica* (Figure 66-Figure 67) on agar that had been previously treated with 1-cm plugs of agar containing old protonemata, plugs with mature plants, and fresh agar. In all treatments, germination occurred within 48 hours, and spores even germinated on some of the plugs. Buds appeared within 10 days, with abundant buds on plates with protonemata, young plants, or mature gametophores. Furthermore, new buds were induced on the protonemata of mature plants. We must therefore conclude that either *Funaria* is not inhibited by any chemical that is diffused from existing plants into the agar or that the older cultures were too old and the inhibitor had broken down or become too dilute. These results do not, however, preclude the possibility of an accumulation of products as the plant grows, or the production of a gas (ethylene?) that inhibits encroaching plants.

Figure 66. *Funaria hygrometrica* mature plants with capsules. Photo by Michael Lüth, with permission.

Figure 67. *Funaria hygrometrica* germinating spores. Photo by Yenhung Li, with permission.

Since *Funaria* (Figure 66-Figure 67) grows in a wide range of habitats, allelopathy seemed unlikely, though not impossible. The toxic source should be a widespread one such as that of humic acid decomposition (Hoffman 1966). Humic acids could lower the pH, and Armentano and Caponetti (1972) have shown that a lower pH retards its germination. It is significant that *Funaria* seldom occurs among other vegetation. Bopp (pers. comm.) has suggested that its growth after fires might be possible because of the ability of charcoal to absorb an inhibitor, although it might relate to nutrient availability as discussed above.

Therefore Raeymaekers and Glime (unpubl.) chose to experiment with humic acid effects on germination, using humic concentrations from 0 to 10%. Mean percent of germinated spores two days after inoculation decreased as the concentration of humic acid increased (Figure 68). At high humic acid concentrations (5% and 10%) the protonemata grew upward (away from the agar) and clustered together with other protonemata. Some protonemata in those concentrations formed swollen cells similar to those found by Sood (1975) in *Pogonatum aloides* (Figure 25). Buds were observed 8 days after inoculation in control plants, and 10 days after inoculation on protonemata of the 0.5% and 1% humic acid treatments. No buds were formed after 14 days on protonemata of the 5% and 10% humic acid treatments; however, after three weeks buds were present in 5% and 10% treatments, but in lower quantities than in the other humic acid treatments and the control.

Figure 68. Effects of humic acid concentration on mean percent spore germination in *Funaria hygrometrica*. From Raeymaekers, unpublished data.

We can conclude that spore germination and bud formation are retarded at high concentrations of humic

acids. A concentration of 5% humic acid is not unusual in nature and occurs, at least in the **A horizon** (dark-colored soil layer with organic content and minerals intermixed), of spruce (*Picea*) forest soils (Remezov & Progrebnyak 1965). Fire can remove the humic acids by burning off the organic matter and returning the soil to the mineral layer, or **C horizon**. This may be a factor in permitting such bryophytes as *Funaria hygrometrica* (Figure 66-Figure 67) and *Marchantia polymorpha* (Figure 26) to colonize rapidly. But how quickly can new growth on a burned area return the lethally high concentrations of humic acids?

Could humic acids alone account for the disappearance of *Funaria* (Figure 66-Figure 67) from the areas where it has been a pioneer? It appears that leaf litter may offer more of a deterrent than simply blocking light. That litter is a major source of humic acids. In my moss garden, I discovered that when I left the leaf litter on the mosses all winter, they did poorly the next growing season, even though I removed the litter within days after snowmelt. Even the hardy *Fissidens* that had been doing well for several years showed signs of stress. But this unreplicated anecdotal record hardly is conclusive evidence.

In addition to endogenous inhibitors, spore germination may be affected by its surroundings. The lichen *Cladonia* can be a strong inhibitor, as can humic acids. Such signals would prevent spores from germinating in habitats that would otherwise be unsuitable, on one hand by competition for space from lichens, and on the other by competition for light with trees that drop leaves that release humic acids. A species can even stimulate bud production of its own colony, as in *Funaria hygrometrica*, by releasing substances that stimulate protonemata to produce buds.

Interspecific Competition

Competition can be a problem of limited physical space, nutrients, or shading (light competition). For a tiny moss, physical space is available between larger plants that invade, and such spaces are usually still available long after *Funaria* (Figure 66-Figure 67) has disappeared. Because most nutrients are absorbed through the leaves in **ectohydric** mosses (those conducting water outside the plant) like *Funaria*, nutrient competition can occur when a canopy intercepts and absorbs or diverts rainwater nutrients before they reach the moss. Since mosses such as *Funaria hygrometrica* absorb little or no nutrients from the **rhizosphere**, early invading roots present little nutrient threat.

Light quality alone could account for the restriction of *Funaria* (Figure 66-Figure 67) to exposed, barren habitats because the predominant wavelength transmitted through vegetation is green. However, this simple explanation cannot be applied to the distension phase of *Funaria* germination, wherein maximum distension occurs in yellow-green and far-red light, with the fewest protonemal cells in blue-green and red light (Valanne 1966). With such a seeming contradiction, I decided to culture *Funaria* spores under *Taraxacum* (dandelion) leaves to determine if in fact germination was less successful than in the open.

Few spores germinated on agar under *Taraxacum*, and protonema development was very slow. After 14 days all

control cultures at $29.5 \mu\text{E m}^{-2} \text{s}^{-1}$ (2000 lux) had buds, but those cultures under *Taraxacum* leaves at $9.4 \mu\text{E m}^{-2} \text{s}^{-1}$ (700 lux) failed to produce buds during the next four days, except for a few at the edge of the plate where white light entered. By 23 days, one experimental plate had young plants that were strongly bent toward the light at the edge of the plate. All gametophores under the *Taraxacum* were **etiolated** (abnormally elongated stems, usually in response to low light). While this demonstrates the possible role of other plants in inhibiting germination, it does not indicate whether the difference was caused by light quality or light intensity. As already discussed, the change in ratio of red to far-red light may have been the inhibitory factor (Bauer & Mohr 1959)

External Growth Promoters

It is interesting that bryophytes respond positively to application of herbicides (Balcerkiewicz 1985). On paths sprayed with herbicides, *Funaria hygrometrica* (Figure 66-Figure 67), together with *Marchantia polymorpha* (Figure 26), stayed a long time and was only slowly replaced by *Marchantia*, which is a perennial (Raeymaekers pers. obs., Bowers *et al.* 1982). This suggests that herbicides might provide some growth-promoting substance. On the other hand, it might simply be absence of competitors and whatever they do to alter the environment.

Fungi are common growth promoters because of their production of gibberellic acid, which invades their environment. Experiments on *Dicranum scoparium* (Figure 50), *D. undulatum* (Figure 69), *Dicranoweisia crispula* (Figure 70), and *Pogonatum urnigerum* (Figure 71), using 0.01% GA, showed that GA can promote both spore germination and protonema growth (Vaarama & Tarén 1959). But most of these experiments with gibberellic acid failed to cause any increase in germination of bryophyte spores, e.g. in *Tetraphis pellucida* (Figure 72-Figure 73), *Racomitrium fasciculare* (Figure 74), and *Polytrichum strictum* (Figure 75). Gemmrich (1976) tried to induce germination of *Marchantia polymorpha* (Figure 26) in the dark by using GA, but was unsuccessful. However, Vaarama and Tarén discovered that spores stored dry at room temperature lost their viability, but that GA stimulated them to germinate.

Merwin (2003) reports that in orchards post-emergence herbicides favor bryophytes. Several studies have noted that long-term use of these herbicides promote the growth of *Bryum argenteum* (Figure 76) and *Marchantia polymorpha* (Figure 26) under the trees. These actually provide an advantage to the orchard growers because they stabilize the soil, resist trampling, and do not compete with the trees for nutrients. In this case, spores may not be involved because of vegetative propagules, but they cannot be ruled out.

Perhaps the most ecologically relevant evidence in those experiments is that several fungi (*Aspergillus flavus*, *Penicillium martensii*, *Mucor racemosus*, *Fusarium scirpi*, *Rhodotorula mucilaginosa*) promoted germination and growth even more than GA! Fungi isolated from the rotting wood where *Tetraphis pellucida* (Figure 73) was growing also stimulated the germination of the spores

(Figure 72), but that does not account for its ability to grow on rock faces. It may be interaction with fungal GA that accounts for the production of gametophores of *Fontinalis squamosa* (Figure 77, Figure 93) in contaminated laboratory cultures when none of the sterile cultures reached that stage, suggesting that *F. squamosa* protonemata might be most likely to succeed on damp rocks that have a fungal mat on them (Glime & Knoop 1986). Vaarama & Tarén obtained similar stimulatory results with fungi and *Pogonatum urnigerum* (Figure 71), a soil moss. However, they failed to obtain germination of spores from the rock-dwelling *Racomitrium fasciculare* (Figure 74) when culturing it with the mold *Aspergillus flavus*. Although results have varied widely in the GA treatments, one certainly cannot ignore the potential influence of fungi in the development of at least some bryophytes.

Figure 76. *Bryum argenteum* with capsules, a species in which herbicides promote growth. Photo by Jan-Peter Frahm, with permission.

Figure 77. *Fontinalis squamosa* protonema. Photo by Janice Glime.

Additional evidence for fungal intervention in bryophyte development occurs in *Funaria hygrometrica* (Figure 66-Figure 67). Hahn and Bopp (1972) concluded that the addition of fungi hastened bud formation in this species and considered this to be a symbiotic interaction.

Inorganic substances also have an effect on germination and may account for the presence or absence

of species on newly disturbed soil. Gemmrich (1976) found that while gibberellic acid did not induce dark germination of *Marchantia polymorpha* (Figure 26), various forms of Fe and Ca did, as well as KNO_3 and MgSO_4 , with optimum germination on $\text{Ca}(\text{NO}_3)_2$.

Pollutants

We seldom consider germination when considering the effects of environmental contaminants. Yet, reductions in numbers of bryophytes from many substrates may indeed be the result of failure to germinate. For example, Francis and Petersen (1989) recommend that spore germination is a good bioassay technique for determining the toxicity of heavy metals. But much work remains to determine the effects of the many contaminants on the many species of bryophytes.

Numerous possibilities of inhibition exist with the presence of pollutants. These can include greater dryness, UV exposure, and a myriad of chemicals. Field studies on effects of such pollutants on spores are lacking. However, laboratory studies can suggest potential problems. One early study on pollutant effects on spores is that by Lewis (1973) on suspended solids from coal. She found that increasing concentrations of coal particles resulted in decreasing germination of spores of *Platyhypnidium riparioides* (Figure 78) suspended in Bold's (nutrient culture) medium (Figure 85).

Figure 78. *Platyhypnidium riparioides* with capsules, a species in which suspended coal particles caused decreased germination. Photo by Hermann Schachner, through Creative Commons.

Spore Size

Greater spore size may offer an advantage at germination by providing a reservoir of energy that permits long-term storage (see Chapter 3-1, Polyploidy and Spore Size). The trade-off, one would presume, is that large spores do not disperse far, so we should expect taxa with extremely large spores, such as *Archidium* (Figure 5-Figure 6) (50-130 μm), to have a small distribution. Surprisingly, *Archidium* is relatively widespread in southeastern North America, Eurasia, and New Caledonia (Schofield 1985), and because it is so often overlooked due to its small size, it is likely that it is even more widespread

and frequent than that reported. Its large spores seem to permit it to be successful on disturbed soils, but its means of arrival remains a mystery.

Convey and Smith (1993) considered that short-lived species in the Antarctic typically had large spores that could help them in local colonization, whereas small spores characterized more widespread species. In assessing the spore sizes of Michigan mosses, as published in Crum (1973), I found that the perennial, pleurocarpous mosses all had relatively small spores, the largest being 24 μm . Acrocarpous mosses, on the other hand, ranged up to 68 μm with roughly 40% of the species larger than 24 μm . *Buxbaumia aphylla* (Figure 79), a species with one of the largest capsules, has the smallest spores of 6.5-8 μm , perhaps accounting for its ability to colonize disturbed sites. The largest Michigan spores, being multicellular and measuring 60-100 μm , occur on *Drummondia prorepens* (Figure 80), an epiphyte. *Sphagnum* shows no correlation of spore size with plant size, ranging from a minimum of 17 μm in *S. squarrosum* (Figure 82) and *S. warnstorffii* (Figure 83) to a maximum of 42 μm in *S. cuspidatum* (Figure 84).

McLetchie and Johnson (1997) found an interesting effect of spore size in the liverwort *Sphaerocarpos texanus* (Figure 86). As discussed earlier, this liverwort disperses its spores in tetrads with two male and two female spores, ensuring close neighbors of the opposite sex. However, when the spore size is abnormally small (<90μm), the sex ratio is biased toward females.

Anisospory and False Anisospory

Most mosses and liverworts have only one size of spore, *i.e.*, they have **isospory**. Few have **anisospory**, or two different spore sizes determined genetically. However, **false anisospory** (non-genetic size differences) exists in several genera. Mogensen (1978b) used acetocarmine stain to demonstrate that false anisospory in *Fissidens dubius* (Figure 87), *Macromitrium incurvum*, and *Rhizomnium magnifolium* (Figure 88) was due to death of spores; only live ones stain red. In this case, some spores may abort at some point during development, rendering them smaller than those spores that have continued to develop. These arrested spores seem unable to germinate. However, in other cases, there appears to be arrested development of some spores, perhaps due to crowding, that permits other spores to continue their development in the limited space inside the capsule. These aborted spores may or may not be able to germinate, apparently depending on their ensuing conditions. This relationship is much like that of baby birds. The larger (often older) babies get all the food, sometimes leaving the smaller ones to starve, rendering them small or dead. It does not appear that any particular spore has a genetic predisposition to develop or to abort, so the two sizes diverge randomly and there can be multiple sizes due to more than one event of arrested or aborted development.

Figure 88. *Rhizomnium magnifolium*, a species in which some spores abort, creating large and small spores. Photo by Michael Lüth, with permission.

Most reported cases of anisospory seem to be in mosses, not liverworts. However, Pant and Singh (1989) reported the possibility in the liverworts *Targionia* (Figure 89-Figure 90) and *Cyathodium* (Figure 91). They found a few cases of abnormally shaped spores of unequal size in several species of these two genera. It is more likely, however, that these were again cases of false anisospory due to spore abortion.

Fontinalis (Figure 93) has false anisospory. At the completion of sporogenesis, tetrads frequently have 1, 2, or occasionally 3 collapsed spores (Figure 92; Glime & Knoop 1986). At any subsequent stage of development of the capsule, one can find two sizes of spores in the same capsule (Figure 93). In early stages, these can both be brown, and only the larger spore becomes swollen and green when cultured on nutrient agar. At later stages, both large and small spores can be green. Large green spores become distended after five days of culturing, whereas small green ones do not. It appears that the smaller ones never germinate, but they do swell in response to the culture medium. These might have insufficient food reserves to succeed.

Figure 92. SEM of spore tetrad of *Fontinalis squamosa* showing one normal and at least two aborted spores (arrows) in the middle tetrad. The remaining visible spore is larger than nearby spores. Photo by Janice Glime.

Figure 93. Normal (left) and aborted (right) spores of *Fontinalis squamosa*. Photo by Janice Glime.

In the moss *Bryowijkia ambigua* (Figure 94), DeLuna (1990) found that anisospory is really a case of aborted small spores and large, multicellular spores. He found that in a tetrad, two spores abort and two remain viable, dividing to become multicellular.

These examples demonstrate the inequality of the spores, but do not provide any genetic clues. The randomness with which collapsed spores of *Fontinalis* (Figure 92-Figure 93) occur in the tetrads precludes sex linkage. Furthermore, in a conversation with Gert Mogensen, I was convinced that I could not rule out the continual death of spores, so that there is always a mixture

of healthy spores and smaller dead ones. This explanation is further supported by the absence or reduction of chlorophyll fluorescence in the smaller spores, even when they are still green (Figure 24).

Figure 94. *Bryowijkia ambigua*, a species that has anisospory due to aborted smaller spores. Photo by Li Zhang, with permission.

By using acetocarmine to stain the nucleus, Mogensen (1978a) has demonstrated false anisospory from spore mortality in *Cinclidium* (Figure 95). In that genus, mortality predominates in the stationary spore stage, with little occurring later, contrasting with *Fontinalis squamosa* (Figure 24, Figure 92), where it occurs at all phases. If Mogensen's model applies, a physiological failure can result from a pair of lethal genes on separate chromosomes, one of which is a sex chromosome. If this results in failure of a developmental process, then we should expect death of the spores to occur at one developmental stage, as Mogensen observed in *Cinclidium*. Valanne (1966) observed that some spores fail to use their reserves in the dark, even with added GA, IAA, or kinetin, and therefore require light to provide the energy to move to the next life cycle stage, suggesting a potential mechanism for failure.

Figure 95. *Cinclidium arcticum* with capsules, a genus in which death of the spores occurs at one developmental stage. Photo by Michael Lüth, with permission.

In *Fontinalis*, lethality does not seem to be so simple, as it apparently can occur at several spore stages rather than

one. I observed about equal numbers of two spore types in the capsules of *Fontinalis squamosa* (Figure 92-Figure 93) at three different stages in spore development. If the early smaller spores were dead, then a new set of dead ones appeared when spores were larger. Without obtaining counts of spores at each of these stages, we cannot eliminate the possibility that two sets of truly anisporous spores were developing in consort, with no spore death, and that perhaps the two sizes had different germination requirements.

If we assume that spores are dying, one advantage for post-meiotic death would be to reduce competition for resources such as moisture, space, and sugar reserves within the capsule. Furthermore, 50% retarded development could provide a dispersal advantage. Small spores, if still viable, would be adapted for long-distance dispersal, larger ones for germinating close to home. This strategy of functional heterospory is known for the epiphytic moss *Leptodontium viticulosoides* (Figure 96) in the Andes (Kürschner & Parolly 1998).

Figure 96. *Leptodontium viticulosoides*, a species with functional heterospory due to delayed development of some spores. Photo by Claudio Delgadillo Moya, with permission.

If the theory of retarded development is correct, why is non-sex-linked (false) **anisospory** unique to bryophytes? In other groups of plants, **heterospory** is associated with sex, with the female being larger. In bryophytes this is usually not the case, with large females and dwarf males resulting from anisospory known only in *Macromitrium* (Figure 97; Ramsay 1979). In flowering plants, retarded development of the seed can permit some seeds to germinate in the fall and others to wait until spring, as in *Melampyrum*. But in that case, it is a result of seed production over an extended period of time, causing different degrees of maturity at fall germination time.

In other groups of plants, heterospory usually occurs in those organisms having endosporous development of the female gametophyte. There is an advantage for the female to be large and provide food for the developing embryo, and it is also an advantage for the male to be small for dispersal (e.g. *Marsilea*, *Selaginella*, seed plants). These are strong selection pressures that would favor sex-linked heterospory in endosporous organisms. In mosses,

endosporic development does not occur, although a few taxa do increase to about 4 cells before germination. Hence, this sex-linked advantage is lacking. On the contrary, there is an advantage for heterospory to occur within both sexes to provide for both long distance dispersal of some of the smaller spores and immediate fitness of large spores, in both sexes. Van Zanten and Pocs (1981) feel that green spores are adapted for immediate fitness and short dispersal only, and non-green spores are adapted for long range dispersal. However in *Macromitrium* (Figure 97), where dwarf males must sit on females (Ramsay 1979), one might argue for an advantage to short distance dispersal of the annual male so that the perennial female has a supply of sperm each year.

Figure 97. *Macromitrium* sp., a genus with true anisospory. Photo by Janice Glime.

However, *Fontinalis* (Figure 92-Figure 93) does not have dwarf males. Is it possible that long-range dispersal might occur in the immature brown spores, with germination being a slow process in a suitable habitat, and immaturity delaying germination, allowing an even greater chance for distance dispersal? Certainly their small size would permit them to have wind dispersal, and their roughened surface might serve as protection in the atmosphere.

This leaves us with a developmental question. What determines that non-sex-linked spores in a capsule will be of two sizes? Genetic differences can exist to program different developmental rates. Environmental differences within the capsule could alter the rate of development. If a genetic difference exists, it must separate at meiosis. In this case, we would predict equal numbers of large and small (or fast and slow) spores in all capsules only if the controlling gene is on a sex chromosome. In fact, however, we see varying percentages: 0-14% abortion in *Pleurozium schreberi* (Longton & Greene 1979); 49-61% physiological anisospory in *Ceratodon purpureus* (Figure 112) (Valanne 1966); 11-50% in *Cinclidium* (Figure 95) (Mogensen 1978a). If the trait is genetic, either it is absent in both gametes, present in only one, or present in both. Following meiosis, three combinations could occur: all small, half small - half large, all large. This pattern is not evident, but Mogensen (1981) has suggested this may be due to the counting technique. On the other hand, if the trait is coupled with differential viability, some capsules of the species should exist with only one kind of spore. This is not the case for *Fontinalis squamosa* (Figure 92-Figure 93); however, differential viability might not be 100% effective. If we can demonstrate that both types of spores

germinate, we have proved that Mogensen's explanation for *Cinclidium* does not apply to this case.

Whereas Mogensen used acetocarmine, a vital stain, to demonstrate viable DNA in *Cinclidium* (Figure 95), we used germination to demonstrate that at least some small spores in *Fontinalis* (Figure 92-Figure 93) could germinate. We have not tested both species by the same method, and we do not have evidence that viable DNA in the spore means it is capable of germination. If the spore lacks sufficient stored energy, it still is unlikely to be able to germinate and reach the distention or protonema stage in nature.

The second developmental possibility, internal environmental differences, could result from unequal nutrition or moisture within the capsule. This can easily account for differences in percentages between capsules, as different plants and different positions within the capsule could have different abilities to provide energy. In fact, differentiation could be related to the position of the cells at the time of meiosis. This is supported with the suggestion that the columella serves as a water reservoir, and it could also serve as a nutrient source.

Longton and Greene (1979) found a bisporic composition of spores in *Pleurozium schreberi* (Figure 98), similar to the *Fontinalis squamosa* (Figure 92-Figure 93) condition. Spores were of two types: green and papillose, or small, brown, and hyaline. Viability of large, green spores was 90-100%, whereas total spore abortion was commonly 0-40%. No "aborted" spores germinated. The observations on *Fontinalis squamosa* can likewise be compared with those of Paolillo and Kass (1973) for *Polytrichum* (Figure 8). In the two species they studied, they could obtain no germination from "immature" spores. Perhaps they did not wait long enough, or the conditions in the culture did not permit ripening of the *Polytrichum* spores, but the spores may have been dead. Some immature spores germinated on agar with sucrose, indicating the importance of nutrition and confirming that not all the small spores were dead, but rather that they lacked sufficient energy.

Fischer (1911) found that non-green fern spores took 4-210 days to germinate. *Fontinalis squamosa* (Figure 24) required only five days for ripe spores to germinate in culture, but 18 days for unripened spores, and during that same period spores in capsules at 10°C in the dark also ripened (Glime & Knoop 1986). This observation on *F. squamosa* (Figure 92-Figure 93) suggests that light is not necessary for maturation of spores in the capsule, and that food reserves of the sporophyte or gametophyte suffice for ripening. Those spores cultured in the dark on agar, on the other hand, did not become green and swollen during this time. This indicates these spores are dependent on having either light or a parent plant to provide energy during ripening.

Based on these responses, it appears that maturation of *F. squamosa* (Figure 24) spores is dependent on a sugar source. The obvious experiment is to culture immature spores in the dark on agar with sucrose or glucose. However, Paolillo and Kass (1973) used a 2% sucrose solution with *Polytrichum* spp. (Figure 8), but spores that lacked fluorescence (suggesting no active chlorophyll) did not germinate in 14 days of culture at 11,800 lux, 28°C. Possibly the light was too high for maturation, or the

temperature too high, but one would expect at least a small percentage to germinate. Spores kept in the capsule for seven days did germinate. This suggests that the mechanism in *Polytrichum* (Figure 8) might require more than sugar, or that development outside the capsule was much slower than in the capsule.

Figure 98. Branches of moss *Pleurozium schreberi* showing the red stem that distinguishes it. Photo by Michael Lüth, with permission.

Three spore size conditions exist among bryophytes. **Isospory** is the typical condition in which all spores are the same size. **Anisospory** exists in only a few taxa in which there are genetically determined size differences among spores. In some species of *Macromitrium* the small spore develops into a **dwarf male**. The remaining species with two spore sizes appear to be cases of **false anisospory** in which some spores abort or mature more slowly, most likely with different causes in different species, some resulting from spore death and some developing more slowly from insufficient nutrition or water. Either of these conditions could be caused environmentally or genetically. If small spores are simply less developed but viable, the two sizes could provide the bryophyte with a bet-hedging strategy in which large spores are ready to germinate and most likely fall close to their parents. Small spores, on the other hand, could require more time for maturity, perhaps outside the capsule, and would be small enough to travel greater distances.

Tradeoffs

As already mentioned, having large spores insures a greater success at germination, but decreases the range of dispersal. Large spores also result in a smaller number of spores, both between species and within a species. But another tradeoff exists that may be more costly. A smaller number or absence of asexual propagules coincides with having large spores in Great Britain (Söderström & During 2005). This may be especially important for many annual shuttle species whose life cycle is too short to accomplish production of both.

Wiklund and Rydin (2004) suggested that spores may have a tradeoff between moisture and suitable pH. They interpreted the interaction between pH and moisture to indicate that spores can germinate at suboptimal pH when abundant water is available, and vice versa. The wood-inhabiting *Buxbaumia viridis* (Figure 99) germinated

better than did the epiphytic *Neckera pennata* (Figure 100-Figure 101) at low pH. *Neckera pennata*, on the other hand, had earlier spore germination in conditions of low water potential and spores survived longer in a dry state. The researchers considered this represented a trade-off between the ability to colonize substrates with low moisture-holding capacity and low pH, favoring *Buxbaumia viridis*, vs the positive effect that high pH has on germination by permitting it to exploit short, moist periods, favoring *Neckera pennata*.

Germination Success

Most of what we know about success of germination is based on laboratory results. Field success is likely to be much lower due to decay, herbivory, and inappropriate location. In a study by Hassel and Söderström (1999), it would appear that most spores might be successful if the appropriate conditions are found. They grew spores from *Pogonatum dentatum* (Figure 102) on Petri plates and had 96.6% germination after 21 days. However, when they sowed the spores from a half, one, and two capsules in 10x10 cm plots on a newly built forest road in Sweden, only 11, 10, and 12 shoots per block developed, respectively, after one year. However, more appeared the second year, resulting in 17, 20, and 22 shoots. These late appearances could have come from protonemata already established the first year rather than from new germinations. In any case, the success rate from the estimated 712,000 spores per capsule is quite low!

Figure 102. *Pogonatum dentatum* with capsules, a species in which not all spores germinate the first year. Photo by Matt Goff <www.sitkanature.org>, with permission.

Germination Time

Germination times vary with type of propagule, size, age, and available water. And light seems to be required for most spores to germinate, although some germinate in the low light of the capsule. *Aloina* (Figure 103-Figure 104) and *Bryum* (Figure 28, Figure 76) spores germinate in 7-10 days (Llo Stark, pers. comm. 3 February 2015). On the other hand, propagula can germinate in 2-4 days in *Bryum* and *Syntrichia* (Figure 49). Germination of *Pogonatum dentatum* (Figure 102) spores occurred after 21 days (Hassel & Söderström 1999). Bhatla (1994) states that *Funaria hygrometrica* (Figure 66-Figure 67) spores germinate in 48 hours, a time period known for a number of mosses, but Krupa (1964) found that some (1%) germinate in as little as 15 hours in continuous light. The epiphytic *Lindbergia brachyptera* (Figure 105) spores germinate in 3 days, with 95% germination in 8 days (Zhao *et al.* 2004). *Brachythecium velutinum* germinated in 13-39 days from fresh material (Herguido & Ron 1990).

Figure 105. *Lindbergia brachyptera* with capsules, a species whose spores germinate in 3 days. Photo by Martin Hutten, with permission.

Maciel da Silva *et al.* (2010) found that nutrients affect the time required for germination in *Bryum argenteum* (Figure 76). In distilled water, the spores required three days to germinate, whereas when nutrients were added they germinated in two days. Following germination, nutrients were needed for protonema growth to occur.

Heald (1898; Meyer 1948) established the need for light for germination in *Funaria hygrometrica* (Figure 66-Figure 67), *Brachythecium rutabulum* (Figure 106), *Bryum algovicum* (Figure 107-Figure 108), and *Plagiomnium cuspidatum* (Figure 109). These species all germinated in three days in the light, but had not germinated after one month in darkness.

In summary, germination time depends on the species and the germination conditions.

Spore Resiliency and Longevity

The most remarkable physiological observations I have made are on the capabilities of the spores themselves. I have observed *Funaria hygrometrica* (Figure 66-Figure 67) growing from spores that remained in a plate that had been autoclaved at 120°C, +1 G for 20 minutes. A similar resiliency is demonstrated by the retention of the green color of *Fontinalis squamosa* (Figure 92-Figure 93) spores after critical point drying for SEM observation. Becquerel (1932) even reported that moss spores could survive to near absolute zero when dry in a vacuum tube.

Spores of widespread taxa such as *Funaria hygrometrica* (Figure 66-Figure 67) are able to survive for more than a year under more natural conditions. During (1986) has found *Funaria* gametophytes growing from soil samples that had been stored for two years before sowing them in the greenhouse. However, those sown in the field did not germinate. Kessler (1914) reported germination after four years and Lesage (1918) reported germination after seven years. However, Janzen (1909) was unsuccessful at germinating them after eight and twenty years.

Meyer (1941) collected spores of *Physcomitrium pyriforme* (as *P. turbinatum*; Figure 111) from seven herbaria and attempted to germinate them. Only those collected in the current and previous year germinated. In the same study, spores of *Funaria hygrometrica* (Figure 23) germinated for the most recent eight years.

More strikingly, Malta (1921) germinated spores of *Grimmia pulvinata* (Figure 110) from specimens that had resided in a herbarium for 70 years, but then he retracted this claim (Malta 1922) when he was unable to repeat the success, assuming that the specimen had been contaminated with fresh spores. In his study of 200 species (Malta 1922), those with the greatest longevity were *Funaria hygrometrica* (13 years; Figure 66-Figure 67) and *Ceratodon purpureus* (16 years; Figure 112). Mogensen (1983) reports that spores can survive from only an hour to

decades. But do we have any clear evidence that bryophyte spores are viable for lengthy periods similar to those of lotus seeds, reputedly of 1000 years? Although Schimper (1848) reported spore viability for fifty years, Wettstein (1925) felt this claim required re-examination. The experience of Malta (1922) supports this caution. When we examine bryophyte specimens, it is not unusual to be looking at another herbarium specimen to verify a new collection. While we are careful not to mix the specimens, spores can easily escape and join the nearby open packets. Such contamination could lead to a misrepresentation of the viability. And herbarium conditions do not represent those found in nature. Quite to the contrary, the dry conditions of the spores may permit them to go into a suspended animation state (Lipman 1936) in which respiration is all but stopped.

Figure 112. *Ceratodon purpureus*, with its typically prolific capsules. Photo by Michael Lüth, with permission.

Van Zanten (1976, 1978a, b) has demonstrated the long viability periods of various spores, but even more remarkable is the resiliency of the spores to adverse conditions. Van Zanten (1978a, b) found that even though spores of many species could survive 2-7 months of desiccation, these species did not occur on neighboring land masses that could easily be reached in that time. In his experiments UV radiation was definitely deleterious. Perhaps long exposures to high light intensities and longer day lengths at low temperatures in the atmosphere could result in spore death during dispersal.

Even the aquatic habitat can serve as a sporebank, although we do not have many indications of the longevity. *Riella americana* spores (Figure 113) from dried mud germinated after 13 years of storage (Studhalter (1931). In a Delaware River freshwater tidal wetland, Leck and Simpson (1987) found that the greatest densities of spores occurred in the upper 2 cm, and that *Bryum* (Figure 28, Figure 76) species were the most common bryophytes, perhaps due to prolific capsule production. Spores of mosses (and ferns) from these muds were much slower to germinate than seeds.

Figure 113. *Riella americana* showing spores and decaying thallus. Photo by Jan-Peter Frahm, with permission.

In fact, in flood plains of the Murray River valley of Australia, borders of cypress swamps in Florida, and low areas of southern Illinois, and most likely numerous other places, taxa such as *Riccia* (Figure 114-Figure 115) typically appear and survive in these periodically disturbed habitats. Spore longevity in this genus, such as that of *Riccia albovestita* reported by Perold (1990) to germinate from six-year-old spores, could favor rapid colonization on such disturbed sites.

Figure 114. *Riccia cavernosa* on mud. Photo by Michael Lüth, with permission.

Figure 115. SEM of *Riccia cavernosa* spore SEM. Photo by William T. Doyle, with permission.

Even in wet peatlands, *Sphagnum* spores persist and germinate after several years. Sundberg and Rydin (2000) found that while viability decreased, spores buried at various depths in peat still germinated after three years. Oddly, the light-colored spores of *Sphagnum balticum* (Figure 116) and *S. tenellum* (Figure 117) maintained a higher viability than did the dark-colored spores of *S. fuscum* (Figure 118) and *S. lindbergii* (Figure 119). Surprisingly, spores that were under wet aerobic conditions survived better than did spores under wet anaerobic conditions, which died in 2-3 years. Another anomaly is that the small spores from small capsules of *S. balticum* and *S. tenellum* survived better than did the spores from medium and large capsules of the same species. Refrigerated spores maintained 13-15% viability for 13 years. Based on experiments, they estimated that *Sphagnum* spores can maintain a half-life in sporebanks for 1-20 years. Sundberg and Rydin attributed the widespread occurrence of *Sphagnum* in northern climates to the long viability of their spores in sporebanks and the ability for the spores to germinate whenever favorable conditions become available.

Figure 117. *Sphagnum tenellum* with capsules. Photo by Dick Haaksma, with permission.

Figure 118. *Sphagnum fuscum* with capsules, a species with dark-colored spores. Photo by Dale Vitt, with permission.

But wet habitats are not favorable locations for all spores. Dalen and Söderström (1999) found that survival of spores from five species of mosses was much better when dry than in water. The highest survival rate was for *Schistidium rivulare* (Figure 120), perhaps accounting for its common occurrence on emergent rocks in streams. Success was lower in *Ceratodon purpureus* (Figure 112), *Dicranoweisia crispula* (Figure 70), *Oligotrichum hercynicum* (Figure 121), and *Racomitrium aciculare* (Figure 122). Nevertheless, survival of some spores for up to six months meant that submerged spore banks and water

transport cannot be ruled out. See further discussion of spore longevity in the chapter on dispersal.

Bryophyte spores are known to survive dormant in mud for up to 13 years, but reports of up to 23 years exist for herbarium specimens. Herbarium specimens can become contaminated with more recent spores; field spores are subject to damage by UV, earthworms, decay, and loss of energy, whereas herbarium specimens are protected from all those factors. Nevertheless, some dormant spores from the sporebank permit bryophytes to colonize newly disturbed sites.

Adaptations to Moisture Extremes

Most spores are adapted to travelling in a dry atmosphere that permits them to be wafted vertically considerable distances. Although spores could be dispersed on damp, cool, cloudy days, they can become clumped and heavy under these conditions, preventing long-distance dispersal. But when it is time to germinate, spores need water. The thickness of the exine layer of the spore may be an adaptation to desiccation. More water needs to be present for distension of the spores when the exine layer is thicker, and this requirement might be a protection against precocious germination.

Certainly the problems of germination of desert mosses differ considerably from those of aquatic mosses. On the one hand, the spore must delay germination until sufficient water is present to permit not only germination but subsequent development of the protonema. On the other hand, spores that are constantly surrounded by water must time their germination with a season during which they can get established and grow, *i.e.*, not too hot, not imbedded in snow or ice, and not subjected to torrential water flow that carries them off to some less suitable place.

Dry Habitats

Although some protonemata may have the ability to withstand desiccation, this ability is more likely to occur in a mature protonema than in one just emerging from the spore, when cell walls are still thin and pliable to permit elongation. Therefore, it appears that timing of spore germination is critical.

Desert bryophytes can be, compared to non-desert bryophytes, very fertile, at least in Australia. Their spore production there is high and asexual production low (Scott 1982). (See Mishler and Oliver, 1991, for contrary evidence in *Syntrichia ruralis* (Figure 49) in North American deserts). This high rate of fertility, together with their life strategy (**annual shuttle species**), is an adaptation to the **xeric** (dry) environment. Salt-tolerant, or **halophytic**, species share the same characters with desert bryophytes and are often very productive, *e.g.* *Schistidium maritimum* (Figure 123), *Hennediella heimii* (Figure 124), *Ulota phyllantha* (Figure 125). Some species form polymorphic spores, so that not all spores germinate at once and a false start with too little water will not use up all the spores (Scott 1982), a phenomenon discussed above for some non-desert taxa.

Figure 123. *Schistidium maritimum* with capsules. Photo by David T. Holyoak, with permission.

Figure 124. *Hennediella heimii* with capsules. Photo by David T. Holyoak, with permission.

Figure 125. *Ulota phyllantha* with capsules. Photo by Michael Lüth, with permission.

An interesting adaptation to desiccation is formation of **multicellular spores**. Parihar (1970) gives a complete list of species with multicellular spores. In hepatics these are mainly thallose liverworts and in mosses the species belong to closely related families: Dicnemonaceae, Calymperaceae, and Pottiaceae, all from relatively dry habitats. Mogensen (1981) interprets multicellular spores as an adaptation to desiccation and, at least in mosses, we see that the species that show this characteristic are relatively **xerophytic** (adapted to dry habitats).

Multicellular spores are possible when the **glyoxysomes** [organelle in plant or microorganism cell, containing catalase, where acetate and fatty acids can be used as sole carbon source (glyoxylate cycle)] are not blocked and material for the cell wall can be provided (Neidhart 1979; Mogensen 1981). This is possible through the **glyoxylate cycle** that provides sugars as a source for the carbon skeletons and energy for the synthesis of new cell walls. In unicellular spores the glyoxysomes are blocked prior to germination (Neidhart 1979). This seems to parallel the seeds that are adapted to dry habitats and are rich in fatty acids, using the glyoxylate cycle to germinate.

The environmental signals that cause spores to divide and that prevent germination are not known. From higher plants we know that chilling (5°C for 6 hours) lowers the **isocitratase** activity. Isocitratase is an enzyme of the glyoxylate cycle and its activity is depressed by an exogenous source of succinic acid (Noggle & Fites 1964). Succinate is a product in the biochemical pathway from fatty acids to carbohydrates. Perhaps the low temperature causes an accumulation of succinate, thus halting germination. A careful study of timing of multicellular development in moss spores and temperature might be an interesting approach to finding mechanisms of control of germination.

Precocious Germination

Precocious germination, like a precocious child, reaches a developmental stager earlier than usual. In the case of germination, the spores germinate within the capsule. This is not a general occurrence among bryophytes.

In *Brachymenium leptophyllum* (Figure 127) in South Arabia, spores germinate within the capsule (Kürschner

2004). In this habitat, it permits new plants to establish rapidly near the mother plant, decreasing their risk of extinction in long-range dispersal.

Dendroceros (Figure 126) is a tropical hornwort that differs from other hornworts by growing on tree bark and leaves (Schuette & Renzaglia 2010). It produces green multicellular spores which begin as unicellular **tetrads** (groups of four) following meiosis. These spores expand to 60-75 μ in diameter. These fill the available space around them, resulting in many different shapes and sizes of spores within the capsule. When the spore divides, the resulting cells develop a single large, star-shaped chloroplast with a **pyrenoid** (organelle that facilitates starch formation by concentrating CO₂) in each cell. Individual cells become smaller during this division process. Cell content increases, particularly the protein storage bodies in vacuoles. As in *Brachymenium leptophyllum* (Figure 127), this multicellular condition appears to be an adaptation to drying. *Dendroceros* is the only desiccation-tolerant hornwort and this same adaptation is also present in a number of other epiphytes among the mosses and leafy liverworts (e.g. **Porellaceae**, Figure 128).

Figure 126. *Dendroceros crispus* with sporophytes. Photo by Jan-Peter Frahm, with permission.

Desert mosses have several adaptations within their spores to increase their chances of success. Those in the Mojave Desert contrast sharply with those in Australian deserts, with the latter producing prolific sporophytes. Among these, one strategy is to have a delayed germination in which not all spores germinate at one time, thus providing **multiple chances** to have sufficient water following germination. There seems to be a good correlation between those spores that succeed in xeric conditions and the **absence of an inhibitor** of the **glyoxysomes**. When glyoxysomes are free to operate, they are able to provide a **carbon source** for building **cell walls** through the breakdown of **fatty acids**. Others succeed by having **precocious** germination.

Aquatic

In submerged aquatic mosses such as *Fontinalis* (Figure 131), the opposite problem exists. Special adaptations must be present to prevent germination within a continuously wet capsule. One can suppose that the dark-colored capsule might have a high concentration of phenolic compounds that could serve as inhibitors (Figure 129). On the other hand, just by being in a dark-colored capsule, spores may fail to germinate due to lack of light. Furthermore, the glossy, thick capsule wall might effectively prevent water from entering the capsule. However, spores can become swollen and green within the capsule (Glime, pers. obs.; Figure 130). Since these swollen green spores fail to show distension, an inhibitory factor might be implicated. On the other hand, as already discussed, light is most likely necessary for distension, and the level inside the capsule may be too low.

Figure 129. Dark mature capsule of *Fontinalis squamosa*. Photo by Janice Glime.

Figure 130. Longitudinal section through nearly mature capsule of *Fontinalis squamosa* showing green spores and dark capsule wall. Photo by Janice Glime.

Elssmann (1923-1925) has made the interesting observation that at least several species of aquatic bryophytes fail to have operculum dehiscence: *Platyhypnidium riparioides* (Figure 78), *Fissidens fontanus*, (Figure 132), and *Fontinalis antipyretica* (Figure 133), as I have in *F. novae-angliae* (Figure 134) and *F. dalecarlica* (Figure 131). In most mosses, the annulus forms a circle of cells delineating the separation between operculum and capsule. These cells are often mucilaginous. According to Elssmann, there are small "rifts" in the cuticle due to stresses as the capsule dries, and these provide entry regions where moisture can reach the mucilaginous cells of the annulus. This of course causes the annulus cells to swell and can henceforth separate the operculum from its capsule. For such a process to occur, the capsule must experience drying to create the rifts and permit entry of moisture that swells the annulus. Dihm (in Elssmann 1923-1925) also believed the annulus was important in this context, and indicated "that the ring attains a lower degree of development and mechanical effectiveness in mosses growing on moist earth." Elssmann points out that Loeske likewise referred to a "retrogressive" annulus in *Fontinalis* (Figure 129-Figure 135) and *Fissidens fontanus*. Elssmann sectioned the capsule and determined that annulus cells of *Fontinalis antipyretica* were very small and seemed to have no mucilage at all (or perhaps in a very dilute form). In *Fontinalis*, it appears that abrasion may be a more important factor in exposing the inside of the capsule, and hence the spores.

Figure 131. *Fontinalis dalecarlica* capsules, a species which often fails to dehisce its operculum. Photo by Janice Glime.

Once the spores are liberated into the aquatic environment, they face the problem of germinating at the right time. Unless they are under ice and snow, we can assume they have both water and light. Some amphibious mosses appear to solve this problem by producing their capsules only when they are above water. But this requires "planning" – coordinated timing of capsule maturation and spore dispersal. What do they use as signals?

Figure 132. *Fissidens fontanus*, a species in which capsules do not open. Photo by Michael Lüth, with permission.

Figure 133. *Fontinalis antipyretica* with capsules, a species with very small annulus cells that do not dehisce. Photo courtesy of Rienk-Jan Bijlsma (per Joop Kortselius).

Temperature differences in streams and lakes are moderate compared to those on land, and therefore we might hypothesize that temperature has little influence on time of germination. But in *Fontinalis squamosa* (Figure 135), temperature does seem to play a role. At any given time, there are usually two sizes of spores within these capsules: small brown ones, presumably less mature, and larger green ones. It took 18 days before any of the brown *F. squamosa* (Figure 24) spores germinated, with many more germinating at 20°C than at 14°C (Glime & Knoop 1986).

Figure 134. *Fontinalis novae-angliae* with capsules, a species that seems to fail in operculum dehiscence. Photo by Janice Glime.

Glime and Knoop (1986) reasoned that *Fontinalis squamosa* (Figure 24) is able to take advantage of a long period of spore dispersal, but with different behaviors on the part of the two spore sizes. Since capsules seem to depend on abrasion for dispersal of spores, this is likely to be a somewhat unpredictable event, most likely occurring among the capsules over an extended period of time. Since the greatest abrasion will occur with spring runoff, the cold temperature of the water during runoff could prevent germination, or at least protonema formation, and once warmer temperatures arrived in the spring, the moss could be assured of having continued warm water and no ice to block the light. Once the ice is gone, the temperatures warm rapidly, providing conditions more favorable to the protonemata. But it would seem that germination at 20°C would in most cases be detrimental to *Fontinalis* because prolonged exposure of the gametophore to that temperature causes growth to cease in most of its species (Fornwall & Glime 1982, Glime 1982, 1987a, b), and danger of desiccation is imminent due to low stream and lake water levels. Perhaps this higher temperature permits the protonema to become well established over a sizeable area before it produces its temperature-sensitive gametophores, hence permitting development of numerous gametophores that afford each other protection from the drag effect of running water by "safety in numbers."

Figure 135. The brook moss, *Fontinalis squamosa*. Photo by Michael Lüth, with permission.

Summary

Spores are protected by an inner intine, outer exine, and plates most likely of **sporopollenin**. **Perine** may be deposited by the sporophyte from disintegrating **columella** tissue and the sporocyte wall. Germination of spores begins with **swelling** that results from water intake, followed by **distension** that requires light, resulting in **rupture** of the cell wall and formation of the **germ tube**.

Germination and production of the germ tube require energy that may either be stored in the spore or result from immediate photosynthesis. Various hormones may be involved either in promoting germination or maintaining dormancy, both in the capsule and after dispersal. Evidence of the role of temperature, pH, and nutrients, especially in field conditions, is scant. However, some spores require **vernalization** (chilling).

Capsule characteristics may contribute to within capsule **dormancy** through such interventions as light blockage, altered wavelength, lack of water, and dormancy hormones.

Other species, such as the lichen *Cladonia*, may inhibit germination of some species, whereas hormones from some fungi might promote it. Humic acid from litter breakdown may also inhibit germination and contribute to the scarcity of bryophytes on the deciduous forest floor.

Some bryophytes have two sizes of spores, but with the exception of *Macromitrium*, these appear to be a case of **false anisospory** resulting from one or more abortion events during spore development within the capsule.

Although germination success in the lab is generally high, success of the same species in the field is extremely low. Spore survival, on the other hand, can be extensive, lasting for up to 20 years in some, and probably longer.

Acknowledgments

Inspiration for this chapter evolved from discussions with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen. Several of the experiments were conducted at the Botanisches Institut, Universität Heidelberg, Germany. L. W. Winchester, Research Engineer, Keweenaw Research Center, Michigan Technological University Houghton, MI, provided information on light quality through the snow pack. I appreciate the many suggestions from a student's perspective by Medora Burke-Scoll and KT McConnell.

CHAPTER 5-3

ECOPHYSIOLOGY OF DEVELOPMENT: PROTONEMATA

Figure 1. Protonema of *Fontinalis squamosa*. **Left:** white light. **Right:** UV light showing chlorophyll fluorescence. Photo by Janice Glime.

The Protonema

The **protonema** is an elongate, thread-like structure that develops from the germinated spore of mosses and some liverworts. In most liverworts it is thalloid.

It was Sironval (1947) who defined two clear stages in protonema development. All mosses have the **chloronema** stage (Figure 2), which is the one that develops first from the germinating spore. The **caulonema** (Figure 2) stage is second and in some mosses it is not distinguishable from the chloronema.

The moss protonema typically branches (Figure 1) and can develop into **chloronema**, **caulonema**, or **rhizoids** (Figure 2), depending on the species, conditions, and developmental stage. The **chloronema** is the first thread formed by the germinating spore and is distinguished by its perpendicular crosswalls, short cells, numerous chloroplasts, colorless cell walls, and irregular branching. The **caulonema**, when present, develops later and is the source of gametophore buds in those species with both types of protonemal segments. It is distinguished by its distal position relative to the spore, longer cells with diagonal cross walls, usually brownish cell walls, and fewer, less evenly distributed, smaller, spindle-shaped chloroplasts. The chloronema, at least in culture, is able to grow vertically as well as horizontally, but the caulonema grows only horizontally (Bhatla 1994).

The protonemal stage is the best-studied part of bryophyte development. Due to its relative ease of culture and one-cell-wide structure, it has been the subject of

numerous physiological studies to elucidate basic physiological mechanisms in plants.

Figure 2. Distinction of chloronema and caulonema on the protonema of *Funaria hygrometrica*. Photo by Janice Glime.

As discussed earlier with life cycles, spores in most true moss (**Bryopsida**) germinate to form filamentous protonemata, whereas **Sphagnopsida** has a thalloid form, **Andreaeopsida** a massive one, and liverwort protonemata may range from filamentous to thalloid (Mishler & DeLuna 1991). In the **Bryopsida**, non-filamentous protonemata occur in the **Schistostegales**, **Tetraphidales**, and some

genera in the **Grimmiales**, **Dicranales**, **Orthotrichales**, **Hypnobryales**, and **Isobryales** (Nishida 1978, Nehira 1983).

Fulford (1956, in Watson 1974) identified 10 protonemal types in the leafy liverworts, but Nehira (1966) and Schuster (1966) warn us that the protonema form is plastic and can be strongly modified by the environment. Nevertheless, Nehira (1966) identified 24 liverwort sporeling types.

The protonema, simple as it is, has a variety of forms. For example, in *Lindbergia brachyptera* (Figure 3), there is no caulonema (Zhao *et al.* 2004). The rhizoids and buds develop from the chloronema. And it takes only three days for the spore to germinate, with 95% of the spores germinated by 8 days.

Figure 3. *Lindbergia brachyptera*, a species that does not develop a caulonema. Photo by Bob Klips, with permission.

But the environment can likewise cause modifications to the protonema. Such characters as cell shape, growth polarity, rate of mitosis, differentiation of chloronema into caulonema, and branching frequency of filamentous protonemata can change in response to changes in response to light quality and intensity, photoperiod, temperature, hydration, pH, hormonal levels, and interaction with microorganisms (Chopra and Kumra 1988; Mishler & DeLuna 1991). Nevertheless, Anderson and Crosby (1965) found that the basic thalloid and massive forms of the Sphagnopsida and Andreaopsida remained unchanged.

Even in mosses such as *Funaria hygrometrica* (Figure 2, Figure 8) with well-developed caulonemata, culture in liquid media can inhibit formation of caulonema, resulting in reduced bud formation – suggesting very wet conditions would be detrimental to development of gametophores in these taxa (Johri & Desai 1973). Furthermore, high cell densities cause failure of caulonema differentiation, suggesting some sort of self-inhibition. This might be another adaptive mechanism that prevents gametophores from competing with each other and that permits the protonema time to revert to chloronema, spread to a wider area, or partially die off before putting forth upright plants.

By contrast, *Tetraphis pellucida* (Figure 6; **Tetraphidopsida**) produces a bladelike structure from the protonema, described as **protonemal flaps** (Figure 4-Figure 5). Gemmae can develop at the base of the flap. The changes from distended spore to protonema growth to gametophore buds can require increasingly more specialized conditions in this and other species. For example, Forman (1964) found that spore germination in *Tetraphis pellucida* (Figure 4-Figure 5) requires a pH of 3.0-7.3 whereas growth of the leafy shoot occurs in the

much narrower pH range of 5.1 to 5.8. This has limiting implications for species that arrive as spores.

Figure 4. Protonemal flaps of the moss *Tetraphis pellucida*. Photo from botany website and University of British Columbia, Canada, with permission.

Figure 6. *Tetraphis pellucida* with gemmae cups, a species that develops protonemal flaps. Photo by Andrew Spink, with permission.

Temperature requirements, on the other hand, are broader for the leafy shoot, but as the humidity drops, the viable temperature range narrows. Furthermore, the change from chloronema to caulonema can be delayed by inappropriate environmental conditions. Bopp (1961) found that the caulonema stage, and thus the bud stage, can be delayed by low temperature, submersion, or low light.

There seems to be controversy over the degree of difference between chloronema and caulonema, with Bopp (1959) contending that they are distinct stages, and Kofler (1958) and others finding no consistent distinction, even in *Funaria hygrometrica* (Figure 2, Figure 7-Figure 8), for which Bopp first made his claim. Several factors appear to lead to these disagreements (Watson 1974). The plasticity of the protonema permits it to respond differently to the varying environmental conditions. The distinction is exhibited more strongly in some species than others, and in some species, apparently no distinction exists. And, Kofler contended that genetic differences are more likely to be expressed in the protonema than in the gametophore or sporophyte because the environment has less time to exert selective pressure on the protonema. Hmmm...

Application of IAA induces the switch from chloronema to caulonema side branches (Johri & Desai

1973; Christianson 2000) and inhibits the further growth and initiation of chloronema branches (Johri & Desai 1973). Application of ABA to chloronema instead results in cell division and the formation of asexual reproductive cells, but not in caulonemata (Christianson 2000). Inadequate calcium causes the chloronema cells to divide unevenly and to form **tmema** (abscission cell that ruptures to release moss gemmae; see below), but not in caulonemata. Cytokinin stimulates the formation of gametophore buds in the caulonema, but not in the chloronema. Perhaps even more surprising, chloronemata exhibit positive phototropism, whereas caulonemata exhibit negative phototropism, much like the differences in response to IAA in stems vs roots of tracheophytes.

But are these applied hormone responses initiated by moss hormone productions? In the well-studied *Physcomitrella patens* (Figure 9-Figure 10), we do know that transition from chloronema to caulonema cells is under control of auxin (Gonneau *et al.* 2001). Since IAA concentrations seem to be under environmental influence, variability and inconsistencies may be explained in the near future as we unravel the cryptochrome/IAA complex of reactions in this moss, and plants in general, using gene knockout techniques.

Figure 10. *Physcomitrella patens* protonema. Photo from Ralf Reski Lab, through Creative Commons.

Bittisnich and Williamson (1989) identified H^+ efflux at the tips of the chloronema (Figure 2) in *Funaria hygrometrica* (Figure 2, Figure 7-Figure 8) and elaborated

the role of acid flux in the extension of the protonema. However, unlike fungal hyphae, pollen tubes, and root hairs, the growth of the moss protonema is slow (Bhatla 1994) and is not confined to the apex. Growth apparently occurs in accordance with the acid growth mechanism, in which H^+ ions, induced by light and IAA, loosen the cell wall. In *Funaria hygrometrica*, acidification of the medium to pH 5.5 increases the extension of the tip cells (Figure 8), whereas buffering to a pH of 6.8 prevents it. Calcium seems necessary for the acquisition of new materials to the wall and the ability to extend the wall.

The development of protonemata has not been widely studied, and those studies have concentrated on the changes in morphology resulting from cytoskeletal aspects of tip growth and production of asexual propagules (Pressel *et al.* 2008). Pressel *et al.* set out to remedy the situation by examining the differentiation of the caulonemata and rhizoids. This comprehensive study included more than 200 moss species! They found that the differentiation of caulonemata and rhizoids results in fully differentiated cells that have a remarkable resemblance to the moss food-conducting cells. In both rhizoids and caulonemata, the cytology is dependent on having an intact microtubule cytoskeleton. The vacuole disappears during the differentiation process, a phenomenon that Pressel *et al.* consider to be related to the solute transport functions of the caulonemata and rhizoids.

Water Relations

We have often assumed that the protonema stage is the most susceptible to desiccation damage. However, this is not always true. During (pers. comm.) found that unsuccessful cultures of xerophytes such as *Grimmia* (Figure 11-Figure 12) produced gametophores only after being put aside and forgotten, *i.e.*, after desiccation. But it is surprising that Glime and Knoop (1986) found that after cultures of the aquatic moss *Fontinalis squamosa* (Figure 1) had dried out, added water caused the protonemata to swell and again become active. This is further supported by observations on protonemata that dried overnight on a microscope slide. When I added water to observe them for fluorescence, they produced vivid red chlorophyll fluorescence and regained their normal shape. It appears that protonemata may have considerable desiccation tolerance.

Further evidence that the protonema is desiccation tolerant can be gleaned from their dispersal period. As seen in the chapter on phenology, dispersal in spring is commonplace. It would seem, therefore, that the protonema must be growing in summer, when desiccation is most likely. The other period of high spore dispersal is fall, again preceding the dry season of winter in many temperate regions. Although we have insufficient evidence to show that the protonemata are present during these two relatively dry seasons, it appears likely that they are in at least some, if not many, species. Figure 13 shows a hydrated protonema in the field.

Seasonal Light/Temperature Changes

It is hard to talk about light without also considering temperature, since brighter light generally means greater exposure and higher temperatures. Higher temperatures and brighter light are also usually coupled with a longer photoperiod. Knowledge of their effects on protonemal growth and development is based on laboratory cultures.

Light, coupled with temperature, seems to play a role in the pattern of development of protonemata in the aquatic

moss *Fontinalis*. *Fontinalis squamosa* (Figure 15) spores germinated throughout the range of 40 to 3000 lux, and cultures exhibited unipolar, bipolar, tripolar, and one tetrapolar germination (Figure 14, Figure 15) (Glime & Knoop 1986). The number of germ tubes was generally consistent within a single plate, despite having bands of spores from three different capsules. At 3°C and 120 lux, germination required four weeks, and only distended spores with a single protrusion were present (Figure 16). At 14°C, 1200 lux, two plates of spores had single threads (Figure 14), one had double threads, and one had short single and double threads. At 20°C, 2100 lux, two plates had only single germ threads that formed weak spirals and two had many spores with two or three germ threads and no spiral growth (Figure 15); branching was much more extensive than at 14°C and 1200 lux. Although effects of temperature cannot be separated from those of light intensity, they mimic environmental conditions as they change from winter to summer. Such environmental controls can prevent spores from germinating or protonemata from developing too early in the season. The high degree of branching at higher light and temperatures could afford more self-protection from desiccation by providing overlapping threads (Figure 17). Bipolar and tripolar germination is also likely to be a response to the greater ability to photosynthesize with more light and provide energy for the developing germ tube.

Light

Light Intensity

High light intensity can promote protonemal growth, as in *Microdus* (Figure 18), *Hymenostylium* (Figure 19), and *Campylopus* (Figure 20) (Mehta 1988). In the ephemeral *Physcomitrella patens* (Figure 9-Figure 10), high light intensities promote branching of the caulonema, thus proliferating the potential bud sites (Cove *et al.* 1978, 1979). By contrast, *Bartramia ithyphylla* (Figure 21) can exhibit branching from the first cell emerging from the spore (Figure 22) (Cove *et al.* 1978, 1979), as can *Brachythecium velutinum* (Figure 23) (Herguido & Ron 1990). *Gymnostomum* sp. *s.l.* (Figure 24) can branch from multiple caulonemal cells (Figure 25) (Cove *et al.* 1978, 1979). These multiple branches can produce multiple buds, forming a colony or cushion of plants (Figure 26) that help each other to maintain moisture. In species like *Atrichum altecristatum* (Figure 27), a large mat of protonemata commonly forms before buds develop, ensuring a colony of plants to protect each other (Figure 28).

Continued high light promotes secondary caulonemata instead of bud formation. Is this adaptive by extending the plant to a darker location? Or is it merely a way of measuring all the available illuminated space for successful gametophores? Sood (1975) also observed an effect of light intensity on the number of germ tubes arising from the spore in *Pogonatum aloides* (Figure 29-Figure 30). At 1000 lux germination was unipolar, increasing at 3000 lux. At 6-8000 lux some spores swelled but failed to germinate. In germinating spores of *Polytrichum commune* (Figure 31) and *P. juniperinum* (Figure 32), there was a lag in synthesis of chlorophyll, being longer in *P. commune* (Karunen 1973). The chlorophyll *a/b* ratio at that time in *P. commune* was 1.4-1.8, thus providing little antenna effect by chlorophyll *b*. The low concentration of chlorophyll in general and the reduced relative amount of light-gathering chlorophyll *b* would force the gametophyte to require food reserves during early development.

High temperatures required for the protonemata can force a species into a narrow geographic range despite the ability of the spores to germinate at cooler temperatures. For example, *Anisothecium molliculum* has an optimum temperature of 25°C, not only for protonemal growth, but also bud formation (Kumra & Chopra 1985), preventing it from living in polar regions.

Although light generally seems to be necessary for spore distension, in some cases the protonema can even grow in the dark. In *Ceratodon purpureus* (Figure 33) darkness first induces an increase of starch grains in the chloroplast (Valanne 1971). This is followed by disappearance of starch and an increase in the number of grana lamellae.

Figure 33. *Ceratodon purpureus* with capsules, a species in which protonemata can grow in the dark despite its typical exposed habitat. Photo by Michael Lüth, with permission.

At least for *Fontinalis squamosa*, higher light intensity and temperatures result in more germ tubes arising from the spore, suggesting that more sugars might be available, both for energy and for creating a high osmotic potential. The increased number of protonematal branches at higher light intensities and temperatures could provide a thicker mat to decrease evaporative losses and to increase self-shading against UV light damage.

Protonemata can form numerous branches, leading to numerous buds. When these buds develop into upright gametophores, the presence of many in close proximity permits them to protect each other from desiccation.

Light Quality

It is clear that light quality affects the growth and development of at least some protonemata. Light quality shift from white light to green and far red, as found in the forest, resulted in reduced protonemal growth in *Pohlia nutans* (Figure 34), with the least growth occurring in green light (Mitra *et al.* 1959). Giles and von Maltzahn (1967) found that red light stimulates mature leaf cells of *Plagiomnium affine* (see Figure 13) to regenerate by protonemata, and they suggested that phytochrome was most likely involved. Although liverworts seem to lack any consistent kind of photoregulation (Hartmann & Weber 1990), mosses respond differently to different wavelengths. Their best chloronema growth seems to be in white light (Bhatla 1994), but we must question whether this is true for all species that grow only under a canopy of green. In *Funaria hygrometrica* (Figure 2), the red range stimulates normal growth, whereas the blue range leads to the development of caulonema-like cells. It is possible that these shifts in light quality response could help to signal the time to develop gametophores as the protonemal mat thickens from extensive growth, changing the light quality of underlying strands.

Figure 34. *Pohlia nutans* with capsules. This widespread species of open habitats has reduced protonema growth in green light as it might experience in a forest. Photo by Štěpán Koval, with permission.

Imaizumi and coworkers (2002) demonstrated that **cryptochromes** are sensitive to blue light in *Physcomitrella patens* (Figure 9-Figure 10). Their reception of blue light permits them to mediate the light response. This moss has two identified cryptochrome genes. Using disruptants of these genes permitted Imaizumi and coworkers to elucidate the method of action of the cryptochromes. Cryptochromes, it turns out, mediate many steps in moss development. These include the induction of side branching of the protonema and induction of the leafy gametophyte. Disrupting cryptochromes caused changes in the auxin responses and revealed that cryptochromes respond to light to repress auxin signals as a means of controlling the development of the bryophyte.

Light quality could also serve to signal that it is time to break dormancy. Both blue and red light will permit maintenance of normal chloroplasts in *Ceratodon purpureus* (Figure 33) protonemata, but blue light results in richer starch, denser stromata (colorless matrix of chloroplast in which packets of chlorophyll are embedded), and more mitochondria, whereas red results in a more effective use of lipids (Valanne 1971). Is there any adaptive value in this? Is the moss able to sense the decreasing cover by snow (Figure 35), as voles do, based on light quality and intensity?

Figure 35. *Atrichum undulatum* in melting snow. How do mosses sense the coming of snowmelt? Photo by Michael Lüth, with permission.

Photoperiod

In *Ceratodon purpureus* (Figure 33), long days stimulate elongation of the protonema, whereas short days result in protonemal branching (Larpent-Gourgaud & Aumaitre 1980). The two systems are antagonists. This relationship suggests that an IAA/cytokinin balance may be the important controlling factor, with long days promoting IAA, probably through phytochrome mediation.

In *Bryum pseudotriquetrum* (Figure 36) a day length of ten or more hours is required for germination and protonema growth (Kinugawa & Nakao 1965, Figure 37). However two minutes of light during a 16-hr dark period is sufficient to remove the inhibitory effect developed during the dark period and will likewise stimulate germination and growth. In other words, it is the length of a continuous dark period that is important. This further supports the

hypothesis of a phytochrome response and is much like the photoperiodic control of flowering.

Figure 36. *Bryum pseudotriquetrum*, a species that requires at least 10 hours of daylight for germination and protonema growth. Photo by David T. Holyoak, with permission.

Figure 37. Effect of photoperiod on spore germination after 5 days (left) and protonema growth after 3 days (right) of *Bryum pseudotriquetrum*. Redrawn from Kinugawa & Nakao (1965).

Hormonal Response

The complexity of these light responses and the implications of involvement by phytochrome is undoubtedly under the control of hormones. In the ephemeral *Physcomitrella patens* (Figure 9-Figure 10), light and hormonal combinations coordinate development (Cove *et al.* 1978, 1979). Bierfreund *et al.* (2003) supported this earlier conclusion by demonstrating that red light retarded the growth of protonemal filaments in *Physcomitrella patens*. **Gametophores** (upright plants), on the other hand, responded by producing an elongated plant with shorter and narrower leaves. Responses of both protonemata and gametophores were even more pronounced when illuminated with far red light.

Cytokinin in the presence of auxin promotes buds (Gorton & Eakin 1957), and high concentrations inhibit caulonemata (Cove *et al.* 1978, 1979). This combination would therefore promote caulonema growth while the caulonemata are sparse, ensuring sufficient plants for a viable population and providing a sufficiently dense protonematal mat to help maintain moisture at the soil surface. When this mat becomes very dense, self-shading could stimulate the production of auxin and cytokinin and shift the development to bud formation. Once these self-shaded protonemata have shifted to bud development, they are likely to communicate this signal to the surface protonemata and induce buds throughout the mat. Figure 38 shows a developmental scheme modified from Cove *et al.* (1979) to include these environmental stimuli.

Figure 38. Effects of auxin and cytokinin on *Physcomitrella patens*. Redrawn from Cove *et al.* (1979).

Bierfreund *et al.* (2003) used *Physcomitrella patens* (Figure 9-Figure 10) to determine the distribution of auxin (IAA) in the protonema. As in higher plants, the highest concentrations were in the dividing and young cells. Concentrations declined from the tip cells back to the basal cells of the protonema, supporting earlier work of Bopp and Atzorn (1992).

Auxin is important in the transition of chloronema to caulonema (Johri & Desai 1973; Figure 38) and the appropriate concentration maintains the caulonema state (Bopp 2000). Although we generally think that endogenous hormones from one plant cannot affect another, in *Funaria hygrometrica* (Figure 39) the minute quantity of 10^{-16} mol IAA/mg fw seems to be responsible for the change from chloronema to caulonema (Bhatla & Dhingra-Babbar 1990). Such a small quantity could surely leak from other members of the same species or from a different species to help coordinate behavior among individuals. In fact, as the protonema matures, the protonema can excrete most of its auxin to its substrate, as shown in *Physcomitrella patens* (Figure 9-Figure 10) (Reutter *et al.* 1998).

Figure 39. Culture of *Funaria hygrometrica* showing distinct colonies resulting most likely from hormonal interaction between clones at the protonemal stage. Each clump is the product of one spore. Photo by Janice Glime.

We already know that uptake of IAA by the protonema occurs; in the lab, uptake of IAA by protonematal cells is both passive and active. The passive component is pH-dependent, with the greatest increase in uptake occurring at pH 4.5-4.7, indicating a dissociation of the IAA molecule ($pK = 4.7$; pK is pH at which equal concentrations of acidic and basic forms of substance are present). The potential for an exogenous developmental regulator has enormous environmental implications not only for development, but for systematics and ecology as well.

Rose *et al.* (1983) used *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39) to show a strong pH dependence for the accumulation of auxins. The uptake of the auxin IAA increases when the pH is lowered from 7.6 to 4. The IAA appears to have influx and efflux carriers that help to determine the rate of this hormone in and out of the protonema. But these carriers seemed to be present only in low light intensities. At high light intensities ($2.0-2.3 \text{ W m}^{-2}$) there was no evidence for them.

Physcomitrella patens (Figure 9-Figure 10) has become a widely used model for plant physiology. It is easy to grow and to standardize the cell culture protocol. Its complete genome is known. These characteristics make it useful to study plant physiological responses. And the protonema is an especially useful tool because it provides an isolated single cell type. ABA causes the subapical cells to form round **brachycytes** (short, thick-walled cells that are drought-tolerant brood cells) or nearly empty **tmema** (abscission cell) (Decker *et al.* 2006). When the cells are subsequently grown free of ABA, the brachycytes serve as propagules and germinate to form new protonema filaments (Schnepf & Reinhard 1997).

These brachycytes also occur in auxin-deficient mutants of *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39) (Schnepf & Reinhard 1997). Experiments in this species likewise confirm that ABA induces their production, and that it is concentration dependent. These brachycytes store lipids instead of starch and have altered chloroplast structure. This suggests that they provide a fallback mechanism to maintain the population if it becomes desiccated, a condition known to increase ABA production in mosses (Hajek & Vicherova 2014). Also, in *Funaria hygrometrica*, application of auxin causes a change in development from the chloronema stage to the caulonema stage (Jayaswal & Johri 1980).

But having the right hormones isn't enough. There must be sufficient energy as well. We have seen that development of the protonema can occur in the dark, and in the early stages that energy is soon exhausted. To this end, the chloronemata are heavily endowed with chloroplasts (Thelander *et al.* 2005). The caulonemata, on the other hand, have more scattered chloroplasts and function to spread the colony by radial growth. The balance between the two protonema types is controlled by light and plant hormones. In *Physcomitrella patens* (Figure 9-Figure 10), caulonema formation is induced by high light, thus providing greater photosynthesis. External glucose also stimulates growth. But under low light conditions, the chloronema stage predominates, with chloronemal branching being stimulated by the low light (or perhaps high light suppresses chloronemal branching).

How widespread are these principles when we look at species outside the *Funariaceae*? In *Hyophila involuta*

(**Pottiaceae**; Figure 40), **nurse protonemata** enhance the growth of other protonemata (Mehta 1990). This is the phenomenon in which substances diffused from an older protonema enhance the growth of the younger, developing protonema. It applies the rule of safety in numbers, in this case helping to protect the protonema and developing buds and gametophytes from desiccation.

Figure 40. *Hyophila involuta*, a species that benefits from **nurse protonemata**. Photo by Bob Klips, with permission.

Tropisms

Tropisms, the bending, resulting from unequal growth on two sides of a stem, of a plant in response to a stimulus, are adaptive in orienting the plant into its most beneficial position. When the spore germinates, the developing protonema orients to gain the most light. When protonemal buds develop, they orient to obtain light. For the leafy gametophyte, this could mean extending away from gravity, as seen in acrocarpous mosses, or extending outward across the ground, as seen in pleurocarpous mosses. Both strategies of orientation have their advantages and disadvantages in obtaining sufficient light and consequent energy, and both are under control of hormones.

Phototropism

In bryophytes, protonemata are **positively phototropic** (bend toward light), whereas rhizoids are **photonegative** (bend away from light) (Heitz 1942). Although Kofler and coworkers investigated the effects of the environment on bryophyte tropisms as early as 1958 (Kofler 1958, 1971; Kofler *et al.* 1963), bryophyte tropisms have remained largely unstudied until recently. However, because of their simple protonemal structure, much of our current understanding of tropisms in plants has been learned from using bryophytes as model systems.

Yet bryophytes have different **phototropic** responses (directional growth in response to light) from those of tracheophytes. Rather than responding to blue light, as do the tracheophytes, most bryophytes seem to respond to red light, using **phytochromes** instead of **cryptochromes** as their sensory pigments (Wada & Kadota 1989; Esch *et al.* 1999). Jaffe and Etzold (1965) demonstrated that even spores (Figure 41) in *Funaria* (Figure 7-Figure 8, Figure 39) respond to red light, resulting in chloronema growth in the opposite direction from that of rhizoids. And even

more intriguing is the ability of bryophytes to store a phototropic stimulus (Hartmann & Weber 1988), further suggesting the use of phytochromes. However, the expected dark reversal does not occur, indicating something else is involved (Christianson 2000). Phototropism will be discussed further under gravitropism because of the interaction of these two forces.

Figure 41. *Funaria hygrometrica* spore germination. Photo by Janice Glime.

Gravitropism

Gravitropisms respond to gravity, just as your spoon does when you drop it. But in plants, gravity has a different effect on different bryophyte plant parts and different life stages. In the protonema, it often is masked by the effects of light. Rhizoids are **positively gravitropic**, hence growing toward the earth, but for some species this is not the right position, so other responses have evolved. For acrocarpous mosses, the stems typically grow upward, as do the sporophytes. But like the rhizoids, stems may not always start in the right position. And likewise, the sporophyte might be pointed perpendicular to a vertical rock or tree trunk. For some species, there is a clear tropism in both gametophyte and sporophyte, for some only the sporophyte responds (Figure 42), and for some, both grow straight out from the vertical substrate (Figure 24), perpendicular to it.

Figure 42. *Oligotrichum hercynicum* showing a strong tropism in the seta but none in the gametophyte on this vertical surface. Photo by Michael Lüth, with permission.

Gravitropism is well documented in moss protonemata (Sack *et al.* 1998). Barlow (1995) suggested that the more evolutionarily advanced species will possess more systems for sensing gravity, arguing that if a system works, it is not likely to be discarded, thus being kept as new ones evolve. These multiple gravity-sensing systems permit gravity to be involved in a wider range of developmental responses. The sensing of gravity involves a membrane system to sense the gravity.

Schwuchow and Sack (1990) reported for the first time an effect of gravity on **microtubule** (essential protein filament of cell structural skeleton; Figure 43) distribution in plants, based on studies in protonemata of *Ceratodon purpureus* (Figure 33). In fact, this moss served as the model organism to demonstrate that microtubules help organelles to maintain their positions within the cell (Schwuchow & Sack 1994). Nevertheless, our understanding of **gravitropism** in protonemata is still in its early stages. We don't even have a very long list yet of mosses with demonstrated protonemal gravitropism, and we seem to know even less about liverworts. Schwuchow *et al.* (2002) have only recently found tropisms in protonemata of *Barbula unguiculata* (Figure 44), *Fissidens adianthoides* (Figure 45), *Fissidens cristatus* (Figure 46), and *Physcomitrium pyriforme* (Figure 47-Figure 48), despite the report of positive phototropism in *Funaria* protonemata in 1942 by Heitz.

Figure 48. *Physcomitrium pyriforme* protonema, a protonema that exhibits tropisms. Photo by Bob Klips, with permission.

The one-cell-thick protonema makes it easy to observe the **amyloplasts** (colorless plastids containing starch, sometimes referred to as statoliths) that respond to gravity. These statoliths are involved in **gravitropism** (directional growth in response to gravity). The ability to knock out or add genes that are easily expressed in the *ln* plants (having only 1 set of chromosomes) has made the necessary manipulation much easier than in tracheophytes. Walker and Sack (1990) observed that **amyloplast sedimentation** occurred in horizontal protonemata of *Ceratodon purpureus* (Figure 33) grown in the dark. Protonemata grew straight up – away from the pull of gravity – at a rate of 20–25 $\mu\text{m h}^{-1}$, reaching an angle of 84° with the substrate by 24 hours. The tip cells exhibited a cluster of non-sedimenting amyloplasts, a zone free of amyloplasts, and a zone with pronounced amyloplast sedimentation. The sedimentation zone occurs only along lateral walls with some degree toward the horizontal and does not occur toward end walls regardless of their position. The beginnings of this gravitational rearrangement are visible within ~15 minutes of change in the direction of the gravitational pull. At this time Walker and Sack (and also Young and Sack 1992) suggested that the amyloplasts might act like the statoliths that help to orient crayfish and other organisms.

Young and Sack (1992) used time lapse photography to gain further understanding of the gravitropic response in *Ceratodon purpureus* (Figure 33). By this method, they observed that a "wrong-way" response occurred first. That is, the protonema initially curved downward in as little as 2 minutes after the protonemata were re-oriented. It required 30–45 minutes for upward curvature to begin. No amyloplast sedimentation occurred before the wrong-way response, but sedimentation seemed necessary for the onset of negative (correct) gravitropism.

But this brings to mind the question of their avoidance of the end walls when those walls are in the position closest to the gravitational pull. In succeeding experiments, Walker and Sack (1991) used centrifugation to displace all the amyloplasts in the apical cell to the end wall. In this position, the amyloplasts acted in the wrong way and the protonema curved downward, likewise in the wrong way. Upward curvature did not occur until sedimentation of amyloplasts occurred toward the lateral wall.

Later Wagner and Sack (1998) reported that the gravitropic response occurs within 1–2 cell divisions in the protonemal tip cells of *Ceratodon purpureus* (Figure 33), which grow upward in the dark (Wagner *et al.* 1997). Five mosses and four other species, representing five orders, support the hypothesis that amyloplast sedimentation probably serves in gravity sensing in moss protonemata. It appears that these amyloplasts tug on the **cytoskeleton** (structural support within cell), pulling down on it, much like trapped insects on a spider web. One theory is that this causes the cytoskeleton to pull on the cell membrane, creating larger holes in the membrane that facilitate the entry of Ca^{++} . This creates a higher concentration of Ca^{++} on the upper side of the cell, possibly causing it to inhibit the IAA on that side of the cell.

When auxin transport inhibitors were applied to *Ceratodon purpureus* (Figure 33), they strongly inhibited the gravitropic curvature of the apex of the protonema, suggesting the role of IAA in the process (Schwuchow *et al.* 2001). Reducing the concentration of inhibitors reduced the inhibition effect. Applications of high levels of IAA (40 μM) had no effect on the gravitropic response of the protonema apex, suggesting the mechanism differs from that in tracheophytes. But perhaps it is only the effective concentrations that differ. We know that roots respond to different levels from stems in tracheophytes, so we have no reason to expect bryophytes to respond to the same levels.

What little we thought we knew about gravitropisms in moss protonemata was further confused when growing protonemata of the moss *Ceratodon purpureus* (Figure 33) took a two-week trip in space on the space shuttle Columbia (Miller & Phillips 2003; Kern *et al.* 2005). On 16 July 2002, plant physiologist Fred Sack carefully opened a Petri dish that had spent the two weeks without gravity and without light. To his surprise, the protonemata had grown in a spiral pattern (Figure 49). This is quite different from the normal tangle of protonemata grown on Earth.

Figure 49. Spiral growth of protonemata of *Ceratodon purpureus* aboard space shuttle Columbia. Photo courtesy of Fred Sack.

According to Fred Sack (Miller & Phillips 2003), "These odd spirals mark the first time in space that a plant

normally oriented by gravity has grown in a non-random pattern." The puzzle begins with the **amyloplasts**. These starch bodies experience sedimentation in gravity and seem to tug on the cell skeleton. However, on the shuttle, with no gravity, this should not happen. Rather, they should float at random within the cell. Instead, they bunched together. This indicates a natural propensity for growing in a spiral that is overridden by the gravity of Earth. Perhaps Seifritz was right – all life does have a twist in it.

Another piece of this gravitropic puzzle is that a high-gradient magnetic field can substitute for gravity, causing curvature of tip cells in *Ceratodon purpureus* (Figure 33) (Kuznetsov *et al.* 1999). Genetically modified protonemata with larger plastids responded more strongly, supporting the hypothesis that plastids are involved in gravity sensing.

The caulonemata in *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39) are negatively gravitropic (Schwuchow *et al.* 1995). So in the dark, they grow upward. Such behavior can increase the opportunity to grow toward more light before there is light for them to sense. As in *Ceratodon purpureus* (Figure 33) and *Physcomitrella patens* (Figure 9-Figure 10), this upward curvature is temporarily reversed when the cell reaches its final stages of division. Tropism behavior in all three species indicates that subapical amyloplast sedimentation may be a common phenomenon in the protonemata of mosses.

Using *Physcomitrella* (Figure 9-Figure 10), Schwuchow *et al.* (1995) provided details of the gravitropic response within the cell. In the dark, a thin strip lacking amyloplasts was visible in the cytoplasm on the upper side of the cell. At this point, they suggested that amyloplast sedimentation might be a common gravitropic response in moss caulonemata. In 2002, Schwuchow *et al.* added *Barbula unguiculata* (Figure 44), *Fissidens adianthoides* (Figure 45), *Fissidens cristatus* (Figure 46), and *Physcomitrium pyriforme* (Figure 47-Figure 48) to the list of species with gravitropic protonemata that exhibited amyloplast sedimentation. Ultimately they demonstrated this sedimentation in nine species representing five different orders of mosses. Thus, we can conclude that this phenomenon is widespread among mosses and may be present in all of them.

This scenario is further explained by observations on *Tortula modica* (Figure 50-Figure 51) (Chaban *et al.* 1998). Amyloplast sedimentation occurs in the sub-apical zone. These amyloplasts seem to be important in signalling the direction of gravity and sedimentation is present before the tropic response occurs. Although spores require light for germination, the protonema is able to continue development in the dark, but both growth and number of filaments are limited (while resources last). Deprived of light, the protonemata are negatively gravitropic.

Secondary caulonemata, arising from a wound or fragment, likewise are strongly negatively gravitropic in the dark (Chaban *et al.* 1998). These are able to survive and grow well in the dark, most likely gaining resources from the wounded leafy gametophyte. In *Tortula modica* (Figure 50), these secondary caulonemata usually arise at the leaf bases. These tropic responses are rapid. When upright caulonemata are moved to make them horizontal or upside-down, the tropism can be seen within an hour and re-orientation to become vertical is completed in 1-2 days.

We know that amyloplasts sediment in response to gravity (Walker & Sack 1992, 1997), just like sand grains dropped into a glass of water. So how do the plant organelles maintain their positions against the pull of gravity? The amyloplasts themselves may help us understand this. Using *Ceratodon purpureus* (Figure 33), several groups of researchers demonstrated that only some of the amyloplasts sediment along the length of the protonemal tip cell (Schwuchow & Sack 1993; Kern & Sack 2001; Kern *et al.* 2001). They reasoned that if gravity is the only or the major force determining the position of the amyloplasts, then they should be randomly distributed in space. But instead they are clustered in the subapical region when in **microgravity** (very weak gravity). The same occurs when the cells are rotated in a clinostat. But when controls are inverted and kept stationary, the distribution of the amyloplasts differs considerably due to sedimentation. This indicates that the amyloplast forces and mechanisms are normally masked in stationary cells. Kern and coworkers (2001) hypothesized that a "microtubule-based mechanism normally compensates for the drag of gravity, but at the same time it allows for the regulated amyloplast sedimentation." This basically agrees with the interpretation already put forth by Schwuchow *et al.* (1994) for *Ceratodon*.

The foregoing research implies that gravity is not alone in controlling direction of growth. Using *Ceratodon purpureus* (Figure 33), Wagner *et al.* (1997) showed that in the dark, plastid sedimentation is more pronounced than in the light. In *Ceratodon purpureus*, the apical protonema cells are negatively gravitropic in the dark, but in unilateral red light they are positively phototropic, thus overriding the gravitropic response (Kern & Sack 1999a, b). At light intensities of $\geq 140 \text{ nmol m}^{-2} \text{ s}^{-1}$, the phototropism completely overrides the gravitropic response. Partial gravitropic response occurs at lower light intensities. In microgravity, phototropic responses occur. In normal gravity, gravitropism and phototropism compete and "winning" depends on the light intensity. *Ceratodon purpureus* demonstrates that phototropism is phytochrome-mediated (Lamparter *et al.* 1996, 1998; Kern & Sack 1999b). **Phytochrome** is a blue-green pigment in plants that regulates various developmental responses such as long-day and short-day responses.

Autotropism (tendency of plant organs to grow in a straight line when not influenced by external stimuli) occurs when no external stimuli (gravity, light) are present. Again using *Ceratodon purpureus* (Figure 33), Demkiv *et al.* (1997) determined that three stimuli are involved in the direction of protonema growth. In darkness, the protonemata have negative gravitropism. When illumination is uniform from all directions, they grow radially over the substrate, much like those in space or microgravity. In blue or far-red light the gravitropism is blocked, but in red light both gravitropism and autotropism are blocked. Green light (typical light in the forest) allows both gravi- and autotropism (Demkiv *et al.* 1998). Reversal of autotropism inhibition involves the phytochrome system, indicated by the red and far-red effects. Gravitropism occurs simultaneously with starch synthesis and amyloplast formation (Demkiv *et al.* 1997).

Using mutants of *Physcomitrella patens* (Figure 9-Figure 10), Jenkins *et al.* (1986) demonstrated that the genes that control gravitropisms of the caulonema do not appear to be involved in the control the tropisms of the leafy gametophyte.

Repp *et al.* (2004) used genetically modified *Physcomitrella patens* (Figure 9-Figure 10) to demonstrate the role of **cytokinin** signalling for gravitropism. When a knockout mutant lost its sensitivity to cytokinin, it had greatly reduced ability to respond gravitropically in the dark. Based on several studies, it appears that the cytokinins serve the protonemata primarily to induce gametophore buds (Lehnert & Bopp 1983; Bopp 1984).

Here you are, sitting in the dark, and you need light to continue life for long. What do you do? If you are a young protonema, you grow in the direction where you will most likely encounter light. And to do that, you exercise a **negative gravitropism**. That is, you grow away from gravity and toward the daytime sun. Once you reach sunlight, your **phototropism** takes over and you grow toward light.

Mosses may be "smarter" than seed plants. The moss protonemata apical cells can respond to both gravity and light, unlike most cell types (Kern & Sack 1999b). This permits these tiny structures to advance toward the most advantageous position. Even if they are anchored in a crevice, they can follow the path of light to reach the

surface. For example, in *Ceratodon purpureus* (Figure 33), a species that is common in such cracks, the tips of the protonemata are negatively gravitropic in the dark and positively phototropic in unilateral red light. Thus, they would grow toward the opening in a crack.

It appears, based on our observations with protonemata, that the statoliths (**amyloplasts**) settle downward within the cell in response to gravity. This pulls on the **cytoskeleton**. The cytoskeleton is attached to the cell membrane, so this downward pull tugs on the membrane in the upper portion of the cell (Figure 43). A plausible theory is that this stretches the membrane, making it more permeable. This in turn permits more Ca^{++} to enter the upper side of the cell, where it inhibits the action of IAA, permitting the lower side of the cell to grow more.

Nutation

Under some circumstances, the protonema will exhibit **nutantion** – a spiral or circular growth pattern that is displayed in time-lapse photography by apparent movements of the stem (or protonema) in a circle. In *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39), red light causes the protonema to grow into a ring (Simon & Naef 1981). I have observed the same nutation in contaminated cultures of *Fontinalis squamosa* (Figure 52) and in air-grown rhizoids of that species. Nutation appears to facilitate a kind of seeking – altering growth directions until a more favorable condition is located. It is beneficial when no directional stimulus is present, such as spiral growth of rhizoids until they contact a substrate, as observed in *Fontinalis squamosa*. Although nutation is an IAA/ethylene response in higher plants (Morgan & Powell 1970), its occurrence as a response to red light suggests it results from a somewhat different mechanism here since red light is known to inhibit ethylene production. Could this be the same spiraling mechanism seen in the space-travelling *Ceratodon purpureus* (Figure 33) protonemata (Figure 49)? The curiosity there is that the entire population of protonemata grew in a spiral.

Figure 52. *Fontinalis squamosa* rhizoids showing spiral growth. Photo by Janice Glime.

Interactions

We have already implied that exogenous growth regulators could determine events in the development of the moss protonema. Protonemata in nature grow on substrata that are not sterile. Rather, they are teaming with fungi, bacteria, algae, and exudates of other plants. One might then predict that at least some of the protonemata respond in positive or negative ways to these companions.

One possible outcome of cohabitation is that bacteria, fungi, or other organisms may provide the growth substances needed to stimulate the next phase of development. Fungi commonly produce **gibberellic acid** that escapes into the environment. Vaarama and Tarén (1959) found that not only did 0.01% GA promote both spore germination and protonema growth in several mosses [*Dicranum scoparium* (Figure 53), *D. undulatum* (Figure 54), *Dicranoweisia crispula* (Figure 55), and *Pogonatum urnigerum* (Figure 56)], but also inoculation with several fungi [*Aspergillus flavus* (Figure 57), *Penicillium martensii*, *Mucor racemosus*, *Fusarium scirpi*, and *Rhodotorula mucilaginosa* (Figure 58)] had even more effect than did the gibberellic acid.

Figure 58. *Rhodotorula mucilaginosa* colonies, a yeast species that interacts with protonemata through Creative Commons.

In contaminated cultures of *Fontinalis squamosa* (Figure 1, Figure 15) most of the protonemata formed mature caulonemata in less than four weeks, whereas in uncontaminated cultures the chloronema state predominated (Glime & Knoop 1986; Glime, unpub data). And only the contaminated cultures ever produced buds. This suggests that at least some microbes might alter the developmental state of the moss.

Spiess *et al.* (1971) found that the bacterium *Agrobacterium tumefaciens* (Figure 59) influenced the development of *Pylaisia selwynii* (Figure 60). Spiess *et al.* (1986) found 48-68% of six groups of bacterial isolates (283 isolates) from separate samples [*Pylaisia selwynii*, *Callicladium haldanianum* (Figure 61)] increased the development of the moss species from which they were isolated but not that of *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39). There seemed to be both specificity and fidelity at nearby locations, but species differed between latitudes. Bacterial interaction may be important in bryophyte development.

Kutschera (2007) demonstrated a positive interaction between the methanol-using purple bacterium *Methylobacterium* [Figure 62; *M. mesophilicum* and two other unknown *Methylobacterium* species isolated from *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39) and sunflower achenes] and the protonemata of bryophytes [moss *Funaria hygrometrica*; thallose liverworts *Marchantia polymorpha* (Figure 63) and *Lunularia cruciata* (Figure 64), but there was no benefit observed for the angiosperms studied. The same positive effect occurred for development from gemmae of the two liverworts. Methanol appears to be a waste product of the pectin metabolism of growing plant cell walls. Kutschera postulated that the *Methylobacterium* cells accomplished this protonemal developmental stimulation through their secretion of the plant hormones cytokinin and IAA (indole-3-acetic acid). Hence, the sequence seems to be:

1. Uptake and metabolism of plant waste products (methanol, amino acids, *etc.*) by the bacteria
2. Possible release of ammonium ions by bacteria
3. Secretion of cytokinins and IAA by bacterial "waste managers"

4. Bacterial hormonal signals may indicate to the plant that bacterial epiphytes are present and active
5. Hormones stimulate growth of the bryophyte gametophyte
6. Cross signals may help to regulate bryophyte growth.

This hormonal interaction may account for the success of bryophytes in some habitats in nature and the lack of success of at least some protonemata when grown in sterile culture.

Fungi have effects on other bryophyte protonemata as well. Hildebrand and coworkers (1978) found that fungal exudates promoted the growth of *Atrichum* (Figure 27-Figure 28), *Funaria* (Figure 7-Figure 8, Figure 39), and *Brachythecium* (Figure 65) protonemata (Figure 66) at low pH. As suggested above for spore germination, *Splachnum ampullaceum* (Figure 67) protonematal growth is promoted by several species of fungi (von Maltzahn & MacQuarrie 1958). Certainly growth hormones exuded by the fungi could be of importance here (see Bopp 1980).

In addition, contributions of vitamins from algae or amino acids or other organic compounds from bacteria might either be essential or promote a growth rate that is compatible with the seasons. Gibberellic acid, produced by many fungi, has a variety of effects, depending on the species of moss. It increases the number and length of protonemal cells in *Dicranum* (Figure 53-Figure 54) and *Dicranoweisia* (Figure 55), but it has no effect on *Racomitrium fasciculare* (Figure 68) (Vaarama & Tarén 1959). Since *R. fasciculare* grows on rocks where fungi are less likely to occur, and fungi are a natural source of GA, these differences in responses are consistent with habitat differences.

Figure 68. *Racomitrium fasciculare*, a rock-dwelling species whose protonemata are not stimulated by GA. Photo by Janice Glime.

We know that the induction **Factor H** (an adenine derivative discussed in subchapter 5-1 on Hormones) is present in *Funaria* (Figure 7-Figure 8, Figure 39). It will induce not only other protonemata of *Funaria*, but it can be induced by other species [e.g. *Leptobryum pyriforme* (Figure 69)] as well (Klein 1967; Bopp 1976). Such a factor is adaptive in insuring a sufficient breeding population, but perhaps more importantly it insures a community organization that offers resistance against desiccation, where middle plants are protected by outer ones in the population. In submerged mosses such as *Fontinalis* (Figure 70-Figure 71) species, on the other hand, moisture conservation is not so critical, and multiple gametophores would only offer competition for the limited substrate available for anchorage.

Figure 69. *Leptobryum pyriforme*, a species whose protonemata can induce the protonemata of *Funaria hygrometrica*. Photo by Michael Lüth, with permission.

Whereas some interactions can enhance growth of moss protonemata, others inhibit it, preventing the colonization of that substrate. Shrimal (1975) showed that bark extracts of several trees inhibited mitosis in onion root tips and caused non-separation of chromosomes. If these substances have the same effects on mosses, it could explain why some trees lack bryophytic epiphytes.

Inhibition can also occur within a species, as already suggested for *Funaria* (Figure 7-Figure 8, Figure 39). In this species, protonemata from several spores in one culture will not intersect (Watson 1981). The mat attains the same density when the protonemata are derived from many spores as when they are derived from only one. Watson also suggests that one species may inhibit another, thus making time an important factor in access to a habitat. And *Funaria* is not the only moss where some exudate of the protonema retards development of competing protonemata of the same species. This has been observed in culture in *Physcomitrella patens* (Figure 9-Figure 10) as well (Schween *et al.* 2003). It is perhaps a widespread phenomenon.

In *Funaria* (Figure 7-Figure 8, Figure 39), this factor of inhibition seems to break down in mature cultures. When I placed disks of agar from a mature culture onto fresh plates and inoculated the plates with spores, some of

the protonemata grew on the disks from the mature cultures. In no case did I find a zone of inhibition around the agar disk. This suggests to me that the substance preventing live protonemata from intersecting might be a gas produced by the growing protonemata. Gases are instrumental in maintaining maximum distance among sporangia of some slime molds, and one gas that could accomplish this in mosses is ethylene. Since ethylene is known to affect *Funaria* protonemata (Rohwer & Bopp 1985) and it is a known inhibitor of cell division (Abeles 1973), small concentrations produced by the tips could easily signal their presence to neighbors. Ethylene production is stimulated by the action of IAA on S-adenosylmethionine (SAM), so we might expect the tip (where there is the most IAA) to have the highest ethylene concentration. The longest branches will interact first, and these are the ones most likely to be IAA-rich and apically dominant.

Hormones produced by other organisms in the environment can affect the development of protonemata, and in some cases these may be required to take the bryophyte to its next developmental stage. Among these, GA (gibberellic acid) is a likely candidate. It is produced by many fungi and readily enters the environment. It is known to increase the number and length of protonematal cells in some soil-inhabiting species, but may have no effect on rock-dwelling taxa that normally would have much less contact with soil fungi. Bark exudates may also inhibit growth of some bryophyte protonemata, and some bryophytes may inhibit each other, both of different species and of other clones of their own species.

Nutrients

In some mosses, the form of the protonema is dependent on available nutrients. For example, in nature *Sphagnum* (Figure 72-Figure 74) normally has a thalloid protonema (Figure 73-Figure 74). However, in a medium with high potassium, the protonema becomes filamentous (Schofield 1985). Since *Sphagnum* normally grows in habitats very low in potassium, this filamentous growth form is not observed in nature.

Sucrose may not be a problem in nature, but in culture added sucrose enhances growth, provided the culture does not become contaminated. Yu *et al.* 2008 pointed out that sucrose effects vary among species. The optimal sucrose concentration for the moss *Microdus brasiliensis* (Figure 18) was 1-2% (Sarla 1992), whereas both *Splachnum ampullaceum* (Figure 75-Figure 76) and *Atrichum undulatum* (Figure 35) grew better with no added sucrose (Sabovljević *et al.* 2005; González *et al.* 2006). One problem is that when the concentration of sucrose is too high it causes exosmosis, hence dehydrating the protonema (Fernández & Revilla 2003). Sabovljević *et al.* (2006) demonstrated that a 3% sucrose concentration inhibited the protonemal growth of the moss *Atrichum undulatum*. Yu *et al.* (2008) tested sucrose:nitrogen effects on protonemata of *Polytrichum commune* (Figure 31) at sucrose levels of 0, 10, and 40 g L⁻¹ and ammonium nitrate of 0, 0.2, and 0.4 g L⁻¹. The best growth of those protonemata were at ratios of sucrose to nitrogen of 10:0.2, 40:0.2, and 40:0.4.

Figure 76. *Splachnum ampullaceum* peristome and spores that grow best on agar with no sucrose. Photo by Janice Glime.

Nitrogen in the medium can be detrimental to the protonemata at concentrations suitable for tracheophytes (see Chapt 8-1, pp. 1-4). Fangmeier *et al.* (1994) found that high concentrations of ammonium ions in plant cells can cause membrane dysfunction. It appears that established protonemata and plants can harbor sufficient nitrogen that they can be grown in the absence of nitrogen (Duckett *et al.* 2004). Nevertheless, Yu *et al.* (2008) found that when sucrose was added to the medium, growth was better in low concentrations of accompanying nitrogen as ammonium nitrate than with sucrose alone. In fact, the

detrimental effects of high concentrations of sucrose can be counteracted by the addition of nitrogen (George 1993; González *et al.* 2006), and for *Polytrichum commune* (Figure 31) Yu *et al.* found that even at 4% sucrose there was a positive effect on protonemal growth when sucrose was combined with the appropriate level of ammonium nitrate.

Sundberg and Rydin (2000) showed that *Sphagnum* (Figure 73-Figure 74) establishment from spores was limited by the amount of phosphate released by underlying litter. Added moose dung likewise promoted establishment. They concluded that cover of other plants and nutrient release from litter provided safe sites where *Sphagnum* spores could germinate and establish new plants.

Calcium seems important to protonema development in some species and may be the actual factor where pH affects viability. For *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39), Reiss and Herth (1979) suggest that a calcium gradient is responsible for protonemal tip growth. The calcium concentration is highest at the tip where fluorescence is strongest. It is likely that calcium is involved in transport of substances across cell membranes.

Nutrient availability is affected by pH. Thus pH could affect success of protonemata. In *Physcomitrella patens* (Figure 9-Figure 10, Figure 77, Figure 78), changes in pH in the range of 4.5 to 7.0 influenced differentiation of protonemata but did not have any negative impact on growth rate (Hohe *et al.* 2002). In another example, *Anisothecium molliculum* has an optimum pH of 5.5 for not only protonemal growth, but also for bud formation (Kumra & Chopra 1985). The pH may not only alter the ability of bryophyte protonemata to obtain nutrients, but also affect their susceptibility to exudates from other plants and fungi. Following fire, invasion by bryophytes onto the charred substrate seems to be likewise influenced by both pH and residual chemicals (Thomas *et al.* 1994). Germination success in the moss *Campylopus pyriformis* (Figure 79) is positively influenced by increases in the pH in the range of 3.5-6.4.

Figure 79. *Campylopus pyriformis*, a species whose protonemata grow better as pH is increased in the range of 3.5-6.4. Photo by Michael Lüth, with permission.

Various heavy metals seem to alter protonematal form. Kapur and Chopra (1989) found that in the moss *Timmiella anomala* (Figure 80), when grown aseptically (conditions free of microorganisms), aluminum causes protonemal cells to become rounded and packed with chloroplasts and starch grains; the filaments themselves form bunches. Zinc and arsenic likewise cause rounded cells, with zinc-damaged cells becoming reddish; most arsenic effects are seen at the terminal and intercalary positions. Mercury causes cells to become broad with dense particles, whereas nickel results in long, thin protonemata with little branching. At 10^{-6} M, nickel increases protonemal growth slightly, but at 10^{-5} M it drastically decreases the number of gametophore buds. Cobalt inhibits protonemal growth but seems to have no effect on bud formation. What do these effects mean to development of the moss, and are they likely to occur in nature where soil chelators (organic compounds that bind metal by forming ring structure around it) may inhibit uptake, or concentrations never reach these levels? Could they actually affect appearance of mature gametophytes resulting from these anomalous forms and hence confound our understanding of the taxonomy?

Landing in the wrong place can inhibit spore germination, but it can also permit germination but inhibit protonema development. In some cases, these unfavorable conditions might cause the protonema to produce dormant cells that can act like gemmae to grow when favorable conditions are forthcoming. Such seems to be the case for protonemata of *Dicranella heteromalla* (Figure 81-Figure 82) that spent the winter in a lake with acid mine waste (Jan Fott, pers. comm.).

Our knowledge of nutrient requirements is based mostly on cultures of bryophytes and we know little of the generalities that might be important. For example, elevated potassium causes *Sphagnum* protonemata to become filamentous instead of thalloid, but in nature we have not observed protonemata in habitats where this condition exists. The level of phosphorus is often limiting and we can assume this plays a role in nature as well. An important observation is that heavy metals such as aluminum, zinc, mercury, and arsenic can cause abnormal protonemata with such symptoms as rounded cells with dense chloroplasts and starch. Elevated nickel, on the other hand, causes the protonemata to be thin. Calcium is undoubtedly important and its function may relate to membrane transport of other ions into the cell. All of these nutrient effects are likely to be affected by the pH because a lower (acidic) pH generally makes most nutrient ions more soluble.

Rhizoids

Botanists have traditionally considered rhizoids to function in anchorage only. In some cases they provide capillary spaces that aid in moving water externally to and even up the stem. But Duckett and Matcham (1995) discovered that the structure of rhizoids in *Dicranella heteromalla* (Figure 81-Figure 82) is cytologically similar to the food-conducting cells (**leptoids**) in many leafy mosses and moss sporophytes. This realization suggests that a major role of rhizoids may indeed be uptake, much like the root hairs of tracheophytes.

Rhizoids (Figure 83) form on the protonema at different stages, depending on the species and the growing conditions. On nutrient-free agar and in distilled water the first filaments to emerge from the spore are rhizoidal (Bhatla 1994). They are distinguished by their pigmented (usually brown) cell walls, oblique crosswalls, and discoid or cylindrical plastids. The rhizoids seem to depend on forced calcium entry (active uptake requiring energy) for growth and at least in those tested, respond positively to a calcium gradient (Bhatla 1994).

Figure 83. *Fissidens tenellus* bud with rhizoids at its base. Photo by Tom Thekathiyil, with permission.

Rhizoids usually exhibit strong positive **gravitropism** (grow toward the center of gravity), negative **phototropism** (grow away from light), and **thigmotropism** (alter their growth upon contact), with the latter overriding the effects of the former once a substrate is contacted (Bhatla 1994). When growing in air, they often exhibit a spiral growth (**nutation**) until a substrate is contacted (Glime 1987). Upon contact, they may branch into short, fingerlike tips (Odu 1988), as noted in *Lophocolea cuspidata* (Figure 84) (Odu & Richards 1976) and *Fontinalis squamosa* (Figure 85) (Glime 1987). Among the liverworts, apical branching seems to be in part phylogenetically constrained, appearing commonly in the **Jungermanniales** (Figure 84) but only in the **Metzgeriineae** (Figure 86) of the **Metzgeriales** and not at all in the **Marchantiopsida** (Figure 87) (Pocock & Duckett 1985). Those liverworts with swollen rhizoids grow exclusively on peat and rotten wood associated with fungal hyphae. Pleurocarpous moss rhizoids become flattened near the tips, but in acrocarpous mosses these flattenings extend well behind the tips of the rhizoids (Odu 1988).

Figure 87. *Cyathodium* sp., representing the **Marchantiopsida** with the protonema lacking apical branching. Photo courtesy of Noris Salazar Allen.

Adhesion of rhizoids seems to be stimulated by the substrate itself (Odu 1988). Upon contact, rhizoids produce such extra-wall materials as sulfated mucopolysaccharides. These are highly viscous substances that serve as a sticky adhesive, also known in algae and other microorganisms.

But what controls the production of these rhizoids? Goode *et al.* (1992) were unable to get *Tetraphis pellucida* (Figure 6) to produce any protonemal rhizoids in culture, yet these occurred routinely in nature. They ascribed this difference to the limited nutrients and different irradiance in the wild. But hormones available from surrounding vegetation, bacteria, and fungi could play a role as well, as they apparently do for the protonemata.

Tmema

Tmema cells (Figure 88) are rounded cells that rupture, setting free a protonemal gemma (Figure 89) (Bopp *et al.* 1991). These cells result from a very unequal division of the cell near the proximal cross wall and divide the chloronema filaments into fragments of only a few cells. The tmema cells have few chloroplasts which soon become reduced in size, but the cell elongates in its proximal direction by expanding its newly formed wall, progressing in the opposite direction from normal cells.

The new tmema wall forms inside the old lateral wall and the subsequent loosening of the old wall results in fragmentation of the protonema. This separation also occurs in older, untreated cultures of *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39) (>25 days) (Bhatla & Dhingra-Babbar 1990).

Figure 88. **Tmema** cell in protonema. Redrawn from Decker *et al.* 2006.

Figure 89. *Bartramia ithyphylla* with protonemal gemmae. Photo by Eugenia Ron Alvarez & Tomas Sobota – Plant Actions, with permission

In *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39), the ageing protonemata form tmema cells. Formation of these is inhibited by 10 μ M IAA, indicating that they form when the protonema is auxin deficient (Bopp *et al.* 1991). Once formed, the cell elongates in the proximal direction by forming a new tmema cell wall, thus reversing its polarity compared to normal cells, which elongate distally. This new wall replaces the old lateral wall and also covers the tip of the tmema cell. The new wall is, however, lacking at the cross wall toward the sister cell of its division. The new wall contains a higher cellulose content and an array of microtubules and microfibrils compared to other cells in the protonema. The old lateral wall loosens and ruptures and the tmema disintegrates as its wall swells and dissipates.

But these are laboratory results. Does the tmema occur in nature? Is it adaptive? Could it permit small fragments of the protonema to have one more chance at dispersal before producing its upright gametophore, hence possibly allowing it to arrive at a place where it could indeed produce enough of its own IAA in a more favorable setting? How remarkable a survival mechanism if indeed it permits another chance at dispersal.

Tmemata seem to have received little attention among bryologists and we seem to have little knowledge of their occurrence in nature. In their cultures of *Dicranella*

heteromalla (Figure 81-Figure 82), Duckett and Matcham (1995) found that tmemata had formed. These shortened cells were common on chloronemal side branches that produced both terminal and within-filament gemmae. The tmemata serve as abscission cells that permit the detachment of the gemmae. This occurs through the swelling of a new internal wall in the tmema cell, as seen in *Funaria hygrometrica* (Figure 7-Figure 8, Figure 39). If this species is grown on nutrient-free agar, the protonemata fail to produce gemmae, but rather produce filaments of different diameters, down to 4-5 μm , that make a spiral path through the medium or form knot-like aggregations if grown on cellophane-covered agar.

Goode *et al.* (1993) observed similar tmemata in cultures of *Bryum tenuisetum* (Figure 90). Ligrone *et al.* (1996) described a similar development for tmemata and gemmae in protonemata of *Aulacomnium palustre* (Figure 91). Edwards (1978) described tmemata associated with protonemal gemmae in collections of *Schistostega pennata* (Figure 92-Figure 93) and noted that this type of gemma with an associated tmema was rare among moss species. Based on my hunt in Google Scholar, I would conclude that they are either rare, or rarely reported.

In the copper moss *Scopelophila cataractae* (Figure 94-Figure 95), copper concentrations, but not other metals tested, affect the production of protonemal gemmae and associated tmemata (Nomura & Hasezawa 2011). Making the assumption that this moss is able to invade copper-rich substrata because of gemmae, the researchers tested the sensitivity of the protonema. Although the gemmae were suppressed, the copper promoted the growth of the protonema.

Tmemata are one means of providing vegetative reproductive structures on the protonema. Various types of protonematal asexual reproductive structures will be discussed in Chapter 5-7 on asexual reproduction. A brief discussion of those associated with protonemata is provided here.

Protonemal Gemmae and Tubers

Production of gemmae on the protonema seems to be affected by a variety of substances and conditions. Chopra and Dhingra-Babbar (1984) found that a variety of substances affect gemma initiation and growth rates of the protonema in *Trematodon brevicalyx*. These included IAA, GA, ABA, chelates, salicylic acid. In addition, responses were altered by temperature, pH, agar, sucrose levels, light levels, and photoperiod.

In *Hyophila involuta* (Figure 40), in addition to promoting growth, the protonemal diffusate (from gemma-producing protonemata) + kinetin acted synergistically to enhance gemma formation. ABA (10^{-5} - 10^{-7} M) + protonemal diffusate inhibited gemma production (Mehta 1990).

Sarla and Chopra (1989) found that in *Bryum capillare* (Figure 96), kinetin slowed protonemal growth. **Bryokinin** (a type of cytokinin growth hormone found in mosses) inhibited protonemal growth at all levels. Rather, gemmae were produced in response to kinetin and bryokinin.

Figure 96. *Bryum capillare*, a species in which kinetin and bryokinin slow protonemal growth and induce gemmae. Photo by Andrew Spink, with permission.

More recently, Ahmed and Lee (2010) explored the induction of protonemal gemmae in *Palustriella decipiens* (Figure 97). They found that concentration of IAA and kinetin was important in stimulating production of protonemal gemmae. Low concentrations promoted gemmae and bud induction.

Figure 97. *Palustriella decipiens*, a species in which concentration of IAA and kinetin is important in stimulating protonemal gemmae. Photo by Michael Lüth, with permission.

Liverworts

Little seems to be written about the protonemata of liverworts to explain the details of their development in any ways that may differ from that of mosses. Liverwort protonemata differ fundamentally from those of mosses in that the liverwort protonema is thalloid (Figure 98-Figure 100). As mentioned above, the rhizoids of the liverworts in **Marchantiopsida** do not branch apically, but those of the **Jungermanniales** do (Pocock & Duckett 1985).

Ecological Considerations

We have discussed the ability of the protonema to branch, then form many gametophore buds. This permits it to produce many upright gametophores in close enough proximity to create capillary spaces and reduce air movement, thus reducing drying. Furthermore, this mat of protonemata can provide bridges across the tiny soil particles (Ignatov *et al.* 2012), binding the soil and creating more capillary spaces for water retention. In *Schistostega pennata* (Figure 92-Figure 93, Figure 101), the sticky surface of the propaguliferous protonema extends across the soil particles, stabilizing the surface in a way that helps to create its own habitat (Ignatov *et al.* 2012).

Because of this binding ability, and the ability to withstand drought and revive upon rewetting, protonemata of a number of species can contribute significantly to soil binding in disturbed areas. To this end, mosses like *Atrichum* spp. (Figure 27-Figure 28, Figure 35) can stabilize soil on broad paths and soil banks. Mosses with persistent protonemata, like *Pogonatum* spp. (Figure 29-Figure 30, Figure 56) and *Buxbaumia aphylla* (Figure 102) are able to stabilize the otherwise bare soil where they live, often on soil banks. Hence, protonemata can play an important role in stabilized disturbed soil in ecosystems.

Summary

The **filamentous protonema** of Bryophyta can differentiate into two types: **chloronema** and **caulonema**, distinguished by short cells with perpendicular crosswalls, numerous chloroplasts, colorless cell walls, and irregular branching in the former and longer cells, diagonal crosswalls, brownish cell walls, and fewer, scattered, small chloroplasts in the latter. IAA induces the switch to caulonema; cytokinins promote branching. Protonemata of **Sphagnopsida**, **Anthocerotophyta**, and most **Marchantiophyta** are thalloid.

Protonemata can produce a variety of **brood cells**, possibly stimulated by **ABA**, and sometimes disarticulated from the protonema by **tmema** cells. Light quantity, quality, photoperiod, and temperature influence both the rate of development and the form of the protonema. Their direction of growth is influenced by both gravity and light, causing **negative gravitropism** in the dark and **positive phototropism** in the light.

Other organisms, especially bacteria and fungi, may supply **IAA**, **cytokinins**, and **GA** that influence

development, and **Factor H** (a likely **cytokinin**) may be supplied both endogenously and exogenously to control population size. Nutrients can affect the development; the ratio of sucrose:nitrogen determines if they are beneficial or detrimental, and heavy metals generally cause abnormalities or arrested development.

Rhizoids exhibit **positive gravitropism** and **negative phototropism**, but also possess **thigmotropism**, typically expanding, branching, or flattening upon contact with a substrate.

Liverworts have thalloid protonemata and in many the rhizoids do not branch at the tips.

Protonemata are important ecologically as early stabilizers of the soil in disturbed areas. By branching and producing many buds, they quickly create cushions and mats that can support each other in maintaining moisture.

Acknowledgments

Inspiration for this chapter evolved from discussions with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen. Several of the experiments were conducted at the Botanisches Institut, Universität Heidelberg, Germany. I appreciate the many suggestions from a student's perspective by Medora Burke-Scoll. KT McConnell helped with the glossary and suggested the minisummaries after some of the topics. Misha Ignatov sent me his many images of *Schistostega* and provided me with an advanced copy of his publication on its protonemal development. Eugenia Ron provided me with images and papers on her protonema research. Thank you to Wang Zhe (=John Wizzard) for getting me a Chinese thesis on bryophyte tropisms.

CHAPTER 5-5

ECOPHYSIOLOGY OF DEVELOPMENT: GAMETOPHORES

Figure 1. *Bryum pseudotriquetrum* gametophores, showing leaves, stems, and rhizoids. Photo by Janice Glime.

Growth

Bryophytes appear to be simple plants, but if one changes perspective, you might agree with Renzaglia *et al.* (2000) that these gametophytes "are the most elaborate of those produced by any land plant." In mosses, it is the apex of branches or stem tips that ultimately develop into reproductive organs. This contrasts with flowering plants that develop their gametophyte without archegonia and antheridia, reducing the male gametophyte to a pollen grain and the female gametophyte to a partitioned embryo sac within the female sporangium (sporophyte tissue).

In mosses and leafy liverworts, gametophore development can be considered a four-part process: stem growth, branch production, leaf development, and rhizoid formation (Figure 1). Since these four processes must compete for energy, it is expected that they are, at least in most cases, distinct events with different environmental stimuli or optima.

Stem Growth

Stem growth in plants occurs primarily as a result of cell elongation, which is sometimes accompanied by cell division (Bidwell 1979). Cell elongation occurs by a loosening of the side walls of the cell to allow expansion. Auxin helps to loosen the wall but exogenous calcium and ethylene inhibit loosening (Ray *et al.* 1983) (probably because Ca forms Ca pectate, which glues cell walls together). Loosening is followed by an uptake of water by the cell, which is an osmotic response to increase of Ca within the cell. The increased turgor then expands the cell. The turgor can be affected by mineral nutrients, photosynthesis, respiration, transpiration, ethylene, water availability, temperature, etc. If **any** of these factors becomes limiting, it can inhibit stem elongation.

When measuring growth, one consideration must be what to measure. When a layperson thinks of growth, it is usually equated with increase in height, but in biological

terms it can include branching and weight gain as well. Measuring extension in height gets complicated by the fact that if light intensity is insufficient, cells will extend with little or no weight gain, and often at a greater than normal rate – the **etiolation** effect (Figure 2). This is especially a problem in laboratory experiments where light intensity is usually considerably below that in nature, even compared to some forested settings. Plants, including bryophytes, become thin, weak, and lose their green color. In this case, false implications of growth occur. This can easily be seen when bryophytes are collected and kept in a sealed plastic bag. Sufficient moisture remains to permit cell extension, and within days (or even hours), one can see thin extensions of the stem with tiny, pale leaves.

Figure 2. Culture of *Funaria hygrometrica* with Petri plate covered on top and the only light source from the side of the plate. Note the etiolated appearance of the shoots in this dim light compared to those in Figure 3. Photo by Janice Glime.

Figure 3. Culture of *Funaria hygrometrica* with light from above the plants. Photo by Janice Glime.

Therefore, especially in measuring laboratory growth, one needs to consider weight gain, either alone or in addition to height gain. Furthermore, if the species is pleurocarpous, in particular, and more than a few weeks elapse, length gain of branches and number of branches becomes important. This becomes a non-linear relationship as each branch then starts to grow at a rate similar to that of the main stem.

When growth is promoted, energy is diverted from other events. This diversion can manifest itself as a result of a change in environmental conditions. For example, when grown in red light, *Ceratodon purpureus* (Figure 4) exhibited only 20% branching with a weight gain of 16.8 mg per 50 individuals, but when the plants were grown under far-red illumination, there was 100% branching, but only 11.75 mg weight gain per 50 plants (Hoddinott & Bain 1979). This would appear to be counter-intuitive until one recognizes that while the branches were growing, the plants in far-red light were also producing setae, thus diverting energy for another process. Similarly, growth reduction (in length) occurs during archegonia production in *Fontinalis dalecarlica* (Figure 5) (Glime 1984). Energy is clearly needed for processes other than branch growth.

Water

It is certainly nothing new to learn that water is necessary for development of the stem. However, the effect that water availability has on the stem diameter is less well known. In studying *Sphagnum magellanicum* (Figure 6) and *S. papillosum* (Figure 7), Li *et al.* (1992) found that stem diameter increased in stems with capitula that were farther from the water, and hence drier (Figure 8). This increase in stem diameter resulted from having a greater number of rows of the hyaline cells at the outer part of the stem (Figure 9). This increase in diameter appears to be a tradeoff because at the same time growth rate in stem length decreased.

Light

Too high and too low **light intensity** can control bryophyte growth. At high light intensities, it can be inhibitory, destroying chlorophyll in unprotected leaves, but at suboptimal light intensities, it can cause etiolation, resulting in long, slender stems. For example, the aquatic moss *Drepanocladus* (Figure 10) has longer internodes in low light (Lodge 1959), making leaves appear to be sparse.

Figure 10. *Drepanocladus longifolius*, a species with longer internodes in low light, hence in deep water. Photo by John Game, through Flickr Creative Commons.

Since mosses are shade adapted, optimal light intensity for many is likely to be rather low. *Riccia frostii* (Figure 11) females have optimal growth at 3500 lux in continuous light (Vashistha & Chopra 1989), whereas full sunlight is about 70,000 lux. Red light favors their growth (Dagar & Kumra 1988). For *Marchantia palmata*, optimum intensity for vegetative growth is 4500 lux (Kumra & Chopra 1989), the same intensity needed for maximum number of gametophores in *Microdus brasiliensis* (Chopra & Mehta 1987). For *Fontinalis duriaei* (Figure 12) photosynthesis attenuated at 5400 lux (Glime & Acton 1979); field intensities where *Fontinalis duriaei* grew

ranged up to 6000 lux in spring when leaves were not out yet, diminishing to 4000 lux in summer and 500-1000 lux during much of winter (Glime 1987a).

Stem height can be controlled by light, but some bryophytes respond to different wavelengths from those that affect tracheophytes. In some higher plant species, a five-minute exposure to far-red light at the end of an 8-hour day (with white light) is enough to cause a 400% increase in internode expansion (Morgan & Smith 1981). A flash of red light can stop growth. Stem elongation in etiolated plants can also be stopped by exposing the plant to red light, whereas far-red reverses this effect (Ray *et al.* 1983), suggesting that phytochrome is somehow involved. Incandescent bulbs also cause more stem elongation than fluorescent bulbs because of the higher far-red content of the former (Morgan & Smith 1981, p. 120). On the other hand, moss protonemata bend toward red light. And *Ceratodon purpureus* (Figure 4), *Dicranum polysetum* (Figure 13), *Leptobryum pyriforme* (Figure 14), and *Polytrichum juniperinum* (Figure 15) all grew significantly taller in red light than in far-red (Hoddinott & Bain 1979). That may be why these taxa all grow in relatively open areas where full sun is available at least part of the day, providing them with at least some red light.

Figure 13. *Dicranum polysetum*, a moss that grows taller in red light than in far-red light. Photo by Michael Lüth, with permission.

A comparison of sun and shade forms of these moss species would be interesting. Should we expect moss taxa living under the forest canopy to be more sensitive to far-red light? Or are they necessarily adapted to growing poorly in far-red light in order to prevent growing too tall for their meager support system? Could it be that the chlorophyllous palisade layer of tracheophyte leaves necessitate the response to far-red light in the underlying spongy mesophyll (due to filtering out red light), whereas bryophytes have no such chlorophyllous layer to intervene in the light reaching their primary photosynthetic cells?

Figure 14. *Leptobryum pyriforme*, a moss that grows taller in red light than in far-red light. Photo by Michael Lüth, with permission.

Branching seems to be under a different set of wave length controls from that of photosynthesis and growth, at least in some bryophytes. The thallose liverwort *Riccia discolor* has its maximum apical branching in blue light (Dagar *et al.* 1980). But this type of dichotomous branching is developmentally different from that of mosses and may not be physiologically comparable to the type of side branches produced by mosses.

Figure 15. *Polytrichum juniperinum*, a moss that grows taller in red light than in far-red light. Photo by Janice Glime.

The chlorophyll *a/b* ratios of bryophytes are typical of shade-adapted species (Martin 1980). One must ask how the greater proportion of green light on the forest floor affects development and photosynthesis, and might such shade-adapted plants as most bryophytes be likewise adapted to the wavelengths of light that predominate in the forest. The work of Dagar and coworkers (1980, Dagar & Kumra 1988) on *Riccia discolor* may suggest an answer. They found that total chlorophyll content of *Riccia discolor* is highest in green light, again attesting to bryophytic adaptation to the low light of shade conditions. But in this species, green light retards growth (Dagar & Kumra 1988), and branches are favored by blue light over yellow or red (Dagar *et al.* 1980). Further discussion on effects of light is in the chapter on light.

Bierfreund *et al.* (2003) found that red light retarded growth of the protonemata in *Physcomitrella patens* (Figure 26). On the other hand the leafy gametophytes became elongated, but had shorter and narrower leaves. These effects were more pronounced in far red light.

Bryophytes seem to respond differently to the spectrum than do tracheophytes. Whereas tracheophytes grow best in far-red light, bryophytes seem to respond best to red light. Blue light can cause branching. They experience destruction of chlorophyll at high light intensities and etiolation at low light intensities. Light quality can change the morphology, with red and far red light causing stem elongation and leaf retardation.

Tropisms

It seems that most of the research on tropisms has been done on the protonema. **Phototropism** and **gravitropism** are most likely common for bryophyte stems, but aside from field observations, we know almost nothing about them in mature plants. However, it is clear that stems grow up and rhizoids grow down, just as do stems and roots of tracheophytes. One would expect tropisms in acrocarpous mosses, and surely something is causing their normal upright growth. Yet there seem to be a number of acrocarpous mosses that grow on vertical substrata and do not respond to gravity, and perhaps not to light. Genera

such as *Orthotrichum* (Figure 16) typically grow outward from their tree trunk habitat and even the sporophyte seems oblivious to gravity. And at least some species of *Pogonatum* (Figure 17-Figure 18) and *Oligotrichum* (Figure 19) seem to lack a strong gravitropism or phototropism in their gametophytes when growing on a vertical substrate, whereas their sporophytes do bend upward. On the other hand, the stem of the pleurocarpous aquatic moss *Fontinalis* exhibits positive phototropism (bends toward light; Figure 20). A strong phototropism is seen for the acrocarpous *Funaria hygrometrica* in Figure 3.

Photoperiod

Not only do light intensity and quality affect bryophytes, but also light duration. Generally, long days result in longer stems along with increased elongation rates in higher plants, but too much light can inhibit elongation. In bryophytes, on the other hand, long days and elevated temperatures often induce dormancy, presumably acting as protection against desiccation during summer (Schwabe 1976). The response in higher plants suggests that increased day length allows more photosynthesis to occur, which in turn increases growth potential. Melstrom *et al.* (1974) suggest that in long days more auxin oxidase inhibitors are produced, allowing auxin levels to increase. Gibberellins also increase in long days. This combination allows growth to continue until hormone levels become too high or building materials are exhausted. Perhaps an inhibitory level may be reached more easily in bryophytes, resulting in earlier dormancy.

On the other hand, in two species of *Sphagnum* [*S. magellanicum* (Figure 6) & *S. papillosum* (Figure 7)], there is a high correlation of growth with photoperiod greater than 10 hours; short days induce dormancy (Li & Glime 1991). This perhaps relates to the high light intensity to which these mosses are adapted, and to their higher temperature optimum of 30-35°C for growth (Li & Glime 1990), compared to an optimum at 25°C or less in most bryophytes.

But *Sphagnum* (Figure 6-Figure 7) is not alone in showing short-day dormancy, and control appears to be

unrelated to temperature. In the liverwort *Reboulia hemisphaerica* (Figure 21), long days caused archegoniophore elongation at either 15°C or 25°C, whereas short days induced no response at any temperature (Koevenig 1973b). Even application of IAA, NAA, VA, and GA₃ could not break the effect of short days. This leaves us to wonder what ultimately controls the response, and is the controlling factor the same in all bryophytes?

Figure 21. Thallus and archegoniophores of *Reboulia hemisphaerica*. Photo by Michael Lüth, with permission.

In liverworts, it is likely that **lunularic acid**, in response to **phytochrome** activity, plays a role in response to photoperiod (Schwabe 1990). Its ability to induce dormancy would permit it likewise to control growth. Does that mean that ABA controls growth and dormancy in mosses?

Most photoperiod responses in bryophytes have been related to dormancy. While it appears that most bryophytes benefit from cool temperatures of spring and autumn, and are dormant during long, hot days, some taxa such as *Sphagnum* are long-day plants and are dormant during short days. Photoperiod plays a role in gametogenesis, with some archegoniophores, like those of *Reboulia hemisphaerica*, elongating only under long-day conditions.

Temperature

One would expect temperature to play a major role in development of bryophytes, as it does in early spring growth of other plants and a number of **poikilothermic** animals (those, like plants, with their temperatures controlled by the environment). In the aquatic moss *Leptodictyum riparium* (Figure 22), elongation increased with temperature until about 23°C, after which growth declined again (Sanford 1979). This is consistent with the relatively low temperature optimum of most *Fontinalis* species, where sustained temperatures above 20°C are detrimental to growth, and optimal long-term growth is at 10-15°C (Glime 1987a, b). For the terrestrial *Microdus brasiliensis*, the optimum is 18°C (Chopra & Mehta 1987).

Figure 22. *Leptodictyum riparium*, a species where growth increases with temperature up to about 23°C. Photo by Michael Lüth, with permission.

Schwabe (1976) found that long days and elevated temperatures often induce dormancy in liverworts, putting an end to spring growth. On the other hand, Stevenson *et al.* (1972) found a higher rate of cell division in the moss *Atrichum undulatum* (Figure 23) at higher temperatures.

Figure 23. *Atrichum undulatum*, a moss that has a higher rate of cell division at higher temperatures. Photo by Brian Eversham, with permission.

Growth in *Tetraphis pellucida* (Figure 24) seems to be controlled by temperature rather than light (Forman 1964), but in the liverwort *Reboulia hemisphaerica* (Figure 25), temperature affected only elongation rate, not length or elongation of the archegoniophore, which was controlled by photoperiod regardless of temperature (Koevenig 1973b). Clearly the growth strategies differ among the bryophytes, but we have little phenological data to demonstrate the periods of growth for most species. We do know that in many spring plants, temperature and photoperiod work together to stimulate growth and elongation. Temperature effects will be discussed more thoroughly in the chapter on temperature.

Growth Regulators

Hormones in plants seem to defy definition (Christianson 1999). In plants, using the terminology of "growth regulators" permits us to define them as substances produced in one place in the organism that acts in small quantities to affect another part. But Christianson contends that this definition does not work well for the "untidy bundle of phenomena in plants." Rather, plant hormones

can act locally or be transported and often have numerous roles, interact with other hormones, or are concentration dependent for their functions.

Figure 24. *Tetraphis pellucida* with gemmae, a moss in which growth is controlled by temperature rather than light. Photo by Michael Lüth, with permission.

Figure 25. *Reboulia hemisphaerica* with archegoniophores, a liverwort that elongates its thallus in response to temperature, but not its archegoniophore. Photo by Michael Lüth, with permission.

Growth and developmental processes are primarily controlled by hormones, particularly the auxin IAA (Sztejn *et al.* 1999). In this regard, liverworts differ from mosses and tracheophytes in the way that they regulate their hormone concentrations and activities. Liverworts (and charophytes) regulate free IAA levels by a biosynthesis-degradation strategy, whereas mosses, hornworts, and tracheophytes use conjugation-hydrolysis (Sztejn *et al.* 1995, 1999). These lead to differences in total amount of IAA metabolites, proportion of free and conjugated IAA, chemical nature of IAA conjugates, and rates of IAA conjugation. Sztejn *et al.* (1999) consider this difference in control mechanisms to have "profound implications for macroevolutionary processes in these plant groups."

Bryophyte hormones operate very much as they do in tracheophytes (Maravolo 1980). In bryophytes, **auxins** are transported directionally, permitting **apical dominance** to occur, and their activity is concentration dependent. The

highest concentrations of auxin occur at the tip and base of the upright gametophore, with distribution throughout the stem, as demonstrated in *Physcomitrella patens* (Figure 26) (Bierfreund *et al.* 2003). This species also requires profilin for tip growth (Vidali *et al.* 2007). Profilin is an actin-binding protein and has important regulatory functions, particularly related to the actin cytoskeleton (Wikipedia 2012). Thus it is important in development of organs, wound healing, and identification of "infectious intruders" by the immune system.

Figure 26. *Physcomitrella patens* with capsules, a moss that has demonstrated the concentration of auxin at the tip and base of the upright gametophore, with distribution throughout the stem. Photo by Michael Lüth, with permission.

Chopra and Vashistha (1990) examined the effects of auxins during various stages of the life cycle of *Bryum atrovirens* (Figure 27). They found that at lower concentrations of IAA and other auxins the leafy plants developed normally, but at higher levels their forms were not normal.

Figure 27. *Bryum atrovirens*, a species that exhibits abnormal development at higher concentrations of auxins. Photo by Jan-Peter Frahm, with permission.

Gibberellic acid promotes cell enlargement, development of chloroplasts, and degradation of starch, and causes ultrastructural changes in starch granules and **thylakoids** (flattened, membranous vesicle containing chlorophyll; location of photosynthesis), just as in tracheophytes. It influences gravitropic curvature, depending on photoperiod.

While working with *Avena* (wheat) and two liverworts, Kaufman *et al.* (1982) found several basic generalities in

hormone-induced cell elongation of plants. During phase one, in which the cellulose fiber matrix of the cell is stretched, rapid growth is due to hormone-induced secretion of H^+ , which aids in loosening the cell wall for growth. They discovered that stimulated plants acidified their immediate environment. This rapid response suggests the involvement of H^+ transport (**proton pump**), much like the closing of the Venus flytrap leaf. Ellis and Thomas (1985) demonstrated the same sort of **auxin-stimulated acid efflux** in *Pellia* (Figure 28) to create a pH of 4.8 in the medium, in this case as a result of stimulation by light on one side of the seta.

Phase two consists of long-term growth that occurs as new proteins are synthesized. This response occurs much later than phase one, which is basically instantaneous. Hormones and other plant growth regulators can affect both of these steps in a variety of ways.

Bryophytes seem to respond to different concentrations and respond at different rates from those exhibited by tracheophytes. While working with *Avena* (wheat), Kaufman and coworkers (1982) discovered that a tenfold increase in the growth rate of *Avena* internodes appeared about three hours after application of 10^{-5} M **GA₃**, but that 10^{-5} M **IAA** had no effect. On the other hand, when working with the liverworts *Pellia epiphylla* (Figure 28) and *Conocephalum conicum* (Figure 29), they found that the setae and archegoniophore stalks responded to 10^{-5} M IAA with a two-fold increase in growth rate within 10-15 minutes. Many higher plants also show this rapid response to IAA, but this depends again on the concentration (Osborne 1974; Muir 1974). The rapid response in the liverworts suggested to Kaufman and coworkers (1982) that IAA had a direct effect on the cell membrane, allowing expansion by drawing water into the cell, since growth of the cytoplasm would require slow protein synthesis. We now know that IAA probably works on the cell wall (Goodwin & Mercer 1983), most likely by facilitating the breakdown of **calcium pectate** so the fibers can slide and expand, and this most likely involves an acid efflux via the proton pump from the cells, hence the H^+ observed by Kaufman *et al.* (1982). The freed Ca^{++} is then available to enter the cell, most likely accounting for the observed increase in Ca^{++} there.

Figure 29. *Conocephalum conicum*, a species that responds within 10-15 minutes of an application of 10^{-5} M IAA by rapidly increasing archegoniophore growth. Photo by Jan-Peter Frahm, with permission.

Movement of auxin within the plant is directed and may follow the vascular tissue. In *Marchantia polymorpha* (Figure 30), it is transported in the midrib (Maravolo 1976) and movement occurs in both directions at equal velocity. However, the basipetal (away from apical bud) transport is much greater in intensity. Transport can be inhibited by cinnamic acid and ethylene.

Figure 30. *Marchantia polymorpha* males with gemmae cups, demonstrating the midribs. Note the notches at the end of each and the dominance of one of them. Photo by Nancy Leonard, with permission.

As is typical with hormone responses, not all bryophytes respond the same way. *Marchantia palmata* growth was inhibited by most levels and kinds of auxins (Kumra & Chopra 1989). Furthermore, many chemicals can stop action of IAA (Muir 1974), including other growth hormones. These may actively compete for a binding site on the wall or plasma membrane. Could other plants outcompete bryophytes with a hormonal chemical warfare?

Ethylene is likely to have an early role in gametophore development. We know that seedlings produce ethylene in response to physical contact (Abeles 1973). Thus, if an emerging seedling encounters dense soil or rock, ethylene production inhibits mitosis, thus halting meristematic

activity, and the cells respond by less elongation and by growing wider and thicker, giving the stem greater strength. This greater strength, coupled with continuing but reduced cell elongation, can dislodge small obstructions or push through dense soil. If the obstruction is a rock, ethylene production on the side of contact slows elongation on that side, resulting in plant curvature around the rock.

If we apply this principle to a developing or buried moss gametophore, ethylene could respond to particles of dirt and redirect gametophore growth. We have no studies on this aspect of ethylene in mosses, but I have grown *Funaria hygrometrica* (Figure 2-Figure 3, Figure 54) cultures where spores were germinated **under** the cellophane sheet on top of agar. An accumulation of ethylene is to be expected in this confined space. Here the normal vertical growth of the moss was prevented and a very etiolated-looking horizontal growth occurred. The leaves were short and the stem was long.

In *Fontinalis squamosa* (Figure 31), ethylene causes crumpled branches and stem tips (Figure 32; Glime & Rohwer 1983). G. Mogensen (pers. comm.) has seen similar crumpled branches as a common phenomenon in the Arctic. The crumpling follows a period of late spring or early autumn snow that results in an ice layer on the moss. Because the ice is thin, light is still available, but growth is obstructed. As the moss pushes against the ice, ethylene might be produced as a stress response. If ice surrounds the plant, only a slight space exists between the moss and the ice, permitting an ethylene build up.

Figure 31. *Fontinalis squamosa* in alpine water. Photo from <www.aphotofauna.com>, with permission.

Figure 32. Effects of ACC (and presumably ethylene) on apical leaves of *Fontinalis squamosa*. Photo by Janice Glime.

Submersed mosses [*Fontinalis* (Figure 31), *Drepanocladus* (Figure 33-Figure 34)] often possess widely spaced leaves and thin stems, whereas the same species in shallow water will have thick stems and overlapping leaves. Fuchsig (1926) observed that this gives the shallow water individuals a greater resistance to desiccation with weight loss during desiccation being greatest in the deep water form. Two factors would implicate ethylene and IAA as the controlling factors here. In deep water, light is dim and no light inhibition of IAA should occur since UV light in particular is filtered out. Therefore an etiolation response is expected. At the surface, two factors known to enhance ethylene production occur: (1) stress due to wave action and alternate wetting and drying; (2) a high ratio of $O_2:CO_2$ relative to deep water. Endogenous ethylene could easily account for thicker cells and greater stem strength at the water surface.

Figure 33. *Drepanocladus aduncus* in an emergent population with leaves close together. Photo by Michael Lüth, with permission.

Figure 34. *Drepanocladus aduncus* branch showing leaves close together. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

As with other processes in plants, the production of ethylene requires energy, as demonstrated by De Greef and coworkers (1979) in the thallose liverwort *Marchantia polymorpha* (Figure 30). We can therefore assume that when it enters into the development process there will be a tradeoff of energy that might otherwise be used elsewhere in the plant.

Bryophytes seem to respond to many of the same hormones as do tracheophytes, but generally they respond at lower concentrations and may be inhibited at the concentrations that are effective for tracheophytes. Little is known of **ethylene** effects, but it may account for the contorted growth of bryophytes that have been encased in ice. **GA** is important in cell elongation and **IAA** is important in growth, most likely being the initiator of the rapid acid growth phase. It appears that IAA may provide the signal that initiates the **proton pump**. The **H⁺ flux** into the cell wall spaces causes the **calcium pectate** bonds to break, freeing **Ca⁺⁺** that then enters the cell, replacing the positive H⁺ ions that were just lost. **Anions** that come with the Ca⁺⁺ create a salt within the cell, causing an osmotic gradient. Water follows by **osmosis**.

As already noted, the thallose liverwort *Marchantia polymorpha* (Figure 30) exhibits apical dominance. The thallus produces its own auxin, creating a **basipetal** (toward the base) gradient (Binns & Maravolo 1972). The auxin accumulates in the midribs and the **acropetal** (outward toward shoot apices) regions of excised thallus discs. Binns and Maravolo concluded that maintaining this gradient is essential for normal growth and regeneration. High concentrations of cytokinin in the tissues destroy the polarity by causing an increase in the auxin-synthesizing capacity of the affected tissues.

External application of auxins had no influence on the growth of the thallus, with no growth acceleration or inhibition of regeneration of the thallus (Binns & Maravolo 1972). Transcinnamic acid and dinitrophenol inhibited regeneration, but auxin reversed the inhibition.

Branches and Apical Dominance

Like tracheophytes, bryophytes exhibit a variety of branching types, ranging from total lack of appearance of apical dominance to strong apical dominance (Figure 35). A spruce tree with its strong central trunk and its secondary side branches is the epitome of apical dominance in tracheophytes. Yet, if the tip is broken, one of the side branches becomes a new leader, taking over the dominance that retards development of other secondary branches. In bryophytes, the acrocarpous mosses realize this type of apical dominance. In some cases, the dominance persists even if the tip is lost and the ability for branches to overtake the damaged central stem seems to be absent. But in others, such severance of the controlling tip results in increased growth of side branches, as in *Fontinalis* (Figure 36). Nevertheless, the ability of a single side branch to dominate the others after such a decapitation of the apex seems to be absent in the bryophytes. Rather, multiple side branches develop as **innovations**. This is not unlike the response of many herbaceous taxa of tracheophytes. For example, in snapdragons (*Antirrhinum*) the loss of the apex results in the development of a more bushy plant, and for any number of herbaceous garden flowers, pinching off the apex is a common technique for developing a more robust plant with multiple flowering apices.

Figure 35. Effects of apical dominance on growth forms of bryophytes and tracheophytes. Drawings by Janice Glime.

Figure 36. Branch buds developing near the broken tip of *Fontinalis squamosa*. Photo by Janice Glime.

In acrocarpous mosses, the production of sexual structures terminates the apical growth, particularly the production of antheridial splash cups or capsules. But in some taxa, such as many **Polytrichaceae** (Figure 37), once the splash cup ceases to function in production of sperm, a new stem growth may develop, rendering a series of markers on the stem where remnants of the old splash cups remain (Figure 37). Certainly no flower accomplishes such a strange phenomenon, but cones of the European larch can develop new branches from the ends of the female cones!

Bryophyte branching differs from that of typical tracheophytes in other ways as well. Bryophytes branch below the leaf insertion, whereas tracheophytes produce branch buds in the leaf axil (Figure 38; Schofield 1985). For the tracheophytes, this altered arrangement could provide protection of the developing bud cradled in the leaf base. Furthermore, in tracheophytes, the buds have a meristematic region of dividing cells, whereas in the bryophytes, it is an outer cell of the stem that becomes specialized to form a branch, subsequently forming the apical cell of this branch (Figure 39-Figure 40).

Figure 37. New growth from a senescent antheridial splash cup of *Polytrichum ohioense*. Photo by Janice Glime.

Figure 38. Position of branch buds in bryophytes vs. tracheophytes. Drawing by Janice Glime.

Figure 39. *Polytrichum* stem apex cross section showing three cutting faces. Photo by Magda Turzańska, with permission.

Figure 40. Mature *Polytrichum* stem cross section. Photo by Magda Turzańska, with permission.

Despite the differences in their apical development that uses apical cell cutting faces instead of a meristematic region, many bryophytes have apical dominance. In these taxa, removal of the apex promotes the development of branch buds, with those nearest the cut apex developing the most, as one sees in tracheophytes. Once these buds begin development, they re-establish the inhibition of the lateral buds beneath them.

We have already discussed the energy tradeoffs inherent in growth. One thing that is common among the species of mosses studied is the growth of either the main stem or the lateral branches to the exclusion of the other. *Racomitrium lanuginosum* (Figure 68) has two periods of main stem growth, one in spring and the other in autumn, whereas the lateral branches are initiated and elongate in the first part of summer (Tallis 1959). *Hylocomium splendens* (Figure 41) appears to have one period of elongation during which the bud for the next year of growth is initiated. This bud will not develop further until the present stem section has completed its growth (Busby *et al.* 1978). Sanford (1979), in his studies with the aquatic moss *Leptodictyum riparium* (Figure 22), also found that increased branch growth was correlated with decreased main axis growth. With this kind of tradeoff, we should expect an environmental role in determining when the plant elongates shoots and when it elongates branches.

Figure 41. *Hylocomium splendens* showing buds for next years growth. Photo from website of the Botany Department, University of British Columbia, Canada, with permission.

Environmental Factors

In his work with *Racomitrium lanuginosum* (Figure 68), Tallis (1959) observed that low main stem growth and favorable growth conditions such as temperatures between 12 and 15°C best favored shoot growth. Furthermore, in a cold, humid environment, his plants had few branches and these were small, but in a warm, moist environment, his plants had several long lateral branches. He also found that high humidity and shading may inhibit branching for up to a full year. He suggests that lateral branching might be induced by high light in combination with alternate wetting and drying at a mean temperature that is above the minimum threshold.

Chopra and Rashid (1969) likewise found that increased light intensity promoted lateral bud formation in

mosses. This apparent action by light intensity is supported by the fact that in many plant species, bud expansion is initiated in the spring when light intensity increases and tree canopy closure is incomplete. Low light and low temperatures also delay budding in mosses (Bopp 1968).

But when light intensity increases in the spring, the temperature also increases. However, Pitkin (1975) states that the direct effect of temperature on bryophyte growth is small, except at low temperatures, but that temperature has a strong indirect effect through its effect on humidity and **evapotranspiration** (loss of water through evaporation from among plants and from plants themselves). However, temperature may be more direct through control by growth regulators.

Alghamdi (2003) found that the type of available N can greatly influence the production of branches. In solutions containing only amino acids as the N source, the Java moss (*Taxiphyllum barbieri*; Figure 42), an aquatic moss, produced more branches as concentrations increased with four different amino acid sources (but not **methionine** – amino acid that is relatively insoluble in water), while producing many fewer branches in ammonium or nitrate at the same concentrations of N (Figure 43). Could seasonal pulses of leaf litter decomposition, providing pulses of amino acids, play a role in the seasonal timing of branching vs stem elongation for forest bryophytes? What else can play a role?

Figure 42. *Taxiphyllum barbieri*, an aquatic moss that produces more branches when supplemented with some amino acids than when supplemented with ammonium or nitrate. Photo by Buchling, through Creative Commons.

Figure 43. Effects of different types of nitrogen source on branch production in the Java moss, *Taxiphyllum barbieri*. gly = glycine. Graph from Alghamdi 2003.

As discussed in the chapter on Nutrients, deficiencies can alter morphology and color of the bryophytes. Shaw (1991) suggested that for *Funaria hygrometrica* (Figure 2-Figure 3, Figure 54) growing on a mine site, differences in morphology might have been caused by heavy metal toxicity. But coupled with these metal-caused malformations, he suggested that **somatic** (cellular level) mutations could also contribute to the extensive **phenotypic** (form) variability.

Growth Regulators

Apical dominance is indicative of hormone actions. In tracheophytes, IAA produced in the tip of the plant and interacting with cytokinins inhibits the development of branches below the tip, permitting the main stem to be the leader. In bryophytes, we have indications that the same sort of action is present.

Bryophyte apical dominance appears to work the same way as in the meristematic tracheophytes. MacQuarrie and von Maltzahn (1959) linked apical dominance with IAA in the acrocarpous moss *Splachnum ampullaceum* (Figure 44). Stange (1964) demonstrated apical dominance in another acrocarpous moss, *Funaria hygrometrica* (Figure 2-Figure 3, Figure 54).

Figure 44. *Splachnum ampullaceum*, a moss with known apical dominance due to IAA distribution. Photo by Michael Lüth, with permission.

Many acrocarpous mosses lose apical dominance when sporophytes are produced, resulting in innovations such as those in *Bryum* (Figure 45) or when antheridia develop as in *Philonotis* (Figure 46). This suggests that the sporophyte or archegonium causes the stem apex to cease producing IAA. We have already seen that in *Polytrichum*, male plants (Figure 37) retain their apical dominance and resume growth from the center of the male splash cup when the succeeding year's growth begins.

Figure 45. Innovation (arrow) in *Bryum versicolor*. Photo by Michael Lüth, with permission.

Figure 46. *Philonotis fontana* showing multiple branches just below the antheridial head. Photo by Janice Glime.

The role of apically supplied IAA is indicated in experiments where the gametophore is decapitated and an agar block containing 1mg/ml IAA is placed on the cut tip (Knoop 1984). In this case, stems without the agar block develop buds and branches, but in those with the agar block, the IAA inhibits lateral development in the same manner as an intact apex. Application of kinetin (a cytokinin) induces bud formation in those stems with an apical IAA source. A theoretical relationship to bud development is shown in Figure 47.

Figure 47. Theoretical relationship of auxin (IAA) and cytokinin in controlling branch production. **a)** Apical region during active growing season shows large production of IAA (arrow), inhibiting localized concentrations of cytokinin. **b)** End of growing season slows apical activity and production of IAA. **c)** Increased cytokinin:IAA ratio stimulates bud initiation. **d)** New apices become dominant and begin IAA production with new growing season.

The genus *Plagiomnium* exhibits a mix of upright growth that ultimately terminates in gametangia and

horizontal growth (**plagiotropic**). The moss *Plagiomnium cuspidatum* (Figure 48) responds to addition of IAA on a decapitated stem by exhibiting varying degrees of lateral bud suppression (Nyman & Cutter 1981). However, for the behavior to mimic that of controls with no decapitation, cytokinin must also be present.

Figure 48. Upright and plagiotropic growth forms of the moss *Plagiomnium cuspidatum*. Photo by Michael Lüth, with permission.

This relationship of buds with cytokinin does not seem to apply to all mosses. In the moss *Plagiomnium cuspidatum* (Figure 48), the cytokinin is synergistic with IAA in inhibiting bud development; IAA alone is unable to inhibit branch buds (Knoop 1984). Because bryophytes have very low concentrations of IAA, they are probably extraordinarily sensitive to it. Thus budding might be inhibited at quite low levels. The apparent synergism may be based on a concentration problem. Furthermore, both cytokinin and IAA can induce production of ethylene, and this could explain the apparent synergism between IAA and cytokinin in *Plagiomnium*.

Ethylene is known to inhibit development under some circumstances in plants. If ethylene is in fact the effector in branch inhibition, one might look for differences in ethylene production between acrocarpous and pleurocarpous mosses. Inhibition of branches by ethylene suggests that pleurocarpous mosses, or highly branched mosses, must have low endogenous ethylene relative to acrocarpous or unbranched mosses. If this is true, we should expect pleurocarpous mosses to be more sensitive to exogenous ethylene than acrocarpous mosses and that they might be less likely to produce ethylene in response to environmental stimuli; alternatively, they may be highly branched because they are not responsive to it. Whatever the mechanism, we should expect mosses lacking apical dominance to respond differently.

Cytokinins have been shown to enhance IAA-induced ethylene formation (Goodwin & Mercer 1983), which is likely to cause senescence. But in the acrocarpous moss *Anoetangium thomsonii*, Chopra and Rashid (1969) observed that, at any concentration of added kinetin, there was an increase in the number of buds and the rate of bud initiation. However, further shoot development was inhibited.

We need to further examine the case of *Plagiomnium cuspidatum* (Figure 48). Although this moss is acrocarpous, it has lateral (**plagiotropic**) branches in addition to its upright stem (Figure 48). These branches may behave more like branches of pleurocarpous mosses in their response to ethylene, IAA, and cytokinins. Because ethylene is a gas, it is more difficult to work with and quantify.

Pleurocarpous Mosses

Studies on the effects of growth substances on pleurocarpous mosses appear to be rare, probably due to the greater convenience in growing small acrocarpous mosses on agar [e.g. *Physcomitrium* (Figure 49), *Funaria* (Figure 2-Figure 3)]. However, our own studies on *Fontinalis* (Figure 50-Figure 51) may offer some insight.

Figure 49. *Physcomitrium pyriforme* with capsules, showing its small size. Photo by Jan-Peter Frahm, with permission.

Tremaine and Glime (unpub.) grew *Fontinalis duriaei* (Figure 12) in liquid culture with 10^{-6} and 10^{-8} M IAA and found that after two weeks there was significantly more growth at 10^{-8} M than at 10^{-6} M or controls (no IAA), with intermediate growth in the controls (Duncan's New Multiple Range test, $p < 0.05$). This contrasts sharply with the optimum of 10^{-5} M for higher plants (Haney 1978). But effects on branching and apical dominance were inconclusive even after 8 weeks.

In a separate study, Hover and Glime (1983, unpubl) grew *Fontinalis duriaei* (Figure 12) with kinetin additions and got rather confusing results. At 0.001 and 0.01 mg L⁻¹ added kinetin, the mosses produced fewer branches per stem than did the controls with no kinetin addition, but at 1.0 mg L⁻¹ they produced significantly more branches than did controls. They speculated that this may have been due to a competitive action between the exogenous kinetin and the plant's own cytokinin that could have resulted in suppressing production of the natural cytokinin.

Berthier (1966) found that maximum apical dominance in *Fontinalis* (Figure 50) occurred at 5% sunlight and that full sunlight caused maximum inhibition of axis growth. Shade inhibited branching. This and the studies mentioned above suggest that shade increases IAA and sun reduces the IAA:cytokinin ratio. This is consistent with events leading

to an etiolation response and the known destruction of IAA by high light intensity, especially UV, in tracheophytes.

Figure 50. *Fontinalis antipyretica* with wounded tip that now has grown rhizoids and a new branch. Photo by Janice Glime.

Figure 51. *Fontinalis antipyretica* var. *gigantea*, showing broken branch tip (center) with single new branch that has presumably resulted from loss of apical dominance. Photo by Malcolm Storey, through Creative Commons.

We know that high concentrations of ACC, an ethylene precursor and presumably resulting in ethylene production, inhibit branch development and bud production in *Fontinalis squamosa* (Figure 31) and *F. antipyretica* (Figure 50) (Glime & Rohwer 1983). Inhibitory effects of high IAA concentrations seem to be due to its effects in increasing ethylene production (Goodwin & Mercer 1983). This relationship implies that it could actually be ethylene that inhibits branch formation. Valadon and Mummery (1971) have shown that abscisic acid (ABA) also has a linear relation to bud reduction in *Funaria hygrometrica* (Figure 2-Figure 3, Figure 54). But abscisic acid is also known to promote ethylene production in some tissues (Craker & Abeles 1969), so it is possible that again ethylene was the actual inhibitor.

Although *Fontinalis* (Figure 50) does not appear to have a strong apical dominance, Berthier (1966) demonstrated that removal of its apex resulted in branches on each side of the apex. I (Glime) have observed similar phenomena in explants of *Fontinalis antipyretica* var. *antipyretica* (Figure 50, see also Figure 36), but when my student and I removed the apices from *F. antipyretica* var. *gigantea* (Figure 51), the removal had no observable effect

on branching. Since this variety does little branching normally, it may have been an inappropriate taxon to test.

But why does it appear that *Fontinalis* can't grow branches and stems simultaneously? Since both produce leaves that are photosynthetic, where is the tradeoff? Perhaps the experiments of Tremaine and Glime (unpub.) on *Fontinalis duriaei* (Figure 12) provide some insight into the relationship. They found the mosses in 10^{-6} M IAA to look healthiest (bright green) at the end of the experiment compared to the controls or those at 10^{-8} M, both of which grew more than those at 10^{-6} M. It appears that the tradeoff may be that the energy used for growth reduces the concentration of chlorophyll in the leaves as it distributes its building materials to new cells and tissues. This will reduce the leaf weight and the magnitude of photosynthesis per leaf area. Hence, it is most likely beneficial to hold one growth type constant while the other expands.

Spiess *et al.* (1972), working with the pleurocarpous *Pylaisiella selwynii* (Figure 52), also found that cytokinins increased bud formation but not further development, and thus concluded that the auxin:cytokinin ratio was important. They observed also that the number and morphology of the buds were both concentration dependent.

Figure 52. *Pylaisiella selwynii* on bark, where bud formation depends on cytokinin, but not further development. Photo by Janice Glime.

Thallose Liverworts

Even thallose liverworts exhibit apical dominance. In *Marchantia polymorpha* (Figure 30), hormones may control the fan shape of the thalli. The apical dominance of these plants is expressed as greater growth of one lobe compared to the other one. When the thallus develops, two apical notches are present. The larger lobe that develops is the one nearest to the midrib. If the two notches are cut at an early growth stage, inhibition of the smaller lobes ceases and it grows to equal the size of the dominant lobe. But it is not IAA that causes the new growth, but rather IAA inhibits the growth of the smaller lobe. The larger lobe, on the other hand, is not affected by IAA. This suggests that once a branch of the thallus becomes dominant the two lobes have different sensitivity to IAA as an inhibitor.

Branch buds of bryophytes are known to be sensitive to both cytokinin and auxin concentration. Three cytokinins tested stimulated vegetative growth, as well as archegonial production, in *Riccia frostii* (Figure 11),

whereas the auxin NAA only enhanced archegonial induction (Vashistha 1987). In studies on mosses, Chopra and Rashid (1969) found that low concentrations of exogenously applied IAA somewhat increases bud formation. At higher concentrations, IAA is inhibitory (Spiess *et al.* 1973).

Both cytokinins (Chopra & Gupta 1992) and IAA (Tremaine & Glime unpub.) appear to be important in controlling bryophyte growth. Chopra and Gupta (1992) found that of the three cytokinins they tested, 10^{-4} M was optimal for vegetative growth in *Riccia discolor*.

Nutrients

Koevenig (1973a) suggests that the growth hormones IAA, NAA, BA (6-benzyladenine, a cytokinin), and GA₃ may only aid in elongation but not actually induce it, implying that other substances are needed, such as the metals. Many compounds influence plant growth. Sharma *et al.* (1960) reported that *Haplomitrium* (Figure 53) gametophytes grew better on media containing various amino acids, indicating that organic material must be present in the substrate. Copper can stimulate growth of some bryophytes at elevated concentrations (0.01 ppm), presumably through greater photosynthesis (Sommer 1931; Glime & Keen 1984), wherein it is needed in plastocyanin, a chloroplast protein. Nevertheless, it soon becomes inhibitory at higher concentrations.

Figure 53. *Haplomitrium hookeri*, a leafy liverwort that grows best on a medium with amino acids as its nitrogen source. Photo by Janice Glime.

Laboratory cultures are usually much richer in nutrients than are the places where bryophytes normally grow. For example, in *Funaria hygrometrica* (Figure 2-Figure 3, Figure 54), field stem length never reaches that observed in the laboratory. One reason for this might be a deficiency of magnesium in its habitat and ample quantity in the culture medium. Hoffman (1966) found that *Funaria* remained small but healthy in a magnesium-deficient medium. Tamm (1953) found that rainwater, the major source of nutrients for ectohydric mosses, contained no magnesium in the open, although it did under spruce trees. Since *Funaria* does not grow in the shade of trees, it is likely to be suffering from a magnesium deficiency in the open, and this might account for its shorter stature in

nature. However, etioliation due to lower light intensity in the laboratory cannot be ruled out.

Leaves

Leaf development occurs when sufficient nutrients are available and temperature and light are adequate for growth. Thus leaf expansion can occur in consort with apical growth and branch growth, or the plant may produce numerous branches and leaves, delaying stem expansion until later, as in the capitula of *Sphagnum* (Figure 55). However, controls of these phenomena are different, and the reduced leaves on elongated stems in the *Funaria* (Figure 2-Figure 3, Figure 54) cultures under cellophane discussed earlier attest to this fact.

Figure 55. Dense branches in capitula of *Sphagnum wulfianum*. Photo by Jan-Peter Frahm, with permission.

Moss leaves typically are endowed with pigments and antiherbivore compounds that permit them to survive in their habitats. One of the compounds occurring in some moss cell walls appears to be a phenolic compound, as suggested by its ability to fluoresce under UV light (Figure 56).

Figure 56. Fluorescence of cell walls under UV light in a leaf of *Fontinalis antipyretica*. Photo by Janice Glime.

Light

In some species leaf dimensions and leaf shape are highly plastic and dependent on light and moisture conditions. Hoddinott and Bain (1979) found that red vs. far-red light caused significant differences in leaf dimensions. *Ceratodon purpureus* (Figure 4) and *Polytrichum juniperinum* (Figure 15) had longer leaves in red light, whereas *Leptobryum pyriforme* (Figure 14) and *Pohlia prolifera* (Figure 57) had longer leaves in far-red light. In *Ceratodon* and *Leptobryum*, leaf width was greater in red light, whereas in *Polytrichum* it was greater in far-red light. These wave length changes resulted in overall leaf shape changes in *Leptobryum*, *Pohlia*, and *Polytrichum*. *Dicranum polysetum* (Figure 13) and *Funaria hygrometrica* (Figure 58) leaf shapes were indifferent to red/far-red differences. Hopefully our new molecular techniques will help us sort out some of the environmentally induced differences.

Water

Water modifies leaf form as well. *Drepanocladus* (Figure 59) has longer and proportionally narrower leaves and loses its **falcation** (curved shape; Figure 60-Figure 61) in water (Lodge 1959). Furthermore, the normally straight *Fontinalis* leaves (Figure 62) become falcate (Figure 63) when grown in air (pers obs).

Figure 59. *Drepanocladus fluitans* growing above water and demonstrating curved leaves. Photo by Michael Lüth, with permission.

Figure 60. Modifications in leaf morphology of *Drepanocladus fluitans* due to submergence, in this case causing elongation. Redrawn from Lodge 1959.

Figure 64. Relationship between leaf cell length and salt concentration in *Drepanocladus fluitans*. Concentrations are relative percents of highest concentration with individual ions kept in same proportions. Redrawn from Lodge 1959.

Figure 62. *Fontinalis novae-angliae* with normal submerged leaves. Photo by Janice Glime.

Figure 63. Falcate leaves of *Fontinalis novae-angliae* grown on moist paper out of water. Compare these to the straight leaves in Figure 62. Photo by Janice Glime.

Salt can cause similar modifications to effects of being above water, suggesting that loss of water from the leaves can trigger these changes. For example, cell length of *Drepanocladus* leaves increases as salt concentrations increase (Figure 64; Lodge 1959). On the other hand, Voth (1943) found that *Marchantia polymorpha* (Figure 30) had rapid maturity and slightly smaller cells in higher concentrations of salts.

In *Sphagnum*, leaf response differs among species. In *S. papillosum* (Figure 7), the leaf becomes significantly longer when the capitulum is farther from water, but in *S. magellanicum* (Figure 6), there is little difference (Li *et al.* 1992; Figure 65). *Sphagnum* cell dimensions are also altered by water availability, with leaves of these two species grown under drier conditions having longer cells with unaltered width (Figure 66) and more pores per cell (Figure 65 right; Figure 67). Such evidence demonstrates the plasticity of species to respond to the environment and emphasizes the importance for common garden experiments in systematic studies.

Figure 65. Effect of water level (water availability) on **left:** leaf length and **right:** number of pores per cell in *Sphagnum magellanicum* (Figure 6) and *S. papillosum* (Figure 7). Hair points (hair-like extensions of leaf tip) in *Racomitrium lanuginosum* (Figure 68) are shortened by 50-100% in high humidity or shade (Tallis 1959). Cyclic weather conditions reduce hairs, causing maximal hair length on lateral branch zones but short hairs on in-between zones of the main axis. When the stem apex is removed, leaves have short or no hair points. When branches are produced, hair points arise on their leaves, suggesting that a controlling substance is produced by the stem apex and to a lesser extent by branch apices.

Figure 68. Apical hairs of *Racomitrium lanuginosum* showing reduced hairs at arrow. Photo by Michael Lüth, with permission.

The moss *Schistidium apocarpum* (Figure 69-Figure 70) varies considerably in the development of hair points, even on the same plant. *Schistidium rivulare* (Figure 71), which does not produce hair points, probably differs from *S. apocarpum* in its production of some growth-controlling substance.

Figure 70. *Schistidium apocarpum* with no hair points on leaves. Photo by Christophe Quintin, with permission.

Figure 71. *Schistidium rivulare* showing the absence of leaf hair points. Photo courtesy of Betsy St. Pierre.

Nutrients

Generally we look at the way nutrients affect whole plants, but they can especially affect development of leaves. For example, the difference between nitrogen as ammonium or organic N rather than nitrates in a low carbohydrate medium caused *Sphagnum fallax* (Figure 72) to develop leaves with no hyaline cells (Hintikka 1972). And nutrients can affect color (Glime & Marr unpublished). The role of nutrients on growth and development will be discussed in the chapter on nutrients.

Figure 72. *Sphagnum fallax*, a species that alters its hyaline cells depending on the form of nitrogen. Photo by David T. Holyoak, with permission.

Growth Regulators

Little seems to be known about the hormonal control of leaf development. Exogenous application of auxin stimulates activity of the GUS-stained GH3 and DR5 genes in leaves of bryophytes, as demonstrated in *Physcomitrella patens* (Figure 26), but these genes did not demonstrate activity without the external auxin stimulus (Bierfreund *et al.* 2003).

We do know something about the role of ethylene in creating anomalous effects in leaf development, and these certainly have ecological relevance. As mentioned earlier, when growth of moss leaves and branches in the Arctic is impeded by ice, the result is crumpled leaves and branch ends. Similar crumpling resulted from growing *Fontinalis squamosa* (Figure 31-Figure 32) in high concentrations of ACC (resulting in elevated ethylene) and is consistent with effects of ethylene in lignified vascular plants. In some cases, *F. squamosa* leaves became wavy, much as the normal form of *Neckera pennata* (Figure 74), and in others they were more contorted, like stepping on a wadded up ball of paper (Figure 32; Glime & Rohwer 1983).

In *Fontinalis antipyretica* (Figure 73), application of ACC resulted in undulations on both young leaves and old, mature leaves (Figure 74; Glime & Rohwer 1983). Ethylene permits cells that have reached a certain stage to continue elongation, but inhibits it in younger cells. This results in uncoordinated development of the leaf cells and a surface that is not flat. It is very likely that similar hormonal regulation results in the natural waviness of leaves like those of *Neckera* (Figure 74). Since *Fontinalis* has been considered as closely related to the Neckeraceae, where undulations are characteristic of several species, it suggests that a gene controlling ethylene production or ACC distribution might be responsible for this morphology.

Figure 73. *Fontinalis antipyretica* showing normal, smooth leaves. Photo by Kristian Peters, with permission.

In nature, such events are likely to occur in response to leaf litter cover, ice, snow, and other physical barriers. By preventing diffusion of ethylene, unequal concentrations of ethylene result around different parts of plants, and as ethylene buildup occurs, contorted growth can result. An ethylene-induced growth differential between stems and leaves could explain the appearance of reduced leaves on

stolons (horizontal stems from which upright stems arise) of certain species of *Fontinalis* (Glime 1980). If these stolons are a response to burial in a sandy substrate, or even burial among other *Fontinalis* branches that impede flow, ethylene production and accumulation could be the biochemical agent.

Figure 74. **Left:** *Fontinalis antipyretica* exhibiting undulate leaves induced by 10^{-4} M ACC. **Right:** *Neckera pennata* exhibiting genetically undulate leaves. Photos by Janice Glime.

In *Fontinalis antipyretica* (Figure 73), the response to ethylene precursor ACC was similar (Glime & Rohwer 1983) to the response of fern gametophytes, where mitosis ceased and cell elongation was enhanced by ethylene (Edwards & Miller 1972). In *F. antipyretica*, shoot apices appeared truncated because older leaves with yet undeveloped cells had sustained cell elongation, whereas the center of the bud, where cell formation was incomplete, ceased its production of new cells and remained small (Figure 75). In these plants, elongation of outer leaves accounted for all growth of the plant during the 8-week experiment (Glime & Rohwer 1983).

Figure 75. Effects of ACC (and presumably ethylene) on the shoot apex of *Fontinalis squamosa*. Note truncated tip where leaves did not elongate while nearby leaves continued growth. Photo by Janice Glime.

The modified apex of *Fontinalis squamosa* (Figure 31) is usually accompanied by red to brown leaf coloration in elevated ACC (Figure 76). It appears that ethylene (or ACC) stimulates a color change to a reddened color in the cell walls.

Figure 76. Effect of ACC on leaf cell wall color in *Fontinalis antipyretica*. **Left:** Normal cells. **Right:** Cells subjected to 10^{-4} M ACC. Photo by Janice Glime.

As noted above, *Fontinalis* also can develop a modified leaf shape when grown exposed to air. When it is submersed during growth, leaves are straight, but in our lab cultures where it grew in a thin film of water and continuously received exposure to air while remaining wet, leaves became falcate (curved like a sickle; Figure 63). This may have been another example of ethylene production in the high oxygen, low CO₂ environment of air, as opposed to that in water. It is interesting that the other two genera in the family, *Brachelyma* and *Dichelyma* (Figure 77), have falcate leaves and grow most of the year out of the water.

Figure 77. *Dichelyma falcata* exhibiting falcate leaves. Photo by Michael Lüth, with permission.

Liverwort Leaf Suppression

Something happens as liverwort leaves develop! Something suppresses every third leaf during development. The result is that liverworts have two rows of leaves and a third row that may fail to develop completely or that develops into small leaves called **amphigastria** or **underleaves**.

Ethylene seems to have played a major evolutionary role in these bryophyte leaf arrangements. Basile and Basile (1983a, b, 1984, 1994) have shown that **hydroxyproline** (crystalline amino acid abundant in major glycoprotein of plant primary cell wall) will induce underleaves of liverworts to reach the size of lateral leaves, and in some cases induce development of underleaves when they are unknown in nature. They contend that loss of normal-sized underleaves in bryophytes, such as seen in

Haplomitrium (Figure 78), is an evolutionary result of inhibition by ethylene, because ethylene antagonists such as hydroxyproline can induce these bryophytes to produce normal leaves where small underleaves would normally be. This is consistent with the widespread belief that 3-ranked leafy liverworts (Figure 78) are the primitive form, with 2-ranked ones being derived (and as implied here, derived due to suppression of the third row that results in reduced underleaves typical of many leafy liverworts; Figure 79).

Figure 78. *Haplomitrium mnioides*, a leafy liverwort with three equal rows of leaves. Photo by Li Zhang, with permission.

Ethylene is known as a **senescence** hormone, *i.e.* it causes aging. In high concentrations it can cause cells to **plasmolyze** (cell membrane & contents pull away from cell wall) and die (Figure 80), as shown by Glime and Rohwer (unpub. data).

Figure 79. Ventral view of *Calypogeia fissa*, a leafy liverwort with the underneath row of leaves suppressed. Photo by Michael Lüth, with permission.

Figure 80. Plasmolyzed basal leaf cells in *Fontinalis antipyretica* subjected to 10^{-3} M ACC. Photo by Janice Glime.

Ethylene has a number of potential effects on leaves, but these have rarely been documented. It causes cell walls to become red, makes leaves wavy, and gives stem apices a truncated appearance (due to inability of young cells to elongate while older ones continue to elongate). Its most important role appears to be in the evolution of leafy liverworts with **underleaves** or no underleaves, compared to those with three equal rows.

Cuticle

Bryophytes, for a long time, were considered to lack a cuticle. But in fact, many do have varying degrees of cuticle (Figure 81) (Stránský *et al.* 1967; Nilsson & Mårtensson 1971; Haas 1982). Cook and Graham (1998) noted the structural similarities between the osmiophilic surface layer on the liverwort *Monoclea gottschei*, the moss *Sphagnum fimbriatum*, and the hornwort *Notothylas orbicularis* with those of tracheophyte cuticles in that there is an "osmiophilic layer on the outer cell wall that bears some structural resemblance to early developmental stages of vascular plant cuticles." Of 43 moss species tested, Proctor (1979) demonstrated cuticles on 12 that were comparable to those on tracheophyte leaves.

We now know that cuticles in bryophytes can be present in the sporangial epidermis, spiral thickenings of elaters, rhizoids, and leaves (Kroken *et al.* 1996). As time progressed, so did regulation of their deposition. These cuticles initially seemingly had the functions of desiccation resistance and/or microbial resistance, as seen in lower charophytes. They have played a role in embryogenesis in the early land alga/plant *Coleochaete* and in embryophytes. Ultimately, they have an important role in decay resistance such as that of rhizoids, sporangial epidermis, and elaters of bryophytes.

Salminen *et al.* (2018) noted that as photosynthetic organisms ventured onto land they developed new polymers such as cutin and suberin as a protection against water loss, solar radiation, and other potentially harmful abiotic factors. But we know little about these in bryophytes. Nevertheless, because of the variability of habitats exhibited by bryophytes and their early position in evolution on land, Salminen and coworkers proposed that liverworts and mosses were an attractive model systems for determining the specific functions and activity of lipid transfer proteins (LTPs) associated with cuticle synthesis and evolution of the plant cuticle.

Figure 81. *Mylia anomala* showing cuticle. Photo by Paul G. Davison, with permission.

But our ecological knowledge of bryophyte cuticles seems to stop at recognition of their existence. I could find no reports on environmental or physiological control, and thus far there does not even seem to be evidence to support environmental correlation. Nor do we know at what developmental stage the bryophyte leaf or thallus begins production of the cuticle. We know that in tracheophytes, the cuticle can at times serve as a barrier to the entry of fungi and other pathogens (Kolattukudy 1985), but that role seems to be controversial, with many fungi possessing the enzymes needed to gain entry through the cuticle (Köller 1991). Stomata or wounding usually are the points of entry for fungal hyphae.

Do cuticles add to the ability of bryophytes to deter invasion of fungi? Is there any correlation between presence of cuticles similar to those of tracheophytes and the absence of fungal pathogens in bryophytes in nature? Do such pathogens attack the bryophytes only after they have been wounded? And how do the cuticles affect decomposition of dead and dying bryophytes?

Cuticles are **hydrophobic** (repelling water) and thus could facilitate photosynthesis by preventing the water barrier to CO_2 entry in bryophytes. In some cases, this hydrophobia could direct water to the base of the leaf

where there may be no cuticle and water entry is possible, while permitting photosynthesis in the rest of the leaf. This also could facilitate the spreading of the leaf upon hydration by dew or rain. This hydrophobia works on its inner surface as well, reducing water loss through the surface. In tracheophytes, interaction between the plant cell walls and cuticle in the presence of a pathogen on the surface can trigger internal plant chemical defenses (Ziv *et al.* 2018). But do bryophytes benefit from any of these possibilities?

Calyptrae

Since I seem to have neglected the gametophyte role in the protection of the sporophyte, this is perhaps an appropriate place to discuss it because of the role of the cuticle. Further information on the role of the calyptra is discussed in subchapter 5-9 of this volume on the Sporophyte. Budke *et al.* (2011) asked "A hundred-year-old question: Is the moss calyptra covered by a cuticle?"

Using the easily cultured *Funaria hygrometrica* as the study object, Budke and coworkers noted the role of the calyptra in protecting the developing sporophyte from desiccation. Using both SEM and TEM, they compared the calyptra, leafy gametophyte, and sporophyte sporangia. These methods revealed a multi-layered cuticle on the calyptra, including layers analogous to the cuticular layer, cell wall projections, electron-lucent, and electron-dense cuticle proper observed in tracheophytes. They hypothesized that the apex of the developing sporophyte in particular would be well protected. They found that the calyptra rostrum has a significantly thicker cuticle than the other tissues examined and differs by specialized thickenings of the cuticular layer (cuticular pegs) at the regions of the anticlinal cell walls – the first report of cuticular pegs in bryophytes.

Budke *et al.* (2013) followed these observations by experiments to verify the role of the cuticle in protecting the developing embryo in *Funaria hygrometrica*. When the cuticle of the calyptra was removed chemically, they found that under low humidity conditions there is significant negative impact to moss sporophyte fitness, including decreased survival, increased tissue damage, incomplete sporophyte development, more peristome malformations, and decreased reproductive output.

Using four bryophyte species, Budke and Goffinet (2016) subsequently found that shorter sporophytes are associated with smaller calyptrae and thinner calyptra cuticles, whereas taller sporophytes are associated with larger calyptrae and thicker calyptra cuticles. Using sectioning techniques, they found that the cuticle of the sporophyte thickens during later development. The calyptrae, on the other hand, have a mature cuticle early in their development, and this persists throughout development. This can become an adaptive strategy in which resources are allocated, or not, to a thickened cuticle. Limited cuticle development can provide resources for other types of development for survival in different developments. Therefore, we should expect differences in cuticle thickness of the calyptra in wet vs dry environments, or at least in the species restricted to each.

Rhizoids

Rhizoids in bryophytes have an important role in anchoring the plants to the substrate and thus helping them adhere under the force of wind, water, or animal activities. It is therefore not surprising that these factors, along with temperature, are influential in the development of rhizoids.

Temperature

Furness and Grime (1982) demonstrated that switching of developmental processes can be due to different temperature optima. In *Brachythecium rutabulum* (Figure 82) growth is greatest at 20°C, primary branching at 16°C, and rhizoid production at 12°C. By contrast, in *Fontinalis hypnoides* (Figure 83), rhizoids are produced at 15-20°C (Figure 84-Figure 86), whereas the growth optimum is 10-15°C (Glime 1980, 1982; Glime & Raeymaekers 1987), and branching occurs during late winter, spring, and early autumn when the temperature is usually less than 10°C (Figure 86). In *F. dalecarlica* rhizoid production is negatively correlated with branch production (Glime 1984). This timing for *Fontinalis* permits the rhizoids to grow during warm summer months when the moss is most likely to have a sustained period without disturbance of heavy flow, thus affording it an opportunity to attach.

Figure 84. Flow and temperature effects on mean number ($n=40$ stem tips in each condition) of rhizoid clumps in *Fontinalis hypnoides* from the Keweenaw Peninsula of Michigan, USA, after 15 weeks in flowing water and pool conditions in artificial streams. From Glime & Raeymaekers 1987.

Light

Light can influence both form and production of rhizoids in bryophytes. In *Riccia crystallina* (Figure 85) red light favors smooth rhizoid production, whereas at high intensities more rhizoids are produced and more are **tuberculate** (having "pegs" or extensions of cell wall protruding into cell; Figure 87) (Chopra & Sood 1973). In 0.5% sucrose, there are 50% more smooth ones than tuberculate ones, but at 2% sucrose there are twice as many tuberculate as smooth ones, suggesting that the role of light in governing morphology may be one of sugar concentration, thus implicating a role for photosynthesis.

Figure 85. *Riccia crystallina*, a liverwort in which red light favors production of smooth rhizoids. Photo by Des Callaghan, with permission.

Figure 86. Flow and temperature effects on mean number (40 replicates at each condition) of rhizoid clumps (**dotted line**), branches per cm (**dashed line**), and cm growth of stem + branches (**solid line**) after 15 weeks in flowing water and standing water (pool) conditions in artificial streams. There are no data for *F. dalecarlica* at 20°C. All populations are from the Keweenaw Peninsula of Michigan, USA, except where noted for New York, USA. From Glime & Raeymaekers 1987.

Figure 87. *Conocephalum conicum* showing an example of smooth (**upper**) and pegged (**lower**) rhizoids. Photo by Paul Davison, with permission.

On the other hand, **phytochrome** is implicated, not photosynthesis, in controlling rhizoid production, based on research on *Marchantia polymorpha* (Figure 88) (Otto & Halbsguth 1976). Production of rhizoids at different wavelengths is subject to the typical red/far-red reversibility that characterizes involvement of phytochrome. Further implication in the role of phytochrome is that application of 10^{-4} M IAA for one hour has the same effect as one hour of red radiation.

Figure 88. *Marchantia polymorpha* showing rhizoids. Their production differs depending on wavelength of light and application of IAA. Photo from Botany Website, University of British Columbia, Canada, with permission.

Tropisms

We know a lot about tropisms in protonemata, but that does not seem to be the case for gametophores. As late as 2004, Cove and Quatrano determined that there are no extensive studies on gametophore tropisms. A search in Google Scholar in 2017 confirmed that is still the case, but some genetic studies are helping us to understand tropic responses in bryophytes. We understand that tropisms permit the plant to position its leafy shoot in the best position to obtain the maximum light for photosynthesis (Knight *et al.* 1991).

Early studies by Rawitscher (1932) indicated that *Marchantia polymorpha* (Figure 30) exhibits tropic responses to gravity, light and other factors. Miller and Voth (1962) demonstrated negative gravitropism of the thallus of this species. On thalli grown in an inverted position, the gemmae cups curved back toward the thallus. Furthermore, when the thalli were oriented vertically, the gemmae cups curve upward. Position had no effect on rhizoids, internal structure, pores, or position of terminal scales.

Physcomitrella patens (Figure 26) has not escaped tropism studies. Upright stems of this moss exhibit negative gravitropism, with no gravitropic response when the plants are rotated slowly vertically (Jenkins *et al.* 1986). At least three genes appear to be involved in the protonema gravitropism, with mutations in these altering the gravitropic form of the protonema, but none of these mutations affects the gravitropism of the leafy plant.

Genetic knock-out experiments are enabling us to understand many processes in plants, including tropisms in bryophytes. Knight and coworkers (Knight & Cove 1989; Knight *et al.* 1991) used genetic analysis of mutant *Physcomitrella patens* (Figure 26) in which the gravitropism was reversed. They found that both protonemata and gametophores respond to re-orientation by growing with negative gravitropism. In the mutant, the protonemata respond, but the gametophores do not, indicating control by mutation of a single gene.

Using *Physcomitrella patens* (Figure 26), Bao *et al.* (2015) were able to observe the phototropic response of the gametophore. In this species, the response is slow, taking more than 24 hours after the onset of a directed light source. They attributed the slow response to the slow growth of the moss. They found that red and far-red light were more effective than blue light.

Bennett *et al.* (2014) contributed to the story by experimenting with auxins and auxin transport inhibitors on the gametophytic shoot of *Physcomitrella patens* (Figure 26). These disrupt the apical function and leaf development. **PIN-mediated** (a protein) auxin transport regulates apical cell function, leaf initiation, leaf shape, and shoot tropisms in moss gametophytes. PIN mutants sometimes produce sporophytes that are branched, a condition rarely seen among natural moss variants.

In *Physcomitrella patens* (Figure 26), we know that cryptochrome signals are important regulators in many stages of moss development (Imaizumi 2002). These include the induction of side branching on protonemata, induction of the leafy gametophyte, and development of the leafy plant. When the cryptochromes are disrupted, auxin responses were altered, including altering the expression of auxin-inducible genes. This study indicates that light signals received by the **cryptochromes** act to repress auxin signals and in that way they control plant development.

In the moss *Ceratodon purpureus* (Figure 89), the polarity of the axis from regenerating protoplasts is influenced by the direction of light (Cove & Quatrano 2004). There is a delay in the response when the light direction is changed – a limitation that prevents the stem from tracking the sun as the Earth turns. For example, when protoplasts regenerate in red light at 25°C, there is a delay of about 9 hours before any response is observed. The lag is shorter with far-red light. Their ability to "memorize light direction" indicates use of **phytochrome**. They indicated that the phototropic response "turns off" the gravitropic response in this species and in *Physcomitrella patens* (Figure 26).

Figure 89. *Ceratodon purpureus*, a moss in which polarity is influenced by light. Photo by Michael Lüth, with permission.

Rhizoids locate their substrate by a combination of gravitropism and phototropism, followed by a **thigmotactic** response (contact response) (Glime 1987c). Light can play a strong role in determining the direction of rhizoid growth. In *Fontinalis squamosa* (Figure 31), rhizoid growth was strongly photonegative (Figure 90), just as that of roots in tracheophytes. In most cases, this negative phototropism will permit the rhizoids to locate the substrate, which typically occurs in the same direction as the gravitational pull.

Figure 90. Strong negative phototropism of *Fontinalis squamosa* rhizoids at broken ends of stems. Photo by Janice Glime.

But in *Fontinalis squamosa*, direction of light can be overridden by contact. Although the rhizoids were initially negatively phototropic, once they contacted the substrate they continued growing in that direction even when the light was reversed to come through the glass substrate (Glime 1987c).

One might suspect that **gravitropism** (directional growth in response to gravity) could be a cue for direction of growth in *Fontinalis* rhizoids, but I have not been able to induce a gravitropic response in *Fontinalis antipyretica* or *F. squamosa* (Glime 1987c). Instead, a strong negative phototropism occurs, even when it means rhizoids must grow pointed toward the stem apex, as in Figure 90. *Funaria hygrometrica* (Figure 2-Figure 3, Figure 54), on the other hand, has positively gravitropic rhizoids (Figure 91) that are indifferent to light (Kofler 1958). *Funaria* does not grow on vertical substrata, so gravitropism would be an adaptive feature for *Funaria*, whereas in *Fontinalis* it could be maladaptive for a plant that tends to grow on

vertical faces on downstream sides of rocks. On the other hand, light will always be from above in habitats suitable for *Funaria*, so absence of phototropism may have no selective disadvantage.

Figure 91. *Funaria hygrometrica* showing rhizoids growing downward toward gravity. Photo by Jan-Peter Frahm, with permission.

Schofield (1985) has concluded that in general rhizoids are negatively phototropic and positively gravitropic (Schofield 1985). However, this behavior might be different if we look at taxa that typically grow on vertical rocks, as suggested by *Fontinalis* (Figure 92) data (Glime 1987c). Despite all the basic physiological work on plant tropisms in protonemata, we know very little about bryophyte tropisms in other parts of the plants.

Figure 92. *Fontinalis novae-angliae* becoming established on a rock. Photo by Janice Glime.

Otto (1976) demonstrated several attributes of the rhizoids of gemmae of *Marchantia polymorpha* (Figure 30, Figure 93). They always grow from the **ventral** (lower) side – a response that could be either gravity or light driven. However, in alternating gravity in the darkness they form no rhizoids, but when gravity is constant they produce them with or without light. They also respond to contact, producing more rhizoids when contacting the substrate than when growing free in the air.

Adhesion

Once a bryophyte makes contact with a solid surface, the tips tend to flatten and branch (Figure 94). These branched tips typically produce an adhesive substance that is especially important on vertical surfaces and in streams. Odu (1989) characterized this substance in the leafy liverwort *Lophocolea cuspidata* (Figure 95) and determined that it is a sulfated mucopolysaccharide. But attachment to a submersed rock in flowing water is much more challenging. Hence, we might find that this glue is different from that of *L. cuspidata*.

Figure 94. Branched tip of *Fontinalis squamosa* rhizoid in response to contact. Photo by Janice Glime; drawing by Margaret Minahan.

It is interesting that the flattened portion of the rhizoid occurs only at the tips in the pleurocarpous mosses, whereas in the acrocarpous mosses it extends far back from the tip (Odu 1989). Yet few acrocarpous mosses occur on

vertical surfaces, most likely due to the small area available for adhesion compared to the weight of an outward-growing moss. Pleurocarpous mosses, on the other hand, have abundant surface area in contact with the substrate, and rhizoids typically occur throughout.

Growth Regulators

Hormones are certainly involved in the differentiation of rhizoids. Maravolo (1980) found that auxins and gibberellic acid both stimulate the formation of rhizoids and cause cell division and elongation. Auxins in tracheophytes are known to stimulate roots and stems differently, so it is not surprising that rhizoids and stems of bryophytes respond differently to the same concentrations. Kumra and Chopra (1987) have shown that in callus cultures, lower concentrations of auxins stimulate differentiation into thalli and rhizoids, but at higher concentrations, only the rhizoids develop. Kaul *et al.* (1962) likewise found that high concentrations of NOA, 2,4-D, TCPA, IBA, and IPA stimulate rhizoid production in *Marchantia* (Figure 96). They also found that the responses of rhizoids to growth hormones differed in liquid vs solid culture media. Others have shown that IAA induces rhizoid production in wounded parts of plants (LaRue 1942; Maravolo & Voth 1966).

Figure 96. *Marchantia polymorpha* ventral side showing rhizoids. Photo by Botany Website, UBC, with permission.

Contrary to the popular belief that rhizoids function only in anchorage, Rose and Bopp (1983) found that rhizoids actually take up auxins from the environment. They found that the auxins are transported from the tip to the base of the rhizoids, where it accumulates.

Wounding

New growth results in most bryophytes as a result of wounding. In *Fontinalis* (Figure 97), this is typically preceded by the production of rhizoids that appear to be highly negatively phototropic. Furthermore, the rhizoids are **thigmotactic**, responding to contact by branching. But to find that surface, they have an interesting growth habit. They grow in a spiral (Figure 97). This spiral permits them to experience a larger area in which to locate a surface to which they need to attach. I am unaware of this behavior in other bryophytes, and it may indeed be peculiar to aquatic bryophytes.

Figure 97. Rhizoids on an explant of *Fontinalis squamosa*, exhibiting spiral growth from the cut stem. Photo by Janice Glime.

LaRue (1942) has shown that in liverworts wounding induces rhizoids. He also showed that 1% IAA induced rhizoids all over the setae and capsules of *Amblystegium* sp. (Figure 98). IAA is produced by the breakdown of tryptophan in dying cells (Sheldrake 1971), and Maravolo and Voth (1966) have shown that IAA stimulates rhizoid production in gametophytes. In *Fontinalis* (Figure 100), I have found that my explants always produce rhizoids at or near the broken lower end of a stem piece, as in Figure 97, suggesting a polar substance such as IAA is responsible. However, the ultimate effector could be IAA-induced ethylene. Disintegrating xylem is a major source of IAA, as a result of tryptophan breakdown, so that this may be an important source for some bryophytes that establish primarily on rotting logs.

Numerous experiments show that ethylene levels rise as a result of wounding. In fact, most experiments on plants probably begin with elevated ethylene due to handling by the experimenter. If this is true, what occurs in a moss subjected to continual stress of a fast current? Using artificial streams in the laboratory, Glime and her students (Glime *et al.* 1979) found that rhizoids of several aquatic mosses [*Hygroamblystegium fluviatile* (Figure 99), *Fontinalis duriaei* (Figure 100)] began to adhere to rocks after about 9 weeks and little additional attachment occurred after 14 weeks of contact (Figure 101). In these experiments, pieces of freshly wounded moss were tied to

the rocks to insure contact and maintain their location. Odu (1978b) found a much shorter period of rhizoid growth for *Calliergonella cuspidatum* (Figure 102), *Pleurozium schreberi* (Figure 103), and *Brachythecium rutabulum* (Figure 104), species that grow mostly on soil or in standing water. Their rhizoid growth rates leveled off after about 6 weeks, and after 10 weeks there was no further growth.

Habitat Conditions

Odu (1978a, 1979) has found that acrocarpous mosses produce rhizoids all the way around the stem, but these are

generally restricted to the stem base (Figure 106-Figure 105). These patterns are adaptive to the growth habit since acrocarpous mosses grow outward from a substrate and therefore can utilize only basal attachment. Compare that to the ventral positions in the two pleurocarpous mosses in Figure 99 and Figure 100. But substrate is not the only determining factor in rhizoid form. Acrocarpous moss rhizoids typically are longer, due to longer cells, than those of pleurocarpous mosses, even on vertical substrata (Figure 107; Odu 1978a).

Figure 104. *Brachythecium rutabulum*, a ground- and rock-dwelling species with rapid rhizoid development. Photo by J. C. Schou, with permission.

Figure 107. Relationship of cell length to rhizoid length in acrocarpous (\diamond *Bryum capillare*, \triangle *Pohlia nutans*, \square *Dicranum scoparium*) and pleurocarpous (\bullet *Hypnum cupressiforme* var. *cupressiforme*, \blacksquare *Rhynchostegium confertum*, \blacklozenge *Homalothecium sericeum*) mosses, showing the greater length typical of acrocarpous mosses. Means are of 50 cells with 10 rhizoids used per species. Redrawn from Odu 1978a.

Mosses that grow prostrate on hard substrates typically develop rhizoid tufts (Odu 1978a), as seen for *Fontinalis* (Figure 100). In some cases these fuse, creating even greater physical strength. Pleurocarpous mosses generally produce rhizoids on only one side of the stem and these can occur throughout the stem (Odu 1979), as they do in most Jungermanniopsida (leafy liverworts; Schuster 1966). They have a **dorsi-ventral** (top-bottom) orientation so that if a pleurocarpous moss is turned upside down, its rhizoids initially grow from its new **dorsal** (upper) surface and then bend downward. However, eventually the stem itself twists so that it once again has the original ventral side next to the ground (Odu 1979). This twisting takes 5-18 days to turn 90° in *Hypnum cupressiforme* (Figure 108) and 10-30 days to turn 180°. Rhizoid production increases on the new growth in this twisted position. This twisting indicates that the stem has a top-bottom polarity that controls rhizoid orientation and that the growth of the rhizoids on that side of the stem is not a tropic response. Even in pleurocarpous mosses that initially grow upright, such as *Pleurozium schreberi* (Figure 103) and *Calliergonella cuspidatum* (Figure 102), rhizoids grow on only one side of that vertical stem. That upright stem eventually becomes the horizontal stem and the rhizoids are on the ventral side. In *Funaria hygrometrica* (Figure 2-Figure 3, Figure 54), rhizoids of germinating spores formed toward the positive electrode (Chen & Jaffe 1979), suggesting that this polarity may begin at the spore stage.

Figure 108. *Hypnum cupressiforme* on one of its many substrates. Photo by Dick Haaksma, with permission.

Based on Odu's (1978b, 1979) observations, I predicted that the pleurocarpous *Fontinalis* (Figure 31) should have rhizoids arising on all sides of the stem, since moving water prevents it from having one side that is always down. That is exactly what I observed in my culture experiments (Figure 109) (Glime 1980). Such an arrangement in stream mosses facilitates attachment in moving water. But how do these rhizoids attach without wasting energy by growing in all the wrong directions? Perhaps the rhizoids release ethylene upon contacting a substrate and the ethylene serves to inhibit further lengthening and instead serves to thicken the cells to provide a more secure attachment. We know, in fact, that once the rhizoids of *Fontinalis squamosa* (Figure 94, Figure 97) contact a surface they branch prolifically and attach (Glime 1987c; Figure 94). This is consistent with observations of Odu and Richards (1976) on the leafy liverwort *Lophocolea cuspidata* (Figure 95) and the mosses *Hypnum cupressiforme* var. *cupressiforme* (Figure 108) and *Platyhypnidium riparioides* (Figure 110) that respond similarly to contact.

The number of rhizoids produced by gametophores is also related to substrate. Odu (1978a, b) found that mosses that grew on boulders or tree trunks produced more rhizoids than did those on soil. When several species were moved from boulders to soil, they produced fewer rhizoids.

Stream mosses often produce abundant rhizoids (Figure 99-Figure 100), but taxa from other wet habitats often lack them. This absence is typified by such genera as *Sphagnum* (Figure 6-Figure 7) and *Drepanocladus s.l.* (Figure 111). The only species of *Sphagnum* known to have rhizoids is an epiphyte. If wet habitat species are grown out of water, will rhizoids develop? I tested this by gathering submersed *Drepanocladus exannulatus* (Figure 111) with no rhizoids and placing explants on a Petri plate of inorganic nutrient agar. Rhizoids appeared. Thus rhizoids in *D. exannulatus* seem to be under environmental control.

Figure 109. Rhizoids of *Fontinalis* on stoloniferous branches. **a.** *Fontinalis dalecarlica*. **b.** cross section of stoloniferous branch of *Fontinalis dalecarlica*. **c.** *Fontinalis novae-angliae*. From Glime 1980.

Figure 110. *Platyhypnidium riparioides*, a rock-dwelling species that produces rhizoids in response to contact. Photo by Hermann Schachner, through Creative Commons.

My observations on *Fontinalis hypnoides* (Figure 100) (Glime 1980) help to explain the control of rhizoid production in the aquatic habitat. The number of rhizoids increased with temperature when cultured at 1, 5, 10, 15, and 20°C. Furthermore, mosses in flowing water produced more rhizoids than those in standing water. The latter observation might be explained by **ethylene** control, since

ethylene is known as an inhibitor of rhizoid elongation in ferns (Miller *et al.* 1970). In our experiments on *F. squamosa* (Figure 31), ACC (ethylene precursor) inhibited rhizoid production with increasing concentrations in cultures on wet filter paper, and the inhibition was more severe in mosses in water (Glime & Rohwer 1983). Since ethylene is not very soluble in water, it could easily accumulate around the moss and be a cause for the retardation of rhizoids in standing water, whereas flowing water would remove the ethylene. On the other hand, this removal action must counteract the increased production of ethylene we might expect to result from the mechanical stress of flowing water. But no one has demonstrated that mechanical stress does indeed induce ethylene production in bryophytes, as it does in tracheophytes. And we can reasonably expect the effective concentrations are different in bryophytes. Just as roots and shoots respond differently in tracheophytes, different parts of bryophytes can respond differently from each other and from parts with similar functions in tracheophytes.

Figure 111. *Drepanocladus exannulatus*, a species that is devoid of rhizoids under water, but that can produce them when grown on an agar substrate. Photo by Michael Lüth, with permission.

Rhizoids seem to have evolved in adaptive ways to fit the habitats of their owners. Acrocarpous mosses that generally are upright have rhizoids that surround the base of the stem; pleurocarpous mosses that generally grow horizontally produce rhizoids only on their lower sides. The aquatic pleurocarpous moss *Fontinalis* produces them all around the stem, enabling it to attach from whatever side makes contact with a substrate. Mosses that grow on vertical substrata produce numerous rhizoids. Many mosses, especially on vertical substrata, have rhizoids that branch upon contact, permitting them to occupy a greater cementing surface. Stream mosses produce many rhizoids, whereas quiet-water species usually lack them, and this can differ within the same species in response to flow. Quiet water species may similarly produce rhizoids when growing out of the water. ACC inhibits the production of rhizoids, suggesting ethylene may be involved in these environmental responses.

Conduction

If *Dicranella heteromalla* is in any way typical of mosses, we have been underselling the role of the bryophyte rhizoid. Rather than simply anchoring the mosses, it appears that they may have important roles in nutrient absorption (Duckett & Matcham 1995). Their structure is very similar to that of food-conducting cells in leafy gametophyte stems and sporophytes. From this they suggested that the major role of the rhizoids might be solute uptake.

Bryophyte Senescence

Senescence is the process in which the cell reaches a state wherein it cannot undergo either progressive or regressive development and its only future change will lead toward death of the cell (Giles 1971).

Only in bryophytes can the lower part of the plant be completely dead while the upper part is still very much alive. *Sphagnum* is a classic example, exhibiting healthy, reproductive tops and dead bases, decades old (Figure 112). In mosses such as *Hylocomium splendens* (Figure 113), one might find 4-7 years of live growth atop several more years of senescent or dead plant.

Figure 112. *Sphagnum girgensohnii*, showing dying and dead lower parts. Photo by Bernd Haynold through Wikimedia Commons.

At least in some taxa, the initiation for senescence results from the production of male gametangia or capsules. In many acrocarpous mosses, these structures can effectively prevent further growth of the plant by occupying what would have been the region of apical growth, as shown for *Tetraphis pellucida* (Figure 114) (Kimmerer 1991). In this species, high density increases sexual reproduction, which increases capsule production and proportion of males, which in turn initiate senescence for the population. Some mosses overcome this apical growth termination by producing innovations – side branches near the tip that become new tips and continue the growth upward (see chapter on gametophore development).

Figure 113. Living plants of *Hylocomium splendens* forming a turf on top of their own senescent branches (arrow). Photo by Michael Lüth, with permission.

Figure 114. Mature capsules that mark the onset of senescence in *Tetraphis pellucida*. Photo by Janice Glime.

As in higher plants, it appears that ethylene induces senescence, as shown in *Marchantia* (Figure 30) (Stanislaus & Maravalo 1994). Spermine, spermidine, and putrescine can reverse it. If we dare to generalize from this meager example, the story makes sense. As the moss grows and the cushion or mat (or whatever) becomes more dense, there is less and less air movement in the lower part of the growth form (see Figure 115). This permits gases to accumulate, so if ethylene is being produced, this surely is a place for it to reach higher concentrations. Now all we need to do is show that indeed there is ethylene given off here, that it accumulates, that it reaches high enough concentration, and that it indeed induces senescence in most (all?) bryophytes!

Ecological Interaction

External factors may control differentiation and growth of gametophores in bryophytes. The physical effects of accompanying plants are widely recognized. However, with sensitivities at such microlevels as affect bryophytes, exudates from other organisms also have the potential to effect changes in developmental patterns. This might be especially true if dying plants leak substances that collect on the surfaces of the bryophytes, dissolved only in the adhering humidity and readily absorbed by the mosses in what would, under these circumstances, be relatively high concentrations. Nevertheless, although the potential seems relatively high, few studies have addressed these potentials.

The presence of other plants will naturally affect moisture and light availability. In general, other plants help to maintain a more humid environment than would be available if the bryophyte were directly exposed to air. This seems to be accomplished mostly by maintaining a small space in which air movement is reduced, thus reducing the evaporation rate from the bryophyte. In *Brachythecium* (Figure 104) populations, litter of the stinging nettle (*Urtica*) stimulates growth (Willis 1978). Willis attributes this added growth to moisture and nutrient release, but we cannot rule out the possibility of hormonal interaction as well.

The reduction in light caused by accompanying plants may provide an advantage by reducing the destructive effect of UV light when the bryophyte is dry. However, when the surrounding plants become too dense, they can effectively block the light and also prevent the bryophyte from occupying the substrate, thus crowding it out. Deciduous trees are very effective at this by losing their leaves and completely covering the bryophytes, thus preventing them from getting any light. They may further inhibit bryophyte growth during decay by releasing humic acids that can inhibit growth (see discussion under spore germination), or possibly even releasing growth regulating substances. Whatever their action, leaves seem to be destructive to my moss garden if I leave them there over winter, even if I remove them as soon as the snow melts. Considerable decay occurs during that snow-covered period.

Leaf litter seems to be the major cause for the paucity of bryophytes on the forest floor in a deciduous forest. Bryophytes there are restricted to elevated areas such as rocks or slopes where leaves do not collect. In one set of experiments to determine what species of plants would grow following a disturbance similar to a tip-up hole (from a tree falling over), researchers dug holes in the forest floor. Bryophytes invaded the holes, but only on the sides. Litter collected on the bottoms of the holes, and although tracheophytes germinated there, no bryophytes succeeded.

Sheldrake (1971) has suggested that natural exogenous hormones could be important in bryophyte distribution. He found IAA in many substrates inhabited by bryophytes, and he concluded the IAA was not produced by the bryophyte because the same concentrations occurred without bryophytes. Garjeane (1932) noted that contact with soil and decaying vegetation stimulated rhizoids in liverworts, and Maravolo and Voth (1966) showed that liverwort rhizoid length and rhizoid formation are stimulated by IAA. Therefore, bryophytes might grow better in microhabitats where these hormones collect. Disintegrating xylem is a major source of IAA, so this may be a contributing factor to the luxuriant growths of liverworts on logs in moist woods.

Odu (1978b) found that living tracheophytes had just the opposite effect on moss rhizoids. Mosses transplanted from grassland to bare soil increased their number of rhizoids and those transplanted from boulders to bare soil produced more rhizoids than those transplanted to grasslands. It would seem that IAA was not the inhibitor involved since we have already seen that it stimulates rhizoids, but perhaps concentration is a factor. Furthermore, bare soil may have more available IAA as a result of bacterial breakdown of organic matter (Sheldrake 1973), with a cover of grass depriving the mosses of access (Odu 1978b). On the other hand, an easily diffusible substance such as **ethylene** could account for the ability of living plants to inhibit the rhizoids, since no inhibition occurred on soil with plants removed but with the litter remaining.

Neighboring plants can affect bryophyte growth by altering the available light and level of humidity. They can serve as a filter, protecting the bryophytes from damaging UV rays. The environment experiences a wide range of exudates from the plants that live there, undoubtedly influencing development of some bryophyte taxa. Litter provides humic acids that are known to inhibit bryophyte growth, and decaying xylem releases IAA that can stimulate rhizoid production. Crowding is likely to create patches of elevated ethylene that could be inhibitory to bryophyte development.

Summary

Growth in bryophytes is both stem and branch growth, making it non-linear, but can also be a weight gain without any elongation. Growth in very low light causes etiolation. Water and light are necessary for growth, with a wide range of light being optimal among

the various taxa. A common optimum seems to be around 3500-5500 lux for shade-adapted taxa.

Stems usually exhibit a strong positive phototropism and negative gravitropism, whereas rhizoids exhibit the opposite. Short or long photoperiods may induce dormancy, depending on the habitat and species.

Bryophytes respond to most of the same hormones as tracheophytes but at different, usually lower, concentration levels. Among other things, IAA enhances growth, cytokinins stimulate buds, gibberellins affect rhizoid growth and form, and ethylene causes senescence and in leafy liverworts inhibits dorsal leaf development. These hormones furthermore affect each other's actions. Many bryophytes exhibit apical dominance, facilitated by IAA. In addition, the form in which N is available can alter the growth form, branching, and growth rate.

Apical sexual structures usually terminate growth of that stem, but innovations (new branches near the tip) can cause the plant to continue growth and may facilitate lateral spread.

Humidity, light, salt concentration, and nutrients all influence the leaf shape, hairs, and color, and can cause the species to appear to be a different one in a different habitat.

Rhizoids respond to contact with a substrate by flattening and widening their tips, branching, and halting growth in other directions. Wounding causes the production of rhizoids and/or protonemal growth at the site of the wound.

Leaf litter inhibits the growth of bryophytes, in part by blocking light, but apparently also by depositing humic substances that are inhibitory or even lethal. In other cases, other plants, fungi, or bacteria in association with the bryophytes provide them with needed hormones.

Bryophytes are the only plants where the lower portion of the plant can be senescent or dead and still maintain a healthy upper portion.

Acknowledgments

Inspiration for this chapter evolved from discussions with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen. Several of the experiments were conducted at the Botanisches Institut, Universitat Heidelberg, Germany. I appreciate the many suggestions from a student's perspective by Medora Burke-Scoll. KT McConnell checked for glossary words, helped improve the clarity, checked the literature cited, and suggested the minisummaries at the ends of some sections.

CHAPTER 5-6

ECOPHYSIOLOGY OF DEVELOPMENT: FRAGMENTS

Figure 1. *Dicranum viride*, a moss that fragments regularly by a row of abscission cells across the upper half of the leaf. Note the broken leaf tips. Photo by Michael Lüth, with permission.

Fragmentation

Fragmentation may be random pieces that break due to abrasion, decay, or animal severance, or they may be programmed genetically by means of an abscission layer such as demonstrated in *Dicranum viride* (Figure 1). In certain habitats, fragmentation may be a regular phenomenon, accounting for nearly all the reproduction.

Even fossil evidence supports the importance of fragments in the dispersal and reproduction of bryophytes (Miller 1985). And buried fragments often retain viability, providing the source for the flora when a disturbance returns an area to previous conditions (Wasley 2004).

Yet, when we diagram life cycles, fragmentation is usually ignored, and certainly for many flowering plants it is unimportant. However, in bryophytes it is often the fragments that perpetuate the species. Likewise, Giordana and coworkers (1996) found that regeneration from the

detached leaves was the major form of regeneration in moss *Pleurochaete squarrosa* (Figure 2). Other bryophytes, such as *Hyophila crenulata*, share their successful regeneration from fragmentation with other means such as gemmae (Olarinmoye 1981).

Mishler and Newton (1988) contend that in perennial mosses reproduction and spreading is almost entirely by means other than spores. Many populations exist for which capsules are unknown, particularly for dioicous taxa (having males and females on separate plants; unisexual). Even when all individuals in the population can produce both sexes (monoicous; bisexual), water is needed at the right time for sperm and egg to meet, so success rate will vary with habitat and with weather in a given year. Newton and Mishler (1994) suggest that vegetative reproduction, including specialized propagules, can occur

under more stressful conditions. Whereas spores germinate best on previously uncolonized substrates, vegetative reproductive units can do well even in contact with existing colonies. However, they suggest that such vegetative units cannot travel as far as spores – tradeoffs again.

Figure 2. *Pleurochaete squarrosa*, a moss that relies on detached leaves for regeneration. Photo by Michael Lüth, with permission.

Some mosses even provide special means to accomplish fragmentation. *Dicranum viride* (Figure 1), *D. fragilifolium* (Figure 3), and *Tortella fragilis* (Figure 4) have a weakened area of cells that break easily, releasing the upper portion of the leaf. This is so typical that these species can be identified by their chopped off appearance. Other species have **caducous** leaves (leaves that normally detach).

Figure 4. Broken tips on leaves of *Tortella fragilis*. Photo by Michael Lüth, with permission.

The success of fragments within short range (Newton & Mishler 1994) is supported by experiments by Nehira and Nakagoshi (1987). They removed a community of bryophytes and found that the community became re-established within 1-2 years. Most of the growth occurred in spring and autumn despite little seasonal variation in propagule dispersal. Thallose liverworts and pleurocarpous mosses were able to regenerate more quickly than the acrocarpous mosses. Yet these same fragments may have been eaten or decayed before ever growing if the researchers had not removed the parent colony. Newton and Mishler (1994) found that at least for the dry habitat mosses they studied, the parent plants seemed to inhibit growth of the fragments, with growth commencing once they were separated.

Fragmentation is likely to determine success of the species in some environments. Miles and Longton (1990) found that *Funaria hygrometrica* (Figure 5) reproduced and spread easily by spores, whereas *Atrichum undulatum* (Figure 6) and *Bryum argenteum* (Figure 7) were likely to experience failure before sporelings produced gametophores. On the other hand, these latter two species freely accomplished regeneration from shoot fragments. This ability of *Atrichum* to regenerate easily from leaf fragments permitted it to dominate the ground cover rapidly after the construction of a parking lot on the Michigan Technological University campus (Glime 1982). *Funaria hygrometrica*, on the other hand, apparently manages to arrive, presumably by spores, and colonize charred ground within a year after a fire, as occurred after the big Yellowstone fire (Glime pers. obs.).

Figure 5. *Funaria hygrometrica*, demonstrating the prolific production of capsules. Photo by Niels Klazenga, with permission.

Even on rocks, where one might expect a small spore and protonema to have more success than a large fragment, it seems that fragments dominate the reproductive success. Keever (1957) did find that spores germinated on granite, but colonization through fragmentation was more rapid. One such rock-dwelling (and bark-dwelling) species is *Orthodicranum montanum* (Figure 8). Chrobak and Sharp (1955) established that this species grew well from leaf fragments. The proximal (basal) half of the broken leaf was more successful than whole leaves or the distal portion of the leaf (Figure 9).

Arctic and Alpine

Mogensen (1986) found that *Platydictya* (Figure 10) was dispersed in Greenland primarily by vegetative propagules and Bonde (1959) found viable *Polytrichum piliferum* (Figure 11) fragments among the wind-blown debris of a Colorado glacier. Lindskog and Eriksen (1995) found that the fragments of mosses, in particular, that were on the glacier reflected accurately the composition of the surrounding vegetation.

Figure 10. *Platydictya jungermannioides*. Photo by Des Callaghan, with permission.

Figure 11. *Polytrichum piliferum*, a moss that reproduces by fragments on the Colorado Glacier. Photo by David T. Holyoak, with permission.

McDaniel and Miller (2000) demonstrated the importance of fragments in alpine areas of the Adirondack Mountains of New York, USA, and suggested that fragments dispersed in winter might be a significant means of establishing new populations following spring snowmelt. It would certainly much easier for fragments to glide across a snow pack than to travel amid ground vegetation.

In the Arctic, fragments on the ice are common, and are easily moved around over the smooth surface, permitting rapid transport over considerable distances. Miller and Howe Ambrose (1976) found that fragments of mosses were distributed across the snow by wind on Bathurst Island in the Canadian high Arctic. They were able to grow these fragments in culture, with only 12% of the fragments producing evidence of viability by growth of protonemata, shoots, or rhizoids. The leaf-bearing tips of leafy shoots were the most likely to produce new growth. Nevertheless, this yielded an estimate of more than 4000 viable fragments per cubic meter of snow! Liverworts, however, did not fare as well, with only one fragment producing new growth. They surmised that such moss fragments may be "routine" in Arctic climates.

The importance of fragments may reach its climax in the Antarctic. In colonizing a new Antarctic volcanic island, fragments of *Campylopus* (Figure 12), *Marchantia*, (Figure 13) and *Bryum* (Figure 7) species seemed to be the most important means of arrival (Smith 1984).

Figure 12. *Campylopus pilifer* showing fragments formed by tips of plants. Photo by Michael Lüth, with permission.

Figure 13. *Marchantia polymorpha* with dead portions that can create fragments. Photo by Michael Lüth, with permission.

In Antarctica on Mt. Rittmann, *Pohlia nutans* (Figure 14-Figure 17) only establishes on geothermally heated ground (Skotnicki *et al.* 2002). The geothermal heat (17-35°C) permits the moss to survive. It is apparently dispersed only by fragments (Figure 16-Figure 17) from elsewhere in Antarctica.

Streams and Other Aquatic Habitats

In flowing streams, sporophytes seem rare, and asexual propagules seem to be unimportant. However, significant dispersal can occur from fragments during spring runoff, and entire clumps as well as branches and smaller fragments become impinged on rocks and roots in the stream. The larger surface area of fragments makes it more likely that they will become lodged than will the small spores and asexual propagules. Glime *et al.* (1979) demonstrated that for *Fontinalis duriaei* these actually do become established in nature, occasionally even achieving upstream movement (by feet of bears?).

For aquatic mosses and liverworts, fragmentation may be the only means of reproduction for many years before appropriate conditions exist for completing sexual reproduction. In dioicous mosses such as *Fontinalis*, sexual reproduction seems to be so infrequent as to be totally ineffective as a means of providing dispersal units (spores), whereas fragments are numerous during times of ice melt and high water (Figure 18; Conboy & Glime 1971, Glime *et al.* 1979, Glime & Knoop 1986). Even when spores are produced in this genus, the spore faces numerous challenges in becoming located where its subsequent protonema will neither be washed away nor desiccated, and sufficient light will be available for development. Since there is no documentation of the occurrence of any protonema of any *Fontinalis* species in the field, we can only conjecture about the success of reproduction by spores in this genus.

Dedifferentiation

Dedifferentiation is the process involved in the return of a cell to its embryonic state (Figure 19). It is necessary before a mature cell can form into a different kind of cell, or into a protonema, permitting the development of new plants from fragments. In bryophytes, virtually all cells seem to have the ability to undergo dedifferentiation once they have been isolated from the intact plant (Giles 1971). This is not the case for cells such as xylem elements of tracheophytes, which no longer have protoplasm and hence are non-living.

Figure 19. *Warnstorfia fluitans* leaf fragment with rhizoid that has dedifferentiated and redifferentiated into a different kind of cell. Photo by Heike Hofmann © swissbryophytes <swissbryophytes.ch>, with permission.

Moss fragments seem to retain their polarity, resulting in protonemata at the apical end and rhizoids at the basal end, but inverting them causes the base to act as the apex and vice versa (Westerdijk 1907), suggesting a gravimetric response by some growth factor. Mosses tend to have more regenerative ability at the base of the gametophyte than at the apex. Their sporophytes, however, are strongly polar in regeneration (von Wettstein 1924). Liverworts, on the other hand, seem to be much more strongly polar, and new growth is nearly restricted to the apical end of the gametophytes, but the sporophyte seems to lack polarity (Giles 1971). This strong polarity of the liverwort gametophyte regeneration, however, decreases with tissue age (Kreh 1909).

Earliest known reports on regeneration from bryophyte fragments come from Necker in 1774 (Giles 1971). Kreh (1909) showed that for liverworts, every part of the plant except the antheridia could regenerate. Nevertheless, few reports of liverwort regeneration from fragments are known. In mosses, even the seta will regenerate into a protonema, forming diploid gametophytes (von Wettstein 1924).

It is common for the nuclei to increase in size in dedifferentiating cells (Giles 1971). The dedifferentiation process involves a sort of "budding" of the chloroplasts and mitochondria, producing more of these organelles. At the same time, nucleolar volume increases only in regenerating cells. We now understand that the nucleolus is not an organelle in its own right, but rather that it is the site of extensive protein synthesis, hence staining more densely. This is an indication of building activity in the regenerating cell.

In *Campylopus pyriformis* (Figure 20) fragments, it is the chloronema that gives rise to buds, with no caulonema forming. By contrast, and unlike the growth from a spore, the caulonema of *Plagiomnium affine* (Figure 21) grows nearest the plant fragment and the chloronema is the farthest and youngest tissue (Sironval 1947; Bopp 1959a,b; Giles 1971). The ensuing buds develop, therefore, nearest the leaf fragment from the caulonema. Up to 100 secondary protonemata may originate from the dedifferentiated leaf cells of a single leaf in this species.

Figure 20. *Campylopus pyriformis* showing fragments of branch tips. Photo by Michael Lüth, with permission.

Figure 21. *Plagiomnium affine*, a moss that develops protonemata from fragments. Photo by Janice Glime.

Secondary Protonemata from Fragments

Secondary protonemata are those produced from mature tissues that have been damaged or cut. Hence, these protonemata develop on fragments. At first thought, one might expect that these would behave in the same way as primary protonemata (produced from a spore), but further consideration should remind us that fragments provide a large store of nutrients, including energy sources, from the plant fragment.

Like primary protonemata, the secondary protonemata of the moss *Tortula modica* is negatively gravitropic in the dark (Ripetskyj *et al.* 1999). When placed in the light, the apical parts of the protonemata begin to branch and apical cells of side branches and main protonemal filaments frequently differentiate as buds. One might consider this event as being possible because of the energy sources available from the fragment. When the fragments were illuminated from below, an intensity of at least $4.5 \mu\text{mol m}^{-2} \text{s}^{-1}$ was necessary to induce phototropism and light-directed development of branch buds and directed growth of side branches. In lower light intensities the apical cells grew away from the light (*i.e.*, away from gravity as well).

To further understand the role of spore grown vs secondary protonemata, Wagner and Sack (1998) grew the moss *Ceratodon purpureus* from protoplasts. In these protoplasts, the emerging filament was mostly gravimorphic, with more than 66% of the filaments emerging above the horizontal. The tip-growing cells of these filaments began to exhibit a gravitropic response within 1-2 cell divisions. But in these filaments, plastid sedimentation did not occur, contrasting with dark-grown filaments.

Gravity Effects

As we might expect, based on studies on protonemata, secondary protonemata also respond to gravity. In *Tortula modica*, the secondary protonemata are negatively gravitropic in the dark (Ripetskyj *et al.* 1999). In the light, these protonemata branch near the apical cells and these branch tips typically differentiate as buds. A light intensity of at least $4.5 \mu\text{mol m}^{-2} \text{s}^{-1}$ was required to induce phototropism in apical cells, cause light-directed initiation of branch primordia, and direct development of side branches and bud initiation. At lower light intensities, the apical cells grew away from light (*i.e.* negatively gravitropic).

Callose Formation

Scherp *et al.* (2001) documented the formation of callose in tissue fragments in all groups of multicellular photosynthetic organisms, including bryophytes. They found that in bryophytes and other multicellular green plants, callose is a regular component of the developing septa in juvenile cells during cytokinesis. Wound callose did not occur in cells that already had callose in the newly formed septa.

Establishment

It appears that fragments may survive better in water than spores, thus providing an additional means of long-distance dispersal. Dalen and Söderström (1999) tested

five species of mostly terrestrial mosses and found that in all five taxa, regeneration frequency of fragments was lower than that of spores, but that fragments survived as well in water as they did dry, whereas spores did not.

Light quality and intensity may be influential in success of fragments. Dagar and coworkers (1980) found that for the thallose liverwort *Riccia discolor* regeneration is best in diffused light. Red light can induce regeneration; far-red inhibits it (Giles & von Maltzahn 1967, 1968). There is evidence the red/far-red system may affect the "budding" or division of the chloroplasts (Hahn & Miller 1966), and its reversibility suggests that phytochrome may be active during the process. Little else seems to be known about light effects specifically on fragments, so these phenomena may be restricted to certain taxa or habitats.

When dispersal occurs over long distances, it is quite likely that only one gender will arrive, making its survival dependent on asexual means. As discussed elsewhere, fragments seem to provide the easiest means by which bryophytes can be propagated for gardens, so one should expect that nature makes widespread use of this ability as well. When a plant is damaged, the damaged surface will often produce protonemata and/or rhizoids (LaRue 1942) and subsequently develop a new leafy gametophore. In other cases, the new plant may develop directly with no protonemal intermediary, as in the leafy liverwort *Scapania undulata* (Figure 22) that developed from a leaf fragment (Figure 23; Glime 1970).

Figure 22. *Scapania undulata* growing in its streamside, wet habitat. Photo by Michael Lüth, with permission.

Figure 23. *Scapania undulata*, leafy liverwort known to reproduce from fragments. 1: Young plant growing from detached leaf. 2: Bud of young plant growing on leaf still attached to living stem. Drawings by Flora Mace.

It is the parent plant that determines which of these will develop – chloronema, caulonema, or rhizoids. Knoop (1984) tells us that small explants result in reversion to an early developmental stage wherein single leaf cells behave like spores and form chloronemata. On the other hand, large fragments revert back only to caulonemata, or go directly to buds and gametophore plants. Furthermore, apical leaves regenerate more easily than basal leaves (Gay 1971). It is puzzling that in *Plagiomnium undulatum* (Figure 24), basal leaves regenerate only from the lamina, whereas apical ones regenerate only from the costa (Schröder *et al.* 1970).

Figure 24. *Plagiomnium undulatum*; basal leaves regenerate from the lamina, apical cells from the costa. Photo by Janice Glime.

Mishler and Newton (1988) demonstrated that fragments can require conditions opposite to those required for spores. In their study, *Syntrichia princeps* (Figure 25) fragments were slightly more successful when they experienced periodic drying, whereas the spores required continuously hydrated conditions. With such requirements, it is easy to understand why fragments are more successful on rocks and sand than are spores. Mishler and Newton attribute this success to the ability of fragments to produce a protonemal mat and new shoots much more rapidly than could spores. Furthermore, as mentioned earlier, the existing plants exhibited a much stronger inhibitory effect on the spores than on the fragments.

Figure 25. *Syntrichia princeps*, a moss whose fragments fare better with periodic drying. Photo by Jan-Peter Frahm, with permission.

On the other hand, both spores and fragments can be inhibited by the presence of mature plants (Mishler & Newton 1988). *Dicranum* (Figure 1, Figure 3) seemed to be more inhibitory than *Syntrichia princeps* (Figure 25), perhaps relating to the dry habitat of the latter. They considered that at least some of this inhibition was due to chemical exudates.

In an aquatic habitat, Florschütz and coworkers (1972) found that fragments of *Fissidens crassipes* (Figure 26) produced caulonemata, this time on moist bricks. This ability permitted them to spread rapidly in response to a rise in water temperature.

Figure 26. *Fissidens crassipes* growing on rock. Photo by Michael Lüth, with permission.

Regeneration often occurs from small leaf fragments that have begun to decay. This could be an indication that an inhibitor has been lost, or some colonizing microorganism could be providing a hormonal signal that starts the development. When growing *Leucolejeunea clypeata* on Ca-free media, Geldreich (1948) discovered that only contaminated leaves of Ca-deficient plants produced regenerants. It was only mature or old and necrotic leaves that regenerated, and these Ca-deficient leaves had oil bodies that were characteristic of old, senescent leaves. Since the contaminating microorganisms were typical of soil flora, and regenerants of this species are known in nature (Fulford 1947), perhaps the microorganisms do indeed play a role in providing the necessary stimulus.

Liverworts rarely regenerate from fragments. Occasionally a leaf may produce a new plant, as for example that of *Scapania undulata* (Figure 22-Figure 23), an aquatic leafy liverwort mentioned earlier (Glime 1970). Could it be that liverworts dry out too rapidly and cells lose their viability before new plants can arise? Would this explain the accomplishment of this aquatic species?

Growth Regulators

Like all other developmental processes, hormones and other growth regulators influence the developmental pathway of fragments. Patidar and coworkers (1987) found that 0.03 ppm gibberellin can stimulate regeneration in the thallose liverwort *Targionia hypophylla* (Figure 27). Concentration is of course important; at 0.1 ppm gibberellin is inhibitory to *T. hypophylla*.

Figure 27. *Targionia hypophylla*. Photo by Michael Lüth, with permission.

Few studies seem to have centered specifically on growth regulators of fragments, yet many in vitro studies are actually studies of fragments, particularly those of pleurocarpous mosses. Presumably, the same growth regulation applies to fragments as to the intact plants covered earlier. Yet, literature on the wound response seems to be lacking, as is literature on the remarkable ability of some fragments to persist under extremely stressful conditions. For example, we have grown *Fontinalis flaccida* from specimens dried for three months under herbarium conditions (ca. 30% relative humidity). In another case, *Fontinalis novae-angliae* that had been boiled for about 12 hours daily for two weeks developed new leaves on one portion of the remaining stem when it was returned to its native stream (Glime & Carr 1974). And what permits a partially decayed stem to suddenly spring forth a new plant after it has been uncovered from many years of burial (During *et al.* 1987)?

Using the aquatic moss *Palustriella decipiens* (Figure 28-Figure 29), Ahmed and Lee (2010) experimented with a wide range of IAA and kinetin concentrations on fragments. They found that protonemal gemma production varied with concentration, but was best at 10^{-8} M IAA and kinetin. Higher concentrations caused the gemmae to become brown. Low concentrations of IAA and kinetin induced bud formation.

Figure 28. *Palustriella decipiens*, an aquatic moss that regenerates from fragments and protonemata of those fragments respond to applications of IAA + kinetin to produce buds. Photo by Michael Lüth, with permission.

Figure 29. *Palustriella decipiens* protonemata with gemmae, produced at 10^{-8} M kinetin. Photo by Ahmed and Lee, with permission.

Animal Dispersal

Dispersal by animals is scarcely known in the bryophytes. Yet, we must suppose that the various activities of animals contribute to bryophyte movement. Various aquatic insects, especially Trichoptera (caddis flies), use mosses or liverworts in their cases, so the insect will carry the bits around wherever it goes. When drift carries the insect downstream, the moss goes too, and if the insect crawls upstream in the quiet interface at the bottom, the moss comes along. Lacewings [*Leucochrysa* (*Nodita*) *pavida*] carry viable bryophytes (and lichens) on their backs as camouflage (Slocum & Lawrey 1976).

Bears, beaver, and other animals can get mosses tangled among their toes and carry them for miles. Birds carry them off to build nests. I have even concluded that the turtle in my garden room was responsible for the distribution of *Conocephalum conicum* (Figure 30) all over the room from the single spot where it had been planted. When the turtle died, the spread of the liverwort stopped. In a field experiment, I found fragments of tagged *Fontinalis duriaei* (Figure 31-Figure 32) upstream from their initial location, a movement that could only have been effected by animals such as bears or humans.

Figure 30. *Conocephalum conicum* showing evidence of herbivory (arrows) that could lead to dispersal of fragments. Photo by Janice Glime.

Figure 31. *Fontinalis duriaei* held by Janice Glime, demonstrating how easily mosses might be dispersed by flowing water and trapped by branches and roots in the water. Photo by Zen Iwatsuki, with permission.

Figure 32. *Fontinalis duriaei* fragment. Photo by Janice Glime.

It is likely that rodents contribute to dispersal, although they may do more harm than good. I have watched chipmunks run across my moss garden and kick up clumps as they ran. Nancy Ironsides (Bryonet 10 June 2011) found rhizoids on the apical leaves of *Leucobryum glaucum* (Figure 33) and attributed these to disturbance by animals. Péntzes Kónya (2003) considered "big wild animals" to be major dispersers of *Leucobryum juniperoideum* (Figure 34) during dry periods. The caducous leaves function as gemmae by producing rhizoids (Figure 35) and forming new plants, especially during the rainy spring, but the disturbance of dry mosses seems to outpace the regeneration from disturbed plants.

Others may spread bryophytes as they eat them (Slack 1936, Mutch & Pritchard 1984), particularly if they only digest the surface organisms and return the moss fragments with their feces. Suren and Winterbourn (1991) found that 14 aquatic invertebrate taxa had bryophyte fragments in their guts, and two tipulid larvae regularly consumed bryophytes. I tested the hypothesis that rainbow trout, known to strike at anything, could serve as dispersal agents by eating the aquatic *Fontinalis duriaei* (Figure 31-Figure 32). However, the fish could not be tempted to strike at or eat the moss, even when it housed numerous aquatic insects. Finally, we force fed the fish. The moss was

delivered back as feces in a neat, cylindrical package with bright green moss (Figure 36). At last it seemed we had demonstrated a potential upstream dispersal mechanism! But, alas, we were surprised the following day to find that the moss had lost all its color, even though it was maintained in a gallon jar of its own stream water at a cool temperature. It does not appear that rainbow trout are likely dispersal vectors after all!

Figure 36. Feces of rainbow trout consisting primarily of *Fontinalis duriaei* as a result of force-feeding. Photo by Janice Glime.

I have watched larvae of the **Rhyphidae** dipteran eat wet, dirty (most likely with diatoms) mosses and observed fragments of green moss come out the other end, clean. These fragments would be ideal propagules, although not dispersed very far, but I did not culture them to see if they met the same fate as the trout package.

Further discussion of bryophyte fragment dispersal is in the adaptations subchapter on dispersal.

Summary

Fragmentation results from random breakage or from genetically programmed cleavage areas on leaves, buds, or stems. For perennial mosses, especially pleurocarpous mosses, it is typically the primary means of spreading. Arctic/alpine and aquatic habitats may rely primarily on this type of reproduction. Fragments are more likely to become established than spores and survive better in water than do spores. Their establishment can be inhibited by the presence of mature plants, but they have a greater competitive ability than spores.

Regeneration from mature cells requires **dedifferentiation** and may begin as protonemata, rhizoids, or both. Light quality and intensity may play a role in early development. Little is known about growth regulation, but gibberellin can stimulate regeneration in at least some bryophytes. Dispersal can be accomplished by wind, water, and animals, sometimes because the animal transports the bryophyte for use in a nest or house.

Acknowledgments

Inspiration for this chapter evolved from discussions with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen. I appreciate the many suggestions from a student's perspective by Medora Burke-Scoll and KT McConnell. Nancy Ironsides introduced me to the rhizoids on *Leucobryum* leaves and provided images; Noris Salazar Allen and Erika Pérez-Kónya helped me to piece together the story.

CHAPTER 5-7

ECOPHYSIOLOGY OF DEVELOPMENT: BROOD BODIES

Figure 1. *Syntrichia laevipila* (= *Tortula pagorum*), an acrocarpous moss with terminal gemmae. Photo by Michael Lüth, with permission.

Introduction

Ecology is a field of interconnections. Hence, writing any chapter brings with it many choices about where to include information. This chapter is in part redundant with the chapters on dispersal because an understanding of propagules was necessary to complete the dispersal story. That chapter emphasized travelling about and the environmental factors that influenced the success of that travel. This chapter emphasizes the physiology, but for clarity there is considerable overlap in what one must understand. The chapter is written to be independent so that one can read it without having to read the earlier chapter in order for it to make sense.

Definitions

Imura and Iwatsuki (1990) defined **propagules** as vegetative **diaspores** that have an apical cell and can grow directly into leafy shoots. However, most diaspores produce a protonema. **Gemmae**, by their definition, are vegetative diaspores that lack an apical cell and in which a

protonema precedes development of a leafy shoot (Figure 2, Figure 37). While this is a clean separation, it is not always practical to determine the germination pattern, and multicellular gemmae may be construed as propagules. In the multilingual glossary for bryology (Magill 1990), **propagule** (Figure 3-Figure 4) is defined in a more practical way as a reduced bud, branch, or leaf serving in reproduction. This does not imply absence of a protonema, and indeed, there often is one. **Diaspore** is given as a synonym. **Gemmae** (Figure 2) are distinguished as uni- or multicellular, filamentous, globose, ellipsoidal, cylindrical, stellate, or discoid brood bodies, **relatively undifferentiated**, serving in vegetative reproduction. In other words, they are specialized structures. **Brood body** is the more inclusive category, including both propagules and gemmae. These are genetically identical to their parents, thus producing clones (Laaka-Lindberg 2000). Bryophytes are the only group of plants with any sort of gametophytic brood body (Wyatt 1994).

Figure 3. *Leskeella nervosa* with bulbils at leaf bases. Photo by Michael Lüth, with permission.

Figure 4. *Bryum gemmilucens* showing axillary propagules. Photo by Michael Lüth, with permission.

The evolutionary pathway has capitalized on success of fragments by selecting more and more specialized fragments. Mosses such as *Leskeella nervosa* (Figure 3), *Platygyrium repens* (Figure 5), *Dicranum flagellare* (Figure 6), and *Bryum argenteum* (Figure 7-Figure 8), to name a few, have special shoots that easily break off and disperse. This explains why *Bryum argenteum* is so common along paths in open areas such as cemeteries and roadsides. Each step of a boot carries tiny branches from the parent plants to a new location. To demonstrate its remarkable dispersal success, Clare and Terry (1960) prepared bare soil, then used a matchbook to "walk" on *Bryum argenteum* (Figure 7-Figure 8). They then "walked" on the bare soil with the same matchbook. As a

control, they "walked" on a different part of the prepared soil with a different matchbook. True to its natural success, the *Bryum argenteum* grew well where the matchbook had previously walked on the moss, but did not appear on the control area.

Imura (1994) recognized specialized vegetative reproductive structures in 186 species (15.7%) of Japanese mosses, including deciduous shoot apices, caducous branchlets, bulbils, flagella, rhizoidal tubers, gemmae, caducous leaves, and endogenous gemmae. He considered these to be adaptations to the dioicous habit (e.g. *Syntrichia laevipila*, Figure 1) and unstable habitat conditions.

Brood Bodies

Brood bodies are a specialized means of asexual reproduction that permit plants to propagate and disperse, often when conditions are unfavorable in the present location. Perhaps this is why, among dioicous mosses, they are more common on upright mosses (Figure 4), where there is some hope of falling away from the parent plant, rather than landing within a mat that keeps them where they started. Herben (1994) claims that reproductive processes, including brood bodies, are crucial for between-habitat dispersal. Those mosses in the British flora that inhabit small patches and unstable habitats are more likely to have vegetative brood bodies. But shoot density also can determine the number of brood bodies. Kimmerer (1991a) found that low-density populations of *Tetraphis pellucida* (Figure 9) were more likely to reproduce asexually by gemmae, whereas greater density increased incidence of sexual reproduction and subsequent spores. She (1991b) found that most **gemmae** landed within 10 cm of the colony, whereas spores travelled as far as 2 m. [Brodie (1951) considered that *T. pellucida* was too delicate to benefit much from splashing by raindrops, perhaps accounting for the much shorter dispersal distance compared to that of sperm in *Polytrichum* of up to 60 cm.] The asexual strategy permits mosses to colonize an area rapidly by gemmae, then move on by spores when space is saturated. Kimmerer (1991a) felt this was of particular importance in unstable environments such as rotting stumps where *T. pellucida* commonly occurs. On the other hand, ability to "move" by gemmae provides an opportunity to seek a mate when stranded in a single-sex clone.

Chrobak and Sharp (1955) showed that scales from the deciduous flagelliform branches of *Dicranum flagellare* (Figure 6) were more likely to form protonemata than whole leaves or their proximal or distal halves (Figure 10).

Figure 9. *Tetraphis pellucida* with terminal gemma cups, the only moss with gemma splash cups. Upper photo by Janice Glime, lower by Paul Davison, University of North Alabama, with permission.

Figure 10. Success of producing protonemata from various leaf parts of *Dicranum flagellare* compared to that of the scales on the flagelliform brood branches. Redrawn from Chrobak & Sharp (1955).

Even in the *Sphagnum*-dominated peatlands, dispersal by gemmae is an advantage in regeneration. While *Sphagnum* must wait for recolonization by spores that often have poor success on the acid peatland substrate with its low nutrient quality, *Aulacomnium palustre* (Figure 11) can colonize rapidly from gemmae that have survived the disturbance (Li & Vitt 1994). Furthermore, perhaps again due to the more advanced state of the propagula, *A. palustre* had a much wider tolerance range for nutrient concentrations, being the only species not inhibited by N inputs. *Sphagnum angustifolium* (Figure 12), *S.*

magellanicum (Figure 13), and *Polytrichum strictum* (Figure 14) all had poor regenerative ability.

Figure 11. *Aulacomnium palustre* showing special extension of the stem with gemmae. Photo by Zen Iwatsuki, with permission.

Figure 12. *Sphagnum angustifolium*, a species that does not regenerate well. Photo by Michael Lüth, with permission.

Figure 13. *Sphagnum magellanicum*, a species that has poor regenerative ability. Photo by Michael Lüth, with permission.

Figure 14. *Polytrichum strictum*, a species with poor regenerative ability. Photo by Des Callaghan, with permission.

It is reasonable then, that certain habitat conditions might favor the **apogamous** (condition of producing sporophytes without union of gametes) or **aposporous** (producing gametophyte from sporophyte tissue without meiosis) reproduction of bryophytes. Chopra (1988) was able to increase apogamy by reducing water or light levels and by raising the sugar concentrations in the growth medium. Likewise, low hormone concentrations favored apogamy. Not surprisingly, this plasticity was correlated with a high chromosome number (suggesting polyploidy) and genetic variation. Apospory, on the other hand, was favored by the opposite conditions: suitable temperature and light, sufficient humidity, and lack of sugar in the medium. It was furthermore stimulated by wounding and the removal of apical dominance.

In the leafy liverwort *Odontoschisma denudatum* (Figure 15-Figure 16), gemmae are produced in branched chains on the leaf margins (Duckett & Ligrone 1995). The initial cells of these gemmae are distinguished by forming a protrusion that contains a large central nucleus, small vacuoles, starch-free chloroplasts, and scattered cytoplasmic lipid droplets. Unlike other leaf cells, they lack oil bodies. However, as the gemmiferous filaments develop, oil bodies arise. These are closely associated with the cytoplasmic lipid bodies. These bodies swell rapidly, quickly reaching their final diameter. As the gemmae mature, the walls become dense and may account for their extreme water repellence. This repellant surface could permit them to be dispersed on the surface of a water film or in the air.

Figure 15. *Odontoschisma denudatum*, a species with apical gemmae. Photo by Michael Lüth, with permission.

Figure 16. *Odontoschisma denudatum* showing apical gemmae. Photo by Paul Davison, with permission.

The germination and development of gemmae in the tropical moss *Calymperes* have been described (Egunyomi & Olarinmoye 1983; Duckett & Ligrone 1991).

Tubers

Tubers are defined very differently in mosses and liverworts (Magill 1990). In liverworts, they are extensions from the growing apex, growing downward gravitropically, and serving as perennating structures during conditions unfavorable for growth. In mosses, they are gemmae formed on the rhizoids (Figure 17).

Figure 17. *Bryum radiculosum* rhizoids with tubers. Photo by Michael Lüth, with permission.

A number of moss species form tubers on their rhizoids (Arts 1987a; Table 1). Risse (1987) described these rhizoidal gemmae in 82 species of European mosses. They serve as asexual means of reproduction, although one must question just how they get dispersed. Perhaps earthworms and other forms of disturbance accomplish the task. However, in their study of plant diaspores from earthworm guts, van Tooren and During (1988) found few bryophytes that regenerated from tubers so obtained, although bryophytes emerged frequently from some samples by other means. They interpreted this as a low survival rate of vegetative diaspores in the earthworm

digestive tract. Risse (1987) reported that mites disperse protonemal gemmae in *Schistostega pennata* (Figure 18).

Figure 18. *Schistostega pennata* showing pinched off gemmae on the protonema. Photo by Irene Bisang, with permission.

These tubers are densely packed with lipid droplets or starch grains (Duckett & Pressel 2003). In *Phaeoceros laevis* (hornwort; Figure 19), tuber cells deposit protein into the cell vacuoles as the cells differentiate, forming abundant starch in their plastids and lipid droplets in the cytoplasm (Ligrone & Lopes 1989). Such rich storage contents suggest that they should germinate rapidly and produce new plants quickly, using their abundant food reserves. Using *Haplodontium notarissii* (Figure 20), Arts (1988a) showed that this moss did just that, germinating in two weeks, and several weeks later producing numerous upright gametophores to form a colony.

Figure 19. *Phaeoceros laevis* with sporophytes. Photo by Bob Klips, with permission.

Figure 20. *Haplodontium notarisii*, a moss that stores dense starch in its tubers, permitting them to germinate and grow rapidly. Photo by Jan-Peter Frahm, with permission.

Such tubers provide a diaspore bank that can help to revegetate disturbed ground (During *et al.* 1987) and benefit from extended longevity. Arts (1989) has demonstrated that even in a state of desiccation in a herbarium, such tubers can survive and germinate after 10 years. Such a strategy is common among colonist species (During *et al.* 1987; Arts 1990a; Table 1), and seems to be confined among the mosses to acrocarpous species. This colonist connection suggests that perhaps they do not have to arrive, but are already there, much like buried seeds awaiting the day they once more arrive at the surface and receive light. During (1995) suggests that such colonist populations are maintained completely through occasional recruitment. He suggests that within extant populations there must be a density-dependent tuber mortality to regulate the population.

Development

There are more developmental pathways for propagules than there are kinds of propagules. Even within the same genus, Ligrone and coworkers (1996) found differences in the origins of the gemmae. In *Tortula latifolia* (Figure 21), gemmae develop on the upper leaf surface from single initial cells of both the lamina and the costa, whereas in *Syntrichia* (= *Tortula papillosa*) (Figure 22) they develop only on the costa. In both cases the old wall and cuticle of the cell initial rupture and a new, highly extensible wall replaces it. Subsequent divisions of this gemma **primordium** produce a 6-8-celled gemma.

Mucilage develops around these gemmae and eventually the plasmodesmatal connections are severed, leaving only the mucilage to connect the gemmae to the leaf. Multiple gemmae may form in this way from the same initial and remain in a chain until the leaf becomes fully hydrated. Despite their disconnection from the parent leaf, these gemmae accumulate lipids, indicating that they are functionally photosynthetic.

Table 1. Examples of bryophytes with tubers reported in the literature.

Lipids are commonly stored in brood bodies of mosses, including *Aloina aloides* var. *ambigua* (Figure 23), *Pohlia annotina* (Figure 24), *Ephemerum serratum* (Figure 25), *Leptodictyum riparium* (Figure 26), *Weissia controversa* (Figure 27) (Goode *et al.* 1993), and *Splachnum ampullaceum* (Figure 28) (Mallón *et al.* 2006). Due to the hydrophobic properties of lipids, large amounts can be stored, permitting these brood bodies to survive when the protonema or plant is damaged by desiccation. Such lipids are most common in long-lived propagules.

Some gemmae can even produce more gemmae. In *Bryoerythrophyllum campylocarpum* (= *Hyophila crenulata*), the still-attached gemmae can germinate to produce more gemmae (Olarinmoye 1981).

Hormonal Effects

Hormones control every stage of development, but their role in gemma production and germination is not clear, or at the very least, differs among species.

Rawat and Chopra (1976) found that secondary protonemata of *Bryum klinggraeffii* (Figure 29) produce a diffusible substance when gemmae are produced. This induces gemma production on young protonemata that have not yet reached the critical size. Such a mechanism could insure maximum gemma production and greater survival if the initial stimulus for gemma production was indeed an unfavorable environment. The biggest advantage may be that it creates a colony that can reduce water loss.

Auxins

Stange (1971, 1977, 1983) suggested that gemmae require **auxin** transport from the parent plant, based on disruption of gemma differentiation in *Riella helicophylla* (Figure 30) when treated with an auxin antagonist. Contrasting with the auxin requirement suggested by

Stange (1983) for *Riella helicophylla* gemmae, external auxins inhibit production of gemma cups in *Marchantia palmata* (Kumra & Chopra 1989). In *Lunularia cruciata* (Figure 31), auxins produced in the apical buds of the thalli inhibit the germination of the gemmae on the thallus (LaRue & Narayanaswami 1957).

Figure 30. *Riella helicophylla*, a liverwort that seems to require external auxins for gemma differentiation. Photo from NACICCA, through Creative Commons.

Figure 31. *Lunularia cruciata* showing ungerminated gemmae on the thallus. Photo by Martin Hutten, with permission.

However, when ethylene and IAA are applied together in cultures of *Riella helicophylla* (Figure 30), the combination has positive, additive effects on cell elongation of gemmae (Stange & Osborne 1988). On the other hand, gemmae generally fail to germinate while still on the parent thallus of *Marchantia* (Figure 44-Figure 45) species, suggesting that these two genera might, like roots and stems of tracheophytes, respond differently to the same hormones. Botanists have assumed that the inhibition of gemmae on the parent thallus is due to an inhibitory substance diffused from the parent. That inhibition can carry over to germination in the vicinity of the parent as well. Schneider and Sharp (1962) found that when gemmae of *Tetraphis pellucida* (Figure 32) were grown on culture media that previously had had mature plants, the germination was inhibited. This suggests some sort of hormone leakage, but probably not the gaseous ethylene.

Figure 32. *Tetraphis pellucida* with gemmae, a species where the gemmae are inhibited by the parents. Photo by Michael Lüth, with permission.

Marchantia polymorpha (Figure 44) exhibits apical dominance, resulting from polarity (Binns & Maravolo 1972). This can be attributed to the behavior of auxins. Binns and Maravolo found evidence that there is an endogenous, basipetal auxin gradient that is vital to normal growth. Interestingly, cytokinins can destroy the polarity by causing the auxin-synthesizing capacity to increase.

Since gemmae are such diverse structures, arising from protonemata, thallus, apical branches, leaf axils, and leaves, one might expect a variety of environmental and hormonal controls over their production. Naming the hormones would be pure speculation, but we know that IAA moves basipetally, hence accumulating downward. We also know that more ethylene is likely to be produced in the older part of the stem, and there is less air movement, resulting in more accumulation. Perhaps it is some interaction of these two hormones that results in the basal propagules, but why in some taxa and not others? Bulbils are apical in some taxa, such as *Platygyrium repens* (Figure 3), and gemma cups are apical in *Tetraphis pellucida* (Figure 32).

Cytokinins

We know that cytokinins are needed to stimulate bud production on protonemata, so early researchers experimented with cytokinin effects on gemma production on the protonema. Logic would suggest that if cytokinins stimulate buds, they might inhibit protonemal gemma production.

Rahbar and Chopra (1982) found that the usual substances did not induce buds in the moss *Hyophila involuta* (Figure 33). In fact, when the protonemata were grown on basal Knop's medium, auxins, gibberellic acid, abscisic acid, chelates, vitamin B₁₂, activated charcoal, coconut milk, and altered hydration, pH, temperature, and light intensity and duration all failed to induce buds. Rather, they found that added cytokinins could initiate multicellular protonemal gemmae. Chopra and Dhingra-Babbar (1984) found similar responses in the moss *Trematodon breviculax*. Demonstrating the complexity of the bryophyte developmental system, Rahbar and Chopra (1982) demonstrated that for bud induction *H. involuta* required the interaction of IAA with kinetin or DMAAP.

Figure 33. *Hyophila involuta*, a moss in which cytokinins can induce gemma production. Photo by Niels Klazenga, with permission.

Mehta (1990) further explored the role of kinetin on *H. involuta* (Figure 33) and was able to isolate a protonemal diffusate from those protonemata that had gemmae. These protonemata served as "nurse protonemata" by promoting the growth of nearby protonemata. He found that kinetin (10^{-5} - 10^{-8} M) plus the protonemal diffusate acted synergistically on gemma formation. ABA (abscisic acid, 10^{-5} - 10^{-7} M), on the other hand, was inhibitory, resulting in no gemma formation.

Unlike *Hyophila involuta* (Figure 33) in Knop's plus Nitsch's medium, *Ptychostomum* (= *Bryum*) *capillare* (Figure 34) produced gemmae in both solid and liquid Nitsch's basal medium (Sarla & Chopra 1989). When the medium was supplemented with kinetin or 2iP (bryokinin), the protonemata produced gemmae, whereas the cytokinin 6-benzylaminopurine (BAP) caused the formation of buds instead, while the 2iP inhibited the growth of the protonemata. Gemmae on media with kinetin or BAP regenerated, producing secondary protonemata, but these failed to produce gemmae or buds in response to kinetin. Hence, not all cytokinins are created equal – they may cause opposite responses.

Figure 34. *Bryum capillare*, a moss that responds differently to different cytokinins, in some cases producing protonemal gemmae whereas in others they are inhibited. Photo by David T. Holyoak, with permission.

More recent work by Ahmed and Lee (2010) demonstrated that production of protonemal gemmae can vary with the concentration of IAA and kinetin in the moss *Palustriella* (= *Cratoneuron*) *decipiens* (Figure 35-Figure

36). In this species, kinetin influenced both gemma formation and gametophyte regeneration. Only low concentrations of IAA and kinetin (10^{-8}M) caused production of green, oval, mostly intercalary gemmae. Higher concentrations resulted in brown gemmae.

Figure 35. *Palustriella decipiens*. Photo by Michael Lüth, with permission.

Figure 36. Effects of 10^{-8}M IAA (left) and 10^{-8}M kinetin (right) on gemma formation on protonemata of *Palustriella decipiens*. Photos modified from Ahmed & Lee 2010.

But the role of cytokinin not only interacts to control production of gemmae, in *Marchantia polymorpha* (Figure 44) it inhibits the germination of the gemmae (Binns & Maravolo 1972). Could production of exogenous cytokinins be the factor that prevents germination of gemmae on the parent thallus?

Environmental Effects

For any plant system to be effective, it must be tuned to its environment. Propagules are no exception, being finely tuned to kick in when conditions favor their growth and development.

Temperature

For plants living outside the tropical regions, cold can inhibit growth and freezing may actually kill the tissues. Therefore, it is reasonable to expect that those species that survive have developed means to sense temperature conditions in both the production and germination of gemmae and to maximize these when conditions are best suited to continued growth.

In Arctic populations of *Tetraphis pellucida* (Figure 32), gemmae (Figure 37) have a broad range of germination conditions similar to those of the spores (Forman 1964). The broad 18-30°C range for gemma

production sharply contrasts to sporophyte maturation requirements of -0.2 to 7.3°C, or 0-5°C in dark cultures. Such low temperature requirements account for the capsule maturation in spring. Gemmae, as for example gemmae of *Aulacomnium heterostichum* (Figure 38), which germinated after two years of storage in a freezer, seem to be able to persist as well as spores in cold conditions, and certainly better than some (Imura *et al.* 1991).

Light

Chopra and Rawat (1977) found that the response to temperature can be light dependent. In *Bryum klinggraeffii* (Figure 29) the initiation of secondary protonemata is correlated with protonemal age and growth. Although the gemmae of *B. klinggraeffii* are formed at or above 20°C in both light and dark, at 10-15°C in the light this species forms larger, lobed green structures and stunted gametophores. The addition of 1.0 ppm kinetin causes moruloid buds to differentiate on the protonemata, but at lower concentrations of kinetin, these protonemata produce gemma-like structures. This 1ppm concentration even inhibits previously formed gemmae from developing into gametophores, instead resulting in stunted gametophores. But in a sister species, *Bryum coronatum* (Figure 39), temperatures of 30°C in both light and dark induce the formation of protonemal gemmae that resemble the rhizoidal gemmae. In *Leptobryum pyriforme* (Figure 49), the gemmae develop on both the protonemata and gametophores in the dark. The short story is that for these species low temperatures and sufficient light results in energy being shifted to the development of gametophores. The conditions that favor gemma formation do not favor bud formation.

Whitehouse (1980) found that *Schistostega pennata* (Figure 18), *Eucladium verticillatum* (Figure 40), *Gyroweisia tenuis* (Figure 41), and *Saelania glaucescens* (as *Didymodon trifarius*; Figure 42) all produce protonemal gemmae at low light intensities, but not at higher ones. These species can all grow in rock crevices, and such a mechanism might permit them to "try again" by dispersing if they germinate in a crevice that is too dark to complete the life cycle. A similar low-light response causes many protonemata to produce aerial shoots that break off and presumably serve as propagules (Whitehouse 1980). Similarly, in *Marchantia palmata*, maximum production of gemma cups is attained when the plants receive continuous light at 4500 lux (Kumra & Chopra 1989). Full sunlight is about 70,000 lux. In *Marchantia nepalensis*, having only 50-100 lux inhibits the production of gemma cups (Chopra & Sood 1970).

Hence, we might surmise that photoperiod plays a role in gemma production. Lockwood (1975), working with the leafy liverwort *Cephalozia media*, found that the magnitude of the normal reproductive response could be significantly stimulated or inhibited by low concentrations of certain amino acids or kinetin. Certain metabolites (10^{-6} M arginine, cysteine, tryptophan plus kinetin) could overcome photoperiodic control of the reproductive response. Generally, organic compounds which stimulated asexual reproductivity under short photoperiod inhibited sexual reproductivity under long photoperiod.

Germination of gemmae and other propagula is likewise affected by light. In *Philonotis hastata* (Figure 43), the greatest germination rate for brood branches was around 750 lux, with percentage germinating decreasing in both directions from that figure (Egunyumi 1981). Such a low optimum would permit these propagula to germinate in the presence of tracheophyte ground flora where light is often minimal. In *P. hastata*, elongation of the propagules occurs on older, basal parts of the stem, and these are the most mature, becoming partially detached. However, both young and old brood branches will form new plants from any part. These are able to germinate in both low and high light, but in high light they typically fail to complete development of gametophores.

Figure 43. *Philonotis hastata*. This wet habitat moss has its greatest gemma germination at around 750 lux. Photo by Jan-Peter Frahm, with permission.

Otto and Halbsguth (1976) found that rhizoid induction on gemmae of *Marchantia polymorpha* (Figure 44) was dependent on wavelength of light. The most effective wavelength was 350 nm, whereas no rhizoids were produced at less than 550 or more than 670 nm. They attributed this response to phytochrome and showed that an application of 10^{-4} M IAA for one hour had the same effect as the red-far red reversibility known for phytochrome.

Figure 44. *Marchantia polymorpha* thallus with gemma cups. Photo by Michael Lüth, with permission.

Water Relations

No growth can occur in the absence of water, but water can also affect the production of gemmae as an adaptive strategy to take advantage of flooding. In *Bryoerythrophyllum campylocarpum* (= *Hyophila crenulata*), gemmae occur on the protonema and are sensitive to humidity, with greater humidity causing greater gemmae production (Olarinmoye 1981). Flooding results in abundant basal protonematal gemmae. In its habitats of gutters, drainage areas, and other periodically flooded areas, these abundant gemmae facilitate spreading. The location of gemmae on protonemata provides them with the longest conditions of sufficient humidity compared to those on the stem or leaves.

In *Marchantia*, which is not typically a flood plain species, Kaul *et al.* (1962) found that gemmae did not produce rhizoids when grown in liquid culture, but did in solid media.

Gender

It appears that gender can also play a role in timing of gemmae production. This is expected, since the energy required by production of antheridia and sperm is considerably less than that needed for the development of the sporophyte following fertilization. Thus, we might expect a delay in gemma production in females of a species, providing a longer span of energy to be diverted to the young sporophyte. Fuselier and McLetchie (2002) addressed this relationship in the dioicous *Marchantia inflexa* (Figure 45). In a low-light environment, the onset of gemma production and plant size early in development were under sex-specific selection. Furthermore, females paid a higher price for plasticity in the onset of gemma production under high light. Selection for asexual fitness shifted the offspring toward monomorphism rather than sexual dimorphism. However, there were negative tradeoffs between the asexual and sexual fitness, at least in females, under some light conditions. Fuselier and McLetchie suggest that the opposing selection forces of these two reproductive strategies (sexual and asexual) might explain the persistence of sexual dimorphism of mature plants, while selection favored immature plants in which gender was indistinguishable.

Figure 45. *Marchantia inflexa*, a species where the sexes respond differently to light intensity. Photo by Scott Zona, through Creative Commons.

Mallón *et al.* (2006) experimented with vegetative propagules in the dung moss *Splachnum ampullaceum* (Figure 46) and suggested that ABA might be important in the ability of the protonema to produce brood cells and survive desiccation. This added production of brood cells would also permit the colony to spread, perhaps accounting for the very dense populations that are typical (Figure 46).

Figure 46. *Splachnum ampullaceum* growing on dung in a cow pasture. Photo by Janice Glime.

Nutrients and Inhibitors

We know that sucrose can cause germination of gemmae in *Marchantia nepalensis*, suggesting that a photosynthetic response is needed to provide a continuous energy supply (Chopra & Sood 1970). This is supported by the increased germination with increased light intensity.

One factor we know to be important in any cell growth is calcium. Grotha (1983) found evidence in *Riella helicophylla* (Figure 30) suggesting that the distal lobe of the gemma and the non-dividing cells of the rhizoid initials of the gemma have zones that facilitate Ca^{+2} absorption.

Other plants can have an effect on the success of gemmalings. This is manifest not only in competition for light, but in chemical warfare as well. The epiphytic leafy liverwort *Radula flaccida* is affected by leachates and extracts of the supporting tree upon which it grows (Olarinmoye 1982). Although these seem to have no effect on the germination of the gemmae, they are important in the later establishment of the gemmaling, affecting cell length, leaf size, and rhizoid development. These effects seem to be dependent on the species of tree leaf involved and could account for differences in the colonization success on different species of trees.

Dormancy

One control of gemmae survival under conditions of cold or dehydration lies in their ability to maintain dormancy. We know that *Marchantia* gemmae (Figure 44) are unable to germinate while remaining on the parent plant, a condition in which we assume the parent to be responsible for inhibiting the germination and thus attaining gemma dormancy. But some dormancy seems to be under environmental control in ways that protect the young gemmalings from unfavorable environmental conditions. For example, the leafy liverwort *Lophozia ventricosa* var. *silvicola* (Figure 47) produces gemmae that are able to grow and replace dead shoots of the parent colonies. But these gemmae can be deposited throughout

the growing season, some of them arriving upon favorable substrata when winter is imminent. Laaka-Lindberg and Heino (2001) propose that some gemmae are destined to become non-germinating gemmae, entering a "season-specific" dormancy. They suggest that only the dormant gemmae are able to survive winter. This is a good "bet hedging" strategy that permits some gemmae to get an early start on the competition while the season is still favorable, but permits some gemmae to safely overwinter while some of the germinated gemmalings might not make it through.

Figure 47. *Lophozia ventricosa* with gemmae that can replace dead shoots. Photo by Jan-Peter Frahm, with permission.

Dormancy is an adaptive strategy of utmost importance to organisms inhabiting unpredictable environments. Laaka-Lindberg (2000) considered it a way to spread the risk and enhance survival by making more effective use of resources. By remaining dormant when conditions are less favorable, resources are not lost to competition (Rees 1996; Hyatt & Evans 1998). Dormancy has been viewed by some as an alternative to dispersal, creating a facultative response in patchy environments where some patches are suitable and others are not (Cohen & Levin 1991; McPeck & Kalisz 1998). It is also a way to survive over winter in the leafy liverwort *Lophozia ventricosa* var. *silvicola* (Figure 47), with summer-produced gemmae germinating immediately and late-season gemmae becoming dormant for the winter (Laaka-Lindberg 2000).

Like spores, gemmae are typically under the control of light for germination, failing to germinate in the dark (Risse 1987). Schwabe (1972) reported that *Lunularia cruciata* (Figure 48) could survive dormant for months in total darkness. In *L. cruciata*, long days induce dormancy. Nevertheless, it is a complex interaction of photoperiod, temperature, and phytochrome response that determines dormancy or germination. Furthermore, lunularic acid within the gemma cup promotes dormancy. The presence of other plants of their own or other species also provides an inhibitory function, as discussed earlier. The ability of lunularic acid to inhibit algal and fungal growth and to delay seed germination in some species suggests it may be allelopathic not only to its own offspring, but to other groups of taxa as well, thus potentially making the environment more friendly toward the success of the gemmalings once conditions are suitable for them.

Figure 48. *Lunularia cruciata*, a liverwort where dormancy is induced by a variety of environmental conditions. Photo by David Holyoak, with permission.

This dormancy in *Lunularia cruciata* (Figure 48) permits gemmae to remain dormant underground in soil banks (Schwabe 1972). However, it is not that simple. If they are wet, they will not survive more than 10 days without germinating, and their fat reserves are depleted in 15 days if they are unable to replace it through photosynthesis. Furthermore, once they have imbibed water and begun to germinate, in as few as 12 hours, they are sensitive to desiccation and will not survive if dried at that stage.

Many have observed the dormancy of gemmae while still in the cups on the thallus of *Marchantia polymorpha* (Figure 44). Yet, when these gemmae get splashed onto the soil or the thallus dies around them, they seem able to germinate immediately. Schwabe (1976) has shown that it is lunularic acid from the parent thallus, serving as an inhibitor, that is responsible for this dormancy. Kumra and Chopra (1989) have shown that application of exogenous auxins inhibit growth of both gemma cups and vegetative plants of *Marchantia palmata*. The auxin IAA is likewise known to inhibit germination of gemmae of *Lunularia cruciata* (Figure 48) in the lab (LaRue & Narayanaswamy 1957).

Lunularic acid occurs in the soluble fraction of the cell (as well as in association with the cell wall; Schwabe 1990). Therefore, inhibitors such as lunularic acid can be leached from the plant (Schwabe & Nachmony-Bascomb 1963), especially older parts of the thallus (Schwabe 1990), therefore potentially having an effect on neighbors of the same or even different species. Since leaching is likely to be greater during dry periods or immediately following them, this could cause a seasonal or weather-related response.

Germination Time

Germination times vary with type of propagule, size, age, and available water. And light seems to be required for most (all?). Propagula can germinate in 2-4 days in *Bryum* and *Syntrichia* (Llo Stark, pers. comm. 3 February 2015).

Tradeoffs

There are tradeoffs in using energy to produce brood bodies instead of spores. Whereas spores require a prior fertilization, which requires abundant water for sperm to swim, spores disperse farther than brood bodies and are able to germinate maximally on previously uncolonized substrates; brood bodies do not require fertilization, hence negating the need for excessive water, but can only disperse locally, yet, at least in some cases, are more successful amid other plants than are spores (Newton & Mishler 1994). Egunyomi (1978) found that the protonemata of gemmae grow faster, a factor likely to be true for most bryophytes, but that spores produce more gametophytes. However, one must be cautious in transferring these laboratory results to field generalizations. In the field, protonemata from spores may be less successful than gemmae just because they take longer to develop and therefore are more likely to encounter unfavorable conditions, including competition. In a later study on *Bryum coronatum* (Figure 39) in Nigeria, Egunyomi (1982) found that vegetative propagules may succeed where capsules fail. In that species, 41% of the setae had no capsules and 42% of the capsules did not dehisce. The spore germination was 65-88%, but the protonemal growth was abnormal, suggesting that spreading by spores in nature might be rather limited. On the other hand, this species is likely to succeed in dispersal through its numerous axillary propagules.

But production of gemmae usually comes at a price. Sharing of energy can mean no one does well, so it is not surprising that sporophyte development does not coincide with gemma development. In *Tetraphis pellucida* (Figure 32), one cannot find gemma cups and sporophytes on the same plant. Both need to occupy the same location at the shoot apex, making it physically impossible. But typically, even the population tends to have these at different times.

Risse (1987) found that among colonist species, propagation is almost entirely vegetative, giving little chance for new combinations of genes. Tubers are common among mosses of disturbed habitats. In *Leptobryum pyriforme* (Figure 49), if the protonema is grown in water, gametophore production ceases while tubers and rhizoidal gemmae develop abundantly.

Figure 49. *Leptobryum pyriforme*, a prolific moss in disturbed areas. Photo by Michael Lüth, with permission.

Hedderson (1995) demonstrated that in the **Pottiales**, production of sporophytes decreases with increasing life expectancy and is negatively associated with production of asexual brood bodies. Among the **Funariales**, **Polytrichales**, and **Pottiales**, dioicous taxa are more likely to produce asexual brood bodies, as are monoicous taxa for which gametangia are unknown. However, production of these brood bodies is positively associated with a longer life expectancy, suggesting that at least the brood bodies do not deplete the plant of its energy supply.

Competition for resources and energy are likely to account for the suppression of gemma production during the production of sexual structures (Terui 1981). In *Marchantia polymorpha* (Figure 44), this response can be counter-acted by the application of high sucrose concentrations, thus inducing development of gemma cups.

Because of competing energy requirements, the two genders are likely to differ in their production of gemmae. Female plants require considerably more energy to produce archegonia and sporophytes than do male plants to simply produce antheridia. For example, Laaka-Lindberg (2001) found that in the leafy liverwort *Lophozia ventricosa* var. *silvicola* (Figure 47), shoots lacking gametangia produced three times as many gemmae as female shoots, and that males produced twice as many. In *Marchantia polymorpha* (Figure 44), the number of gemma cups produced by females was less than 1/6 that produced by their male counterparts (Voth 1941). Interestingly, when phosphate supplies decrease to stress levels, the number of cups on male plants decreases while the number on females increases, making them nearly equal!

Ecological Function

Many types of asexual propagules comprise the propagule bank, available to colonize when disturbance brings them to the surface. In this way, taxa such as *Leptobryum pyriforme* (Figure 49) and *Bryum rubens* (Figure 50) readily colonize disturbed habitats and tip-up mounds (Risse 1987).

As Ross-Davis and Frego (2004) pointed out, our understanding of the role of bryophyte propagules in structuring communities is meager. To address this question, they examined the propagule rain and buried propagule banks of the mature mixed forests in southeastern New Brunswick, Canada. They found 51 taxa in the diaspore rain and buried propagule banks, but only 36 of these were present in the forest floor community. Differences in phenology were evident in the high seasonal variability within the aerial diaspore sources. Considering the hundreds of species available in the geographic region, these propagule sources are relatively limited, undoubtedly to nearby sources. The extant community was most similar to that of the aerial diaspores, suggesting that the buried diaspore bank was reminiscent of a different ecosystem and was ready if that set of conditions returned. Further discussion of brood bodies is in the adaptations subchapter on dispersal.

Summary

Brood bodies include both gemmae and propagules (vegetative diaspores). Propagules can be defined as reduced buds, branches, or leaves that serve in reproduction. Gemmae are relatively undifferentiated vegetative reproductive structures and come in a variety of shapes and sizes. Brood bodies provide a safe mode to survive environmental disturbances such as desiccation, physical disturbance, and freezing. Colonist species rely almost entirely on brood bodies to invade newly disturbed habitats. Asexual means are important in colony spread of non-perennial taxa. Brood bodies are most common on dioicous (unisexual) species and compete for energy, thus typically not being present during sporophyte production. As a result, they are often more common on males than on females.

Tubers of mosses occur on the rhizoids, but in liverworts they are extensions of the growing apex and grow toward the ground to serve as a perennating structure. In both cases they provide a diaspore bank that makes the species available when favorable conditions return.

Gemmae seem to require auxin (IAA) to develop and are inhibited from germination by the parent plant, presumably by lunularic acid in liverworts and probably by ABA in mosses. Production is affected by light intensity, wavelength, and moisture availability. These factors plus photoperiod and temperature are known to affect their germination and dormancy as well. Addition of sucrose enhances germination, suggesting the importance of photosynthesis to provide energy.

Acknowledgments

Inspiration for this chapter evolved from discussions with Dr. Heinjo During and especially with Dr. Gert Steen Mogensen. Sanna Laaka-Lindberg kindly provided me with a copy of her thesis on asexual reproduction in hepatics. I appreciate the many suggestions from a student's perspective by Medora Burke-Scoll.

CHAPTER 5-8

ECOPHYSIOLOGY OF DEVELOPMENT: GAMETOGENESIS

Figure 1. Antheridial splash cups of *Polytrichum juniperinum*. Photo by Janice Glime.

Definition

Gametogenesis – the development of gametes (*genesis* means origin) is the essential process leading to sexual reproduction. In bryophytes, gametes are produced by mitotic division of tissue within multicellular structures, the **antheridia** (male) and **archegonia** (female), collectively known as **gametangia**. The location of these structures on the mosses is the basis for dividing the mosses into two large groups, the **acrocarpous** mosses that produce archegonia at the tips of upright stems, and the **pleurocarpous** mosses that produce archegonia on side branches of a generally horizontal stem. The differences in location of these archegonia can present differences in the ease with which the sperm can reach the archegonium, and hence reach the egg.

Developmental Stages

Lal and Bhandari (1968) described the developmental stages of the sex organs of the moss *Physcomitrium carpathicum*. The archegonium begins its development in a manner similar to that of the antheridium. In these early

stages, it produces a stalk, then the two-sided apical cell gains a third cutting face and the archegonium develops from this cell. The antheridial development is similar to that of other mosses. This chapter will examine the interaction of hormones and the environment as they influence this development.

Environmental Factors

The timing of the induction of gametangia is a critical function in the life cycle of bryophytes. For sexual reproduction to be successful, gametangia must form at a time when they can survive and they must mature at a time when it is safe and sufficient water is present for the sperm to reach the egg. This timing is controlled by external signals in the environment, and this is interpreted internally through such controls as hormones and nutrient levels.

Water Availability

Gametogenesis (development of gametes) must be timed in such a way as to take advantage of the most

critical need in fertilization – water. Because sperm in bryophytes must swim to the archegonium, adequate water is critical, but too much water or rapidly flowing water may dilute or carry off the sperm and make directional movement toward the archegonium all but impossible. In fact, timing of moss reproduction, whether a response to day length or temperature or other environmental stimulus, is often related to the season of proper moisture. Since gametangial initiation can occur several (or many) months prior to the actual time of fertilization, environmental cues other than moisture must trigger the process. It is therefore an expected consequence that different species within a genus respond to different environmental cues for gametogenesis, permitting them to live in different habitats. And even within species, populations can differ widely (Clarke & Greene 1970). But for many bryophytes, water is an important signal for gametangia to develop, perhaps because it permits the gametophyte to be active and produce sugars needed for energy.

Gametangium Developmental Need for Water

Waterfalls can provide continuous moisture sufficient for sperm dispersal and even contribute to dispersal itself. At Churchill Falls, Labrador, Canada, the bryophytes are very fertile within the spray zone, whereas other vegetation expresses retarded phenology (Brassard *et al.* 1971). It could be that the spray itself induces gametangial production. Kumra and Chopra (1983) found that culture in liquid media favors antheridial induction in *Barbula indica* var. *gregaria* (Figure 2) and *Bryum coronatum* (Figure 3) over that in solid gel culture, greatly hastening it in *Barbula indica* var. *gregaria*.

Figure 2. *Barbula indica* var. *gregaria*, a moss where liquid medium favors antheridial production. Photo by Li Zhang, with permission.

Figure 3. *Bryum coronatum*, a moss where liquid culture favors antheridial induction. Photo by Michael Lüth, with permission.

Sphagnum (Figure 4) provides a good example of effect of water on gametangial maturation. Sundberg (2002) studied nine sites in Sweden for six years, during which the nine most abundant species produced capsules. Capsule production related most to moisture regime of the previous summer, with more precipitation resulting in more capsules. This presumably relates to success of gametangial formation. Capsule success in wetter pits related positively to spring precipitation in the same year as capsule production, suggesting it was also important for fertilization success. Further discussion of timing of reproduction with moisture availability is in the phenology chapter.

Swimming Sperm

For sperm to reach the archegonium, they must swim. But a tiny sperm cell (Figure 5) cannot carry that much energy with it, so the distance is limited. Some mosses maximize the effect of rainwater by producing **splash cups** (Figure 1) or **splash platforms** (Figure 6) that house the antheridia.

Figure 5. *Marchantia polymorpha* stained sperm. Photo from Botany Website, UBC, with permission.

The study by Andersson (2002) on *Plagiomnium affine* (Figure 6) provides insight into just how this splash works. He is the only one who has published photographs of the arrival and splash of an actual raindrop, eliminating the problem of laboratory tests where the drops do not reach terminal velocity. The splash is somewhat reminiscent of the expulsion of *Sphagnum* (Figure 4) spores from a capsule, both demonstrating fluid dynamics. When the raindrop first hits a hard surface (splash cup or platform), it forms a crater many times the diameter of the drop. A jet of water then rises from the center of the crater (Rayleigh's jet). One or more large drops may be pinched off. In a splash cup, this force is typically sufficient to push all the water out of the cup.

Figure 6. *Plagiomnium affine* showing antheridial platforms and runners. Photo by Janice Glime.

Splash cups and platforms are not flat, so the water angles are oblique (Andersson 2002). As the water flows outward from the point of impact, the edge of the water mass bends upward to form a crown. As the drop collapses, the circle of water widens and the crown bends up more. Wave motions travel both vertically and horizontally; a thick cylinder of water forms around the upper rim of the crown and small jets of water extend outward. As these jets become unstable, they break into many tiny droplets that shoot out from the crown with high velocity. The crown collapse occurs after about 8 ms on a wet surface. Most of the droplets are less than 0.5 mm, and many are less than 0.05 mm. The spermatozooids are only about 1 μm (0.001 mm) in diameter and can therefore easily be carried by the droplets of water.

Most experiments with splash cups have not been at distances that mimic terminal velocity. Based on data from Laws (1941), a 3 mm drop would need to be dropped from about 7 m to reach terminal velocity, a height not available in most labs. Reynolds (1980) considered that distances of 30 cm splash from point of impact would not be uncommon.

But does this splash really disperse the sperm? To be dispersed, sperm must be able to exit the antheridium, and this requires that the antheridium must burst. That criterion is satisfied by the first raindrop to strike a mature antheridium (Andersson 2002). But... members of the **Mniaceae** shrivel when dry and do not rewet easily. *Mnium* (Figure 7-Figure 8) species may require soaking for an hour before they are ready for making a slide (Koponen 1974), indicating that the leaves in a rainstorm

are not ready to make a splash platform in less than an hour. Furthermore, the forest canopy traps many of the raindrops and reduces their velocity (Andersson 2002) or even diverts them so that they run down the trunk instead of striking the forest floor beneath them. Hence, it may take some time before the splash platform is exposed directly to raindrops in a storm, and this might not be achieved at all in a light shower.

Figure 7. *Mnium spinosum* wet. Photo by Michael Luth, with permission.

Figure 8. *Mnium spinosum* dry. In this condition, it is slow to take in water. Photo by Michael Luth, with permission.

To add further to the complications of reaching a female, the sperm are not released directly as individuals from the antheridium. Rather, they are released in a package, a **vesicle** of fluid. This vesicle must be disturbed by water drops before it will break apart. The vesicles become separated from each other by lipid drops and slowly dissolve, freeing the sperm.

Some seed plants have a chemical delay mechanism to prevent seed germination in a short rain shower, with chemical inhibitors being removed in a more significant rainstorm that is sufficient to sustain the young plant. The intervening factors required for a raindrop to splash the bryophyte sperm successfully seems like a mechanical method to delay sperm dispersal until it is certain there will be sufficient water for the sperm to complete their journey after the splash, with the delay in freeing sperm contributing to this mechanism.

The moss *Plagiomnium affine* (Figure 6) is less fortunate than the species with real cups. Its antheridial

platforms succeed only in splashing droplets with sperm about 100 mm (Andersson 2002). Fortunately, most of the females within 80 mm are successfully fertilized, but that does not permit much outcrossing.

In *Polytrichum ohioense* (Figure 9), the 2-3 mm cup permits sperm to be splashed 60 cm or more (Brodie 1951). A similar distance is accomplished by the splash platform of *Marchantia polymorpha* (Figure 10) (Buller 1942). Even greater distances, up to 230 cm, are achieved by antheridial splash cups of *Dawsonia longifolia* (Figure 11-Figure 12) (Clayton-Greene *et al.* 1977; see chapter on sexuality), aided by its greater height (up to 50 cm). These dispersal distances match the observed maximum distances between males and sporophyte-bearing females observed in the field. Very small splashes create an aerosol effect that could permit the sperm to float for considerable distances, and wind can increase the distance downwind.

Monoicous species (having male and female organs on the same plant) have a greater chance for fertilization than **dioicous** species because there will always be gametangia of the opposite sex nearby. Rohrer (1982) compared the success of dioicous species with and without splash cups in an aspen forest and a swamp forest of Michigan's northern Lower Peninsula. Those with splash cups had significantly higher sporophyte production (Figure 13). Unfortunately,

splash cups are relatively uncommon, but leaves surrounding antheridia can sometimes act as splash cups or platforms by spreading when hit by a raindrop (reference forgotten ☺).

Figure 13. Effect of splash cups and epiphytic dwarf males on number of individuals with sporophytes in dioicous mosses of an aspen forest in the northern lower peninsula of Michigan, USA. Based on data from Rohrer 1982.

Paraphyses

This story is not complete without a discussion of **paraphyses**, those sterile structures, usually filamentous, that accompany most gametangia among the bryophytes. For something to persist this commonly while requiring energy for their development, we usually consider them to have some adaptive function. But little if any testing has been done to show that they make a difference.

Paraphyses usually occur in sufficient density to produce capillary spaces. With this knowledge, we can theorize as to their value. Such spaces would mean that water drops would be drawn between them, providing swimming spaces surrounding the archegonia. For antheridia, these can create water pressure that could aid in the rupture of the antheridium and hence the release of sperm.

But this does not seem to be the only excuse for their continued existence. In the Neckeraceae, structures that can be interpreted as paraphyses develop after fertilization in *Neckeropsis* (Figure 14), forming on the perichaetia (Merced-Alejandro & Sastre-De Jesús 2009). These researchers found that transitions between uniseriate and multiseriate paraphyses occur at different stages in the developing reproductive branch. In early stages they are more typical of paraphyses in most mosses; this stage is the terminal stage in some *Neckeropsis* species. In other species, these continue to become multiseriate and ligulate to lanceolate. But what could their function be if they do not develop until after fertilization?

Figure 14. *Neckeropsis undulata*, a genus in which paraphyses develop after fertilization. Photo by Michael Luth, with permission.

As discussed earlier, Reese (1955) tested a very different function for these paraphyses. He was able to demonstrate their ability to regenerate plants in *Bryum capillare* (Figure 15-Figure 16), *Aulacomnium palustre* (Figure 17), and *Funaria hygrometrica* (Figure 18-Figure 19). Could this be a back-up plan for unsuccessful sexual reproduction? Most likely it is actually a rare occurrence in nature, and thus its most frequent function is most likely that surmised by the early bryologists who considered them to have both a capillary function to draw in water, but also to retain water among the developing gametangia.

Photoperiod and Light Intensity

Bryophytes, like flowering plants, can be classified into a variety of short-day and long-day types (Benson-Evans 1964; Maravolo 1980; Glime 1984; Li & Glime

1991). Tracheophyte species that occupy a wide latitudinal range, such as *Typha latifolia*, show population differences in response to day length (McNaughton 1966), and Longton (1972) has demonstrated this for the mosses *Polytrichum* (Figure 1, Figure 9) and *Psilopilum* (Figure 20). The physiological response mechanism in these two taxa is unknown, and a large number of substances can induce the same response, depending on the species.

In 1983, Chopra and Bhatla contended that mosses, except for *Sphagnum plumulosum* (= *S. subnitens*; Figure 21), appeared to be independent of photoperiod for the induction of gametangia. On the other hand, they found that all liverworts tested to date, except *Ricciella crystallina* (= *Riccia crystallina*; Figure 22) (Chopra & Sood 1973a), were either long-day or short-day plants. But they clarified this statement – it appears that even in liverworts, the response seems to be quantitative, with greater light intensities increasing the photoperiod response.

Figure 20. *Psilopilum cavifolium*, member of a genus where populations can show differences in response to day length. Photo by Niklas Lonnell, with permission.

In mosses, other factors such as light intensity and temperature modify the response. For example, *Bartramidula bartramoides* [optimum of 3500-4000 continuous light (Chopra & Rahbar 1982)] and *Leptobryum pyriforme* (Figure 23) respond linearly to increasing light intensity for gametangial response (Chopra

& Rawat 1977; Chopra & Bhatla 1983), whereas *Bryum argenteum* (Figure 44-Figure 45), *B. coronatum* (Figure 3), and *Barbula indica* var. *gregaria* (Figure 2) respond to a specific light intensity for their optimal response (Chopra & Bhatla 1983). In *Bryum coronatum* and *Barbula indica* var. *gregaria*, antheridia develop under "ordinary" cultural conditions (Kumra & Chopra 1983), requiring no specific photoperiod for induction, but having a greater response as the photoperiod increases. *Philonotis turneriana*, on the other hand, remains sterile under "ordinary" conditions. Temperature likewise plays a role, but its role is primarily to constrain the photoperiodic effect within certain temperature limits. However, in *Philonotis turneriana* a temperature of 18°C is needed for induction. In *Barbula indica* var. *gregaria* and *Bryum coronatum*, the antheridial induction increases as the temperature increases, up to 24°C.

Knoop (1984), like Chopra and Bhatla (1983), contends that most mosses seem to be day-neutral. Nevertheless, Benson-Evans (1964) examined a large number of bryophyte taxa with varying environmental influences on initiation of gametangia; photoperiod seemed to be the overriding influence in most cases. In ten liverworts (4 Marchantiales, 6 Jungermanniales), the plants were long-day plants. *Riccia glauca* (Figure 24), *Phaeoceros laevis* (Figure 25), and *Sphagnum plumulosum* (Figure 21) are short-day plants. The moss

Pogonatum aloides (Figure 26) (Benson-Evans 1964) and liverwort *Ricciella crystallina* (Figure 22) (Chopra & Sood 1973b) are day-neutral. *Phaeoceros* spp. (hornworts) are predominantly long-day induced, a condition that may be true for most hornworts (Schofield 1985). Temperature and other external factors can modify these responses, and surely energy will play a role. But are most mosses really day-neutral?

Despite the tendency for liverworts to be controlled by photoperiod, *Lophocolea* (Figure 27) in southern Illinois, USA, is day neutral (Zehr 1979). And the mosses *Diphyscium foliosum* (Figure 28), *Atrichum angustatum* (Figure 29), and liverwort *Trichocolea tomentella* (Figure 31) are long-day plants for gametangial production. *Nowellia curvifolia* (Figure 30) is likewise a long-day liverwort, but only for initiation. They will continue to develop unless the process is halted by desiccation.

Figure 31. *Trichocolea tomentella*, a long-day plant for gametangial production. Photo by Michael Luth, with permission.

Voth and Hamner (1940) found that photoperiod controlled the development of gemma cups vs gametangiophores in *Marchantia polymorpha* (Figure 10). Short days stimulated gemma cup production, whereas long days stimulated more gametangiophores. Miller and Colaiace (1969) found that this species could be grown from gemmae and induced to produce antheridiophores and

archegoniophores in 3-6 weeks under a 24-hour photoperiod at 23°C.

Perhaps *Fontinalis* can again give us insight into these seemingly different results. Members of this genus, like *Fontinalis novae-angliae* (Figure 32), that are common in fast water of mountain streams face the problem of losing their tiny sperm rapidly downstream as soon as they are released. Goebel (1930) suggests that *Fontinalis* can only reproduce when it is in standing water because the water would otherwise wash the sperm away too easily. Hence, it appears that those mosses that live submersed in streams must time their sperm release to coincide with low water levels when the moss is moist, but not in rushing water.

Figure 32. *Fontinalis novae-angliae* in a swift mountain stream in New Hampshire, USA. Photo by Janice Glime.

This need for timing of sperm release suggests that a photoperiod response would be beneficial in those regions where low water level periods are somewhat predictable. Indeed, in *Fontinalis dalecarlica* (Figure 33), photoperiod seems to control production of gametangia quantitatively, rather than being an on-off signal, with short days causing the maximum number of archegonia to be mature when the moss is above water, but wet, during late summer and early autumn (Figure 34; Glime 1984). Longer days seem to lengthen the time for archegonia production, but aeration (from being above water) is also an important factor, resulting in more archegonia compared to those on submersed stems. Maturation of gametangia when the antheridia and archegonia are located above water, but moist, provides moisture for fertilization but protects the sperm from being washed away by fast water (Figure 35). Perhaps initiation of archegonia is more complex in mosses, causing the appearance of being day-neutral when the combination of stimulating factors is not present.

Figure 33. *Fontinalis dalecarlica* archegonia, a genus that responds to day length. Photo by Janice Glime

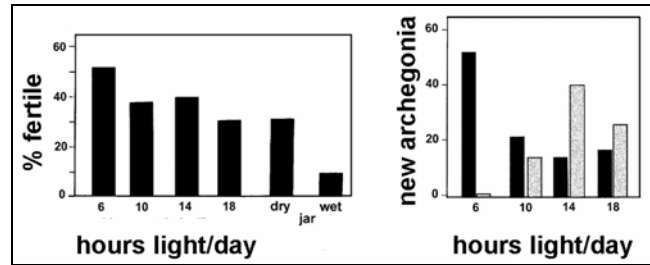

Figure 34. Effects of photoperiod and exposure to air on production of archegonia in *Fontinalis dalecarlica* (Figure 33) after 16 weeks of cultivation in artificial streams. **Left:** Day length effect and effect of submersed (wet) vs emergent (dry) at 14-hr photoperiod. Fertility does not differ significantly among the photoperiods, but emergent mosses produced significantly more than wet ones ($p < 0.01$). **Right:** Effect of photoperiod on development time required for archegonia. Black bars ■ are numbers of archegonia produced during weeks 1-7; gray bars ▨ are numbers produced during weeks 7-16. $n = 40$ plants in each condition. From Glime 1984.

Leitgeb (1868) found *Fontinalis antipyretica* (Figure 35) to produce antheridia from spring until fall, but he did not mention whether the number maturing remained constant. At least for *Fontinalis dalecarlica* (Figure 33) from North Carolina, the fact that production is not perfectly responsive to short days, but rather occurs more slowly during longer days, assures the moss of having at least some gametangia ripe whenever water conditions are right (Glime 1984). It is a bet-hedger in the sense of Stearns' (1976) r and K strategies. *Fontinalis* can afford to be a bet-hedger because its vegetative parts are both persistent and capable of reproducing by fragmentation. Even a series of years when gametangial maturity does not match the right water level would not cause a serious reproductive problem.

Figure 35. *Fontinalis antipyretica* partially above water, providing an opportunity for splashed sperm to locate an archegonium. Photo by Jan-Peter Frahm, with permission.

The suitable photoperiod may be altered by temperature, permitting the plant to be plastic and able to

complete its life cycle in different geographic regions where the photoperiod relationship to temperature is different. For example, *Fossombronina brasiliensis* is a short-day plant at 18°C, requiring 6-12 hours of night, whereas at 10°C its light requirements are more quantitative (Chin *et al.* 1987). Furthermore, photoperiod affected the sex ratio, with more female gametangia being produced at 10°C and more male gametangia at 18°C.

Continuous light can favor some moss gametangial production. For the moss *Microdus brasiliensis* (Figure 36), Chopra and Mehta (1987) found that gametangial production increased with increasing photoperiod, with continuous illumination at 18°C being optimal.

Figure 36. *Microdus brasiliensis*, a moss in which gametangial production increases with increasing photoperiod. Photo by Jan-Peter Frahm, with permission.

Light intensity can also control fertilization success. *Phascum cuspidatum* (Figure 37) has greater fertilization in shade, due to larger antheridia and greater dehiscence, than in sun (Hughes & Wiggin 1969). Since free water is required for fertilization, this mechanism provides a longer period of moisture while the sperm attempts to reach the egg.

Figure 37. *Phascum cuspidatum* with capsules, a moss with greater fertilization in shade. Photo by Michael Lüth, with permission.

Little seems to have been done to understand the relationships of photoperiod in gametangial development in the **Anthocerotophyta**. Benson-Evans (1964) reported that this group is comprised of short-day plants, but I haven't found enough references to justify that assertion. She reported that *Phaeoceros laevis* (Figure 25) is sterile in 18-hour days, but produces gametangia in 8-12 hour days. Ridgeway (1967) found photoperiod to be the critical factor to induce antheridia and *Anthoceros* (Figure 38), *Phaeoceros*, and *Notothylas* (Figure 39), whereas a range of temperatures from 10 to 20°C had almost no effect. However, at 5 and 25°C, the six species studied failed to produce antheridia. At 10°C, none of the species produced antheridia in 18-hour days, whereas all produced them in that photoperiod at 8°C. Most also produced them at 4 and 12°C.

Figure 38. *Anthoceros agrestis*, a hornwort that produces gametangia in response to photoperiod, shown here with sporophytes. Photo by Jan-Peter Frahm, with permission.

Figure 39. *Notothylas orbicularis* with involucres, a species that responds to photoperiod but not temperatures. Photo by Michael Lüth, with permission.

Using single-spore cultures, Lazarenko and Lesniak (1972) found that the long-day (16 hours daylight) *Desmatodon cernuus* is sterile in 24 hours of light. Such requirements from the natural environment could eliminate the sexual reproduction in populations that develop in more northern latitudes and may explain the reliance of some species on asexual reproduction. The sibling species *Desmatodon ucrainicus* is fully self compatible.

In a more recent study, Lee *et al.* (2010) found that it can actually be the change in photoperiod that induces gametangia. In *Pohlia nutans* (Figure 40), changes from long days to short days effected gametangial initiation. It appears we need many more studies before we can assess the importance of photoperiod (and light intensity) on gametangial induction in bryophytes, especially mosses.

Figure 40. *Pohlia nutans* with perigonia, a plant that responds to a change in photoperiod to initiate gametangia. Photo by Michael Lüth, with permission.

But it appears that we know little about the effects of light intensity or light quality on the development of gametangia or the success of fertilization. Could it be that in certain wavelengths the sperm are more likely to die, particularly in the UV range?

Photoperiod response is likely to be one of the most frequent differences seen between populations at different latitudes. Wavelength is also likely to be a selection factor, especially at high altitudes. Selection forces would be strong against those individuals that produced gametangia at times when completion of reproduction was unlikely due to low temperatures and possibly strong UV light. Weitz and Heyn (1981) demonstrated that reaction to day length was one of the traits that differed among populations of the ubiquitous moss *Funaria hygrometrica* (Figure 41) from various geographic-climatic regions.

Figure 41. *Funaria hygrometrica* (Common Cord-moss) male plants with antheridial splash platforms. Photo by Barry Stewart, with permission.

The moss *Bartramidula bartramoides* is unusual in having a high nutrient requirement. Chopra and Rhabar (1982) found that it grew best at full strength Knop's medium plus Nitsch's minor nutrient solution. Gametangial induction (initiation of development) occurred at $25 \pm 2^\circ\text{C}$, 3500-4000 lux continuous light.

Nutrients

Nutrient supply as a control of gametogenesis occurs throughout the plant kingdom, although it is probably best developed in the algae. The green algae *Oedogonium* (Singh & Chaudhary 1990) and *Chlamydomonas* (Figure 42) (Trainor 1959; Matsuda *et al.* 1992) recognize the approach of winter by the diminishing supply of nitrogen in a usable form, developing gametes and creating zygotes (then zygospores) that are able to survive the winter. It is appropriate to ask what role nutrients play in the life cycles for organisms that have quite low nutrient requirements – the bryophytes.

Figure 42. *Chlamydomonas*, a genus that responds to diminishing N supply by producing gametes. Photo by Janice Glime.

Ramina *et al.* (1979) demonstrated the role of nutrients in *Bougainvillea*, where flower production increased in direct relationship to leaf production but decreased in relation to branch production (which used nutrients without making more). In the aquatic moss *Fontinalis dalecarlica* (Figure 43), production of gametangia likewise is inversely related to branch production from 10 August to 14 October (Figure 43), again suggesting an energy limitation (Glime 1984).

Figure 43. Effect of photoperiod on number of archegonia vs branches in *Fontinalis dalecarlica*. Redrawn from Glime 1984.

Selkirk (1979) has shown that limited nitrates cause gamete production in several species of the liverwort *Riccia* (Figure 24), and Joenje and During (1977) showed that lower nutrients stimulate the production of sex organs

in *Bryum argenteum* (Figure 44-Figure 45). A low N:high C ratio in *Marchantia* (Figure 10) likewise stimulated production of sexual branches (Lockwood 1975). On the other hand, in *Fossombronia brasiliensis* (see Figure 46), N as nitrate caused more gametangial production than when it was supplied as ammonium (Chin *et al.* 1987). Such differences can help to explain differences in habitat preferences among species.

Figure 44. *Bryum argenteum* with several plants showing antheridial apices. Photo by Dick Haaksma, with permission.

Figure 45. *Bryum argenteum* perigonium showing antheridia. Photo by George J. Shepherd, through Creative Commons.

Figure 46. *Fossombronia* sp. *Fossombronia brasiliensis* produces gametangia in response to nitrate nitrogen. Photo by Ken-ichi Uedo, through Creative Commons.

Carbohydrates are important for gametangial formation in at least some bryophytes. Whereas *Bryum argenteum* (Figure 44-Figure 45), *B. coronatum* (Figure 3), and *Barbula indica* var. *gregaria* (Figure 2) produce gametangia in the absence of carbohydrates in culture, *Ricciella crystallina* (Figure 22) and *Bartramidula bartramoides* respond to enhanced carbohydrates (Chopra & Bhatla 1983), and addition of sugar in culture seems to be essential for *Bartramidula bartramoides* (Chopra & Rahbar 1982). But, as discussed above, Chopra and Bhatla (1983) found that a high carbohydrate:nitrogen ratio was more important than carbohydrates alone in the initiation of gametangia. In particular, bryophytes are likely to respond to depletion of nitrate or ammonium (depending on species), whereas organic nitrogen (amino acids, peptone, urea) affects gametangial formation differently among various species of liverworts.

Amino acids and kinetin, both found in the environment, can alter the photoperiodic response of gametangial induction in the leafy liverwort *Cephalozia lunulifolia* (= *C. media*; Figure 56) (Lockwood 1975). Arginine, cysteine, and tryptophan plus kinetin negated photoperiodic control. Those compounds that stimulated asexual reproduction (gemmae) under short photoperiods would also inhibit gametangial activity under long-day conditions. Addition of inorganic nitrogen had no effect on these responses.

Thus, as concluded by Chopra and Bhatla (1983), the importance of the nutrient status varies by species. Generally, however, low nutrient levels seem to be the most important in gametangial induction.

The need for sugar may be an artifact of culture. In their study of the liverwort *Cryptomitrium himalayense*, Awasthi *et al.* (2013) found that sugar was necessary in the lab for gametangial induction, but when cultured on soil, this species produced gametangia under the same temperature of 21°C and long day (16 hours light) regime with colder nights (8 hours darkness at 15°C), but with no added sugar necessary.

Belkengren (1962) had some rather unusual results in *Leptodictyum riparium* (Figure 47). In this species, he was able to induce gametangia by culturing in continuous light, using a CO₂-free period followed by addition of sugar or CO₂. I don't know how this relationship would apply in nature.

Figure 47. *Leptodictyum riparium*, a species that can produce gametangia in continuous light. Photo by David T. Holyoak, with permission.

I find it interesting that the same nutrient status that favors gametangial production also favors vegetative growth in *Bartramidula bartramoides* (Chopra & Rahbar 1982). This was demonstrated using Knop's major nutrients plus Nitsch's minor nutrients at full strength with 1% sucrose. Perhaps the added sucrose gave it the energy it needed to support both.

A low nutrient status in the environment can trigger transport of nutrients from leaves to younger, growing parts in tracheophytes (Salisbury & Ross 1978), and Ogawa and King (1979) have shown that in *Pharbitis nil*, translocation of assimilate is essential for flowering. Perhaps translocation of assimilate accounts for the stimulus to produce gametangia under low nutrient conditions in bryophytes as well, but at present we have no clue that this occurs. By contrast, working with *Bartramidula bartramoides*, Chopra and Rahbar (1982) showed that optimum conditions for induction of gametangia included full strength nutrient solution.

In *Ricciella crystallina* (Figure 22), there was no response in growth of thalli when calcium nitrate concentration was doubled or even quadrupled in Knop's solution (Sood 1974). However, increasing potassium nitrate cause a "considerable" increase in growth. Changing to ammonium nitrate or ammonium sulphate caused the formation of callus tissue. Fe-EDDHA and Fe-EDTA had no effect on thalli, but slightly increased production of archegonia (optimum at 10^{-5} M). Urea as a nitrogen source supported both robust growth and increased archegonial production. Amino acids likewise affected sexuality, with hydroxyproline, serine, threonine, asparagine, glutamic acid, alanine, and leucine causing production of more archegonia. Glycine, tryptophan, aspartic acid, and valine caused production of more antheridia.

Figure 49. Comparison of distances between sporophytes in *Pleurozium schreberi* under simulated acid rain treatments. Redrawn from Raeymaekers 1986.

pH

Chopra and Bhatla (1983) concluded that bryophytes exhibit maximal gametangial initiation within a specific pH range, and that the pH of the medium changes during gametangial production. Bhatla (1981) found that a pH of 4.5 inhibited sexual induction in the moss *Bryum argenteum* (Figure 44-Figure 45). Raeymaekers (1986) found that a pH of 3.5 inhibited formation of capsules (Figure 48-Figure 49) in the acid-loving *Pleurozium schreberi* (Figure 50), thus indicating a possible connection with gametangia (Figure 51). Whether pH plays a role in induction of gametangia is unknown, but certainly low pH of acid precipitation can be detrimental to some mosses by interfering with sexual reproduction.

Rahbar and Chopra (1982) found that *Bartramidula bartramoides* produced more gametangia in liquid media than on semi-solid media. The two media exhibit different changes in pH, but these changes do not affect the time of gametangial induction. However, increasing pH, up to pH 7.0, increases the percentage of fertile gametophytes.

Figure 50. *Pleurozium schreberi*, a moss whose sexual reproduction is sensitive to low pH. Photo by Bob Klips, with permission.

One interesting correlation in several species of *Splachnum* (Figure 66) is that low pH, along with low light and nutrient concentration, can favor males over females

(Cameron & Wyatt 1990). This results in clumps of one gender, but the changing pH with aging of the dung could favor a change in gender in later populations, ultimately resulting in the presence of both sexes on the same dung. In fact, the ratios on Isle Royale, Michigan, were typically 2:1 females to males.

In the eleven species of bryophytes from a Brazilian Atlantic Rainforest, Maciel-Silva *et al.* (2012) found that monoicous and dioicous species had different responses to pH. At sea level, the monoicous taxa were favored by a lower pH.

Figure 51. Archegonia of *Pleurozium schreberi* showing the loose perichaetial protection they have. Photo by Janice Glime.

Temperature

Temperature induces a variety of responses in flowering plants (Salisbury & Ross 1978), and we might expect even more variety in bryophytes, where some species remain active throughout winter even at high latitudes and altitudes. For example, *Fontinalis hypnoides* (Figure 52) produces more gametangia at 15°C than at 1, 5, 10, or 20°C (Glime 1982). Clarke and Greene (1970) showed that the reproductive response of *Pohlia nutans* (Figure 40) to day length is dependent upon temperature. In *Leptobryum* (Figure 23), low temperature is necessary for induction of antheridia, but once started they are independent of temperature (Chopra & Rawat 1977). On the other hand, for the thallose liverwort *Ricciella crystallina* (Figure 22), it appears that temperature is the overriding factor, provided there was a certain minimum photoperiod provided (Chopra & Sood 1973a).

Figure 52. *Fontinalis hypnoides*, a moss that produces maximum gametangia (seen in early development here) at 15°C. Photo by Janice Glime.

Chopra and Bhatla (1983) suggest that bryophytes operate in a range of temperatures, and that responses to light intensity and photoperiod might only operate within a range of temperatures that are broad in some species and narrow in others. Nevertheless, bryophytes do not seem to require any low temperature pretreatment for the induction of gametangia.

Hohe and coworkers (2002) found that both temperature and day length affect the expression of a MADS-box gene in *Physcomitrella patens* (Figure 53). In particular, one gene that was concentrated in the shoot apex and developing sporophytes produced higher RNA under conditions of 15°C, 8 hours light per day, whereas vegetative growth was predominant at 25°C, 16 hours light per day, suggesting that lower temperatures and photoperiod were important in sexual reproduction. This interdependence of temperature and photoperiod is an important way to coordinate gametangial production with the appropriate time for sporophyte development.

Figure 53. *Physcomitrella patens*, a moss that responds to both photoperiod and lower temperatures for gametangial development. Photo by Jan-Peter Frahm, with permission.

Environmental Signalling Interactions

In many cases, perhaps most, the response to photoperiod or temperature or nutrients does not respond to just that one factor. The response is likely to differ in different geographic regions, and this can be the result of selection for a different factor as the trigger, perhaps because one factor cannot be expressed in this

environment. In *Fossombronia brasiliensis* (Figure 46), Chin *et al.* (1987) found that at 18°C the plants were short-day plants, requiring a night length of 6-12 hours. (Short-day plants typically are long night plants, measuring number of hours of darkness). When the temperature was only 10°C, this species became a quantitative short-day plant. But temperature also affected the gender expression, with more male gametangia being produced at 18°C and more female gametangia being produced at 10°C. Furthermore, the type of nitrogen available made a difference, with nitrate nitrogen causing production of more gametangia than did nitrogen in the form of ammonia.

In the dioicous moss *Bryum argenteum* (Figure 44-Figure 45), temperature, light intensity, and photoperiod all play a role in gametangial formation (Chopra & Bhatla 1981b). Both males and females produce the maximum gametangia at 25±2°C and in the light intensity range of 1800-2000 lux. At higher light intensities, vegetative growth occurs instead. If the temperature is lowered to 10±2°C, the response decreases. Chopra and Bhatla consider this species of *Bryum* to be a quantitative day-neutral plant because it is able to produce gametangia in as little as 8 hours of light, increasing production as the day lengthens.

The thallose liverwort *Asterella tenella* (Figure 54) requires the right conditions of both temperature and day length (Bostic 1981). For this species, **archegoniophores** (female reproductive branches) were induced under short days (10 hours) with 15°C daytime and 10°C nighttime temperatures.

Hormones

These physical cues must somehow be translated into biochemical responses. In the fern *Blechnum spicant*, gibberellic acid is known to illicit production of antheridia (Fernandez *et al.* 1997). In flowering plants, it can cause flowering. Since one known function of GA in flowering plants is increased water uptake (Salisbury & Ross 1978), this role might be important in maintaining an adequate internal water supply during gametogenesis of bryophytes.

Induction of **gametogenesis** by gibberellic acid is consistent with the role of GA₃ in increasing alpha-amylase activity, thus facilitating the metabolism of starch to sugar through hydrolysis. We know from the studies on *Marchantia* (Figure 10) (Maravolo 1980) that this starch conversion permits energy-supplying sugars to move to the actively growing regions such as gametangia. This sequel is so consistent with the need for sugar to maintain the sporophyte condition in callus culture (Bauer 1963b) and its requirement for gametophore production (Maravolo 1980), that one is tempted to accept this explanation alone. But how does this relate to photoperiod and temperature? And why do some plants respond to short days and others to long ones? I must conclude, as most flowering plant physiologists have done, that more than one substance is involved. In *Fontinalis dalecarlica* (Figure 33), the quantitative response to short days suggests a two-substance response – one present continuously and one that must accumulate as a function of photoperiod/light (Glime 1984).

Salisbury and Ross (1978) state that high auxin concentrations inhibit flowering and Benson-Evans (1961) found that auxins inhibit development of sexual organs in the thallose liverwort *Conocephalum conicum* (Figure 55). Growth substances such as 2,4-D and NAA induced receptacle formation but not gametangial production. Application of auxin at 16°C caused cell elongation of the archegoniophore, but not production of new cells. Therefore, it seems that gametogenesis might require the suppression of IAA.

Figure 55. *Conocephalum conicum* with antheridia whose development is inhibited by auxins. Photo by Malcolm Storey, through Creative Commons.

IAA seems to have other interesting reproductive functions. For example, in the dioecious hemp, IAA caused predominantly female sex expression (Chailakhyan & Khryanin 1978), but Salisbury and Ross (1978) point out that auxin levels and flowering seldom correlate in any meaningful way. In experiments on the leafy liverwort *Cephalozia lunulifolia* (Figure 56), kinetin + IAA inhibited sexual reproduction (Lockwood 1975). Tremaine and Glime (unpub. data) supplied IAA to *Fontinalis duriaei* (Figure 57) at concentrations of 10⁻⁶ and 10⁻⁸ M on a 12 hr light/12 hr dark cycle and there was no sign of gametangial initiation after 5 weeks. Yet this species usually produces gametangia during short days (personal observations).

Figure 57. *Fontinalis duriaei* archegonia, a species in which they fail to initiate with added IAA. Photo by Janice Glime.

Cytokinins can also play a role in sexual development. In the liverwort *Riccia discolor*, 10^{-4} M kinetin proved to be the best concentration for promoting archegonial development as well as enhancing growth (Chopra & Gupta 1992).

Hormones may not affect the antheridial and archegonial inductions equally, possibly explaining how bryophytes manage to begin antheridial development long before archegonial development in most species. Chopra and Bhatla (1983) demonstrated that gibberellins contribute to the stimulation of antheridial formation in the bryophytes they investigated, whereas cytokinins stimulate archegonial induction while inhibiting antheridial induction in *Ricciella crystallina* (Figure 22) and *Bryum argenteum* (Figure 44-Figure 45). They found that auxins, gibberellins, and cytokinins can interact in controlling the gametangial response – no surprise there.

The hormone **IAA** may likewise have the opposite effects on the two sexes (Chopra & Bhatla 1983). In the thallose liverwort *Ricciella crystallina* (Figure 22), IAA increased archegonial induction, but in the mosses tested [*Bryum coronatum* (Figure 3), *B. argenteum* (Figure 44-Figure 45), *Barbula indica* var. *gregaria* (Figure 2)], it favored antheridial induction.

Bhatla and Chopra (1981; Chopra & Bhatla 1981a) examined hormonal regulation of gametangial induction in *Bryum argenteum* (Figure 44-Figure 45) and found that both IAA and gibberellins (GA3) increase the induction of male gametangial branches while inhibiting the female clones in this dioicous moss. Cytokinins (kinetin, DMAAP) increased gametangial induction in the female

clone while slightly inhibiting it in the male clone. When IAA and kinetin were both present, they were able to nullify the inhibitory capacity of each other. Cyclic AMP prevented kinetin from inhibiting male gametangial induction but stimulated the kinetin effect on females. ABA served as an inhibitor of both growth and gametangial induction in both sexes. Females proved to be more sensitive to ABA than males.

Cyclic AMP is one factor that may help in the control of hormone action and hence in controlling gametangial formation (Chopra & Bhatla 1983). This compound is a common mediator of hormone action in animals and is now known to increase gametangial induction in the moss *Bryum argenteum* (Figure 44-Figure 45). Cyclic AMP also increases antheridial induction in *Bryum coronatum* (Figure 3) and *Barbula indica* var. *gregaria* (Figure 2). To further confuse the investigator, it can overcome the inhibitory effects of ammonium ions and concentrations of sucrose that are too high, hence increasing gametangial formation, as Chopra and Bhatla have shown in *Bryum argenteum*.

Environmental Hormone Interactions

Interactions with the environment can supply bryophytes with hormones, such as yeast extract and sex hormones from animals (Chopra & Bhatla 1983). These can increase the induction of both antheridia and archegonia.

Basile *et al.* (1969) found that the leafy liverwort *Scapania nemorea* (Figure 58) regularly associates with the bacterium *Pseudomonas estorquens*. This association provides it with stimulation for both larger growth and earlier reproductive maturity than sterile cultures.

Figure 58. *Scapania nemorea*, a liverwort that associates with *Pseudomonas estorquens* that stimulates earlier reproductive maturity. Photo by Li Zhang, with permission.

Sugars

Chopra and Rhabar (1982) found that sugar (1%) was necessary for gametangial induction in *Bartramidula bartramoides*. On the other hand, *Bryum argenteum* (Figure 44-Figure 45) has markedly lower gametangial induction in 4% sucrose (Bhatla & Chopra 1979). Adding cyclic 3',5'-AMP neutralized the effects of the sucrose, but the concentrations are different for male (10^{-7}) and female (10^{-5}).

Overall Physiology

In summary, metabolic changes are needed for the initiation of gametangia (Chopra & Bhatla 1983). Liverworts may have an increase in cellular levels of carbohydrates, auxins, RNA, and proteins as the gametangial development begins. Enzymes and their concentrations change. Phenolic compounds change. And new colors develop. Reynolds and Maravolo (1973) found that two of the phenolic compounds inhibited IAA oxidase activity and two enhanced it in *Marchantia polymorpha* (Figure 10). The significance of this interaction in gametangial development seems still to be a mystery.

Both vegetative growth and gametangial development are regulated by and favored by iron and copper chelating agents such as EDTA and EDDHA (Chopra & Bhatla 1983). But it is interesting that in *Riccia* (Figure 24) these chelates favor archegonial development more than antheridial formation, whereas the opposite is true in *Bryum argenteum* (Figure 44-Figure 45) (Chopra & Bhatla 1983). Salicylic acid (the effective compound in aspirin) inhibits gametangial formation in most bryophytes, probably by chelating iron and copper or other metals involved in needed enzymes. We know that in *Bryum argenteum* there are marked changes in iron and copper levels. Iron seems to induce the reproductive phase, but copper inhibits it. In *Bartramidula bartramoides*, on the other hand, salicylic acid enhances both vegetative growth and gametangial formation.

Cyclic AMP enhances antheridial production in the moss *Bryum coronatum* (Figure 3) and *Barbula indica* var. *gregaria* (Figure 2) and overcomes the inhibitory effects of ammonium ions and high levels of sucrose on gametangial development in *Bryum argenteum* (Figure 44-Figure 45) (Chopra & Bhatla 1983).

In an attempt to understand the physiological changes leading to development of gametangia in liverworts, Rao and Das (1968) studied *Exormotheca tuberifera*, *Plagiochasma articulatum*, *Reboulia hemisphaerica* (Figure 59), *Fimbriaria angustata*, and *Pallavicinia canara*. In *Fimbriaria angustata*, a sharp rise in respiration and a doubling of the C:N ratio accompanied the transition from vegetative to reproductive state in females. Formation of archegoniophores occurred with an increase in the plant's own IAA, RNA, and protein. Carbohydrates accumulated in the archegoniophore at the expense of the gametophyte as the sporangia developed. By contrast, the antheridial production was correlated with a decrease in levels of IAA, RNA, and protein, and unlike the females, there was no notable increase in the C:N ratio.

Color Changes

Both antheridia and archegonia are often recognizable first by the addition of red coloration as they develop. In archegonia, this is often present in the neck canal cells (Figure 33, Figure 57). In antheridia, the color can be so intense that it is visible through the surrounding leaves, making branch tips red in some species of *Sphagnum* (Figure 60). In *Marchantia berteroana* (Figure 61), production of the flavone acacetin stops and instead 8-hydroxyapigenin and 8-hydroxyluteolin glycosiduronic acids (previously absent) become the predominant

flavonoids (Markham *et al.* 1978). Acacetin seems instead to be important during the asexual phase.

Delay of Gametogenesis

But suppose that gametogenesis is **not** a process to be initiated, but rather it is a natural process that **must be stopped**. Sexual reproduction is ancient. It no doubt began with like cells bumping into each other and managing to stay together long enough to fuse. No special

male and female existed; no special inducers were needed. Perhaps something was needed to cause the two membranes to lose their integrity at the region of contact. Then the process became more sophisticated. Attracting substances drew cells together; different strains arose, some repelling and others attracting. Ultimately, special structures housed these one-celled gametes, and then some control was possible. As this scenario continued, the process became more complex and more controlled. The joining and dividing cycle of primitive cells was then subject to controlled delays. Whole sequences of differentiation were interjected to delay the sexual process. These sequences are the ramifications by which we identify species, genera, even phyla of plants. Therefore, it is reasonable that gametogenesis is controlled by inhibitors, factors of the surrounding tissues that retard gamete production and allow productivity of the organism to increase.

It follows that the multitudinous environments for the many species have caused this problem to be solved in multitudinous ways (see Stebbins & Hill 1980). Thus in one species a high concentration of IAA prevents gametogenesis, whereas in another the lack of alpha-amylase or GA deprives the prospective gametangia of the necessary energy source. As long as the raw ingredients (*e.g.* energy, nitrates, amino acids) are being diverted to other sources, gametogenesis is retarded. Such a multitude of ways can accomplish this that surely no consistent pattern could be recognized or even expected. The possibilities of combinations of concentrations and mobilities necessary to override the limits caused by the parent plant are almost limitless.

Male vs. Female

It is often considered a paradox that bryophytes tend to have female-biased sex ratios, whereas flowering plants usually have male biased sex ratios (Rydgren *et al.* 2010). Early control over gender was most likely simple. Internal environment may have been important. For example, Bhandari and Lal (1968) observed abnormal archegonia in *Physcomitrium immersum* that behaved as antheridia. Each had an egg, ventral canal cell, and neck canal cells as would be found in a normal archegonium, but in some these divided repeatedly, forming instead a mass of antheridial cells. They suggested that this is evidence of common origin of the two sexual organs.

Such behavior is somewhat suggestive of sex determination in maple (*Acer*) flowers. In these plants, the concentration of plants affects the ethylene concentration as the flower develops and determines the sex ratio by abortion of one of the parts. Factors related to sex ratio in bryophytes have been discussed in the chapter on sexuality. Therefore, they will be covered only briefly here.

We have noted that bryophytes, or at least many of them, do have sex chromosomes, a phenomenon known for plants first in the liverwort genus *Sphaerocarpos* (Figure 62) (Allen 1930; Anderson 2000). The gender is expressed only in the gametophyte generation by having either a small Y chromosome (male) or an X chromosome (female). This determination is made at meiosis, providing two male and two female spores. The monoicous (bisexual) taxa seem to have been derived mostly from polyploidy in

which the chromosome number is duplicated and both X and Y chromosomes are present.

Figure 62. *Sphaerocarpos michelii*, member of the genus where X and Y sex chromosomes were first discovered. Photo by Jan-Peter Frahm, with permission.

When the sexes are separate, *i.e.* dioicous/unisexual taxa, it is not unusual to find all male or all female populations, derived from a single spore carrying genes for only one gender. In other cases, one gender may outcompete and overgrow the other. Such is the case with *Marchantia papillata* subsp. *inflexa* (Figure 63), a dioicous thallose liverwort that lives on rock and bark surfaces (McLetchie *et al.* 2001). In this case, the females seemed to benefit from light to moderate disturbance and gradually eliminated the males. However, at high disturbance levels, the males dominated. This change in dominance seemed to result from dispersal of gemmae within the patch. We have seen in the brood body chapter that females typically produce fewer gemmae, instead spending energy to support the female reproductive organs and developing sporophyte.

Figure 63. *Marchantia papillata* subsp. *inflexa*, a species in which females can outcompete males in disturbed areas. Photo by Scott Zona, with permission.

McLetchie *et al.* (2001) found that in *Marchantia papillata* subsp. *inflexa* (Figure 63) spores were needed to colonize large areas following disturbance, and that sexual reproduction predominated. However, as the population grew and the space became fully occupied, reproductive effort shifted to less sexual and more asexual means. Does this strategy predominate? It would seem more advantageous to reproduce asexually to fill the area, then reproduce by more widely dispersed spores when it gets crowded.

Maintaining the sexual specificity can get complicated in regenerants. Bauer (1963a) explained that sex determination in regenerated tissue can take two forms:

1. Sex determination is restored following de-differentiation, as in *Funaria hygrometrica* (Figure 18-Figure 19).
2. Sex determination is disturbed, causing the sexual balance to remain permanent or to slowly return to normal, as seen in members of *Splachnaceae* (Figure 64).

In the *Splachnaceae*, as the tendency toward femaleness is weakened, the male expression becomes more common until eventually only male plants can arise (Bauer 1963a). Surprisingly, this can occur even in species such as *Splachnum rubrum* (Figure 64) wherein sex determination is genetic. This species produces dwarf males, but these are usually sterile. The change in gender from vegetative offspring could be from cytoplasmic or genetic changes. However, Bauer reasoned that the constant changes among intermediate kinds of sex determination provides evidence against gene mutation.

Figure 64. *Splachnum rubrum* with antheridial splash platforms, a species where gender is genetically determined. Photo by Janice Glime.

Rydgren *et al.* (2010) explored the ability of maintaining a female-biased sex ratio by testing it in *Hylocomium splendens* (Figure 68), a dioicous pleurocarpous moss that is common on the boreal forest floor. They found that males had a slightly lower production and survival of vegetative offspring than did the non-sporophytic females. This bias is important in a species such as this where sporophytes are uncommon. The slightly better success of males permitted them to expand into female clones, thus facilitating reproduction.

Differential Survival

Not all sex ratio differences are the result of adult competition. Shaw and Gaughan (1993) studied eleven populations of the moss *Ceratodon purpureus* (Figure 65) and found that at the time of germination female gametophytes outnumbered males 3:2, suggesting differential survival rates of spores or germlings. Furthermore, female clones formed much more biomass than did male clones, further increasing the bias. Nevertheless, male clones produced more stems, permitting them to provide additional gametangia and sperm.

Figure 65. Prolific production of capsules exhibited by *Ceratodon purpureus*, suggesting a predominance of females. Photo by Michael Lüth, with permission.

Sex ratio can often change dependent upon growing conditions, even in species where gender of an individual is genetically predetermined. Shaw and Beer (1999) observed that despite chromosomal sex determination in *Ceratodon purpureus* (Figure 65) that would produce equal numbers of male and female cells at meiosis, the sex ratio varied considerably among families of offspring. Some genetically identical individuals (*i.e.*, grown from a single spore) that maintained a nearly 1:1 gender ratio had progeny that produced either predominately male or predominately female offspring.

This discrepancy between offspring sex ratios of two families of siblings suggests that there is a differential germination of spores, most likely related to environmental factors. Additional factors that may be relevant are the differences in size, maturation rates, and reproductive output of the male and female gametophytes in this species.

One factor that can account for highly biased sex ratios is simply the gender of the spore that lands there. Generally, one spore will produce multiple gametophores of one gender. However, Cameron and Wyatt (1990) rejected this as an explanation of the highly biased sex ratio in *Splachnum*. They concluded that the unbiased and abundant dispersal by flies precluded such a bias by ensuring that both genders would arrive on the substrate. But even more interesting is the fact that in *Splachnum ampullaceum* (Figure 66), a single spore can give rise to both male and female gametophores. Instead, it is low light, pH, and nutrients that favor production of males over females.

Figure 66. Massive number of capsules of the dung moss *Splachnum ampullaceum* resulting from the guaranteed close proximity of males. Photo by Michael Lüth, with permission.

There is some evidence that at least in some bryophytes gender may be determined like that of crocodile eggs – by temperature. For the liverwort *Sphaerocarpos texanus* (Figure 67), sex ratios showed female bias among spores that broke dormancy after treatment at 25/15°C for 1-8 weeks (McLetchie 2001), despite a 1:1 ratio of male:female among spores produced (McLetchie 1992). In both field and laboratory-grown cultures, pure female clones were most common, followed by mixed sex, and least frequently, pure male (McLetchie 1992). It appears that the male spore has a lower survival and germination rate that continues into the gametophyte stage.

There seems also to be a physiological gender bias that depends in part on ecological conditions. In *Mnium hornum* (Figure 77) and *Plagiomnium undulatum* (Figure 76), only female regenerants from fragments survived desiccation (77%) (Newton 1972b). Such a strategy could soon create a population of predominantly females.

McLetchie and coworkers (2001) demonstrated that competitive interactions between genders could account for some sex differences at gametophyte maturity in the dioicous thallose liverwort *Marchantia papillata* subsp. *inflexa* (Figure 63) in Trinidad. Using differential equations, they modelled interactions of the two genders under various disturbance regimes. They found no way to stabilize the sex ratio, but rather, under conditions of low to moderate disturbance, females would gradually eliminate males. Under high disturbance conditions, males would eliminate females. Successful germination of gemmae dispersed within the patch played an important role. Since females of this species have only a narrow window in which to produce gemmae without interfering with energy needed for sexual reproduction, they would have less opportunity for successful gemma dispersal and establishment under large disturbance, but under conditions of small disturbance, already established female thalli might be able to outgrow male thalli. Although gemmae appear to be the most important means of maintaining replacement due to disturbances within patches, spores are the primary means for colonizing areas of major disturbances. Production of spores among initial colonizers when the patch becomes fully occupied is maximal, but that production subsequently declines as the sex ratio drifts toward one or the other gender.

Additional information on the costs and tradeoffs of producing archegonia vs antheridia is covered in Chapter 3 of this volume.

Figure 67. *Sphaerocarpos texanus*, a species in which females seem to outcompete males. Photo by Jan-Peter Frahm, with permission.

Bisexual Gametangial Differentiation

Differentiation of a single cell such as a spore ultimately into an organism with cells of many functional types is always intriguing. Differentiation of parts of an organism into male and other parts into female is no less intriguing. What determines which branch, which gametangial cluster, will become male and which female? If we can understand these processes in plants, perhaps we can begin to understand the complexities that contribute to cross-gender behavior in humans.

Using the dioicous *Hylocomium splendens* (Figure 68) as a model, Rydgren and Økland (2002) examined a Norwegian population for five years. During that time, the tissue devoted to gametangia differed. That population had a 4:1 ratio of male to female branches. Of those females, ~30% produced sporophytes. Production of sporophytes varied three-fold during the five years, relating to weather favorability for growth and development. Large segments with high relative growth rates were more likely to produce sporophytes, with a distinct lower size threshold. Although the size limit increased in years with low sporophyte production, the lowest limit was ~2 mg segment dry weight. Furthermore, production of sporophytes was much greater in upper parts of plants, regardless of size differences, suggesting a role for light in initiation of sexual branches.

Figure 68. *Hylocomium splendens* bearing sporophytes. Photo by Janice Glime.

Hormonal Regulation of Gender

In some trees, such as *Acer*, ethylene concentration affects the male:female ratio. But in the small space of a bryophyte mat, could such a high concentration accumulate? There seems to be no evidence that packing of gametophytes, hence higher ethylene production, is a sex determinant. Nevertheless, lab evidence demonstrates that ethylene control is a possibility. Location of sexual structures on the bryophyte could result from a balance among IAA, ethylene, and GA_3 . Chopra and Sood (1973b) showed that GA_3 plus ethrel (which produces ethylene in water) enhanced antheridia production, whereas IAA + cyclocel (CCC) enhanced archegonia production in *Ricciella crystallina* (Figure 22). This is consistent with the role of IAA in favoring femaleness in flowers (Salisbury & Ross 1978). If this relationship holds true, a strong apical dominance, concomitant with apical production of IAA, should produce archegonia at the apex. This is exactly the correlation seen in acrocarpous mosses. Conversely, lack of apical dominance should result in archegonia on side branches, as we see in pleurocarpous mosses. However, Schofield (1985) reminds us that IAA is not involved in sex determination in the same way in all taxa, inducing female sex organs in the liverwort *Riccia* (Figure 24) and male organs in the mosses *Barbula* (Figure 2) and *Bryum* (Figure 45). Because it is common in the environment, IAA could serve as an environmental control, interfering with sexual coordination and hence sporophyte production for some taxa in some habitats. It is likely that hormones interact and that concentrations or relative concentrations are important in gender determination.

Dwarf Males

Dwarf males present an interesting modification to sexual differentiation. In theory, the presence of dwarf males should increase the success of fertilization for a species, particularly among dioicous taxa. However, in two habitats in Michigan, USA, the presence of dwarf males had no significant impact on sporophyte production of dioicous mosses (Rohrer 1982). Dwarf males have been discussed in detail in Chapter 3; this chapter will concentrate on physiological relationships.

In the moss *Trachybryum megaptilum* (= *Homalothecium megaptilum*; Figure 69), males are typically dwarf, but this is a function of being on a female plant (Wallace 1970). Occasional full-sized males are found growing alone, but dwarf males never occur on these full-size males. Despite differences in gametophore appearance, there is no morphological difference between male and female spores. Wallace suggested that some substance released from the female plant might inhibit growth of the male plant.

In *Dicranum* (Figure 70), it appears that female plants present a growth-inhibiting substance that keeps their epiphytic males small (Loveland 1956). On the other hand, in *Macromitrium* (Figure 71) it is genetically determined in those taxa that are truly **anisoporous** (having a bimodal distribution of spore sizes with smaller spores generally producing males), whereas isoporous taxa again seem to be affected by hormones from females (Une 1985). Auxin, applied as 2,4-d, results in dwarf males, suggesting again a role for IAA.

Figure 69. *Trachybryum megaptilum*, where dwarf males form on female plants. Photo through Creative Commons.

Another puzzle that has physiological implications suggesting hormonal concentration gradients is development of morphs among gametangia of a single reproductive head. In *Plagiomnium medium* (Figure 72), antheridia typically surround archegonia. In the border zone between the two sexes, Bryan (1927) always found at least one abnormal gametangium in each of the 100's of heads examined, from nearly perfect to possessing a combination of antheridial and archegonial cells. This likewise suggests some sort of hormonal control that involves concentrations or interaction – or both.

Different Controls

One consequence of sexual differences is that antheridia and archegonia can be under different controls. This can result in maturation of males and females at different times, perhaps accounting for sterility in many populations. Allsopp (1964) suggested that nutritional factors cause male and female production at different times on monoicous species. Lockwood (1975) found that amino acid additives promoted maleness and inhibited femaleness in *Cephalozia lunulifolia* (Figure 56); ammonium nitrate plus citrate also inhibited female gametangia. Machlis (1962) found that males of *Sphaerocarpos donnellii* (Figure 73) dropped the pH of their media from 5.3 and 7.1 to 4.1 in 15 days, whereas females raised the pH, suggesting physiological and possibly nutritional differences. Riemann (1972) suggested that mild, humid winters may result in maturation of the male and female of *Rhytidiadelphus triquetrus* (Figure 74) at different times, whereas harsh winters regulate their timing. Berthier (1966) has shown that antheridial production in *Fontinalis* (Figure 75) is greater under conditions of minimal growth and greater dominance by the main axis; fewer antheridia occurred in high light at 15°C, whereas 8°C and 90% light produced the most antheridia. It is likely that a wide variety of these mechanisms play a role in **protandry** (male gametangia mature first) and **protogynandry** (female gametangia mature first) among bryophyte species.

One selective factor at work is that antheridia generally require a longer time to mature than do archegonia, as discussed earlier regarding phenology. Therefore, they must begin development sooner to mature when the population of female structures is receptive. *Plagiomnium undulatum* (Figure 76) has met this challenge with very different signals to initiate gametangia. Males require long days and diurnal temperature fluctuations to produce gametangia, whereas females require a short 7.25- to 12-hour day at 10°C or warmer (Newton 1972a). We have already seen that more male gametangia are produced by the liverwort *Fossombronia brasiliensis* at 18°C and more female gametangia at 10°C. These differences in temperature and/or photoperiod can permit male gametangia to start development sooner and be ready when female gametangia are ready. But such timing differences meet new challenges when spores are dispersed to new locations where timing of day length and temperature can be different from that of the parent location, so that males and females are no longer synchronized. If only vegetative reproduction follows after introduction by a single spore, no opportunity arises for selection of synchronized variants; instead the species may persist sterile for centuries.

Figure 76. Vegetative branches of *Plagiomnium undulatum*. Photo by Michael Lüth, with permission.

Newton (1972a, b) found that male and female plants themselves differed in photoperiod response in *Mnium hornum* (Figure 77). In short days, the number of males and females was about equal, but in intermediate and long days significantly more female plants arose from buds and produced mature plants. Even regeneration favored females. Thus, in northern areas where sufficiently warm temperatures may occur only during long days, a disproportionate number of females can result. This shifts the population toward dependence on regeneration, due to insufficient fertilization, further promoting females. Similarly, Longton and Greene (1969a,b) found that *Pleurozium schreberi* (Figure 50-Figure 51) produced capsules predominantly in coniferous forests due to lack of males elsewhere.

Figure 77. Male plants of *Mnium hornum*, exhibiting a splash platform. Photo by Michael Lüth, with permission.

The problem of separate stimuli for the two sexes is further complicated by non-sex-related selection pressures after dispersal. Van Zanten and Pocs (1981) concluded that monoicous species of Jungermanniidae have better dispersal than dioicous species because the percentage of monoicous species with a bipolar distribution is greater than that of dioicous species. This is reasonable since production of spores is more likely to occur in monoicous taxa, and these are dispersed more easily than asexual propagules due to the smaller size of spores. Since selection pressures related to sporophyte development are absent in isolated dioicous individuals, selection pressures would revert to gametophyte benefits. These could easily be different in male and female plants because of different amounts of time required for development of male and female gametangia.

Day length and temperature influence the onset of gametogenesis, and we have good evidence that responses to these variables vary within a species throughout the world (Monroe 1965, Clarke & Greene 1970). In dioicous species, vegetative reproduction is the only mechanism for reproduction until a second spore arrives. By that time environmental selection pressures and genetic drift in these small populations have had ample time to make the two sexes uncoordinated. If the signal for gametogenesis is different in the two sexes, there might never be an opportunity for the two gametes to meet. I would predict what van Zanten and Pocs (1981) have already illustrated, that long range dispersal of dioicous species would result in a large number of physiological species with low or no sexual reproduction.

All of these controlling factors suggest that Dan Norris may have been right in his comments to Bryonet on 2 May 2003 – the conditions of monoicy and dioicy and all their subsets may not be as distinct as we present them. The expression of gender may be under control of the environment and not any predetermined genetic distinction.

Numbers of Gametangia

Although each female branch typically produces only one sporophyte, archegonia occur in clusters within **perigonia**. One might ask why all this wasted energy to produce multiple archegonia if only one is successful. Even if all get fertilized, only one embryo succeeds in emerging from its archegonium. Could it be that multiple archegonia are needed to produce sufficient attractant for the sperm to find the location? Or might there be dangers lurking as sperm enter the archegonia, making backups necessary? Have we examined them closely enough to know that all eggs are simultaneously receptive, or might it be that this is a way to insure that one of the eggs is ready at the time of successful sperm dispersal?

The male gametangia generally outnumber female gametangia, but not always (Table 1). Since males must disperse the sperm, with nearly all of them being unsuccessful in fertilizing an egg, large numbers are necessary to provide enough chances for a few to succeed. Note in Table 1 that the ratio of male to female gametangia is considerably higher in the dioicous taxa.

Table 1. Mean number of gametangia per inflorescence, based on data for inflorescences that had gametangia in immature to dehiscent stages. From Une & Tateishi (1996).

	10.6		
<i>Pleurozium schreberi</i>	8.2	Dioicous	Longton & Greene
	6.1		1969a

In the survey of literature presented by Une and Tateishi (1996), *Pleurozium schreberi* (Figure 50-Figure 51) had more female than male gametangia per inflorescence, and *Bryum argenteum* (Figure 44-Figure 45) had little difference between them. Perhaps this is possible because these species are so successful at vegetative reproduction. In Canada, large geographic areas have only one gender of *Pleurozium schreberi*, yet the species is still quite successful. *Bryum argenteum* is easily spread by broken tips.

Gender Recognition

Recognizing the gender of a bryophyte is often difficult if reproductive structures are absent. For mosses like *Polytrichum*, old splash cups may be present, with new growth proceeding from the center (Figure 78). But even these can eventually change sex and thus determination of the sex of the moment may be less convincing. Size often plays a role, but this is affected by growing conditions as well, so one must assess it for each population. In *Marchantia polymorpha* (Figure 10), the male plants are narrow compared to females if one examines the thallus ~1 cm back from the tip, but then one needs both genders at hand to make the assessment (Voth 1941). Voth has observed another difference that I have not confirmed – the female plants have a smoother upper surface and reflect more light than male plants, at least in culture, but again, one really needs the male plants for comparison.

Figure 78. *Polytrichum juniperinum* with new growth from the antheridial splash cups. Photo by Janice Glime.

Yet, somehow, through biochemical means, a sperm is able to recognize a female of its own species, be it on a separate plant or the same one, and travel in that direction. As discussed in the chapters on life cycles of bryophytes, this recognition is facilitated by a concentration gradient from the disintegrated neck canal cells of the archegonium. But the nature of that exudate, and particularly what makes it specific for that species, remains a mystery.

Fertilization

Success of fertilization varies widely from very successful monoicous annual taxa to poorly successful dioicous perennials (Rohrer 1982). Rohrer found that success varied by habitat, with only 19.3% of the populations of the dioicous, vs 75.9% of monoicous taxa

producing sporophytes in a dry aspen (*Populus*) forest. In a wet coniferous forest, the success of monoicous taxa increased to 84.1%, whereas that of dioicous taxa decreased to 12.3%. Surprisingly, having dwarf males epiphytic on female plants did not significantly increase the production of sporophytes in dioicous taxa.

Although several archegonia are typically present on a branch or stem tip, in most species only one sporophyte develops. Stark and Castetter examined the archegonia of *Trichostomum planifolium* (= *T. perligulatum*) at the end of the fertilization season and found that 8% of the archegonia and 7% of the antheridia were abortive. In 13 of the 47 fertilized perichaetia they examined, there was at least one aborted embryo in addition to the developing embryo. Only two had more than two fertilized archegonia. There were no cases where more than one embryo developed. The abortions were all in early developmental stages. Hughes (1979) found that in *Phascum cuspidatum* (Figure 37) archegonial initiation ceases when one of the archegonia has been fertilized. The archegonial abortion raises the question of causes of this abortion. Is there an inhibitory substance produced by the first developing embryo that stops the others? Is there insufficient energy for more than one to continue? Could the hybrid status enter into the success or failure?

A more in depth discussion of fertilization is in Chapter 3.

Self-incompatibility

Fertilization is the termination of the gametogenesis development phase. Successful fertilization must be followed by successful development of the embryo to the mature sporophyte. We know that seed plants have a variety of mechanisms that prevent self-fertilization, either as prezygotic mechanisms that prevent the sperm from reaching and penetrating the egg or from postzygotic mechanisms that interfere with development of the embryo or mature sporophyte. This self-incompatibility has barely been explored in bryophytes.

We have suggestive evidence that self-compatibility exists among bryophytes. Boisselier-Dubayle *et al.* (1996) found the monoicous leafy liverwort *Plagiochasma rupestre* (Figure 79) to be self-compatible based isozyme markers of progeny. Lazarenko and Lesniak (1972) cultured two species of *Desmatodon* to determine their self-compatibility. *Desmatodon cernuus* was sterile in 24 hours of light, being a long-day plant at 16 hours of illumination and requiring low temperatures in the dark for normal sporophyte development. On the other hand, *Desmatodon ucrainicus* was completely self compatible in 24 hours of light, successfully producing sporophytes in single-spore cultures. However, this study raises a caution. One must reproduce the conditions of gametangial development, fertilization, and sporophyte development to test self-compatibility or other conditions involving reproduction.

When a spore travels to a new geographic area, it can encounter changes to the environmental signals needed for its normal development. Failing these signals, the reproductive state might never be initiated. Absence of such developmental signals seems to interfere with sexual reproduction in *Desmatodon cernuus* (Lazarenko & Lesniak 1972).

Jesson *et al.* (2011) considered that both polyploidy and monoicism could strongly depress inbreeding. They tested this in 21 populations of *Atrichum undulatum* (Figure 80). In one population, using allozyme markers, they found that the rates of selfing were greater than zero, despite the population having only one-third monoicous individuals. Lazarenko (1974) found that an inbred clone of *Tortula cernua* (= *Desmatodon randii*; Figure 81) was able to persist through 15 generations. This clone also gave rise to a sterile line that thus forth reproduced vegetatively, but also by producing apogamous capsules through 14 generations because the few spores, despite lacking an exosporium, were able to germinate. These studies suggest that self-incompatibility is not strong among bryophytes and that self-fertilization is possible.

Stark (1983) reported that the autoicous *Entodon cladorrhizans* (Figure 82) was self-fertile and protandrous on a given stem. He found that approximately 90% of the perichaetia developed sporophytes and that this was independent of the number of perichaetia per stem, attesting to a high success rate for fertilization. Since only one archegonium typically develops a mature sporophyte in any given perichaetium, this is a good percentage. Self-fertilization is evidenced by significantly higher frequency of fertilization on bisexual stems than on those with only perichaetia, by the tendency for unfertilized perichaetia to be near the end of the stem away from perigonia, and by the highest fertilizations occurring on stems with perigonia.

Figure 82. *Entodon cladorrhizans*, an autoicous moss with abundant sporophytes. Photo by Bob Klips, with permission.

Trichostomum planifolium is a protogynous monoicous desert moss, but it has a period of gametangial overlap, ending with a period of only ripe male gametangia

(Stark & Castetter 1995). Based on their observations of the population in southern New Mexico, USA, Stark and Castetter concluded that this moss is self-compatible, with common occurrences of fertilization from gametangia on the same stem. They supported this conclusion by the fact that stems that lacked a sporophyte had fewer antheridia and had no perigonia ($n=3$) and that all stems that produced sporophytes had at least one perigonium. The evidence is circumstantial and not definitive, but does suggest self-compatibility.

Zieliński (1986) used two peroxidase alleles to indicate presence of self-fertilization. He found that 38 of the 40 progeny examined in *Pellia epiphylla* (Figure 83) subsp. *borealis* were monomorphic for one of the two alleles involved and interpreted this to mean that self-fertilization had occurred. But we really need to know more than just the constancy of two alleles. Logic would suggest that in many cases the heterozygosity resulting from cross-fertilization would make those individuals more fit, consequently selecting against those individuals lacking a mechanism to prevent self-fertilization. But does this exist among bryophytes?

Figure 83. *Pellia epiphylla*, a species wherein identity of alleles suggests selfing. Photo by Li Zhang, with permission.

We know that seed plants often (usually?) are self-sterile. They have several mechanisms during and following pollination/fertilization to prevent success of self-fertilization, and these can provide suggestions for possible mechanisms in bryophytes:

- different maturation times of male and female parts
- dispersal vector behavior – moving from mature females to mature males (several animal vectors are now known)
- sperm unable to swim in neck of archegonium
- failure of self-fertilized embryo to develop
- rejection of self-fertilized embryos by plant
- better competition by hybrid embryos
- failure of next generation to reproduce

But do we know that any of these mechanisms occur in bryophytes? Gemmell (1950) suggested that all monoicous species were obligate inbreeders. This seems unlikely since evolution from dioicous to monoicous is a common

direction in bryophytes. Lazarenko and Lesnyak (1972) disproved the suggestion of Gemmell by demonstrating cross breeding in *Desmatodon* (Figure 84), including cross breeding between two different species in the genus. Now we are raising the question whether monoicous bryophytes actually have mechanisms to ensure outbreeding in at least a portion of the population.

Figure 84. *Desmatodon latifolius* with abundant capsules, a species in which hybrids among species in the genus are known. Photo by Michael Lüth, with permission.

Just in time for this writing, Stark and Brinda (2013) published their study on *Aloina bifrons* (Figure 85), a dioicous moss living in the dry Mojave Desert, USA. Despite being dioicous in an environment unfriendly toward fertilization by water, this moss had frequent sporophyte production, leading the researchers to question its dioicous status (Stark & Delgadillo M. 2001). They found that it could, at least occasionally, be **rhizautoicous**. They found **ramets** (individuals in clone of genetically identical individuals that have grown in given location, originating vegetatively from single plant), connected by single rhizoids, that produced both **perichaetia** (archegonial groupings) and **perigonia** (antheridial groupings).

Figure 85. *Aloina bifrons*, a moss that is apparently facultatively autoicous. Photo from Proyecto Musgo, through Creative Commons.

But all is not well for self-fertilization because it leads to all those dangers of inbreeding that make the offspring less fit. Rather, Stark and Brinda (2013) found that *Aloina bifrons* (Figure 85) actually practices self-incompatibility. First, it practices **protandry** – a condition wherein the male reproductive structures mature before the female structures. There was some overlap in maturity times between archegonia and antheridia, and self-fertilization did occur within single clones. However, sporophytes aborted during the embryonic development. Stark and Brinda did allow for the possibility that these cultures might require a resting phase to continue their sporophyte development, so we are still left wondering.

It appears that we know little about incompatibility mechanisms in bryophytes. Let's recall that the monoicous condition in bryophytes is apparently derived from the dioicous condition. Hence, the mechanisms had to arise anew after the monoicous taxa arose. We should perhaps expect that self incompatibility is an imperfect condition that is still evolving. But for now, there are no studies to determine if more embryos abort from self-fertilizations than from outbreeding. There is no evidence to determine the effect of self-fertilization on future generations. There is no study that has examined the success of sperm from the same plant vs different plants in reaching and penetrating the egg. Hence, we have no idea how extensive or important self-incompatibility is in bryophytes.

Geographic and Habitat Relationships

Certainly physiological evolution has occurred as species have broadened their ranges to more and more distant locations. *Pleurozium schreberi* (Figure 50-Figure 51) often is without capsules because no male plants are present. Longton and Greene (1969a,b) found that females are more abundant worldwide, causing us to ponder on the cause. Could it be that male expression requires a temperature and photoperiod combination that is not available in their more cosmopolitan distribution?

Working with *Macromitrium* (Figure 71), Une (1985) found a possible explanation for the absence of mature males in some species. In isosporous *Macromitrium*, female protonemata developed buds at 10°C, but after 160 days the males had failed to produce buds, making it impossible for them to complete a life cycle in a short growing season.

Two *Pohlia* (Figure 86) species provide evidence to suggest that changes in the reproductive response are possible mechanisms for survival in widespread locations, and this plasticity may explain the abundant capsules seen on some *Pohlia* species. Clarke and Greene (1970) found that gametangial maturation was faster in the Arctic and sub-Arctic than in Britain, permitting these species to complete their maturation in the shorter Arctic summer. Lewis Smith and Convey (2002) indicated that in the Antarctic sexual reproduction likewise was highly successful, suggesting that the severe climate with its low temperatures and short growing season is not a severe detriment to successful gametangial production. They consider that microhabitats make this reproduction possible. Most of the fertile species are monoicous, short acrocarpous species on rather calcareous soils. Could it be that calcium is an important part of the reproduction story?

Figure 86. *Pohlia filum* growing in an alpine area and producing abundant sporophytes. Photo by Michael Lüth, with permission.

In the Brazilian Atlantic Rainforest, an altitudinal cline permits us to compare reproductive performance. Maciel-Silva *et al.* (2012) monitored eleven species for fifteen months at sea level and a montane site to compare reproductive performance. The highest level of reproduction was among monoicous taxa, especially for sexual branches and fertilized gametangia. At sea level, there were more females and more sexual branches than at the montane site. But these differences seemed only to compensate for other factors because the sporophyte frequency was similar in both sites. Microhabitats like decaying wood were important in maintaining sufficient water levels for good gametangial production. Water availability and maintenance may have been the major factor influencing the success of sporophyte production.

Another geographic problem is that timing that is ideal in one locality may be all wrong in another. Signals for production of gametangia may come from photoperiod, signalling an upcoming rainy season, but in another, the rainy season may be during a different part of the year. For example, *Octoblepharum albidum* (Figure 87) in Brazil times its reproductive maturity to coincide with the rainy season (Pôrto & Oliveira 2002). The capsules begin their development during the rainy season, but complete it during the subsequent dry season when they disperse their spores. In this case, the rainfall seems actually to enhance development of gametangia, hence ensuring the correct timing. The behavior of *Sematophyllum subpinnatum* (Figure 88) in these tropical lowland forests is similar (Oliveira & Pôrto 2001). Although both antheridia and archegonia develop and mature throughout the year, they increase in number during the rainy season. Subsequent appearance of sporophytes primarily from June to September indicates that most fertilization events occur during the rainy season.

Odu (1981) found similar timing in tropical Africa. The perennial *Racopilum africanum* (Figure 89), *Fissidens weirii*, and *Thuidium gratum*, and an annual *Stereophyllum* sp. (Figure 90) all develop their gametangia at the onset of the rainy season, complete fertilization during that season, and produce mature capsules ready for spore dispersal at the onset of the dry season.

Figure 87. *Octoblepharum albidum*, a moss in which rainfall seems to enhance gametangial production. Photo by Niels Klazenga, with permission.

Figure 90. *Stereophyllum radiculosum*, a moss that develops its gametangia at the beginning of the rainy season. Photo by Scott Zona, with permission.

For the mosses *Bryum coronatum* (Figure 3), *Hyophila involuta* (Figure 91), and *Barbula indica* (Figure 2) in southwestern Nigeria, gametangia development starts at the onset of the rainy season (March), providing them sufficient water to mature (Fatoba 1998). But their maturation requires 8-10 months (ending November – January), whereas the rainy season ends in mid October. The southwestern Nigerian rainy season has a "little dry season" (mid-July to mid-September, but mostly in August) (Adejuwon & Odekunle 2006), although the length decreases away from the coast. This little dry season might influence the persistence of the long developmental period for these gametangia. Temperatures typically range 26-28°C annually, so they have little influence on the bryophyte timing. This 8-10 months for maturation of gametangia places time of fertilization so that it permits the capsules to mature and spores to be dispersed in October – November, early in the regular dry season.

Figure 91. *Hyophila involuta*, a moss that begins gametangial development at the beginning of the rainy season in Nigeria. Photo by Niels Klazenga, with permission.

In desert habitats, even timing can fail to provide an opportunity for gametangial production. The desert moss *Syntrichia caninervis* (Figure 92) had 85% non-sexual ramets in a 10-hectare study area in the southern Mojave

Desert of Nevada, USA (Bowker *et al.* 2000). Those that had sexual expression were associated mostly with shaded microsites, higher soil moisture content, and taller ramets. The taller ramet may have been a result of the greater moisture available, but it also may have been the size that had reached the required threshold for available energy as discussed earlier in this chapter.

Figure 92. *Syntrichia caninervis*, a moss with 85% non-sexual ramets in the Mojave Desert. Photo from Proyecto Musgo, through Creative Commons.

In another desert moss, *Syntrichia inermis* (Figure 93), also from the Mojave Desert, more than 90% of the plants are monoicous (Stark 1997). In this species archegonia are initiated and receptive in the same winter, whereas antheridia require 1-3 years to reach maturity. Abortion is only 3-4% for both gametangia, but only 50% of the current cycle of perichaetia become fertilized. The slowest growth rates known, an 18-month dormancy period during sporophyte maturation, and the longest known period for antheridial maturation attest to limitations placed on reproduction in this moss by its desert habitat.

Figure 93. *Syntrichia inermis* with capsules, showing high sporophyte production of this monoicous moss. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Tradeoffs – Cost of Reproduction

Reproduction of any type comes at a price. Sexual reproduction requires considerable energy, and it benefits a plant to maximize success of its gametes in achieving fertilization. Actual measures of energy costs for any process in bryophytes are rare. The cost of reproduction can be indicated indirectly by its apparent effect on production of other structures and growth. For example, in *Marchantia polymorpha* (Figure 10), gemmae cups are generally not produced on the same portions of a colony as are the sexual structures (Figure 94) (Une 1984). But Une suggested that this might actually be due to age of the thallus, or to available nutrients, assuming that the interior of the colony where the gametangial branches occurred was the older and hence may have used up more of the available nutrients.

Figure 94. Location of gemma cups and archegoniophores in a colony of female *Marchantia polymorpha*. Modified from Une 1984.

The example of the leafy liverwort *Lophozia ventricosa* (Figure 95) var. *silvicola* demonstrates the high cost of being female (Laaka-Lindberg 2001). Female plants allocated 24% of their biomass to sexual reproduction whereas their male counterparts expended only 2.3%. The cost to the female was reduced stem length and both genders exhibited modified branching of gametangial shoots. When compared with asexual shoots, both genders had reduced stem length. Predictably, asexual plants produced the most gemmae (mean 2100), males next (1360), and females least (800).

Figure 95. *Lophozia ventricosa* with gemmae, a species with a high cost for gametangia. Photo by Michael Lüth, with permission.

The desert moss *Syntrichia inermis* (Figure 93) seems to tell a different story. In that species, it is more costly, by an order of magnitude, to produce male sexual organs than female ones (Stark *et al.* 2000). Stark *et al.* attributed this extra cost to the longer time required for development, greater number of male gametangia per perigonium than for archegonia per perichaetium, and presence of paraphyses among antheridia in that species. It would be interesting to see if this sex ratio could be modified by providing the limiting resources, presumably sugar.

Stark and coworkers (1998, 2001) found other indications of tradeoffs resulting from sexual reproduction in *Syntrichia caninervis* (Figure 92). Interestingly, non-sex-expressing individuals exhibited lower biomass, shorter total stem length, fewer branches, and shorter ramets than sex-expressing individuals; all individuals weighing more than 2 mg dry weight were sexually expressing, suggesting a threshold size needed for reproduction in order to provide sufficient energy. Furthermore, when inflorescence number was considered, the biomass of males and females did not differ.

McLetchie (1996) found that distance between male and female plants, as expected, decreased sexual success of the plants, but he also found that smaller males were less successful in accomplishing successful fertilization in the dioicous, thallose *Sphaerocarpos texanus* (Figure 67). From this he concluded that successful fertilization is sperm-limited. One might also argue that these could represent maturity differences.

For the epiphyte *Neckera pennata* (Figure 96), Wiklund and Rydin (2004) found a similar indication of minimum size. The first reproduction occurred at a colony size of 12-79 cm², requiring an estimated 19-29 years until the plants were sexually active! These apparent thresholds suggest that a critical size is important for sex expression. This implies that an energy threshold is required, and thus there must be a tradeoff between stored energy and sexual productivity.

Not only is production of gametangia expensive, but the ensuing production of sporophytes likewise is costly. It is therefore not surprising that Stark and coworkers (2001) found that 63% of the fertilized perichaetia of *Syntrichia caninervis* (Figure 92) had abortive sporophytes. This need for energy to produce the sporophyte seems to be subject to high selection pressure, as most bryophytes produce only one sporophyte per apex despite having multiple archegonia.

Relative fitness of sexual and asexual individuals can depend on the environmental conditions. In *Marchantia papillata* subsp. *inflexa* (Figure 63), Fuselier and McLetchie (2002) found that light intensities can shift sexual fitness and alter the timing of asexual reproduction. There were negative tradeoffs between the asexual and sexual fitness of females at some light intensities. In high light intensities, female plants suffer a sex-specific cost for their plasticity in timing, and asexual fitness shifts the population toward monomorphism of sexes. Fuselier and McLetchie concluded that opposing selective forces on sexual vs asexual expression could explain persistence of sexual dimorphism despite selection against dimorphism in the pre-adult phase.

Bisang and Ehrlén (2002) clearly demonstrated costs of sexual reproduction in female plants of the polysetous

Dicranum polysetum (Figure 97). They used a retrospective method to estimate photosynthetically active gametophyte biomass present at the onset of the sporophyte cycle and determined that reproductive effort, that is the proportional investment into reproductive structures, was 16% when sporophytes were successfully produced and only 1.3% when no fertilization occurred. The reproductive output of capsule number and dry weight were positively correlated with vegetative apical growth, whereas the reproductive effort was inversely related to dry mass of the annual segment preceding sporophyte initiation, indicating that energy was evidently shunted from that apical gametophyte tissue into the sporophyte. But even the next growth cycle paid the price of that reproduction; the probability of initiation of subsequent perichaetia was reduced as a result of sporophyte development, and when new perichaetia did develop, they were reduced in mass. In plants with sporophytes, investments in innovations were negatively correlated with reproductive structures. And, more sporophytes per plant resulted in reduced mass per sporophyte.

Summary

Gametes in bryophytes are produced in **antheridia** (sperm) and **archegonia** (eggs). The location of these structures divides mosses into **acrocarpous** mosses with terminal gametangia and **pleurocarpous** with side-branch gametangia. Water is needed for dispersal of sperm and in some cases this is aided by the presence of splash cups or splash platforms. Once released the sperm swims to the archegonium, attracted by some factor released when the neck canal cells of the archegonium disintegrate.

Both **monoicous** and **dioicous** taxa of bryophytes exist, and chromosome numbers suggest that monoicous taxa are derived through **polyploidy**. Sex determination is under genetic control in at least some bryophytes, with either an X or a small Y chromosome programming females vs males, respectively. There are implications that expression of these genetic differences is manifest in **IAA** differences, but it appears that **ethylene** could interact with IAA or that concentrations or relative concentrations may be important.

Some *Macromitrium* taxa have two spore sizes that translate into dwarf males from small spores, but generally dwarf males seem to be determined by some factor from the female upon which they land. Gender survival ratios, already discussed in the chapter on sexuality, are altered by spore survival, protonemal survival, competition, and survival of the gametophores. It may furthermore be altered by the environment to express one or the other sex.

Initiation of gametangia may be an ancient event that must be controlled by inhibition rather than initiation. The apparent initiation could instead be a set of conditions that override or immobilize inhibitors. Initiation of gametangia can be triggered by light intensity, photoperiod, temperature, and water availability, but it appears that many bryophytes, especially mosses, may respond to some combination of these. Liverworts seem to be more dependent on photoperiod. Other factors that influence gametangial development and gender expression include pH and form and availability of N. There may be a minimum size, at least for some taxa, before gametangia will develop, implying need for sufficient energy supply. Antheridia typically initiate before archegonia and take longer to develop. Because these two gametangia are initiated at different times, they are often under different controls that can cause a mismatch in maturity times. This can be particularly problematic when they disperse to a new geographic region and may account for absence of sporophytes on particular species in some geographic regions.

Acknowledgments

Inspiration for this chapter evolved from discussions with Dr. Martin Bopp and especially with Dr. Gert Steen Mogensen. Several of the experiments were conducted at the Botanisches Institut, Universität Heidelberg, Germany. I appreciate the many suggestions from a student's

perspective by Medora Burke-Scoll. Llo Stark sent me the paper by Lazarenko and Lesniak and led me to elaborate on the issue of self-compatibility.

CHAPTER 6-1

LIMITING FACTORS AND LIMITS OF TOLERANCE

Figure 1. Janice Glime overlooking geothermal vents that stretch the limits of tolerance of bryophytes. Photo by Zen Iwatsuki, with permission.

Sad, faint, and weary, on the sand
Our traveller sat him down; his hand
Cover'd his burning head.
Above, beneath, behind, around.
No resting for the eye he found;
All nature see'd as dead.

One tiny tuft of Moss alone
Mantling with freshest green a stone
Fix'd his delighted gaze;
Through bursting tears of joy he smiled.
And while he raised the tendril wild.
His lips o'flow'd with praise.

O! shall not He who keeps thee green,
Here in the waste, unknown, unseen.
Thy fellow-exile save?
He who commands the dew to feed
Thy gentle flower, can surely lead
Me from a scorching grave.

Pushing the Limits

Crum (2004) quotes from Stark (1860, Popular History of British Mosses) concerning the tiny tuft of *Fissidens* that Mungo Park found in the African interior. Park wrote "I considered my fate as certain, and that I had no alternative but to lie down and perish." Just as Park was giving up, he spied the tiny moss.

So many have failed to see the tenacity with which the bryophytes hold on to life. Their limits of tolerance seem to outrange any other group in the Kingdom Plantae. But the mechanisms by which they do this have remained obscure to the average biologist, and even to most physiologists. Yet they have much to teach us about basic principles of physics and chemistry applied to living organisms to create their physiological processes.

When I began my studies of bryophytes, I did so because no one could answer my questions. It seemed as if we knew almost nothing about them. There was in fact a wonderful literature, mostly from other countries, that I discovered later and that none of my professors (not

bryologists) had ever read. Nevertheless, the mysteries of how bryophytes survived where they did continued to intrigue me, and most answers seemed nowhere to be found in the published literature. Then I became interested in *Fontinalis* and began to question just what determined which streams would have it and which did not. Soon I was testing it to its limits, trying to ascertain why it seemed unable to occur in certain parts of the world and only in certain streams in other parts. In fact, my friends soon began asking, if I liked *Fontinalis* so much, why was I always trying to kill it!? I was testing its limits of tolerance.

Bryophytes have unique physiologies that are often envied by the horticulturalists and agriculturists. Their ability as a group to survive cold and desiccation is unparalleled by any other major group of plants. It is these physiological abilities that permit them to occupy bizarre habitats like iron stoves (Figure 2) and darkened caves, geothermal vents and meltwaters (from snow and ice), and only a liverwort was able to survive on the first samples of moon rock.

Figure 2. Old iron stove with bryophytes growing on it. Photo by Janice Glime.

The tolerance of bryophytes for conditions that would impose severe stress on other members of the kingdom led a group of astrophysicists at a special session on space colonization at the 40th American Institute of Aeronautics and Astronautics (AIAA) Aerospace Sciences Meeting, held in Reno, Nevada, 14-17 January 2002, to suggest that these organisms should be introduced to the moon for **terraforming** (making desert planet etc. habitable; Davis 2002). (Never mind the arguments as to which celestial body should be colonized first.) Indeed, based on their importance in Earth's polar and alpine **ecosystems** (communities & habitat) where most flowering plants are unable to survive, it was suggested that following preparation by the microbial stage, it is the bryophytes that would be able to transform the planet/moon into a habitable body. But, the scientists advised, further research is needed to improve our understanding of the physiological and ecological roles these organisms might play in such a system. Do they realize how little we know of their role on Earth?

Our understanding of bryophyte physiology is at best poor. Compared to tracheophytes, bryophytes have enjoyed few physiological studies, and many assumptions

have been made about their physiology. Perhaps the most widespread and erroneous assumption was that all bryophytes have the same sort of basic physiological mechanisms for obtaining water and nutrients, and for retaining them or losing them. Implicit in this was the assumption that all gained water and nutrients from leaf surfaces. However, recent studies on bryophyte physiology suggest that physiological mechanisms may be the most variable character among different populations and species of bryophytes. While tracheophytes were spending their genetic evolution on morphological adaptations to environmental conditions, it seems that bryophytes may have been spending theirs perfecting a multitude of physiological and biochemical strategies. Before we delve into the physiology itself, we will begin with a discussion of our understanding of stress factors and plants as they might apply to bryophytes.

C-S-R Triangle

In 1976, Stearns reviewed the concepts of life strategy or life history tactic to help explain a system of co-evolved adaptive traits that permit species to survive in a range of habitats, and these concepts have subsequently become known as **life cycle strategies** or **life history strategies**. Numerous papers exist arguing pros and cons of using the term *strategy* for a non-thinking, non-planning plant, but the term conjures up the appropriate concepts in our thinking and I can think of no other that does quite as satisfactory a job, so the term strategy has become part of my own ecological jargon as it has likewise in ecological literature.

While Stearns (1976) was developing the life strategy concepts, Grime (1977) took a slightly different approach and suggested that external factors that limit plant **biomass** (living & dead plants or plant parts) may be classified as either stress or disturbance. Following this concept, **stress** refers to those conditions that restrict production, such as low light, insufficient water or nutrients, or suboptimal temperature. **Disturbance** is the partial or total destruction of the plant biomass arising from herbivores, pathogens, humans, wind damage, frost, desiccation, erosion, or fire. (It seems that pollution belongs there too!) Plants respond to these limiting factors with three types of strategies: **stress-tolerant**, **ruderal**, and **competitive** (Table 1), reminiscent of Ramensky's (1938) **patients** (stress-tolerant), **explerents** (ruderal – growing in wastes or among rubbish), and **violents** (competitive), which will be discussed in more detail with growth forms (During 1992). Using Grime's (1977) scheme, individual species of plants, therefore, represent compromises between the conflicting selection pressures of competition, stress, and disturbance. These relationships can be arranged in a triangle known as the **C-S-R model** (Figure 3). Grime (1979) considers it highly unlikely that plants can tolerate extremes of both stress and disturbance. Some, however, might be able to tolerate each independently.

Table 1. Grime's (1977) suggested basis for the evolution of three strategies in tracheophytes.

Intensity of Disturbance	Intensity of Stress	
	Low	High
Low	competitive strategy	stress-tolerant strategy
High	ruderal strategy	no viable strategy

Figure 3. **Left:** Model of equilibria between competition, stress, and disturbance in plants, showing relative importance (I_c , I_s , I_d). Strategies include competitors (**C**), stress-tolerators (**S**), and ruderals (**R**). **Right:** Diagrams of the strategy ranges of various groups of plants compared to the distribution of competitors, stress-tolerators, and ruderals. Redrawn from Grime 1977.

Grime (1974) proceeds to define **competition** as "the tendency of neighboring plants to utilize the same quantum of light, ion of a mineral nutrient, molecule of water, or volume of space." **Stress**, in Grime's usage, encompasses "the external constraints which limit the rate of dry matter production of all or part of the vegetation."

Competitors tend to have moderate to long life spans, relatively low reproductive efforts, high potential relative growth rates, high dense canopies of leaves, abundant litter, and high morphological plasticity. The plant forms are diverse, including perennial herbs, shrubs, and trees. This strategy generally does not fit the bryophytes due to their relatively slow growth rate. In fact, Grime and coworkers (1990) concluded that none of the bryophytes in their study have a competitive strategy. Rather, they are stress tolerators. Their lack of a "sophisticated" transport system renders them unable to monopolize resources and dominate the vegetation of an undisturbed ecosystem. It is only in aquatic habitats, particularly streams and bogs/poor fens, where they may be able to compete with tracheophytes due to their perennial above-substrate persistence. Nevertheless, competition with such life cycle stages as seedlings is real, with deep mats of bryophytes suspending the young plants where they either are unable to reach the earth to anchor their roots or are unable to reach the light to obtain energy. And competition among bryophytes occurs, although on such a slow, yet dynamic scale that it has seldom been documented. Competition as a strategy will be discussed later.

Stress tolerators similarly have a long life span and low reproductive effort, but they have low potential relative growth rates, little but persistent litter, and little morphological plasticity. The plant forms are most diverse, including such distant ones as lichens, bryophytes, and trees. Among the bryophytes, one advantage is that they are able to reproduce asexually by fragmentation when stress may be too severe for gametes, embryos, or sporogenous tissues to survive.

Ruderals are more like competitors, but they have very short life spans and high reproductive rates. They are mostly ephemerals that tend to have relatively

homogeneous life histories and habitats. Flood plain bryophytes can be considered here (Figure 4).

Figure 4. The floating liverwort *Riccia fluitans* stranded above water as it would be following a flood. It will form a broader thallus on land. Photo by Jan-Peter Frahm, with permission.

Severe Stress

With their inability to move when living conditions become stressful, plants must have plasticity to survive. For most plants, diversity is maintained through the second set of genetic information, available when conditions change, and permitting the next generation to benefit from whatever combination is appropriate. Although self-fertility is usually prevented within flowers, fern gametophytes, and moss branches, it often is not prevented between flowers of the same plant and certainly not among flowers of the same clone; the same seems to be true in bryophytes, although much less evidence supports this contention.

Such genetic diversity, the product of outcrossing (breeding with a different population or genetically different individual), would seem only to benefit plants when they must cope with long-term changes, those that last over the course of several years, decades, or millennia. A different method of coping must be available for those

stresses that are encountered within the course of a single growing year as a result of seasonal changes. Low-level stress is undoubtedly present in all habitats and functions merely as a modifier of growth rates and competition, whereas severe stress, such as coping with winter, has an immediate impact on the survival of the organism (Grime 1977). Not only can severe stress eliminate a species from a habitat directly, but it can also eliminate a species indirectly by reducing its competitive ability, making it vulnerable to replacement by more stress-tolerant species. Strategies of growth thus must respond to seasonal variation in temperature, nutrient, and moisture supplies, a concept consistent with the life-form definition of Mägdefrau (1982). Grime and coworkers (1990) found a functional specialization in the life cycle of bryophytes, with a different set of strategies for the established (adult) phase than those being used in the regenerative (juvenile) phase, thus providing one means for coping with seasonal changes.

The **relative growth rate (RGR)** of a species is generally considered the best measure of the success of the species relative to other individuals or species in a given environment. Furness and Grime (1982) found that RGR for bryophyte species could be correlated with stress conditions in laboratory experiments. For the short-lived ruderal *Funaria hygrometrica* (Figure 5), $RGR = \text{ca. } 50 \text{ mg g}^{-1} \text{ day}^{-1}$, and for the competitive *Brachythecium rutabulum* (Figure 6), $RGR = 70 \text{ mg g}^{-1} \text{ d}^{-1}$. By contrast, stressed bryophytes such as **epilithic** (living on rock) species had much lower productivity ($RGR = 5\text{--}20 \text{ mg g}^{-1} \text{ d}^{-1}$). Since tracheophyte RGR ranges from 4 to 400 $\text{mg g}^{-1} \text{ d}^{-1}$ (Poorter & Remkes 1990), it seems that bryophytes are on the low end of the scale, and if Furness and Grime are right in their conclusion that low RGR relates to stress tolerance, bryophytes in general should be particularly good at it.

Figure 5. The short-lived ruderal species, *Funaria hygrometrica*, illustrating its high reproductive rate. Photo by Michael Lüth, with permission.

Grime (1977) considered four types of environments that impose severe stress. He regarded the arctic-alpine and arid habitats to have low production, with stress being imposed primarily by the environment. In shaded habitats, stress is plant induced, and for bryophytes, this causes a release of competition from less tolerant tracheophytes, giving bryophytes an advantage. In nutrient-deficient

habitats, bryophytes can often again dominate due to lack of tracheophyte competition. To these stressful habitats, I would add the habitats with extremes of high mineral loading, very high or very low pH, or high temperatures. Polluted environments can present any or all of these conditions, as can geothermal fields (Figure 1).

Figure 6. The competitive species *Brachythecium rutabulum*. Photo by Janice Glime.

Bryophytes, as a group, tend to be wide-ranging in this scheme, with their center of distribution being in the stress-tolerant ruderals (During 1992). Økland (1990) considered even the mosses in a Norwegian mire to be stress tolerators. He made this judgment because they occurred in dry, shaded sites, relative to those of *Sphagnum*, and by their narrow habitat niches within the mire. These were generally bryophytes with wide niches in other vegetation types. It seems that bryophytes in general are stress tolerators, relegated to living where other taxa are unable to survive.

Genetic Adaptations

The ability of a plant to tolerate a condition is dependent upon three factors: genetic components, currently interacting factors, and past history. Shaw (1987) used *Funaria hygrometrica* (Figure 5) to illustrate the effect of pretreatment (past history) versus genetics on tolerance to zinc and copper for protonema growth and stem production. For that species, the protonema growth responded to past history, but for the stem production, genetic differences were more important. Furthermore, genetic differences between populations were more important than pretreatment. Such results suggest the possibility of selection as a result of past history in the genetically different populations.

Genetic drift (random changes in gene frequencies due to isolation of a small population) can also account for differences between populations in widely separated areas. I (Glime 1987) found vastly different growth rates between the populations of *Fontinalis novae-angliae* (Figure 7) from New Hampshire and Michigan when they were grown in a common garden. Vitt *et al.* (1993) found that *Scorpidium scorpioides* (Figure 8) from Canada grew best in extreme-rich fen waters, whereas plants from The Netherlands grew best in water from moderate-rich fens and in nutrient-enhanced conditions. Either of these cases could represent genetic drift, but both could also represent past history (*e.g.* physiological acclimation) or natural selection. For the *S. scorpioides*, past history may well play a role because both

populations grew best in water of the type from which they had been collected, suggesting that at least it is possible that osmotic relationships of the existing cells may have been affected by the change in water chemistry.

Figure 7. *Fontinalis novae-angliae* growing on rock at edge of stream. Photo by Janice Glime.

Figure 8. *Scorpidium scorpioides* growing in a fen. Photo by Michael Lüth, with permission.

One significant mechanism that permits plants to respond to stresses in a short period of time is by production of **inducible proteins** (proteins produced only when certain conditions are present) (Wray 1992), a genetically controlled phenomenon, but also potentially a result of past history. Such production is mitigated by inducible enzymes that respond to environmental cues such as toxic metals, salts, anaerobic conditions, temperature extremes, pathogens, and nutrient availability. Others respond secondarily to internal hormonal cues such as ABA (abscisic acid), ethylene, and GA (gibberellic acid). These hormonal mechanisms would appear to be available to the bryophytes, since all of these hormones are known in bryophytes. Inducible proteins are less well known among the bryophytes, but may some day prove to be important in their success. We are already gathering considerable information on stress proteins that respond to dehydrating conditions and high temperatures, as will be discussed when we examine water relations. Furthermore, Grime and coworkers (1990) contend that morphological plasticity is of reduced importance for bryophytes in exploiting disturbed habitats. Rather, their dispersal and regeneration abilities permit them to occupy inaccessible and disturbed habitats such as cliffs, walls, and forest clearings.

We can conclude that genetic components, currently interacting factors, and past history can work together or

alone to elicit the responses we see in many bryophytes as they respond to stress.

Crystals – Adaptive?

Many new things appear due to mutations and developmental errors, but most of these fail to persist into a second generation. Some do persist, to the consternation of humans, with no apparent function. One such genetic invention may have been that of crystals formed by some mosses.

Jean Faubert (Bryonet 24 August 2010) reported a whitish substance under mosses in their fern greenhouse. Joselito Arocena (Bryonet 24 August 2010) suggested that this layer might be an accumulation of crystals of calcium oxalate, perhaps associated with mycorrhizal fungi, although Faubert did not find direct evidence of fungal presence. Such formations occur around roots of tree throws. Arocena *et al.* (2001) suggested that these crystals may protect fungal hyphae (*Piloderma fallax*) from desiccation and decrease the build up of calcium and oxalate in fungal cells. When associated with mosses, the formation of calcium oxalate may help them maintain their phosphorus supply and protect them from predators. The oxalate form could provide a reservoir during times of low calcium (Tuason & Arocena 2009). There is also an association between calcium oxalate and phosphorus, with more calcium oxalate crystals being formed under high levels of phosphorus.

Neil Bell (Bryonet 25 August 2010) reported that *Mniodendron colensoi* (= *Hypnodendron colensoi*; Figure 9), a moss in the preserved patches of Kauri forest on the North Island of New Zealand, has prominent crystals in the costae of leaves. Bryologists have assumed these to be calcium oxalate, but verification is needed.

Figure 9. *Mniodendron colensoi*, Bill Malcolm, with permission.

Jeffrey Duckett and Silvia Pressel (Bryonet 25 August 2010) used X-ray analysis to test fresh material from New Zealand and found abundant calcium but no other cations or anions. They therefore presumed that the substance was indeed calcium oxalate.

Do Nutrients Limit Bryophytes?

Those who culture bryophytes know what nutrients to manipulate and what nutrient levels may be too much. But we seem to know much less about the effects of nutrients in nature.

Wang *et al.* (2014) addressed this question in the cushion moss *Leucobryum juniperoideum* (Figure 10–Figure 12). In eastern China, this moss occurs only in certain habitats. The **epigeic** (ground-dwelling) populations (Figure 10) occur only in areas that have a moso bamboo (*Phyllostachys edulis*) forest. The **epixylous** (on logs lacking bark) (Figure 11) are restricted to areas with Chinese fir (*Cunninghamia lanceolata*) forest. **Epilithic** (rock-dwelling) populations (Figure 12), on the other hand, live in both of these habitats. N and P concentrations differed markedly between the epigeic and epixylous habitats, with soil concentrations of these nutrients being much higher in the latter. So why is this species restricted to logs in the *Cunninghamia* forests? In experiments, growth of *L. juniperoideum* was reduced by N additions of 0.1 mol L⁻¹ over six months. On the other hand, addition of up to 0.1 mol L⁻¹ P caused growth increase. Furthermore, high concentrations of N (200 mg L⁻¹) significantly reduce germination rates and delay early development from spores. P, on the other hand, has no such negative effects. Thus, high soil concentrations of N are limiting in the distribution of this species.

Summary

Some bryophytes are able to live in bizarre habitats like iron stoves, deep caves, and glacial surfaces. These habitats test the limits of tolerance of the species. The high tolerances of some bryophytes led a group of aerospace scientists to suggest that bryophytes should be used for **terraforming** on the moon.

Bryophytes have evolved a variety of life cycle strategies for coping with the wide diversity and seasonal changes in their earthly habitats. Grime categorized plants by their limiting factors into **stress-tolerant**, **ruderal**, and **competitive** (**C-S-R model**), similar to Ramensky's **patients**, **explerents**, and **violents**, respectively. Compared to other plants, bryophytes fall along the bottom of the C-S-R triangle as non-competitors but with many stress tolerants and ruderals.

The **relative growth rate (RGR)** serves as a good measure of the success of a species. The ability of the species to tolerate its conditions and have a healthy growth rate is dependent upon genetic components, currently interacting factors, and past history. Genetic drift and physiological responses to the environment help to make populations look different.

Inducible proteins are able to respond to changes in the environment, thus permitting the plant to behave differently under different environmental circumstances.

Many adaptive mechanisms elude us, while others may have no modern function at all. Incorporation of calcium oxalate is one of those factors that thus far has escaped our understanding.

Acknowledgments

In this, and many other chapters, Jean Faubert has been helpful in reporting errors to me, a service I greatly appreciate. Bryonettors have contributed to the discussion on calcium oxalate.

Movement to Land

The most obvious need for photosynthetic organisms in their move from water to land was the continued need for water. At this time, most photosynthetic organisms still had a dominant gametophyte, and all indications are that the movement onto land carried with it that gametophytic dominance. As life on land progressed through evolution, plants with sophisticated vascular tissue ultimately developed. At the same time, the gametophyte in these highly vascularized tracheophytes (lignified vascular plants) solved its water problems by ultimately being contained within the protection of sporophytic tissues in the seed plants.

This reduction of the gametophyte might necessarily have forced a reduction in conducting tissues because the surrounding sporophytic tissue on the one hand reduced available space and on the other made vascularization much less necessary in the gametophyte. But in gametophyte-dominant bryophytes, survival on land required a means for getting water, and the nutrients carried with it, from one part of the plant to another. Despite their being the first land plants, as Raven (2002) has put it, plant biologists have taken a "top-down" view of land plants, seemingly expecting the bryophytes to have a simpler version of the same system as tracheophytes.

But bryophytes have been around much longer than tracheophytes, and their gametophytes have remained dominant. Hence, should we not expect them to have

evolved means of water movement in the gametophyte generation during all these millennia? First of all, consider the desiccation-tolerant tracheophytes. These are almost all small plants (Raven 2002). Many bryophytes are likewise desiccation tolerant, and they too are small.

Bryophytes as Sponges

Sponges, both animal and synthetic, gain and retain water through small chambers and capillary spaces. Bryophytes, due to their small size and tiny leaves, are natural arrays of chambers and capillary spaces. As this story unfolds, you will soon see that bryophytes are indeed sponges, aiding their own water needs and in some cases massively affecting the **ecosystem** (interacting community & habitat).

All life needs water, and the most severe stress for organisms venturing onto land was undoubtedly just that. But already, algae had developed means of becoming dormant through zygospores when they faced unfavorable circumstances. However, those first land organisms had to find ways to get water to all their internal parts, and often this water was in very limited amounts. For bryophytes, surviving water loss and prolonged periods of drought was a necessity for survival, so it is not surprising that during their 450 million years of evolutionary history (Proctor 2000a) they have perfected physiological mechanisms that

outdistance those of their tracheophyte counterparts (Oliver *et al.* 2000a). This ability has led plant physiologists to use bryophytes as model systems for the study of desiccation tolerance physiology, even to the extent of attempting to introduce those genes to crop plants (Comis 1992; Oliver *et al.* 2000b). And this use has made it into the agricultural literature with articles such as "Miracle Moss" (Comis 1992).

It appears that despite the typical relegation of bryophytes to the category of "non-vascular," conduction has played a major role in the phylogenetic history of bryophytes. Hedenäs (1999) examined the importance of various character states on the phylogenetic history of **pleurocarpous** mosses (typically the ones that grow horizontally) and determined that, based on redundancy analysis, gametophyte variance relates to characters associated with water conduction. Furthermore, one of the most important environmental variables in this phylogeny was the non-wetland to wetland gradient. On the other hand, Proctor (2000b), in "The bryophyte paradox: Tolerance of desiccation, evasion of drought," points out that a desiccation-tolerant tree is hardly conceivable. Height necessitates highly developed conducting systems that are unnecessary in short plants, and even among the bryophytes, it is the tall *Dawsonia* (Figure 2) and *Polytrichum* (Figure 3-Figure 4) that have conducting systems that almost mimic those of **tracheophytes** (plants having tracheids, *i.e.* the lignified vascular plants).

Figure 2. *Dawsonia*, one of the tallest and most highly structured of all mosses. Photo by Janice Glime.

Ecosystem processes cannot be understood without understanding the role of bryophytes and their water relations. A lack of understanding of bryophyte water relations has led ecologists to conduct inappropriate experiments or draw erroneous conclusions about such topics as nutrient cycling and effects of air-borne pollutants on mosses in general in the ecosystem. Mosses such as

Polytrichum (Figure 3-Figure 4), among the most conductive bryophytes in the northern hemisphere, have been used to generalize about the behavior of soil and airborne minerals in mosses during ecosystem processes. But this moss can behave very differently from most of the other genera that carpet forest floors. Puckett (1988) warns that mosses with internal conduction (as in *Polytrichum*) do not make good monitors. Anderson and Bourdeau (1955) concluded that dew and rain were the main sources of water for bryophytes, excluding the groundwater source so vital for tracheophytes. It is therefore important that ecosystem ecologists, especially those studying water relations and nutrient cycling, have a basic understanding of the variety of ways that bryophytes move water and nutrients.

Figure 4. *Polytrichum* stem cross section showing central hydrome and surrounding leptome – the essence of its vascular system. Photo courtesy of Isawo Kawai.

Nearly every botany book on the market defines bryophytes as non-vascular plants, distinguishing them in this way from all other embryophytes. In fact, **many bryophytes are vascular**, but **lacking lignin** [associated with cellulose in cell walls of **sclerenchyma** (thick-walled supporting cells), xylem vessels, and tracheids; Hébert 1977] and the variety of perforated and spirally thickened cells typical of xylem. [Note that **lignin-like** compounds bind to cell walls in bryophytes, especially in spores and

elaters (Ligrone *et al.* 2008).] Rather, many bryophytes have unique cells that perform conduction in rather different ways from the "true vascular plants." Kawai has published a series of colored photographs (*e.g.* Figure 1), using specific stains, that illustrate the wide presence and variety of such tissues among many families of mosses (Kawai 1971a, b, c, 1976, 1977a, b, 1978, 1979, 1980a, b, 1981, 1982, 1989, 1991a, b; Kawai & Ikeda 1970; Kawai & Ochi 1987; Kawai *et al.* 1985, 1986; Ron & Kawai 1990). Hence, it is safer to distinguish the bryophytes as non-lignified plants (still waiting to be disproved) or **non-tracheophytes**, and the lignified vascular plants as **tracheophytes**. This puts a slightly new perspective on the way we look at their roles in ecosystems.

When we consider bryophytes, we are tempted to think about wet habitats where mosses grow close to water, basking in the sun of a bog, or cooling off in the spray of a waterfall. Certainly these are habitats where bryophytes are common, but keep thinking. What about those rocks on the cliff or the sand of the dunes (Figure 5)? In fact, can you think of any habitat that has plants but where it is impossible to find mosses? There are not many, and if you visualize some of the rocky habitats in your mind, you realize that these organisms undergo tremendous changes in moisture and temperature, even within a single day, occupying habitats where no vascular plants can survive.

Figure 5. *Aloina ambigua* growing in sand. Photo by Michael Lüth, with permission.

If we try to speculate about those first organisms to survive on land, we would probably consider them to be simple organisms with no organized vascular systems. There was no selection pressure for any wasteful vascular tissue while these organisms were living in the water. Water may have been the primary force limiting plants from vast colonization of land. Gray (1985) suggests that it was the ecophysiological tolerance to desiccation, appropriate life cycle strategies, and short vegetative life cycle that permitted widespread colonization during the mid **Ordovician** (~441-504 million years ago) to the mid Early Silurian (~400-440 million years ago) – strategies that describe bryophytes.

Even with so many diverse habitats occupied by plants today, we still consider the move from water to land to have been a major one. Imagine the changes that were necessary. Consider that the greatest overriding challenge was to keep their cells wet. Land plants responded to this challenge in two ways. Some, the ones we traditionally

called **vascular plants** (the **tracheophytes**), acquired **lignin**, developed a complex water transport system, and encased themselves in a waxy, waterproof **cuticle**. Others, the **bryophytes**, developed strategies that we are only beginning to understand, including external transport, cell-to-cell transport, and the ability to survive desiccation. In the words of Proctor (2000a), "Bryophytes... evolved desiccation tolerance and represent an alternative strategy of adaptation to life on land, photosynthesizing and growing when water is available, and suspending metabolism when it is not. Limited by mode of life, but also liberated: prominent on hard substrates such as rock and bark, which are impenetrable to roots and untenable to vascular plants. Bryophytes (in species numbers the second biggest group of green land plants) may be seen as mobile phones, notebook computers and diverse other rechargeable battery-powered devices of the plant world – not direct competitors for main-based equivalents, but a lively and sophisticated complement to them."

Bryophytes are adapted to land but restricted in their morphology by a biochemical impasse, *i.e.* the inability to synthesize lignin (Niklas 1976). Because they lack lignin, they lack the tracheids and vessels of other plants, but have produced instead vascular strands with similar elongate shapes. Nevertheless, they are unable to support a large structure or great mass because they lack the strengthening ability of lignin. Because of their importance in both structure and physiology, water relations seem an appropriate place to start in our consideration of the limits imposed on bryophytes, for without that understanding, we cannot understand their other limitations, nor can we fully evaluate their ecological relationships.

Conducting Structures

Conducting structures are not new expressions in bryophytes. Edwards *et al.* (2003) found at least fourteen types of such structures in mesofossils from a Lochkovian (Lower Devonian) locality in the Welsh Borderland, Shropshire. These are distinguished by variation in the combination of cells in the central strand and the cell wall architecture. The elongate cells may have smooth, uniformly thick or thin walls, walls with smooth projections pointed inward, or bilayered walls. The innermost walls are perforated by pores with the dimensions of plasmodesmata. These perforations are not well organized and some resemble the secondary thickenings most similar to the S-type tracheids of the **Rhyniopsida** (Figure 6-Figure 7), a primitive tracheophyte with lignified vascular tissue. Edwards and coworkers suggest that the imperforate bilayered examples may have been used in water conduction, cells that exhibited globular residues may have facilitated metabolite movement, and smooth-walled elongate cells seemed to be involved in support. Edwards and coworkers were unable to identify these mesofossils to genus, but concluded that there was widespread anatomical diversity among these early bryophytes.

Figure 7. *Rhynia gwynne-vaughanii* stem cs fossil. Photo by Plantsurfer, through Creative Commons.

Bryophytes have two paths of water movement, often both in the same plant: internal through a **central cylinder (endohydric)** and external along the surface of the leafy or thallose plant (**ectohydric**) (Buch *et al.* 1938). Some thallose liverworts, **Polytrichaceae**, and **Mniaceae** represent the endohydric groups (Buch 1945, 1947; Proctor 2000b), but there are many others with at least some internal conduction. *Metzgeria furcata* (Figure 12), a "thallose" liverwort in the **Jungermanniopsida**, and others in the **Marchantiopsida**, have midribs (Figure 13) with enlarged internal cells (Figure 14), but the relative importance of these midrib cells for conduction is largely unknown.

In *Asterella wilmsii* (see Figure 8), numerous lipid bodies are present in the thallus cells. Ligrone and Duckett (1994a) suggested that these were associated with the perennation in winter. In the same species, vacuolar microtubule associations resemble the microtubule-based

translocation system of many animals, but they differ greatly from the bulk flow known in sieve elements and actin-based cytoplasmic streaming of tracheophytes.

Figure 8. *Asterella* sp.; *Asterella wilmsii* produces numerous lipid bodies in the thallus cells. Photo by Brian du Preez, through Creative Commons.

Ligrone and Duckett (1994b) also found that food conducting cells in both gametophytes and sporophytes of bryoid mosses have a polarized organization and an axial system of endoplasmic microtubules. The polarity corresponds with a source to sink gradient with distal cellular ends (toward the sink) containing denser cytoplasm than that at the proximal ends. The cytoplasmic polarity and endoplasmic microtubules are unique in the plant kingdom, but are reminiscent of arrangements seen in animal neurons and in fungi.

The arrangement of the microtubules seems to aid in rapid rehydration, at least in *Polytrichastrum formosum* (Figure 9) (Pressel *et al.* 2006). It is this arrangement that permits rapid re-establishment of the cytoplasmic architecture of the leptoids (Figure 58). This reassembly of the endoplasmic microtubule systems establishes the time frame for recovery.

Figure 9. *Polytrichastrum formosum*, a species that experiences rapid rehydration due to its arrangement of microtubules. Photo by Daniel Cahen, through Creative Commons.

But even in conduction structures, mosses once again exhibit diversity. In both *Polytrichum juniperinum* (Figure 10) and *Mnium hornum* (Figure 11) decapitation greatly reduces cellular polarity (Ligrone & Duckett 1996a). But only in *Mnium* was there a disappearance of endoplasmic microtubules, loss of longitudinal alignment of organelles, and accumulation of abundant starch when subjected to decapitation. And in *Polytrichum* starch accumulated in the cortical parenchyma cells.

Sphagnum seems to have found yet another way to accomplish formation of conducting cells. The cytology is very similar to that in bryoid mosses, but the development of the central strand (Figure 37-Figure 40, Figure 42-Figure 45) of the stem in *Sphagnum* is not homologous with that known in other mosses (Ligrone & Duckett 1998b).

Furthermore, mosses differ from liverworts in location of their conduction elements (Ligrone *et al.* 2000). In mosses, these occur in both the gametophyte and sporophyte. In liverworts, however, they occur only in the gametophyte. In the liverworts, the **Calobryales** and **Pallaviciniaceae** have water-conducting cells with walls that are perforated by pores derived from plasmodesmata. In the mosses, this type of water-conducting cell is known only from *Takakia* (Figure 25-Figure 27), a moss initially

considered to be a liverwort until its sporophyte was discovered.

In the liverwort *Symphogyna africana*, conducting cells have a different path or origin (Ligrone & Duckett 1996b). The cortical microtubules, wall microfibrils, and secondarily modified plasmodesmata are consistently aligned to form helices of about 45°, reminiscent of flowering plant vessels. Ultimately, the cytoplasm dissolution causes lysis of all cellular membranes, with membrane-bounded fibrillar material becoming deposited onto the walls. When the plugs of amorphous electron-transport material dissolves, open pits form. This formation of conducting elements resembles, in some aspects, the formation of vessels in flowering plants.

Conduction to other parts of the bryophytes has a similar polarized transport, facilitating long-distance movement of nutrients (Ligrone *et al.* 2000). This occurs in rhizoids and caulonemata and in the thallus parenchyma cells of at least some liverworts.

Diversity presents again when we compare cell wall components, equalling the diversity found in "higher" plants (Ligrone *et al.* 2002). Not only were there differences among the orders, diversity occurred within the order **Polytrichales**. Furthermore, the water-conducting cells of *Takakia* (Figure 25-Figure 27) are not homologous with those of other mosses, nor are they homologous with the *Haplomitrium* (Figure 28) or metzgerialean liverworts.

Broadly speaking, imperforate bilayered examples may have been involved in water conduction, cells with globular residues with or without pitting involved in metabolite movement, and smooth-walled examples with or without projections involved in support.

In liverworts, conducting tissues are restricted to the gametophyte, whereas in mosses, they are sometimes also in the sporophyte (Ligrone *et al.* 2000). Among the liverworts, the **Calobryales** and **Pallaviciniaceae** in the **Metzgeriales** have water-conducting cells with walls perforated by pores derived from plasmodesmata. The **hydroids** (water-conducting cells) of bryoid mosses are imperforate. In the **Polytrichaceae**, there is an axial system of microtubules in the **leptoids** (food-conducting cells) and in the parenchyma cells of the stems and setae of other mosses such as *Sphagnum*, representing the variety of expression of conducting cells in the bryophytes..

Ectohydric mosses typically maintain a constant internal water content by absorbing water from the external capillary spaces as needed (Proctor 2000b). The ectohydric and endohydric modes each require their own structural adaptations. Lacking lignin, xylem is not possible. Furthermore, in the lignified vascular plants, it is the sporophyte generation that carries out organized internal conduction, and the gametophyte, with rare exception, does not. By contrast, in bryophytes it is the leafy gametophyte that must obtain and conduct water and nutrients about the plant, although conduction also occurs in the moss sporophyte (Ligrone *et al.* 2000; see Chapter 5-9).

Although the hornworts (*Anthocerotophyta*) have been considered by some to be reduced from more advanced plants, water-conducting tissue is unknown in this phylum (Ligrone *et al.* 2000), although Héban (1977) reported the presence of cells resembling phloem sieve cells (leptoids?) in *Dendroceros* (Figure 15). Likewise, few liverworts (*Marchantiophyta*) have specialized conducting tissues in their gametophytes (Figure 16-Figure 22), and none have them in the sporophyte. Nonetheless, conducting strands have been known since 1901 in the thallose liverwort *Pallavicinia lyellii* (Figure 23; Tansley & Chick 1901). As in mosses, *Pallavicinia* conducting strands (Figure 24) closely resemble tracheids, with long

cells, tapering ends, and obliquely oriented pits, and they, like xylem cells, are dead at maturity (Richardson 1981).

Unlike the liverworts, as already noted mosses can have conducting cells in both generations (Ligrone *et al.* 2000). In some liverworts of **Calobryales** and in **Pallaviciniaceae** of the **Metzgeriales** (Figure 23-Figure 24) and the moss *Takakia* (a primitive moss once thought to be a liverwort; Figure 26), there exist water-conducting cells with perforated walls derived from **plasmodesmatal pores** (Ligrone *et al.* 2000), but these do not seem to be organized into a distinctive **central strand** (group of elongate cells forming central axis of stems and thalli of some bryophytes, usually thin-walled and often colored; Figure 58). Furthermore, the water conducting cells of *Takakia* (Figure 25-Figure 27) do not seem to be homologous with either the hydroids of other mosses or with those of the **Metzgeriales** or the leafy liverwort *Haplomitrium* (Figure 28), lending support to its basal lineage (Ligrone *et al.* 2000).

Dendroligotrichum dendroides (Figure 29, Figure 49, Figure 73) can reach 60 cm height and transports water **endohydrically** (internally) (Atala & Alfaro 2012). Its water-conducting **hydrome** follows Murray's law, *i.e.* the sum of the radii of the conduits to the third power (Σr^3) is maintained across branching of these conduits. This means that the conduction system is optimized for maximal water transport per unit of 'vascular' tissue biomass. As the vascular tissue ascends toward the apex, there is **acropetal** (base to apex) tapering and an increase in conduit number at ascending levels. Since this architecture is similar to that of tracheophytes, Atala and Alfaro reasoned that it had undergone the same selection pressures in its evolution.

Figure 29. *Dendroligotrichum dendroides*, a moss with non-lignified vascular tissue. Photo by Felipe Osorio-Zúñiga, with permission.

Leptomes and Hydromes

Kawai (1991a) describes the moss stem as having a basic structure much like that of tracheophytes with an **epidermis** surrounding the **cortex** (Figure 30-Figure 31). This basic structure describes most of the **pleurocarpous** mosses that move internal substances mostly horizontally.

Among the **acrocarpous** mosses (those mostly upright mosses with the sporophyte at the stem apex), more complex stems can have a conducting cylinder in the center of the stem. This cylinder connects the base of the stem to the apex, but in most cases it is not connected to the leaves by any sort of leaf trace. The center of this conducting cylinder is comprised of **hydroids** and **stereids**, making up the **central strand** (Figure 32) (Zamski & Trachtenberg 1976). As you can guess from

the name, **hydroids** are water-conducting cells. They are somewhat similar to tracheids but lack any horizontal connections (*i.e.* no pits) and are not lignified. And as you will see later, their chemistry and development are different from that of tracheids. Hydroids collectively make up the **hydrome** (also known as **hadram** or **hydrom**) (Scheirer 1980).

Figure 30. *Trichodon cylindricus* stem cs showing lack of central strand. Photo by Janice Glime.

Figure 31. *Molendoo sendtneriana* (acrocarpous; **Pottiaceae**) stem cross section showing a central tissue that is differentiated. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Stereids are elongate, thick-walled, slender, and fiber-like cells that add support to the stem, typically arranged in a cylinder around the hydrome. The stereids are collectively known as the **sterome** (Héban 1977) (also known as **sterom**; Zamski & Trachtenberg 1976). They can also occur in the leaf **costa** (midrib-like strand; Figure 61), as will be discussed below, where they also serve as support.

Héban (1977) describes the living parenchyma cells around the central strand in the **Polytrichaceae** to be a **hydrom sheath**, a term originated by Tansley and Chick (1901). This seems like an unnecessary term with only limited usage. However, Héban reports that both starch grains and oil droplets are frequent in these cells. In *Polytrichum commune* (Figure 3), these cells have accelerated enzyme activity at the same time the protoplasts of the hydroids degenerate. Furthermore, some members of the **Polytrichaceae** have stereids among the

central strand cells. These have acid phosphatase activity in *Dawsonia longifolia* (Figure 2), suggesting they may have a role in the maturation of the hydroids.

Whereas the hydrome is relatively common, the **leptome** (also known as leptom; Figure 32) is less well known. The simple structure of its cells (**leptoids**) makes them difficult to distinguish from cortex parenchyma cells in cross section, but in vertical section they can be seen as longer cells surrounding the central strand and somewhat resembling phloem sieve cells (Figure 1, Figure 56). Their function, like that of phloem cells, is for photosynthate conduction, but they may also transport hormones or other substances. These cells in the **Polytrichales** (Figure 35) have oblique sieve plates, organized marginal endoplasmic reticulum, and partial nuclear degeneration (Scheirer 1975; Crandall-Stotler 1980).

In mosses like the **Mniaceae** (Figure 32-Figure 34) and **Polytrichaceae** (Figure 35), distinguishing the hydroids is fairly easy. However, not all distinctive cells in the center of the stem are hydroids. In other mosses, small to large cells comprise a distinctive central tissue (Figure 31), but we have no experiments to demonstrate their functions in conduction. It was not until 2002 (Ligrone *et al.* 2002) that immunocytological testing revealed the nature of the central tissue cell walls of 8 mosses and 4 liverworts. Little follow-up work has occurred, hence much of our understanding is still conjecture.

Consider, for example, the genus *Sphagnum* (Figure 36). Central cells can vary considerably among species (Figure 37-Figure 42) and can be much smaller than the outer layer that comprises the epidermis (Figure 43). Yet these small cells of the central core are not conducting cells (Héban 1977). Instead, *Sphagnum* typically uses its descending branches as wicks because they form capillary spaces around the stem (Figure 36).

Figure 36. *Sphagnum obtusum* showing descending branches that help to create capillary spaces and the wicking activity for upward movement of water. Photo by Michael Luth, with permission.

Figure 43. Longitudinal view of *Sphagnum fimbriatum* stem hyalodermis showing pores. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Schimper (1857) determined that the hyaline outer cells of stems and the hyaline cells of leaves in *Sphagnum* were dead at maturity (Figure 44). Furthermore, they have true perforations strengthened by spiral fibers (Figure 45). Branches are smaller than the stem and typically have a single outer hyaline layer and smaller, often thick-walled cells in the central core (Figure 46-Figure 47).

Figure 47. *Sphagnum papillosum* branch cross section. Photo from Botany website, University of British Columbia, Canada, with permission.

Schnepf (1973) later found that microtubules are fundamental in the development of the spiral thickenings of *Sphagnum* by lifting the plasmalemma off the wall to form an extraplasmatic space in which wall material is accumulated. The wall area where the pore will form becomes progressively thinner until only the cuticle remains. The cuticle eventually ruptures, making a pore. The protoplasts likewise eventually disappear.

The **Marchantiophyta** lack water-conducting cells except for two families of leafy and two of thallose liverworts (Ligrone *et al.* 2000, 2002). These conducting cells are formed by protoplasmic degeneration due to acid phosphatases, as in the mosses, but their wall development is different from that of the mosses (Crandall-Stotler 1980). They lack wall hydrolysis but possess numerous plasmodesmata-derived pores on all walls and never develop polyphenolic compounds (Héban 1978). No food-conducting cells are known among the **Marchantiophyta** (Figure 48).

Figure 48. *Porella navicularis* (Marchantiophyta, Jungermanniopsida – a leafy liverwort) stem cross section showing absence of central strand. Photo from Botany website, University of British Columbia, Canada, with permission.

Hydroids

The elongated, water-conducting **hydroids** typically occur in groups of 2-3 in bryophyte stems (Héban 1970); they are similar to tracheids, but lack lignin and secondary wall thickenings (Taylor 1988). Consequently, hydroids are usually thin-walled (Zamski & Trachtenberg 1976) and lack the helices and other thickenings typical of tracheids. Vanderpoorten and Goffinet (2009) sum up three major differences between hydroids of bryophytes and the tracheids and vessels of tracheophytes: hydroids lack secondary wall patterns; bryophyte lignin-like polymers are not cell-specific as they are in tracheophytes and are more likely to offer protection against microbes; hydroids collapse during water stress, making them highly resistant to cavitation (drop in vascular pressure due to vapor pockets resulting from desiccation) (Ligrone *et al.* 2000). This combination creates a fundamental difference in response to drying, with bryophytes being desiccation tolerant and tracheophytes preventing desiccation by pumping water from the soil, closing stomata, and reducing water loss with a waxy cuticle (Vanderpoorten & Goffinet 2009).

Table 1. Comparison of percentage of structural components of tree leaves and of plants of the moss *Polytrichastrum* (=Polytrichum) *ohioense*. From Lawrey 1977.

Litter type	soluble carb	hemi-cellulose	cellulose	"lignin"	ash
<i>Pinus resinosa</i> leaves	35.41	13.44	19.37	23.56	3.68
angiosperm tree leaves	43.89	11.59	20.43	11.04	6.97
<i>Polytrichastrum ohioense</i>	16.51	14.07	24.37	12.90*	4.24

*Not a true lignin in mosses.

Hydroids senesce at maturity and become dead, empty cells, like those of xylem, with slanted end walls that abut on the end wall of the next cell, as in tracheids (Richardson 1981). This change from living cells to empty dead cells is a result of acid phosphatase activity that degenerates the protoplasm (Crandall-Stotler 1980). Hydroids of **Bryophyta** typically lack perforations but sometimes have secondary polyphenolic thickenings on the lateral walls of

cells (Scheirer 1975). Scheirer (1973) used *Dendroligotrichum* (Figure 49) (**Polytrichopsida**) to demonstrate that hydrolysis leaves behind only cellulose remains of the primary walls of end walls of hydroids. Subsequent examination by electron-dense crystals of Prussian blue on the end walls in *Polytrichum commune* (Figure 50) suggests that these end walls are highly permeable (see Figure 51), but that substances are unable to move through the lateral walls (Scheirer & Goldklang 1977).

Figure 49. *Dendroligotrichum dendroides* stem cross section showing hydroids in center (**brown walls and mostly empty**), surrounded by stereids (**brown walls and interior brown**) and leptoids (**rusty-colored walls and contents**). Note vascular branches (**arrows**) that go into the cortex. The central strand has a few sclereids (thick walls) and these are living cells. Photo by Juan Larrain, with permission.

Figure 51. Cross section of *Polytrichum* stem stained with aniline blue to show thin areas in end walls of cortical cells. Photo courtesy of Isawo Kawai.

To understand any relationship between hydroids of bryophytes and tracheids or vessels of tracheophytes, we must understand their structure. We can consider that part of their structural development is similar to that of tracheophytes because they, like xylem cells, are dead at maturity (Richardson 1981). But is their chemical nature similar? It appears that the bryophytes have derived their water conducting cells in a variety of ways.

Hébant (1973a) found that strong activity of acid phosphomonoesterases occurs in the differentiating water-conducting cells of various mosses and at least one liverwort. But a lesser activity is also present in leptome cells and certain parenchyma cells of some *Polytrichales*.

Some chemical labelling tests gave similar results in as divergent taxa as *Takakia* (Figure 25-Figure 27) and *Polytrichum* (Figure 50-Figure 51), but different results in *Mnium* (Figure 74) (Ligrone *et al.* 2002). And Ligrone and coworkers found labelling of both water-conducting cells and parenchyma cells in *Haplomitrium* (Figure 107), but only of water-conducting cells in *Polytrichum*. Ligrone *et al.* found that the arabinogalactan protein (AGP) antibody labelled the water-conducting cells in all Bryophyta tested (8 species) except the large polytrichaceous moss *Dawsonia* (Figure 52). No labelling occurred in the liverworts (4 species). Hence, it appears that the chemicals present are similar, but that they occur at different places within the plants.

Figure 52. *Dawsonia* stem cross section to show hydrome, leptome, and leaf traces. Photo from Wikimedia Creative Commons.

Differences in labelling between the water-conducting cells and the cortical cells appeared to be mostly quantitative in these few species (Ligrone *et al.* 2002). On

the other hand, electron microscopy revealed clearly distinct differences in the location of the antibodies within the cell walls of these two cell types, suggesting that their presence in a particular location was tissue specific in its regulation. Even within the *Polytrichaceae* (Figure 49-Figure 52) there is considerable diversity in the immunocytochemistry. In short, the bryophytes have a widely diverse chemistry in their conducting cells, but as such, they differ strongly from those of tracheophytes. Ligrone *et al.* (2002) consider the presence of several carbohydrate antigens in the cell walls of hydroids to indicate that hydrolysis of non-cellulosic polysaccharides is not part of the maturation process, a strong contrast to that in tracheophytes (see Héban 1977).

Accompanying these chemical differences are differences in structure. True **perforation plates** (end walls of vessels) have not been found in *Polytrichaceae* (Figure 49-Figure 52) (Frey & Richter 1982) or most other mosses (Hébant 1973b). Consequently, Frey and Richter (1982) set out to discover them in mosses. In the dendroid moss *Canalohypopterygium tamariscinum* (Figure 53), they found structures resembling perforation plates of *Ephedra* (Gnetophyta), although they were not numerous and were restricted in location to branching areas. Perhaps this type of vascular structure permits them to be dendroid, lacking the close structure of leaves along the stem needed for capillary action. Smith (1964) had already demonstrated perforations in the conducting elements of the liverwort *Symphyogyna circinata* (Figure 54). Furthermore, pits are known, particularly in end walls, from *Haplomitrium* (Figure 107) [considered to be basal to leafy liverworts (Crandall-Stotler & Stotler 2000)] and *Takakia* (Figure 25-Figure 27) (now classified as a primitive moss in the *Takakiopsida*), as confirmed by electron microscope.

Figure 53. *Canalohypopterygium tamariscinum*. Photo by Pieter Pelsler, with online permission for educational use.

Although hydroids do not seem to contain true lignin, as do tracheophyte xylem cells, they do contain a polyphenolic cell wall component that functions similarly to lignin (Pressel *et al.* 2010). This compound protects the wall from hydrolytic attack and aids in internal transport of water. In *Rhacocarpus purpurascens* (Figure 55), Edelman *et al.* (1998) found walls composed of "mainly

lignin, **hemicellulose** (H-bonded to cellulose in plant cell walls), and cellulose in a ratio of ca. 9:8:5." Although the resonance spectrum indicated various characteristics typical of lignin, some specific peaks associated with known lignin compounds were missing. Thus the question remains, is this true lignin?

Figure 54. *Symphyogyna circinata*. Photo by Filipe Osorio, with permission.

Figure 55. *Rhacocarpus purpurascens*, a moss that produces a cell wall substance similar to lignin. Photo by Michael Lüth, with permission.

Leptoids

Leptoids (Figure 56) are very similar to phloem sieve cells, and in fact, Behnke (1975) calls them just that. Taylor (1988) considers that in some cases they are nearly identical to protophloem cells of certain tracheophytes. They, along with parenchyma cells, comprise the **leptome** (=leptom) (Héban 1970, 1974; Behnke 1975; Figure 32). We know that they are typical in the **Polytrichaceae**, but have also been found in *Sphagnum*, **Hookeriaceae**, **Neckeraceae**, and **Orthotrichaceae** (Ligrone & Duckett 1994b, 1998a; Duckett & Ligrone 2003). Except in the setae of a few species (Héban 1974), leptoids have not been found in the arthroodontous mosses (considered more advanced) and are unknown in liverworts. It is likely that they are much more common than we realize because in cross section without stain they appear no different from the unspecialized parenchyma cells.

Figure 56. Cross section of *Polytrichum juniperinum* and longitudinal section of *Atrichum undulatum* stem to illustrate parts of central strand (leptoids and hydroids) and stem structures. Drawings by Margaret Minahan, modified from Héban (1977).

In the moss family **Polytrichaceae** (Figure 56, Figure 58), leptoids have an axial system of microtubules with polarized cytoplasmic organization (Ligrone *et al.* 2000). In other mosses, including *Sphagnum* (Figure 36-Figure 47), such organization may also occur in stem and seta parenchyma cells. Even rhizoids and caulonemata of mosses and liverworts and thallus parenchyma cells of liverworts may have a similar organization for transporting nutrients **symplastically** (through cells, inside the membrane) for longer distances. But, as will be seen later in this chapter, these food and water conducting cells are fundamentally different from the phloem sieve cells and tracheids of tracheophytes. Nevertheless, Ligrone *et al.* (2002) found that the cell wall and tissue complexity of bryophytes are "on a par with higher plants."

The **leptoids** are distinct in vertical section by their elongate shape and slightly oblique end walls (Figure 59) (Behnke 1975). At maturity, the nucleus degenerates, as in phloem sieve cells (Richardson 1981), but protoplasm remains. In *Polytrichum* (Figure 56), the leptoids are not connected end-to-end by sieve plates or pores as in tracheophytes, but by numerous **plasmodesmata**. However, Cortella and coworkers (1994) considered the thin areas of central strand parenchyma cells to be primary pit fields in *Hookeria lucens* (Figure 57) stems and suggest that these cells have a conducting function.

Figure 57. *Hookeria lucens*. Photo by Jiří Kameníček, with permission.

Even the development of leptoids seems similar to that of phloem sieve cells. During leptoid maturation in **Polytrichaceae**, **ribosomes** (centers of protein synthesis) disintegrate and nuclei become smaller and inactive, although they do not dissolve completely as in tracheophytes; mitochondria persist. The parenchyma cells contain starch-storing chloroplasts. As in their tracheophyte counterparts, leptoids move carbohydrates and other substances away from the apex.

Figure 58. *Polytrichastrum formosum* stem cross section showing central **hydroids** (with orange walls in center) and considerable differentiation in the cells of the **central strand**. **Leptoids** are present outside the central strand and are not discernible in cross sectional view. Figure 59. *Hypnum* sp., a pleurocarpous moss, stem longitudinal section. Note the long cell with what appear to be broken side walls, a disintegrating diagonal cross wall, and a partially missing protoplast. This appears to be a **leptoid**, but we need conduction tests to verify it. Photo courtesy of Isawo Kawai.

Rhizome

The **rhizome** (underground, horizontal stem connecting upright plants), on the other hand, has

hypodermal and **radial strands** but lacks connecting traces and a **sterome**. The **hypodermis** (Figure 60), also present in some stems, consists of one to several layers of distinct cells just beneath the epidermis and may be thick-walled or colored.

Figure 60. *Polytrichum* stem cross section showing **hypodermis**. Photo courtesy of Isawo Kawai.

Long-distance transport brings its own set of problems. These plants can undergo transpiration, causing them to lose water (Raven 2003). In some liverworts and many mosses, but not hornworts, there are dead cells in the tissues. These may function in long-distance **apoplastic** (outside cell membranes) water transport. Symplastic transport, on the other hand, seems to have a high resistance to flow, emphasizing the importance of apoplastic movement.

Leaves

In most tracheophytes, the leaf is a critical structure in creating the movement of water from the roots to the tops of tall plants. This movement, known as the **transpiration stream**, requires the loss of water from the leaf, creating a vapor pressure deficit that brings water upward like someone sucking on a straw. But bryophytes typically do things quite differently, as we shall see in a later sub-chapter. They typically take in water from above, not below, hence requiring a new look at the role of leaves in water movement. It appears that the greatest need is not to move water to the leaves, but rather to move substances made in the leaves to other parts of the plants.

Costa

Within the leaf, water may move cell to cell among the **lamina** cells (Figure 61), but many leaves have a **costa** (Figure 61-Figure 62) that is often accompanied by supporting **stereid** cells (Figure 63). Unlike the midrib of ferns and seed plants, the costa does not branch and rebranch to deliver water or other substances to or from cells of the leaf lamina (Figure 62), although in some taxa, for example *Hygrohypnum* (Figure 64), it may have one or more branches. Nevertheless, the costa has elongate cells

that we might expect to facilitate a more rapid movement of water within the leaf (Figure 62), but does it?

Figure 61. Cross section of moss leaf blade showing arrangement of broad portion (lamina), costa, and supporting stereids. Large cells in costa serve for conduction. Photo by Janice Glime.

Figure 62. *Crumia latifolia* leaf showing elongate costa cells and nearly isodiametric lamina cells. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 63. *Crumia latifolia* leaf cross section showing enlarged costa with many stereids supporting the conducting cells. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 64. *Hygrohypnum eugyrium* leaf showing two branches of the costa (arrows). Photo by Hermann Schachner, through creative Commons.

On closer examination of the costa, we find that those elongate cells are living cells with oblique end walls, thin cell walls, and living protoplasm (Héban 1977)! These are not hydroids, but are **leptoids**. Hence, it appears that in addition to its supporting role, the costa can have the role of conducting substances from the leaf toward the stem. (We will see shortly how this system connects to the leaf traces in the stem.) It appears that the costa should not have a role in conduction of water.

Sphagnum

Sphagnum (Figure 65) has the most unusual water system in its leaves of any bryophyte. Its leaves have two types of cells, and rarely a border in addition. These two types are the water-holding, colorless, dead **hyaline** cells and the green **chlorophyllose** (photosynthetic) cells (Figure 66-Figure 67). The hyaline cells serve as water reservoirs for the photosynthetic cells. Their walls have true perforations and are strengthened by spiral thickenings, suggesting the structure of tracheophyte vessels (Figure 66-Figure 67) (Héban 1977). The pores (perforations) begin with a thinning of an area of the cell wall and presence of a thin membrane. Eventually these rupture to create the pore, using the process already described above for the hyaline cells of *Sphagnum* stems.

Leafy Liverworts

Leafy liverwort leaves never have a costa (Figure 68), leaving us to assume that transport of water and other substances in the leaves, if needed, is cell-to-cell transport through ordinary leaf parenchyma cells. But in this group (*Jungermannioopsida*), leaves are never more than one cell thick, giving all cells direct exposure to water from the atmosphere or other surroundings.

Figure 68. *Calypogeia fissa* (*Jungermannioopsida*) showing absence of costa in leaves and one-cell-layer leaf thickness. Photo by Des Callaghan, with permission.

We might also ask the role of **underleaves** (Figure 69) in this group. These may be non-existent (e.g. *Jamesoniella*, Figure 70) to quite large (e.g. *Porella*, Figure 71). Underleaves may be an evolutionary left over with no function, but their persistence suggests they may offer some advantages in water retention. They create capillary spaces on the under side of the stem and thus may aid in water retention. This space may also aid water uptake by holding water, but in many cases this would require that the stem (Figure 72) absorb the water. It would be interesting to experiment with different types of underleaves to see how they affect water uptake, especially by the stem, and how long they are able to hold a water reservoir.

Figure 71. *Porella platyphylla* showing its large underleaf and lobule. Photo by Paul Davison, with permission.

Figure 72. Leafy liverwort showing parenchymatous cells of stem. Photo by Bill Malcolm, with permission.

Another water reservoir in a number of leafy liverworts is the **lobule** (Figure 71). This structure, present in *Frullania*, *Porella*, *Lejeuneaceae*, and others can create a small reservoir of water suitable for small aquatic invertebrates such as rotifers and Protozoa to carry out their entire life cycle. These are discussed further in Chapter 7-4.

Leaf Traces

Conduction from stems into leaves is typically through the parenchyma cells of the stem cortex, as will be described in a later sub-chapter. True **leaf traces** (conducting cells connecting the leaf costa to the hydrome; Figure 73) exist in some **Polytrichales**, but in other cases they do not quite reach that far. In the **Mniaceae** and **Splachnaceae** there are **false leaf traces** (Figure 74) that extend into the cortex from the leaf but do not connect with the central strand of the stem (Figure 75) (Héban 1977). In *Funaria hygrometrica*, some specimens have true leaf traces that reach the central strand, and others do not.

Héban (1969) found that in *Polytrichum* (Figure 4), the true leaf traces extend from the leaf costa toward the central strand, but they become reduced near the central strand. Nevertheless, Héban (1969) found that 7-8 hydroids of each leaf trace could connect to the central strand in grassland *Polytrichum commune* (Figure 50). This connection, however, seems to be related to water availability. In bog populations, only three hydroids form

the connection. For specimens grown under water, no leaf traces connected to the central strand.

Figure 73. *Dendroligotrichum dendroides* stem cross section showing leaf traces in the cortex (arrows). Photo by Juan Larrain, with permission.

Figure 74. *Mnium* stem cross section showing distinct central strand and false leaf traces (arrow) that do not connect directly to the leaves. Photo by Janice Glime.

Figure 75. *Rhizomnium glabrescens* leaf cross section showing hydroids in center and stereids near the outer margins. In this family (**Mniaceae**), the central strand produces false leaf traces that do not connect to the costa of the leaf. Photo from Botany website, UBC, with permission.

But wait! Many kinds of leaves have a **costa**, the rib that extends part way or all the way down the center of the leaf. But the costa cells are fairly wide cells, albeit elongated, and contain a living protoplast (Héban 1977). The end walls are oblique and have numerous plasmodesmata. They are in fact **leptoids**, not hydroids, and do not seem to have an important water conducting function in many mosses, if any. Rather, they conduct **photosynthate** and other substances from the leaf to the stem. These materials are thus deposited in the stem tissue. Could these actually connect with leptoids in the stem, permitting transport to stem tips or to rhizomes? In fact, in *Polytrichum commune* they do connect to the leptoids of the stem axis. Why then are there hydroids in the leaf traces? What do they connect? Is there any correlation between having a costa with leptoids and a stem with a central strand? Do all leaf leptoids connect with stem leptoids? So little we know...

Rhizoids

Rhizoids have generally been assumed to function in attachment and little else. However, depending on the species and habitat, they may have important roles in water movement as well.

All liverworts except *Haplomitrium* (Figure 28) produce smooth, unicellular rhizoids. Duckett *et al.* (2013) reviewed the **pegged** and **smooth rhizoids** (Figure 76-Figure 78) of the complex thallose liverworts and noted that their roles differ. The mature smooth rhizoids of all liverworts remain alive. This permits them to function in nutrition, anchorage, and as conduits for mycobiont entry (Figure 77). They also collapse when dehydrated, a condition that is irreversible. Pegged rhizoids, on the other hand, are dead at maturity, permitting them to function in a "highly effective internalized external water-conducting system." This works especially well in the archegoniophores (Figure 79-Figure 80) of such liverworts as *Marchantia*. They are cavitation-resistant with elastic walls that permit them to retain functional integrity during desiccation.

Figure 76. *Conocephalum conicum* pegged and smooth rhizoids. Photo by Paul G. Davison, with permission.

Figure 80. *Marchantia polymorpha* archegoniophore, with A indicating archegonia. The large arrow indicates the rhizoids rolled inside the stalk. Photo from Botany Website, UBC, with permission.

But to what degree do rhizoids in bryophytes facilitate the uptake of water and nutrients? Jones and Dolan, as recently as 2012, concluded that there was little direct evidence on nutrient uptake by bryophyte rhizoids. Nevertheless, they suggested that their functions include water transport in some mosses and liverworts. As far as I know, we lack experimental studies to tell us the magnitude of uptake.

Rhizoids can also serve as perennating organs (Frey & Kürschner 2011), often producing propagules.

Sporophyte Conduction

In tracheophytes, it is the sporophyte that has the vascular tissue, and in the setae of mosses, one might find conducting tissues (a central strand) even when it is absent in the gametophyte. This should not be too surprising since the gametophyte is much better adapted to absorbing water from the atmosphere than the cuticle-endowed sporophyte. It is most likely necessary for a number of substances to be transported from the gametophyte into the sporophyte as it develops. And as we might expect, these conducting strands in setae are best developed in the **Polytrichaceae** (Héban 1977), a family in which the peristome exhibits the more primitive character of nematodontous teeth.

Is perhaps no coincidence that a species with a vascularized stem also has a vascular seta. This seems to be the case in *Plagiomnium undulatum* (Figure 81).

On the other hand, leptoids can occur in the setae of some arthrodontous mosses even when they are absent in the gametophytes. Nevertheless, leptoids of setae, unlike those of tracheophytes, show less differentiation than in their gametophytic counterparts. In the setae of the **Polytrichaceae**, leptoids are not intermixed with specialized parenchyma cells and apparently lack enlarged plasmodesmata in their end walls, as seen in gametophytes of some taxa (Héban 1974). To add interest to the picture, the leptoids are present in forms that are transitional between the parenchyma cells and the fully differentiated leptoid cells (Héban 1974).

Figure 81. *Plagiomnium undulatum* seta cs showing central conducting strand. Photo by Norbert J. Stapper, with permission.

Meager evidence exists for the presence of **leptoids** in setae of other genera. Among these are *Funaria*, *Meesia*, and *Splachnum* (Héban 1977). In *Tortula muralis* (Figure 82), Favali and Gianni (1973) have claimed that the leptoids are intermixed with the parenchyma cells in the seta and a similar claim was put forth by Bassi and Favali (1973) for *Mnium orthorrhynchum*, but Héban (1977) was unable to find any convincing evidence that this was true in either case.

Figure 82. *Tortula muralis* seta cross section showing modified cells in center of seta. Photo from Botany website, University of British Columbia, Canada, with permission.

Figure 83. *Tortula muralis* or *plinthobia* stem cs. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Stem sections indicate that at least a central strand is present in the acrocarpous mosses *Dicranum scoparium* (an **arthrodontous** moss; Figure 84-Figure 85) and *Tetraphis pellucida* (a **nematodontous** moss; Figure 86-Figure 87). The presence of leptoids cannot be determined from these views, nor can the function of the central strand. Cross sections of these setae can be compared with stems of the same species in Figure 82-Figure 87.

Figure 85. *Dicranum scoparium* stem cross section showing differentiated central tissue with hydroids, but representing a genus where leptoids are often absent. There appear to be hydroids that are breaking up, possibly surrounded by a narrow band of leptoids. Photo from Botany website, University of British Columbia, Canada, with permission.

Figure 87. *Tetraphis pellucida* stem cross section. As in the seta (Figure 86), most of the cortex is occupied with thick-walled supporting cells. Hydroids occur in the middle but occupy a larger area than in the seta. Photo from Botany website, University of British Columbia, Canada, with permission.

Héban (1977) pointed out that no electron microscope study existed on the histology of the conducting tissue of the capsule. He could offer little on its organization, stating that the conducting strand terminates shortly after it enters the capsule. In *Funaria hygrometrica* and *Polytrichum commune* the hydroids terminate within the capsule as a small ampulla, but such an ampulla is absent in *Dawsonia*, *Dendroligotrichum*, and *Fissidens*.

Adaptation and Evolution

The hydroids and leptoids present interesting evolutionary implications, since it appears that they are primitive characters that are lost in more advanced bryophyte taxa (Héban 1970; Behnke 1975). Unlike most tracheophytes, the mosses retain conducting cells in both generations, but the haploid generation is the first to lose leptoids evolutionarily, as in *Funaria* (Behnke 1975), a moss that still has a central strand in the stem (Malcolm & Malcolm 2006) and leptoids in its setae (Héban 1977).

Being Acrocarpous

Some acrocarpous mosses may lack a central strand. For example, *Leptodontium flexifolium* (Figure 88-Figure 89) grows on acid substrata but lacks the central strand (Figure 89), but it has a leaf costa (Figure 88). Even the ubiquitous *Ceratodon purpureus* (Figure 90), a moss that occurs on substrata from roadsides and exposed rocks to pools in the Antarctic, lacks a central strand (Figure 91), and likewise has a costa (Figure 92-Figure 93). Other taxa that frequently become dry, like *Grimmia* species (Figure 94) also often lack specialized cells in the center of the stem (Héban 1977).

Figure 93. *Ceratodon purpureus* leaf cross section showing costa and involute margins. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Being Pleurocarpous

Pleurocarpous taxa that grow close to the ground may have less need for hydroids when all their leaves are more or less equally placed to gain water, as can be seen in *Calliergonella lindbergii* (= *Hypnum lindbergii*; Figure 95). Pleurocarpous mosses (Figure 95-Figure 98) have fewer problems in getting wet and sharing water among cells because they grow horizontally, compared to the need for upright mosses to distribute water, especially tall ones that grow alone, like *Dawsonia* spp. (Figure 2). On the other hand, these mosses may have evolved the loss of hydroids before our extant species existed and have not regained their hydroids, as might be the case for *Hylocomium splendens* (Figure 97-Figure 98), a moss that grows in fairly open wefts, but lacks a central strand. Nevertheless, it would seem that the pleurocarpous mosses still need to transport photosynthate and hormones, among other things.

Hence, we should expect leptoids in many, if not all, pleurocarpous mosses. Unfortunately, it is hard to find information on leptoids in these taxa. The same need, and lack of information, could be said for leafy liverworts.

In *Climacium* (Figure 99), the stem has very reduced strands of conducting tissue (Héban 1977). This moss stands upright like a small tree. The stem is nearly naked, making external upward transport limited. Hence this moss must rely on water that lands on the leaves. Instead of specialized water conducting cells, *Climacium* species have good supporting tissues in their stems, permitting the stem to support the leafy tree-like portion.

Figure 99. *Climacium dendroides* showing the nearly naked supporting stem. Photo by Keith Bowman, with permission.

Aquatic

It should be no surprise that aquatic taxa like *Fontinalis* (Figure 100-Figure 102) lack hydroids. Likewise, in *Touwia* (Figure 103), a pleurocarpous moss in the *Neckeraceae*, there is no cross-sectional evidence of a central strand (Figure 104). Rather, like *Fontinalis*, this streambed moss has many thick-walled cortex cells that help to protect the stem from breakage in stream flow. Its leaves likewise have a thick **costa** (Figure 105) that can resist the ravages of flow. But even in such epiphytic taxa as *Neckera crispa* conducting cells are lacking, suggesting an evolutionary loss early in this branch. Taxa like *Touwia* with a strong costa but no conducting cells in the stem suggest that the costa cells that are elongate in a leaf where other cells are shorter may serve a function more important than conduction – that of supporting tissue, and may sometimes serve both functions. It is likely that they also have regenerative ability.

Using a Partner

Epiphyllous bryophytes have an unusual habitat on their host leaves. Water usually does not stay and is even repelled by the host leaf surface. *Radula flaccida* (Figure 106) has at least partially solved the problem by producing rhizoids that penetrate the host leaf cuticle and epidermal cells, extending into the tissues of the host (Berrie & Eze

1975). Berrie and Eze found that both water and dissolved phosphorus salts can be obtained from the host leaf. Hence, it appears that the liverwort is at least partially a parasite (Héban 1977).

Figure 106. *Radula flaccida* habit with gemmae, growing on a leaf. Photo by Michaela Sonnleitner, with permission.

Throughout the kingdoms we see examples where two organisms share responsibilities in their mutual survival. Among these partners, the fungi seem to have perfected the strategy, making it possible for plants to greatly increase their available surface area without expending the effort to build the needed tissues. Such is the case for some bryophytes, a partnership for which we have limited understanding. Among those with such a relationship is the genus *Haplomitrium* (Figure 107) (Carafa *et al.* 2003). *Haplomitrium* secretes mucilage (Figure 108) from its underground rhizomes, forming an environment that harbors fungal hyphae. In *H. gibbsiae* (Figure 107), the fungus is restricted to the epidermal cells where it forms lumps, but in *H. ovalifolium* it also infects the adjacent cortical cells, forming lumps. Through such partnerships, these species can gain access to both deeper and wider sources of nutrients in the soil substrate.

In tracheophytes, this partnership strategy has been used by a number of **hemiparasites** that partner with a fungus that partners with a tree or shrub. This arrangement permits them to gain carbohydrate energy from the photosynthesizing canopy while living in the darker environment under its protective cover. Our knowledge of bryophyte partnerships is still too primitive to ascertain how important this relationship is in permitting many bryophytes to subsist in such low light conditions.

Summary

Movement onto land required means of obtaining and retaining water. Bryophytes, reputedly the first colonizers, often are not the nonvascular plants we once thought them to be. They often possess **hydroids**, surrounded by **stereids**, that conduct water and together comprise the **hydrome**. Hydroids lack lignin and spiral thickenings, distinguishing them from tracheids and vessels of tracheophytes. **Leptoids** that conduct sugars, arranged as in tracheophytes, with the water-conducting cells surrounded by the sugar-conducting cells, are less well known because they are distinguishable in longitudinal section. In a few mosses, these stem conducting tissues connect by leaf traces to the leaves. Bryophytes usually have a thin **cuticle**, but it seems to lack wax in most cases. **Rhizoids**, although anchoring the plants as do roots, typically do not serve in obtaining water, but exceptions exist. **Acrocarpous** species more commonly have a central conducting strand, whereas **pleurocarpous** mosses remain close to the substrate and a central strand may not be useful.

Bryophytes function like sponges in the ecosystem by holding water and maintaining moisture in the soil below. But they also absorb water like a sponge, using capillary spaces. At times when water is limiting, the bryophytes are able to survive through their exceptional desiccation tolerance.

Mosses may have a **costa** (rib similar to a midrib) in the leaf, but it does not branch to reach all the cells (as in most tracheophytes) and may not always serve a conduction role. This is connected to the stem vascular strands only in the **Polytrichaceae**. Thallose liverworts may have a midrib to transport water and other substances, but leafy liverworts have no evidence of water-conducting cells in the stem and no **costa** in the leaf.

Even sporophytes have elongated cells in the seta. In younger sporophytes these may be important in conduction of nutrients to the developing capsule.

Aquatic species presumably do not need conduction since they are bathed in water. But they still need to move solutes and especially sugars from leaves to other locations. Some bryophytes have mycorrhizal associates that help take in water and

minerals. Others are connected by rhizomes that permit them to "scavenge" by obtaining photosynthate from connected stems that are in more favorable positions.

Acknowledgments

This chapter has benefitted from the help of Beth Scafone and Medora Burke-Scoll, who read the manuscript for clarity. Linda Luster checked the literature citations, proofread, and made glossary suggestions from a layperson's perspective. Jean Faubert suggested problems in the original chapter and reviewed the revised chapter for me. Isawo Kawai sent me a large parcel of images of stained stem sections. Jeff Duckett and Silvia Pressel invited me to peruse their digital image library for images I could use.

CHAPTER 7-2

WATER RELATIONS: MOVEMENT

Figure 1. *Grimmia nutans* supporting drops of water that will eventually be absorbed into the moss through the leaf surface. Photo by Michael Lüth, with permission.

Water Movement

Early experiments with dyes demonstrated that in mosses water is able to move in conducting tissue of the central cylinder, leaf traces, and the costa (Zacherl 1956), depending on capillary spaces, as it does in tracheophytes (Table 1). Bopp and Stehle (1957) confirmed not only these internal pathways, but that movement also occurs from cell to cell (**symplastic**) in the cortex of the lower part of the stem, as well as on the outer surfaces of leaves and stems (Figure 1). But it is more likely that most of the movement across the cortex and internal leaf is through the free space of the cell walls where it does not have to cross cell membranes until it reaches its destination (Proctor 1984). Such **apoplastic** (outside cell membrane or in free space) movement across the cortex is known even in *Polytrichum juniperinum* (Figure 2) (Trachtenberg & Zamski 1979), where a central strand and leaf traces are available to facilitate movement of water.

Table 1. Relationship of bryophyte structures, size of space, and capillary rise. From Proctor (1982), based on Slatyer (1967).

Radius of meniscus	Ht of capillary rise	Bryophyte structures in similar size range
1 mm	1.5 cm	Large, concave leaves; spaces among shoots
100 μm	15 cm	Spaces between leaves, paraphyllia
10 μm	1.5 m	Space within sheathing leaf base, tomentum, hyalocyst of <i>Sphagnum</i> & <i>Leucobryum</i>
1 μm	15 m	Interstices between leaf-surface papillae
100 nm	150 m	Spaces between cell-walls?
10 nm	1.5 km	Spaces between cell-wall microfibrils
1 nm	15 km	Glucose molecule

As in tracheophytes, water movement in both endohydric and ectohydric mosses is facilitated by tension forces (Zamski & Trachtenberg 1976), but unlike the case in tracheophytes, water moves in both directions in a source-sink fashion dependent upon availability (Bowen

1933a). This bi-directional movement applies not only to external movement, but to the hydrome as well. For bryophytes, the first water availability most commonly does not start with the soil, but with the tips of stems and leaves by way of rain, fog, or dew.

Figure 2. *Polytrichum juniperinum*, a moss with good **symplastic** conduction, but that can also use apoplastic movement. Photo by Des Callaghan, with permission.

Early observations showed that in general external conduction is much more rapid than internal conduction (Bowen 1933a, b, c; Clee 1939). This most likely relates to frictional resistance in the small internal routes. On the other hand, we should expect water to rise higher in small internal capillary spaces (Table 1). What seems strange, however, is that the utility of internal conduction in at least some bryophytes can change with age toward greater use of external conduction. Mizushima (1980) found that in older stems of *Entodon rubicundus* no internal conduction could be detected at 75% atmospheric humidity, but in younger stems, a slow internal conduction could be detected in the **central strand**. Both young and old stems exhibited external conduction, travelling up to 1 cm in 12 hours. This loss of internal conduction in older plants may support the contention of Kawai (1991), among others, that mosses may have been derived from vascular plants by reduction.

One item of curiosity is that not all bryophytes have **vacuoles** (Oliver & Bewley 1984). Surely this plays some role in their ability to hold water, and most likely affects nutrient placement and protection from toxic substances as well, but no one seems to have looked at this role in bryophyte physiology (Bates 2000).

Ectohydric

Ectohydric mosses (almost all mosses) rely primarily on external transport of water and can absorb water over the entire plant surface (Figure 3). These taxa generally have no water repellent layers, or these are restricted to such locations as the apices of papillae, and they are easily wetted (Proctor 1982, 1984). Movement is due to capillarity and the relationships are complex. As the moss becomes hydrated, its capillarity changes due to expansion of leaves, untwisting, and other forms of movement and gyration (Deloire *et al.* 1979). They benefit from a large surface area relative to their volume (Proctor 1984) due to numerous leaves and often such structures as **paraphyllia** (reduced leaflike structures on the stem or branches of

some pleurocarpous mosses) and **tomentum** (felt-like covering of abundant rhizoids on stem).

Figure 3. Capillary water (**arrow**) held among the leaves of *Bryum*. Photo courtesy of John Hribljan.

Castaldo Cobianchi and Giordano (1984) concluded that in the ectohydric *Zygodon viridissimus* (var. *rupestris*) (Figure 4-Figure 5), having an apical cell with no surface wax or papillae might provide a "starting-point" for rehydration since the dry leaves are appressed to the stem. When water repellent layers are lacking, plants generally reach full hydration within minutes (During 1992). Thus, virtually all pleurocarpous mosses, many of acrocarpous mosses, and most of leafy liverworts are readily wet by the first few minutes of rain. You will soon know which ones are resistant to uptake by leaves because they will stubbornly refuse to rehydrate for you when you want to make a leaf slide. Only dousing in boiling water seems to coax the water inside the plant to restore its normal hydrated shape.

Figure 5. *Zygodon viridissimus*, a moss in which the apical cell of the leaf lacks wax, permitting water entry. Photo by David Holyoak, with permission.

The **ectohydric** habit depends on entry of water through the moss surface and permits a moss to respond to dew and fog by absorbing water directly, even though rooted plants may never receive a drop of it. Such bryophytes can live in high elevations and on deserts that receive less than 25 cm rainfall per year, obtaining water that cannot be measured by conventional precipitation methods. Most tuft-forming (acrocarpous) mosses are (partially) endohydric, whereas most mat and carpet formers (pleurocarpous mosses) are ectohydric (Richardson 1981). In addition, some upright mosses such as *Sphagnum* (Figure 6) and *Andreaea* (Figure 7) are ectohydric. Schipperges and Rydin (1998) clearly showed this by clipping the capitula from the stem; these clipped capitula were unable to recover from desiccation, whereas unclipped capitula became rehydrated. But Even *Sphagnum* has highly specialized cells in the stem that have all the traits of a bryophyte type of conducting cell (Ligrone & Duckett 1998).

Figure 7. Cross section of *Andreaea* stem with no central strand. Photo from Biology 321 Course Website, University of British Columbia, with permission.

In **ectohydric** bryophytes, the uppermost leaves and shoot apices have the most rapid conduction of water, so that lower leaves are often supplied last (Zacherl 1956). Zacherl believed that no internal conduction was possible in the absence of a central strand. This apical movement may be beneficial in conserving water when water is scarce and only the leaves at the tips of the stems are receiving enough light for photosynthesis. These also are the leaves most exposed to fog and dew.

Using dyes and *Dicranum scoparium* (Figure 8) as a model subject, Bowen (1933c) demonstrated that external conduction was "exceptionally rapid" and internal conduction slow. Mägdefrau (1935), using the same species, determined internal conduction to be only about 1/3 the total conduction – not bad for a bryophyte. Klepper (1963) found that under conditions of desiccation, the protoplasts of this species become dense and evacuate, undoubtedly developing considerable **imbibitional pressure** (due to adsorption of water by colloidal particles, much as seeds do). This would cause them to readily take in water when it becomes available.

Figure 8. *Dicranum scoparium*. Photo by Michael Lüth, with permission.

Once the water enters the plant the distinction between endohydric and ectohydric no longer matters. Although the initial movement of water is clearly ectohydric in most dry mosses, once it has entered the moss it has the opportunity to move apoplastically to reach places where it is needed

for cellular metabolism. It is interesting that endohydric bryophytes can be facultatively ectohydric. Bayfield (1973) found that *Polytrichum commune* (Figure 9) was ectohydric under moderate moisture flux, but under high evaporative flux (*i.e.* dry air) it was predominantly endohydric.

Figure 9. *Polytrichum commune*, a moss that is ectohydric under moderate moisture flux but endohydric under dry air. Photo by George Shepherd, through Creative Commons.

Despite all the laboratory experiments on conduction, we still have little concept of the relative importance of the two pathways over a large time scale in nature. Certainly, as demonstrated in *Polytrichum* (Figure 9), the relationship changes as the moss dries. Is it not likely that internal movement of water from older to younger parts then predominates, keeping the photosynthetic and growing apical tissue wet as long as possible? Surely the same apoplastic routes available to *Polytrichum* are available to all mosses. The natural transpirational stream that carries water from the shoot apices to the atmosphere could be expected to play a similar role to that found in tracheophytes and maintain upward movement (or outward in pleurocarpous mosses) through capillary spaces as long as water was available and internal tension did not exceed that resulting from transpirational loss.

What quantities do the various mosses move from moss mat to atmosphere and how much is moved from the soil to the moss mat? Do the mosses provide an overall net gain to the soil by preventing rapid loss to the atmosphere following rainfall? Do they retain water that would otherwise be lost as runoff, contributing it slowly to the soil and plant roots beneath? Or is their major contribution that of depriving the soil of water during showers of short duration? There is no mass balance equation that includes the role of bryophytes in the overall water budget in any ecosystem.

Endohydric

Endohydric mosses, including *Polytrichum* (Figure 2, Figure 9, Figure 13), *Mnium* *s.l.* (Figure 10, Figure 17), and *Bryum* (Figure 3), generally have surfaces that contain a water-resistant cuticle (Lorch 1931; Buch 1945; Bayfield 1973; Proctor 1979a), thus reducing their ability to take in water through their leaves. In some of these, that cuticle is endowed with a wax similar to that found in tracheophytes (Proctor 1979b; Haas 1982). However, this waxy coating of a moss leaf offers only a low water diffusion resistance

similar to that of tracheophyte mesophyll (Nobel 1977; Proctor 1980) and may be more important in repelling water to permit a higher CO₂ diffusion into the leaf (Proctor 1984). Among ectohydric mosses, waxy cuticles seem to be either generally lacking or very thin. Mosses like *Polytrichum* and many members of the Marchantiales are actually water repellent, thus requiring half an hour or more to take up water (Proctor 1984). These **endohydric** bryophytes utilize, in the case of mosses, the system of non-lignified **hydroids** and **leptoids** to conduct water and sugars, respectively.

Figure 10. *Mnium spinosum* with water droplets on its leaves. This moss is very slow to absorb water due to its water-resistant cuticle. Photo by Michael Lüth, with permission.

But it appears that even these endohydric mosses rely on ectohydric transport. Instead of moving water inside the moss at the first opportunity during its external vertical rise, it is the tips of the plants that exhibit primary water absorption (Brown 1982). Water travels upward through the capillary spaces created by the leaves. Mosses like *Polytrichum* may facilitate this apical absorption by preventing any significant absorption by the cuticularized lower and more mature leaves.

In these predominantly endohydric mosses, rhizoids may serve functions of conduction much as do roots and root hairs. It appears that endohydric mosses such as *Polytrichum* (Figure 2, Figure 9, Figure 13), *Dawsonia* (Figure 11), and *Climacium* (Figure 12) transport water from the substrate beneath to their tips before moving it through an internal conducting system, sometimes called the **central strand**. Although *Polytrichum commune* (Figure 9) has demonstrated the ability to transport water externally along its stems, Mägdefrau (1938) contended that the major conduction is internal through the central strand. However, Trachtenberg and Zamski (1979) determined that despite the ability of rhizoids to absorb and transmit water, the major absorption is still through the aerial gametophyte, due to its greater efficiency. Because of the extensive development of conduction cells in *Polytrichum* (Figure 13), where central **hydroids** are surrounded by a cylinder of **leptoids**, Héban (1970) considers this and other mosses to have similarities to the xylem and phloem of primitive vascular plants.

Figure 13. Cross section of a *Polytrichum* stem showing green **hydroids** of the **central strand** in center and larger **leptoids** surrounding them. Photo by Isawo Kawai, with permission.

But how does the water reach the leaves in the **endohydric** mosses? Zacherl (1956) used fluorescent dyes to show that in *Polytrichum* (Figure 2, Figure 9, Figure 13), the **costa** (midrib-like structure) links with the central strand, forming true leaf traces. In many taxa, however,

there is no connection between the central strand and the costa, and in some cases there is no costa at all. Furthermore, Colbert (1979) showed that there is no connection between the central strand of the stem and that of the branches in *Climacium americanum* (Figure 14), *C. dendroides* (Figure 12), *Rhytidiadelphus triquetrus* (Figure 15), and *Rhytidium rugosum* (Figure 16).

Figure 14. *Climacium americanum*, a moss with a central strand with no connection to the leaf. Photo by Bob Klips, with permission.

Figure 16. *Rhytidium rugosum*, a moss with a central strand that does not connect to the leaves. Photo by Michael Lüth, with permission.

Nevertheless, in the absence of those connections the extension of the costa into the stem cortex still can function to complete internal transport across normal cortical cells (Zacherl 1956). For example, in *Mnium* (Figure 10) the costa does not link directly with the central strand of the stem, but ends blindly in the ground tissue, forming **false leaf traces** (Figure 17). The ends of the costae (Figure 18) act as wicks, transferring liquids across the ground tissue from the central strand and into the leaf costa, most likely using a diffusion gradient across the cortex.

Figure 17. Cross section of *Mnium* stem showing false leaf traces. Photo by Janice Glime.

Figure 18. Leaf of *Bryum pallescens*, showing costa of conducting cells. Photo by Michael Lüth, with permission.

The cortex behaves as capillary tubes and draws the water across the stem parenchyma to the leaf, much as water traversing the roots of tracheophytes. Trachtenberg and Zamski (1979) demonstrated, using PbS and Pb-EDTA (which accumulates Pb ions in tissues in proportion to the amount of water passing through), that the water actually moves in the capillary spaces of the cell walls – **apoplastic conduction**. Beckett (1997), using pressure volume isotherms, determined that cryptogams, including bryophytes, contain significant amounts of intercellular water when fully hydrated, whereas flowering plants do not. It is this extracellular pathway that permits water to move from leaf surfaces inward and into stems, where it can be conducted in the hydrome as well as apoplastically. It is interesting that the uppermost leaves are the first ones to receive water internally (Zacherl 1956), just as in the ectohydric mosses.

Trachtenberg and Zamski (1979) further learned that the **sterome**, assumed to be supporting tissue, can provide an alternative pathway for water conduction. That its mass was much greater than needed for support had already been

noted by Lorch (1931). Furthermore, xerophytic mosses have a very large sterome (Goebel 1915) that is used for conducting and holding water. In mosses such as Fabroniaceae and Orthotrichaceae that lack a hydrome, the sterome is large (Van der Wijk 1932) and seems to supply this function. In fact, Trachtenberg and Zamski (1979) suggest that the transport from hydrome to leaves in *Mnium* (Figure 17) may take place through stereids. They support their hypothesis by demonstrating that the lead chelate solution applied to the leaves penetrates the sterome. They suggest that the most probable means of translocation of water from leaves into the stem is through the dense mass of stereids in leaves and leaf bases to the central cells of leaves and leaf traces to the hydrome. But only in the Polytrichaceae does there seem to be a connection between the leaf traces and both the leaf and hydrome. Rather, the apoplastic route through cell walls in the stem cortex is a more likely route in most cases.

Mixohydric bryophytes are those in which both endohydric and ectohydric methods are important. Many of the species in this group are small, acrocarpous mosses of loams or clays. These soils dry out frequently, but their fine texture permits them to maintain a moist top layer for a period of time after rain. Héban (1977) contends that truly mixohydric mosses are not very abundant, implying that the ectohydric pathway is far more important in most. However, in reality, most (perhaps all) mosses are mixohydric in that they have both internal and external means of conduction to at least some degree.

Nocturnal

For many mosses, nighttime is the only period of rehydration. This is especially true for desert mosses such as *Syntrichia ruralis* (Figure 19). Csintalan *et al.* (2000) found that this moss obtained sufficient water through nighttime dew to accomplish 1.5 hours of net photosynthetic gain immediately after dawn. They suggested that such early morning periods might permit regular molecular repair due to desiccation damage during prolonged dry periods.

Figure 19. *Syntrichia ruralis*. Photo by Michael Lüth, with permission.

But it appears that desert habitats are not the only places where nighttime moisture benefits the bryophytes. Carleton and Dunham (2003) contended that the uppermost growing tips of mosses could not be hydrated by simple capillary movement of water from the forest floor in the boreal forest. Rather, even in this mossy habitat, they

showed a nocturnal gain in mass due to vapor from the forest floor. As the forest floor cooled at night, distillation occurred with moisture condensing on the moss surface. The cooling temperatures and moisture provided by the forest floor was sufficient to cause the moss tips to reach dew point. This seems to be most evident in late summer when the lower organic layers have warmed the moss and the surface temperature is thus relatively lower at night, causing the condensation. When a vapor barrier was used to prevent ground water from rising, no mass gain was in evidence.

Mechanisms of Water Movement

Bopp and Stehle (1957) found that a mechanism similar to the diffusion pressure deficit seen in higher plants worked in moving water up the moss. By using fluorescent dyes, Bopp and Stehle showed that water moved up the leafy gametophyte both internally and externally, but that dye went quickly to the foot of the sporophyte imbedded in the gametophyte, then moved up the seta through the central strand. In mosses with the calyptra removed, the flow rate increased, suggesting that transpiration loss may perform a function of pulling water, similar to that found in tracheophytes. Maier-Maercker (1982b) found an accumulation of radio-labelled and heavy metal ions in the annulus of the moss *Plagiomnium cuspidatum* (Figure 20), similar to that found in tracheophyte guard cells, suggesting that this area may be one of transpirational water loss.

Figure 20. *Plagiomnium cuspidatum* capsules showing annulus (arrows) where labelled metal ions accumulated, suggesting a site of transpiration loss. Photo by Robert Klips, with permission.

Although bryophytes lack leaf stomata, they do lose water through their wax-free leaves. For example, the transpirational loss rates of the moss cover in the lichen tundra (16-20% of total precipitation) is not unlike that from the ericaceous shrubs of the tundra heath (24-26%) or the alpine dwarf shrub heath (16-20%), whereas tracheophytes in a wet meadow can have 135% loss (Larcher 1983 – data from many authors).

Using mosses from five different habitats ranging from wet to dry, Bowen (1933a,b,c) determined that the water ascends the mosses as capillary films between the leaves and stem, being absorbed at the stem and branch apices by

the younger cells with unthickened walls. From there it diffuses through internal tissues laterally, then downward, not upward as in tracheophytes. Conduction from the base through the central strand is slow in cut stems but much slower when the stem base is still intact (Bowen 1933a,b,c). In the latter case, water must penetrate the thick walls of the rhizoids and stem/rhizome. And at least some of the species have cuticles on the rhizoids!

Once water reaches the central strand, it travels there preferentially (Héban 1977). Internal ascending water travels through the narrow, elongated, thin-walled cells (presumably hydroids). In addition to apical absorption, leaves and stem epidermis absorb some of the water, albeit less readily due to cell-wall thickening and cuticles.

The capacity of both internal and external water conduction seems to diminish as the moisture of the habitat increases (Bowen 1933a, b, c). Mägdefrau (1935) contends that at 90% humidity, *Polytrichum* (Figure 2, Figure 9, Figure 13) can maintain its turgor with internal conduction only, but at 70% both internal and external conduction are necessary. For all other families of mosses, with the possible exception of the Mniaceae, a significant amount of external conduction seems necessary.

Vitt (1990) suggests that those mosses that must endure a greater range of fluctuations in water availability may be more plastic in their responses. At least among the boreal mosses, the ectohydric, drought-tolerant *Hylocomium splendens* exhibits highly variable growth over its North American range, but the endohydric, less drought-tolerant *Polytrichum strictum* (Figure 21) exhibits more constant growth throughout its range (Vitt 1990).

Figure 21. *Polytrichum strictum* with sporophytes. Photo by Michael Lüth, with permission.

It is possible that there is some relationship between the absence of conducting cells and the horizontal growth habit of many mosses. However, Blaikley (1932) and Bowen (1933a) disagree as to the mechanisms for external conduction, arguing about the importance of soil water, presumably more available to the pleurocarpous habit. Blaikley feels that water contributed by the soil surfaces is necessary, whereas Bowen found leaf bases had drops of water when the soil surface was dry. The methodology of tracking the water is important here, and one is encouraged to read the arguments presented by Bowen (1933a) against broad interpretations based on the use of dyes. In most cases, she argues, they would be impossible to distinguish from naturally colored tissues, and the faint stain of cortical cells may be overlooked, whereas the presence of dyes in

the central strand may be more concentrated and thus more easily discerned. Rather, Bowen argues that water, and hence dye, accumulate in the central strand, whereas their movement across the cortex is transitory only. Thus, when water appears to have reached a certain height in the stem from internal movement through the hydrome, it may in fact have arrived there from the aerial surfaces across the cortex. Using 12 plants of *Polytrichum commune* (Figure 9) and blocking the entry of water into the hydrome from the cut surface with wax, she was able to demonstrate rapid movement externally, up to 42 cm in one hour, reaching a maximum of 96 cm in 24 hours (Bowen 1931). When basal leaves were removed (and the wounds sealed) and the cut stems were not blocked, she demonstrated considerably less movement internally through the hydrome. Using only three plants, the greatest rise internally was only 12 cm.

It is interesting that the dependence on endohydric gametophytic conduction seems to have diminished in the evolution of bryophytes, with the creeping (pleurocarpous) taxa exhibiting less developed conducting systems. Instead, the ectohydric habit is well-developed. Yet, no pattern exists (Héban 1977). Even the xerophytic *Orthotrichum* (Figure 22) lacks a central strand, although despite its acrocarpous appearance it is technically pleurocarpous and thus related to taxa that have apparently lost the central strand.

Figure 22. *Orthotrichum pumilum* stem cross section showing absence of central strand. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

It seems that for bryophytes, ectohydric conduction may be adaptive. Mägdefrau (1935) contends that the humidity would need to be at least 90% for the plant to succeed with internal conduction only. Gametophyte conduction is slow. Bopp and Stehle (1957) found that it required 40 hours for water to travel 10 cells in the rhizoids of *Funaria hygrometrica* (Figure 28)! The external pathway is much more rapid. The slowness of internal transport relative to external transport (Table 2) can easily account for the success of the external mechanisms. Furthermore, Bowen (1933a) demonstrated that the time required for movement can be more accurately measured by sensitive chemical tests that measure very small amounts of water which advance most rapidly up (or down)

the plant, suggesting that external conduction is even more rapid than supposed.

Mosses such as *Pleurozium schreberi* and *Hylocomium splendens* form important intermediaries between the soil and atmosphere in the boreal forest (Sokołowska *et al.* 2017). Hence, understanding how water movement functions in these keystone species is important. These researchers examined the conduction of both food and water in these species. Both species exhibit symplastic transport for short distances by using food-conducting cells. *Pleurozium schreberi* is furthermore able to transport substances apoplastically over long distances through the central strand of hydroids. *Hylocomium splendens* lacks hydroids (Figure 27). Both species have increased internal transport when air humidity is reduced significantly, but this increase is somewhat greater in *H. splendens*. These differences affect the desiccation tolerance. *Hylocomium splendens* typically dries faster than *P. schreberi* (Hiejmans *et al.* 2004; Elumeeva *et al.* 2011), perhaps explaining why *H. splendens* prefers wetter habitats (Busby *et al.* 1978).

Figure 27. *Hylocomium splendens* stem cross section showing absence of hydroids. Photo from Botany Website, UBC, with permission.

To summarize, water is known to move from one bryophyte part to another by four pathways: hydroids, free spaces in cell walls, cell to cell, and externally.

Figure 28. *Funaria hygrometrica*. Photo by Michael Lüth, with permission.

Table 2. Effectiveness of internal conduction compared to total in mosses after 24 hours in 70% relative humidity. Conduction measurements are grams water/0.2 grams dry mass; % is percent of internal compared to total rate. From Mägdefrau (1938).

	Internal Conduction	Total Conduction	%
<i>Sphagnum recurvum</i>	0.07	6.54	1
<i>Drepanocladus vernicosus</i>	0.79	22.73	3.5
<i>Rhytidiadelphus triquetrus</i>	0.11	1.67	6.5
<i>Thamnobryum alopecurum</i>	0.007	0.019	37
<i>Plagiommium undulatum</i>	1.13	2.22	51
<i>Polytrichum commune</i>	2.24	3.32	67

Transport to Sporophyte

The seta, lacking leaves, must necessarily conduct water internally. Conduction from the gametophyte to the **sporophyte** tissue seems to be governed by several factors, as observed in *Funaria hygrometrica* (Figure 28) (Bopp & Stehle 1957). The sporophyte receives its water from the **haustorial foot** that is imbedded deeply into the central strand of the gametophyte.

In *Dicranum undulatum* (Figure 29), it appears that the embryo has a role in development of the conducting strand in the gametophyte stem, as no conducting strands were present below archegonia that had not been fertilized (Roth 1969). Héban and Berthier (1972) made similar observations on *Polytrichastrum alpinum* (Figure 30). This underscores the apparent importance of the transfer of water from the gametophyte central strand to the sporophyte. There are no plasmodesmatal connections between the gametophyte and the foot of the seta (Héban 1977). However, the **transfer cells** have extensive wall ingrowths (**labyrinth**, Figure 31) that greatly increase the surface area of the plasma membrane, thus increasing transport (Héban 1977). In *Funaria hygrometrica* (Figure 28) fluorescent dyes showed that the jacket around this foot was separated by a narrow intercellular space which became colored before the central strand (Bopp & Stehle 1957). This capillary space moved the liquid quickly to the

central strand of the sporophyte. When comparing species that had no transfer cells, Bopp and Weniger (1971) found that uptake by the sporophyte was greatly reduced.

Figure 29. *Dicranum undulatum*, a moss where conducting strands seem to develop only in stems under archegonia with embryos. Photo by Jan-Peter Frahm, with permission.

Figure 30. *Polytrichastrum alpinum*, a moss where conducting strands seem to develop only in stems under archegonia with embryos. Photo by Michael Lüth, with permission.

Héban (1977) describes detailed studies of a variety of mosses in which the very tip of the sporophyte foot directly penetrates the central strand of the gametophyte. At the end of the foot, an appendage of mostly necrotic cells is the only separation of the conducting cells between the two generations. Conduction in the sporophyte was increased when the calyptra was removed; the apparently non-closing stomata of the capsule may contribute to transpirational water loss.

As can be observed in *Physcomitrium immersum* (= *Physcomitrium cyathicarpum*), both generations have **transfer cells** at the junction, and the foot epidermal cells are rich in organelles (Lal & Chauhan 1981), especially mitochondria (Héban 1977), suggesting there might be considerable active transport between the two generations.

Figure 31. Transfer cell between gametophyte and sporophyte showing wall labyrinth. Computer-drawn from photo in Lal and Chauhan (1981).

Summary

We have seen that bryophytes have remarkable abilities to gain, retain, and recover from loss of water. They gain it in their cells both through external (**ectohydric**) capillary movement and internal (**endohydric**) transport. Endohydric movement is accomplished either cell-by-cell or through designated elongate cells (**hydroids**). Some mosses survive on moisture in clouds and nighttime dew. Nutrients and water are transferred to the sporophyte through the **foot**, using special **transfer cells** with **labyrinth** walls.

Acknowledgments

This chapter has benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me tow the line in explaining things without leaving too much to one's imagination, but at the same time not repeating myself.

CHAPTER 7-3

WATER RELATIONS: PLANT STRATEGIES

Figure 1. *Tortula muralis* with water drops collected on the leaf awns and setae. Note their collection around the young capsules. Such collection can occur in fog and mist and may serve as the only source of water in some habitats. Photo courtesy of Peggy Edwards.

Water Strategies

Water strategies in bryophytes have been approached in a variety of ways, from splashing gemmae (Brodie 1951) to uptake (Proctor 1981; Rice & Schneider 2004; Rice 2012; Jonas & Dolan 2012; Sand-Jensen & Hammer 2012) to transport (Héban 1977; Mulder *et al.* 2001; Proctor & Tuba 2002; Pressel 2006; Rice 2012) to moving nutrients (Buch 1945, 1947; Proctor 1981) to retention (Kennedy 1993; Mulder *et al.* 2001; Rixen & Mulder 2005).

Mosses often appear to be completely dead, only to be revived by water. Angela Newton (pers. comm., Bryonet) reported that epiphytic mosses in the lowland tropical rainforests, where mosses may appear dead after severe desiccation, recover quickly with actively growing apical and axillary buds on completely dried out plants and even on plants scorched by fire (see Figure 2)! Leaf and stem tissues from xerophytic mosses can regenerate after as many as 19 years of desiccation (Table 1); some spores remain viable after 70 years (Malta 1921). As surmised by Oliver *et al.* (2005), **desiccation tolerance** appears to be a primitive trait that permitted plants to invade land. **Desiccation tolerance (DT)** is the ability of an organism or structure to tolerate and survive after equilibrating to a relative humidity (RH) of $\leq 50\%$ (Alpert & Oliver 2002;

Koster *et al.* 2010). An understanding of this tolerance in modern bryophytes is fundamental to a general understanding of desiccation tolerance.

Table 1. Records of revival after extended periods in a herbarium (Alpert 1982, *Volk 1984, †Glime pers. obs.).

<i>Anoetangium compactum</i>	19 years
<i>Dicranoweisia cirrata</i>	9 years
<i>Riccia canescens</i>	*7 years
<i>Grimmia elatior</i>	5 years
<i>Oxymitra</i>	*4 years
<i>Anomodon longifolius</i>	2 years
<i>Bryum argenteum</i>	2 years
<i>Orthotrichum rupestre</i>	2 years
<i>Grimmia muehlenbeckii</i>	18 months
<i>Andreaea rothii</i>	13 months
<i>Racomitrium lanuginosum</i>	11 months
<i>Syntrichia ruralis</i>	8 months
<i>Fontinalis flaccida</i>	†3 months

Most people who are not very familiar with bryophyte physiology consider them to be plants that require damp or wet habitats. But compared to **tracheophytes** (non-bryophytes; plants with lignified vascular tissue), bryophytes are the ones adapted to drying conditions (Vitt *et al.* 2014). Even in bryophytes that seem to lack physiological desiccation tolerance, morphological or life history adaptations permit them to survive periodic drought.

Although of the known 21,000 species of bryophytes, only 210 have been documented as desiccation tolerant (Wood 2007), but most have never been tested. In fact, Vitt *et al.* (2014) argue that "many members of both moss and liverwort lineages are desiccation tolerant, allowing them to survive in periodically dry habitats, and that in many of the moss lineages this physiological desiccation tolerance is remarkably high." But among seed plants, fewer than 1% of those tested are desiccation tolerant (Proctor & Pence 2002). Among bryophytes, even the aquatic moss *Fontinalis* has at least some desiccation-tolerant species (Glime 1971). For example, *Fontinalis flaccida* survived and grew after three months of drying on a herbarium sheet (pers. obs.). If one considers the types of microhabitats bryophytes occupy, and lack in most species of any kind of water storage organ, we should expect that most have at least some degree of desiccation tolerance. This notion is further supported by the high survival rate of bryophytes despite a high surface-to-volume ratio that facilitates rapid drying (Proctor *et al.* 2007).

Poikilohydry vs Homoiohydric

The strategy of maintaining internal moisture levels that agree closely with the ambient atmospheric levels is a risky physiological strategy and used mostly by lower plants such as bryophytes. Proctor and Tuba (2002) considered there to be two contrasting strategies for land plants to deal with the irregular supply of water they faced on land and that these relate closely to the matter of scale. Tracheophytes use internal transport to carry water from the soil to the distant canopy (**homoiohydric**). **Poikilohydric** bryophytes (and some tracheophytes), on the other hand, depend on desiccation tolerance, becoming dormant when desiccated. Hence, their cells are either **turgid** (swollen) or desiccated. But **desiccation tolerance** (DT) requires a whole series of adaptations to permit the cell to regain its original state. Essential cell components

and their functional relationships must be preserved through the drying-rewetting cycles presented by their environment. In some cases, this tolerance is induced by water stress. This strategy is particularly beneficial on hard substrates such as rocks and on dry soils in seasonally dry climates where lacking roots that would prevent them from obtaining deeper water in soils. Thus, among tracheophytes, this strategy is most common in warm, semiarid climates, whereas in bryophytes the strategy occurs from polar to tropical regions (Proctor & Tuba 2002; Lakatos 2011). The time scale also differs, with tracheophytes requiring one to several days to resume activity whereas bryophytes (and lichens) typically can become dry and rehydrated within an hour or less (Proctor & Tuba 2002).

In bryophytes, external water conduction seems to be present in all species, but is often supplemented by internal conduction. External conduction is typically diffuse (Proctor & Tuba 2002). The plants can survive drying to the point where there is no liquid phase remaining in the cells and water content may be reduced to only 5-10% dry weight (equilibrium water potential of -100 MPa or less). But when these bryophytes are remoistened, mostly normal metabolism returns within minutes to hours. Those capillary spaces between leaves and branches are able to maintain an external water reservoir that is available to the photosynthesizing cells without blocking the free exchange of gasses (Dilks & Proctor 1979; Proctor & Smith 1995; Zotz *et al.* 2000). This relationship seems to be essential to the functioning of the bryophytes. At the same time, cell water content seems to affect photosynthesis in the same way as that in tracheophytes (Dilks & Proctor 1979; Tuba *et al.* 1996; Proctor 2000).

Some mosses, as for example *Barbula convoluta* (Figure 3), can maintain their turgor for some time after rain ceases, an ability that is made possible by contact or proximity to the moist ground surface (Proctor & Tuba 2002). Typically, water is able to reach distant cells either by travelling externally through capillary spaces or internally through free spaces of the cell walls (Figure 4). To permit photosynthesis by making gas exchange possible, many mosses exhibit a water-repellent cuticle on the younger cell surface, preventing them from trapping water droplets there (Kershaw 1972, 1985; Dilks & Proctor 1979; Proctor 1979b; Nash 1996; Tuba *et al.* 1996; Zotz *et al.* 2000) and thus permitting gas exchange.

Figure 3. *Barbula convoluta*, a moss that maintains turgor for a longer time than most mosses following rain. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission from Russ Kleinman & Karen Blisard.

Figure 4. *Barbula convoluta* leaf cells showing small size and papillose surface that hold water longer than large cells. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission from Russ Kleinman & Karen Blisard.

In some cases, the physiological desiccation tolerance is induced by water stress (Proctor & Tuba 2002). Both **constitutive** (always present; fully desiccation tolerant) and **inducible** [produced when drying conditions occur; previously known as modified desiccation-tolerant (Oliver *et al.* 1998)] desiccation tolerance exist among plants (Stark *et al.* 2013) and these will be discussed in Chapter 7-6 of this volume.

Cellular structure remains intact in desiccation, but upon rapid uptake of water it can be disrupted. However, in bryophytes the cellular integrity returns rapidly. Photosynthetic activity recovers quickly, perhaps due to protection of the chlorophyll (Tuba 1984; 1985). During desiccation, there seems to be no gene activity, but gene expression occurs rapidly following rehydration. Among these activities is the production of a number of proteins called **rehydrins**. These seem to be involved in stabilizing and reconstituting membranes that have been damaged by dehydration. Oliver *et al.* (2005) suggest that vegetative desiccation tolerance, at least in bryophytes, has changed little from early land invaders and may be using a mechanism that was first used in spores.

Even though many bryophytes tolerate high degrees of desiccation (Dilks & Proctor 1974; Nörr 1974; Dhindsa & Bewley 1976), **water content** and availability are important for potential accumulation of photosynthates (Alpert 1979). Patidar (1988) found that in *Asterella angusta* the moisture content is the most important determinant of **thallus** (flattened, nonvascular plant body) size. In *Plagiochasma appendiculatum* (Figure 5), optimum growth occurs at 60% moisture, whereas branching and growth are able to occur from 10-100% moisture (Vishvakarma & Kaul 1988)! *Reboulia hemisphaerica* (Figure 6), on the other hand, requires 70-80% moisture for optimum growth, with growth and branching occurring from 40 to 90%. In other words, no matter how desiccation tolerant a plant might be, it requires water to grow. Representative water contents of bryophyte plants from a wide range of field habitats in the temperate zone, Great Britain, are given in Table 2.

Figure 5. *Plagiochasma appendiculatum*, a liverwort with both branching and growth throughout the range of 10-100% moisture. Photo by Michael Lüth, with permission.

Figure 6. *Reboulia hemisphaerica*, a liverwort in which growth and branching occur in the range of 40-90% moisture. Photo by Jan-Peter Frahm, with permission.

Mosses grown in fully hydrated conditions afforded by saturated air enjoy optimal growth and development (Davy 1927). They exhibit more rapid development, more stem branching, more numerous rhizoids, smaller leaves, and smaller and fewer cells with larger chloroplasts than mosses existing at less than full saturation. Even at the scale of a single boulder, bryophytes distribute themselves according to their ability to achieve photosynthetic gain. When examining bryophytes that occupied various microsites on exposed granitic boulders, Alpert and Oechel (1987) found that those species that occurred in microsites with lower water availability were able to attain maximum net photosynthetic gain at a lower water content and to recover better from prolonged desiccation than those taxa in less **xeric** (dry) microsites. Alpert (1985, 2000) supports the hypothesis that the reason even **xerophytic** mosses (those adapted to dry habitats) are limited in their ecological distribution is that they often are unable to maintain positive carbon balance during repeated cycles of wetting and drying. Alpert and Oechel (1985) demonstrated this with *Grimmia laevigata* (Figure 7-Figure 8), a desiccation-tolerant plant that was unable to maintain this balance under a natural, highly xeric regime of wetting

and drying in certain microhabitats on exposed granitic boulders in California chaparral. Thus, there is an "inherent trade-off between desiccation tolerance and growth rate."

Table 2. Percent water content (compared to dry mass) of bryophytes at full turgor, not including free external water. Values represent means of two measurements. Table based on Dilks and Proctor (1979); those marked with * from Skre *et al.* (1983) include new growth and 1-year-old growth; those with ⁺ from Proctor (2000).

species	water content, % dry mass
Mosses	
<i>Sphagnum subsecundum</i> *	1225
<i>Pilotrichella ampullacea</i> ⁺	>1200
<i>Hookeria lucens</i>	516
<i>Pleurozium schreberi</i> *	485-625
<i>Hylocomium splendens</i> *	485-545
<i>Brachythecium rutabulum</i>	249
<i>Syntrichia intermedia</i>	233
<i>Homalothecium sericeum</i>	223
<i>Pseudoscleropodium purum</i>	207
<i>Thuidium tamariscinum</i>	203
<i>Dicranum majus</i>	202
<i>Leptodon smithii</i>	187
<i>Rhytidiadelphus loreus</i>	165
<i>Pleurochaete squarrosa</i>	165
<i>Neckera complanata</i>	162
<i>Racomitrium lanuginosum</i>	142
<i>Anomodon viticulosus</i>	141
<i>Polytrichum commune</i> *	95-125
Liverworts	
<i>Pellia epiphylla</i>	1180
<i>Conocephalum conicum</i>	871
<i>Porella platyphylla</i>	230
<i>Plagiochila spinulosa</i>	222
<i>Bazzania trilobata</i>	210

Figure 7. *Grimmia laevigata*, a poikilohydric moss, in its dry state. Photo by Michael Lüth, with permission.

Rod Seppelt (Bryonet 27 June 2022) summarized some of the Antarctic studies on the role of cushions in maintaining water content. Microbial associates within the cushion provide the CO₂ (~2000 ppm) needed for photosynthesis while ambient concentrations are only 350-400 ppm. When temperatures drop to below 0°C at night, the cushion likewise drops until the water in the cushion begins to freeze. Then latent heat is able to elevate the cushion temperature to ~2°C. This provides time before partial denaturing of proteins begins.

Water content in a bryophyte ranges widely throughout the year. For example, Klepper (1963) measured 23.8-258% in *Dicranum scoparium* (Figure 9), Romose (1940) 10-950% in *Homalothecium sericeum* (Figure 10), Morton (1977) 19-214% in *Pseudoscleropodium purum* (Figure 11), and 58-307% in *Dicranum bonjeanii* (Figure 12). Whereas many mosses benefit from high water content, too much water is not good for photosynthesis. Water on the surface blocks CO₂, and most likely high internal water content also interferes with physiological processes (Proctor 2000). Dilks and Proctor (1979) found optima as low as 200% water content and as high as 1500% among the same bryophytes shown in Table 2. Respiration seems to peak around 200% for most of these taxa.

Figure 9. *Dicranum scoparium*, a moss with measured water content ranging 23.8-258%. Photo by Janice Glime.

Richardson (1981) divides mosses into three water strategies by habitat: **aquatic**, **mesophytic** (living in continually moist habitats), and **poikilohydric** (organism dries as its habitat dries and resumes normal metabolic activity after rehydration; Figure 8). Unlike most other plants, water content of predominantly poikilohydric bryophyte species is highly related to environmental conditions and weakly regulated by their internal and morphological structures. This strategy permits them to colonize such xeric environments as boulders and tree trunks. In these environments, mosses enjoy release from competition by higher plants, but must still survive the low light intensity created by the trees above.

Some bryophytes do appear to be able to survive in absence of precipitation. In caves in Poland, only 18.1% of the species occurred in very wet places or where there was dripping water, whereas in places that were continuously dry(!), 25% occurred (Jedrzejski & Ziobor 1992). Certainly in those dry places atmospheric humidity must have provided the needed water for these very **hygroscopic** (readily absorbing water from air), **ectohydric** (relying mainly on water transport along external surface of plant by capillarity) bryophytes. Shaun Russell (pers. comm.) found that in montane areas of Africa with virtually no rainfall, fog collected on bryophyte surfaces, providing sufficient water for them to survive. A similar phenomenon occurs in geothermal areas (Figure 13).

Figure 13. *Campylopus holomitrius* with water droplets captured from the "steam" emitted by geothermal vents in New Zealand. Photo by Janice Glime.

The drought-tolerant *Pseudocrossidium crinitum* (= *Barbula aurea*; Figure 14) seems to have compensated for its low water availability by having relatively low levels of light compensation and saturation responses for photosynthesis (Rundel & Lange 1980). Such low levels would permit the moss to carry out photosynthesis early in the morning when dew is available and before high evaporation stress occurs. These aerial sources of water are of little use to tracheophytes that must take water in by their roots, not their leaves.

Figure 14. *Pseudocrossidium crinitum*, a xerophyte with low light compensation and saturation levels. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

As one would expect, degree of drought tolerance is generally greatest in plants from dry habitats (Clausen 1952, 1964; Johnson & Kokila 1970; Dilks & Proctor 1974). Seki and Yamaguchi (1985) suggest that on some islands with strong summer winds, Shannon diversity decreases as saturation deficits increase. Richardson (1981) claims that aquatic mosses and those that grow in humid forests are damaged quickly by drought. But even such high humidity plants as *Hookeria lucens* (Figure 15) are able to survive desiccation for days (Horst Tremp, Bryonet).

Figure 15. *Hookeria lucens*, a drought-intolerant moss. Photo by Michael Lüth, with permission.

Glime (1971) found that two aquatic mosses (*Fontinalis* spp.; Figure 16) were able to survive on the stream bank out of water (Figure 17) for up to one year and still grow when rehydrated. However, those dried in the laboratory were apparently dead after only 55 hours, perhaps due to rapid drying. Steere (1976) found that *F. squamosa* (Figure 18) from Alaska could not survive a week of air drying. One reason for apparent differences here is that it is difficult to determine when a moss is dead, and even though all leaves may be dead, the stem may still harbor life. *Fontinalis* is subject to annual emergence when stream level drops (Figure 16), and perhaps slow drying on the stream bank permitted it to become dormant and to preserve sufficient energy to repair its membranes upon rehydration. The rapid drying of a laboratory, with unnaturally low humidity and no acclimation period, may have prevented the necessary physiological changes that could permit it to survive. Oliver and Bewley (1984) have demonstrated that it takes longer for the cellular physiology to return to normal in a rapidly dried bryophyte than in a slowly dried one.

Figure 16. *Fontinalis dalecarlica* and *F. novae-angliae* above water, in Fox Run, New Hampshire, USA. When these mosses were placed away from the stream bed for up to one year, at least some of them survived from all re-submersion dates (Glime & Carr 1974). Photo by Janice Glime.

Figure 17. *Fontinalis antipyretica* in dry stream. Photo by Janice Glime.

Figure 18. *Fontinalis squamosa* on rock above water near Swallow Falls, Wales. Photo by Janice Glime.

A similar pattern of submersion and desiccation is endured by *Hydropogon fontinaloides* in the Amazon basin (Mägdefrau 1973). It hangs from trees during the dry season, but during the wet season it floats in water. The behavior of *Cratoneuron filicinum* (mistakenly published as *Hygrohypnum luridum*; Figure 19), typically a stream margin species, may explain the lab results. This moss was unable to synthesize protein when rehydrated after it was dried quickly over silica gel for one hour (Bewley 1974). However, it was able to tolerate drying down to 33% of its fresh mass when dried slowly, and slow drying for 5 hours to 66% of its fresh mass had no detrimental effects on protein synthesis.

Just what endows bryophytes with the ability to inhabit arid microsites that are totally inhospitable for tracheophytes? As you can see from the foregoing examples, we can divide these adaptations into anatomical/structural, growth/life form, and physiological adaptations.

Life cycle adaptations, a major means for an immobile organism to cope with changing weather and seasons, have been addressed in Chapter 4-6. Schofield (1981) points out that spore germination patterns, protonemal structure, life span, and methods of propagation are all related to the habitat characteristics. Water availability is important to all of these aspects. Multicellular spores are more common in habitats where the spores are subject to desiccation. Protonematal specialization is common in deeply shaded habitats, whereas in mesic habitats the protonemal cells are elongate, *i.e.*, having typical protonematal structure. In the leafy **gametophore** (upright leafy plant), characters such as leaf shape, leaf arrangement and orientation, leaf anatomy, stem cortical cells, hydroids, leptoids, branch arrangement, presence of rhizoids, and presence of paraphyllia all affect water movement. Such small features as surface ornamentation of leaves, stems, and rhizoids affect water absorption and retention and influence habitat specificity.

Role in Ecosystem Water Cycle

In areas where bryophytes dominate the forest floor, their role in the water cycle can be extraordinary. This is especially true where permafrost prevails (Henry Santeford, pers. comm.). Bryophytes hold melt water until they become saturated. At that point in time, all new melt water is suddenly released and can cause flooding. It is important in some areas to be able to predict this flooding regime for the safety of both animals and humans. Hence, we need to understand both holding capacity and evaporation rates of water from the bryophytes.

Penman (1948) helps us to understand evaporation as it might apply to bryophytes. Although he compared evaporation from bare soil, grass, and open water, the principles apply. He suggests that we need to combine two theoretical approaches to evaporation, an aerodynamic basin in which evaporation is due to turbulent transport of vapor by eddy diffusion, and an energy basis in which evaporation is a way of degrading incoming radiation. This approach eliminates the problem of measuring surface temperature and overcomes the problem of estimating effects as if one is measuring evaporation from a lake surface. Using this method, supported by empirical data, indicates that evaporation from grass follows a seasonal cycle relative to that evaporating from open water, a phenomenon Penman attributes to the change in photoperiod.

In other circumstances, bryophytes may prevent the underlying roots from getting water (Beth Scafione, unpubl. data). If there is a quick rain shower, bryophytes act as sponges, trapping the water before it reaches the soil. On the other hand, bryophytes can reduce evaporation of water from the soil following heavy rain, thus permitting the roots to grow for longer periods of time.

Structural Adaptations

When I moved to the Upper Peninsula of Michigan, I was struck by the fact that only red oaks were able to live here. A simple difference in one structure made their survival possible in a cold region with long winters – narrow vessels. Large vessels in other North American species cavitate and the water is unable to reconnect on an appropriate time schedule that permits the oaks to complete their life cycle and gain sufficient energy to continue the establishment of the species.

Watson (1919) warned of the difficulty in dealing with bryophyte identification because of the entirely different appearance they can present in the wet vs dry state. The bryologist must know them in both conditions. I once spent half an hour in an unfamiliar locality trying to identify *Hedwigia ciliata* because I had only seen it dry (Figure 20-Figure 22) and these plants were fully hydrated (Figure 23-Figure 24). The plant may even appear to be dead during drought, only to revive quickly when moistened, resuming its normal functions.

Many studies have demonstrated the importance of anatomy in determining the mechanical properties of plant tissues, including bryophytes (Héban 1977; Rossi *et al.* 1998; Niklas *et al.* 2006; Frenzke *et al.* 2011; Atala & Alfaro 2012; Vincent 2012). Getting water and nutrients into and out of a plant is size dependent. Adaptations vary even within a species due to its plasticity in responding to the environment (Sarafis 1971; Buryová & Shaw 2005). As discussed by Raven and Handley (1987), for plankton organisms, any size above ~50 μm diameter restricts the growth rate because of the greater restriction of uptake by the boundary layer. Thus, for macroscopic aquatic photosynthetic organisms, even favorable velocity of water and plant morphology cannot reduce the boundary layer restrictions on nutrient uptake enough to compensate for the decrease in uptake rate. Movement of nutrients within the plant involves **cyclosis** (cytoplasmic streaming) in algae, phloem and xylem in tracheophytes, and in bryophytes it often involves both cyclosis and transport through leptoids and hydroids.

Raven and Handley (1987) consider that the energy cost for transporting nutrients would be higher for those organisms using cyclosis than for those using vascular tissue. They also consider that there is a penalty for height in tracheophytes, causing reduced specific growth rate under both resource-saturated and resource-limited conditions. Coupled with this penalty is reduced resource use efficiency with increased plant height. The reason for these penalties is the need for greater supporting tissue and a greater percentage of the tissue dedicated to vascular tissue. But there is also some compensation. Taller plants can capture more light energy and reach more nutrients and water in the soil. Smaller plants, on the other hand, have a potentially higher specific growth rate under these same resource-limited or resource-saturated conditions. The lack of need for supporting structures, requiring breadth, permits smaller plants such as bryophytes to have all or nearly all of their tissues as photosynthetic tissues. Raven and Handley left us with the challenge to discover the differences in transport needs and solutions resulting from these different morphologies.

In the desert moss *Syntrichia caninervis* (Figure 25), conservation of moisture is paramount, surpassed only by the need for rapid uptake. It can therefore serve as a model for adaptations against desiccation. Its growth form is tufted and its leaves are folded upward and twisted around the stem when dry (Figure 26 (Zheng *et al.* 2010)). The leaf cells are endowed on both the upper and lower surfaces with C-shaped papillae that may have a role in deflecting sunlight to protect the DNA and chlorophyll during dry periods or to reduce the temperature. The leaf costa extends beyond the leaf to form an awn that has forked teeth and is able to capture moisture from the atmosphere. The protonemal cells are small and have thick walls; their cytoplasm is highly concentrated with only a small vacuole.

Thallose Liverworts

The structure of most thallose liverworts is so different from that of mosses or leafy liverworts that their water relations warrant separate consideration. They are adapted for predominantly ventral uptake. Thallose liverworts like *Conocephalum conicum* (Figure 27) and *Cyathodium cavernarum* (Figure 28) use ventral appendages (**scales**; Figure 27) to provide capillary spaces that conduct water externally on the underside of the thallus. Marchantialian species use specialized capillary systems on the ventral surface of the thallus to conduct water in either direction. Cell walls of the scales contain **tannins** (McConaha 1939), perhaps acting as an antibiotic.

Figure 28. Scales of *Cyathodium cavernarum*. Photo courtesy of Noris Salazar Allen.

Scales

Exposed surfaces of scales and thallus are often reddish-purple due to the flavonoid pigment **phlobaphene**, formed by oxidation of tannic compounds (McConaha 1939), but the role of phlobaphene is not clear. It is possibly a defense against would-be toxins from tannic compounds that contact the ventral surface. (There is evidence that tannins are toxic to bryophytes, not within their cell walls, but when they are able to act on cell constituents.) Since all these ventral surfaces are wettable, these cells are more susceptible to damage by such toxins.

Kürschner (2004) surmised that the anthocyanin pigments in ventral scales (Figure 27) protected the ventral surface from the sun when the thallus was rolled up, as it typically does in many species of *Riccia* (Figure 29-Figure 31). Furthermore, even hyaline scales (Figure 32) of *Riccia* and *Oxymitra* (Figure 33) can reduce desiccation. Some species, especially of *Riccia*, sink into the soil surface as the soil dries, reappearing only after precipitation or heavy dew.

This high degree of wettability provides a greater possibility for water entry in thallose forms. For example, in *Marchantia* (Figure 34-Figure 35), water is conducted along the midrib as well as in interstitial spaces between the blade and scales, distributing water throughout the surface of the thallus. Water movement in *Marchantia* is relatively slow, at 0.4 mm per sec, improving slightly in *Lunularia* (Figure 53-Figure 54) and *Reboulia* (Figure 6), to approximately 0.5 mm per sec, despite their less highly developed capillary systems. However, McConaha (1939) found that movement from base to apex in *Conocephalum conicum* s.l. (probably *C. salebrosum*; Figure 36) generally takes only about 20-30 seconds, roughly 1 mm per sec. Despite its slowness, McConaha found this external movement to be much faster than would be possible by internal conduction.

Rhizoids

Ventral structures seem to be important in this group. In marchantialian liverworts, two types of rhizoids (Figure 37-Figure 38) provide somewhat different functions. The smooth-walled rhizoids (Figure 37-Figure 38) are alive (Duckett & Ligrone 2003) and emerge from beneath the ventral scales (Figure 39), providing contact with the substrate, whereas the **tuberculate** (pegged) rhizoids (Figure 38) are dead (Duckett & Ligrone 2003) and form a capillary system parallel to the thallus beneath each scale (McConaha 1941). The pegged rhizoids begin growth at

right angles to the thallus but change their orientation to follow that of the scales. The pegs, extending into the pegged rhizoid cell, prevent the collapse of the cell when dehydrated, thus maintaining its capillary role (Duckett & Ligrone 2003). When the **archegoniophore** (stalk supporting female reproductive organs) forms, the pegged rhizoids are wrapped within the archegoniophore by the folded thallus (Figure 40) and function in internal water conduction (Duckett & Ligrone 2003). The presence of the pegs also prevents the collapse of this stalk when the thalli dehydrate (Duckett & Ligrone 2003). These rhizoids have an outer layer of pectic material (like that of apples).

Figure 40. *Marchantia polymorpha* archegoniophore showing white rhizoids that are incompletely enclosed by the stalk of the archegoniophore. Photo by George Shepherd, through Creative Commons.

Previously treated mostly as a taxonomic anomaly, it appears that these two types of rhizoids have distinctly different functions (Duckett *et al.* 2013). The smooth rhizoids are alive, functioning in nutrition, anchorage, and as entry locations and conduits for fungal symbionts. Their role for fungal entry does indeed require that these rhizoids be alive. The pegged rhizoids, on the other hand, are dead at maturity, a condition first noted by Kamerling (1897), and function as water conduits through these empty tubes. Kny (1890) was the first to suggest that pegs prevent the rhizoid walls from collapse with water loss. Duckett *et al.* (2013), however, were the first to test this hypothesis. The pegs, along with elasticity, seem to provide the ability of the rhizoids to maintain their functional integrity by preventing their collapse when they are dry. This ability is essential to their function in conduction, a role demonstrated by Bowen (1935) and others (McConaha 1939, 1941), who used dyes to show conduction by capillarity and transpiration. The famous German morphologist Goebel (1905) observed that it is the liverworts with high transpiration rates that also have the most highly developed pegged rhizoids. This is in contrast with those of **hygrophilous** (water-loving) taxa such as *Dumortiera* (Figure 41-Figure 42) and *Cyathodium* (Figure 43).

Figure 41. *Dumortiera hirsuta*, a hygrophilous species showing fringe of hairs on thallus and archegonial heads, but lacking the pegged rhizoids and scales of the dry habitat species. Photo by Jan-Peter Frahm, with permission.

Figure 43. *Cyathodium tuberosum*, a simple thallus lacking the complex scales and two types of rhizoids. Photo by Jan-Peter Frahm, with permission.

Among the leafy liverworts, thallose liverworts, and ferns, living rhizoids die and collapse upon dehydration, an irreversible response (Pressel 2007). Duckett *et al.* (2013) concluded that smooth rhizoids of liverworts grow at the apex, a character they share with root hairs, fungal hyphae, and moss protonemata. Furthermore, the smooth rhizoids exhibit considerable endoreduplication of Golgi bodies similar to that in moss caulonemata. They reach lengths that commonly are greater than 20 mm, sometimes reaching 30 mm in *Marchantia polymorpha* (Figure 35), making them the longest cells in liverworts. Duckett and coworkers suggest that this combination of characters may explain their inability to regenerate when damaged (Pressel *et al.* 2008a; Duckett *et al.* 2013).

On the other hand, rhizoids of mosses (and protonemata) can recover from desiccation except at the apical cell (Pressel 2007; Rowntree *et al.* 2007; Pressel *et al.* 2008b). The pegged rhizoids furthermore are devoid of air bubbles when desiccated, a further indication that they are highly resistant to **cavitation** (formation of a space; air blockage, as when water column in xylem becomes

separated by air; collapse of cells), as are the hydroids of mosses (Ligrone *et al.* 2000).

Duckett *et al.* (2013) identified pegged rhizoids in 26 species of thallose liverworts and absence in 5. They compared the diameters of the smooth and pegged rhizoids and measured the time required for dyes to reach the archegonial heads in the taxa compared to time required in several mosses. The rates ranged 30-150 mm h⁻¹ in the thallose liverworts, 28-14 mm h⁻¹ in mosses, and 127-141 mm h⁻¹ in ferns.

Duckett *et al.* (2013) point out that these pegged rhizoids fulfill the three criteria for conduction defined by Raven (1993): dead at maturity, specialized walls, preferential conduction of water. Duckett and coworkers added a fourth criterion, the ability to maintain functional integrity through periods of dehydration, as in moss hydroids (Ligrone *et al.* 2000). This maintenance of functional integrity becomes a problem, because unlike trees and stems, there is no adjacent cell to help in rehydration.

Xerophytic liverworts such as *Riccia* (Figure 44), *Reboulia* (Figure 6), *Targionia* (Figure 45), *Asterella* (Figure 46), and *Lunularia* (Figure 53-Figure 54) have both **tuberculate** (pegged) and smooth rhizoids, scale leaves, and well-defined assimilatory and storage zones, whereas moisture-loving *Dumortiera* (Figure 41), *Cyathodium* (Figure 43), *Pallavicinia* (Figure 47) (Daniels 1998), *Monoclea* (Figure 48), *Neohodgsonia* (Figure 49), and some aquatic *Riccia* species (Figure 50-Figure 51) (Duckett & Ligrone 2003) lack these complex structures. Even in *Marchantia* (Figure 34-Figure 35), with its strong midrib, water moves externally along the midrib and in the spaces between the scales, providing a film of water throughout the thallus (McConaha 1941).

Figure 51. Cross section of thallus of *Riccia fluitans*, an aquatic species with no rhizoids or scales; note the large air spaces for gas exchange and flotation. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

In *Preissia* (Figure 39), it appears that the numerous rhizoids compensate for a less compact arrangement of the capillary system. Volk (1984) found that *Riccia* (Figure 52), a common inhabitant of ephemeral habitats such as flood plains, absorbs water by capillary action among the rhizoids and the lower surface of the thallus. The thallus rolls or folds when it is dry, thus exposing the rhizoids, scales, and/or cilia. These serve both to absorb water and to provide a reflective surface that protects the chlorophyllous (photosynthetic) cells of the thallus. In others, a crystalloid crust serves a similar function of reflectance.

Fungal Partners

Despite their roles in anchorage (smooth rhizoids) and conduction (pegged rhizoids), it seems that smooth rhizoids have a major role in the **endosymbiosis** (internal partnership) of fungi (Pressel *et al.* 2010, 2012; Duckett *et al.* 2013). Our understanding of the value of this partnership is meager. In other plants, fungi serve to increase absorptive surface area and often tap into the roots of a tracheophyte, transferring carbohydrates from plants that reach the canopy to plants that are in the low light beneath them. Such a role remains unknown in the bryophytes, but I am confident that we shall discover that at least some species have this advantage. After all, these partners have been around much longer than the flowering plants, known as **hemiparasites**, that have succeeded in developing this life style. In the leafy liverworts, infections occur exclusively through rhizoids with the Ascomycete *Rhizoscyphus ericae* as partner (Read *et al.* 2000; Pressel *et al.* 2008a, c). This is a widespread fungus that lacks host specificity. Fungal partnerships are discussed in more detail below under "Mosses and Leafy Liverworts."

Main Thallus Structure

Midribs: Seeing the midribs in valleys (Figure 44, Figure 52) makes me think that water is directed from the thallus surface to the midrib in some species. I have to wonder if water is absorbed more easily there. Once the water enters the midrib cells, it can be carried to more distant parts of the thallus more quickly than by travelling through other, shorter thallus cells. It has fewer cell walls to cross.

Figure 52. *Riccia nigrella* showing valleys with midribs that could be used to direct water into the thallus. These valleys facilitate folding when dry. Photo by Des Callaghan, with permission.

The rib of *Lunularia cruciata* (Figure 53-Figure 54) has parenchymatous cells in which plasmodesmata-derived pores are grouped in small, sparse fields, particularly on transverse oblique walls (Giordano *et al.* 1989). This suggests that the rib cells may be able to transport water and other substances through the ends of cells. These longer cells should, then, move water faster than crossing the many walls of the hyaline parenchyma (Figure 55). Giordano and coworkers suggested that the reticulate cells may serve a water-holding role and facilitate lateral distribution by both **symplastic** (within protoplasm) and

apoplastic (outside the protoplasm, in intercellular spaces) conduction of substances arriving by way of the rib. They suggest this mechanism may be present in all members of **Marchantiales** with this thallus construction.

Figure 55. Cross section of *Marchantia* thallus, showing hyaline parenchyma and two pores. Photo from Department of Botany Teaching Collection, Michigan State University, East Lansing, MI, USA.

Rolling Thallus: Midribs may also facilitate rolling of the thallus by creating a crease through the middle of the plant (compare Figure 52 to Figure 56). Rolling conserves water, but at the same time it exposes the ventral surface where scales help to conserve water (Figure 56). Such rolling is common in species of *Riccia* (Figure 56, Figure 84-Figure 85), often supplemented with hairs that cover the thallus.

Figure 56. *Riccia nigrella* with dry thallus folded at the midrib. Compare this to Figure 52. Photo by Michael Lüth, with permission.

Internal Conduction: The liverwort *Lunularia cruciata* (Figure 53-Figure 54) may exemplify a means for water movement between cells in thallose liverworts (Giordano *et al.* 1989). The thallus has **reticulate** (like network) **hyaline** (colorless) **parenchyma** (thin-walled) cells (Figure 54) with between wall thickenings, large **primary pit fields** (thin area in walls of many cells in which one or more pits usually develop) with numerous pores derived from **plasmodesmata** (narrow threads of cytoplasm that pass through cell walls of adjacent cells and allow communication between cells) on unthickened areas of walls.

Spongy Thallus

The spongy thallus of *Riccia cavernosa* (Figure 57) looks like it should have an important adaptive value. The basal layer gives rise to a layer of irregular vertical column of chlorophyllose cells overtopped by colorless epidermal cells (*Riccia cavernosa* 2012). While these might seem to have functions similar to those of *Exormotheca* (Figure 59-Figure 61), instead some of these epidermal and chlorophyllose cells collapse, creating large air spaces at several levels in the tissue of the thallus. The light that reflects from these cavities has a glistening appearance. But does this sequence of events provide any advantage to the plant? At first glance, it looks very much like a sponge, but at a much smaller scale.

Figure 57. *Riccia cavernosa* showing spongy thallus. Photo by Richard Orr, with permission.

The basal pad of isodiametric cells gives rise to a layer of irregular vertical columns of chloroplast-containing cells, topped by colorless oval epidermal cells (*Riccia cavernosa* 2012). But early in development, large air spaces develop at several levels in this tissue due to the collapse of some of the epidermal and chlorenchyma cells. The light reflecting inside these cavities gives the thallus its characteristic glistening appearance.

Ballooning of Epidermis

In some species of *Riccia* (Figure 29-Figure 32) the epidermal cells are balloon-like (Figure 58) and may contribute to protection from desiccation (Kürschner 2004). However, I wonder if those cells don't provide a greater role in focussing the light into the thallus to the chlorophyllous cells when the thallus is hydrated. Kürschner suggested that the chimney-like, hyaline air chambers of *Exormotheca* (Figure 59-Figure 61) may also have a function in protecting the underlying tissue during dehydration.

Cuticle

For many years we considered the cuticle to be absent in bryophytes, with scattered references referring to them, but with no definitive data on their surface chemistry. However, not only are waxy cuticles present, but waxes are present on the leaves and thalli, albeit in less noticeable quantity than in tracheophytes. In fact, Brockington *et al.* (2013) considered the cuticle in the thallose liverwort *Marchantia polymorpha* (Figure 34) to be "an overlooked innovation in land plants."

Knowing that *Marchantia polymorpha* (Figure 34-Figure 35) has a cuticle, one should not be surprised that the shiny thallose liverwort *Monoclea gottschei* (Figure 48) and the hornwort *Notothylas orbicularis* (Figure 62) have an **osmiophilic layer** (refers to lipid-containing bodies; a cuticle) with structural resemblance to that of early developmental stage tracheophyte cuticles (Cook & Graham 1998).

Figure 62. *Notothylas orbicularis*, a species with a demonstrated osmiophilic layer, *i.e.* cuticle. Photo by Michael Lüth, with permission.

What emerged as more interesting in this study is that not all of these bryophyte versions are created equal. In the liverwort *Monoclea gottschei* (Figure 48) the layer is nodular, in the hornwort *Notothylas orbicularis* (Figure 62) it can be either nodular or sheetlike, and in *Sphagnum fimbriatum* (Figure 63) it is sheetlike with regular ridges that run parallel to the edges of the "thalli" (Cook & Graham 1998). It appears that cuticle is ancient, and Cook and Graham suggest that it may have arisen before the charophycean algae and bryophytes diverged from their common ancestor.

Figure 63. *Sphagnum fimbriatum*, a species with a cuticle. Photo by Michael Lüth, with permission.

The thallose liverwort *Plagiochasma rupestre* (Figure 64) has a non-wettable thallus endowed with hydrophobic wax globules, preventing it from absorbing water through its surface (Kürschner 2004). Instead, it uses the pegged rhizoids for water uptake, a phenomenon that may be common to all members of **Marchantiales**. This dorsal surface wax may have an important role in preventing water logging in the underlying air chambers.

Figure 64. *Plagiochasma rupestre* thallus showing smooth rhizoids on edges and waxy surface. Photo by Hugues Tinguy, with permission.

The presence of a cuticle on the upper surface of a thallose liverwort raises the question of water absorption in these species. But based on the foregoing discussions of scales and rhizoids, we know that it occurs predominantly through the ventral surface, facilitated by the scales and rhizoids. Presumably there is no cuticle on that surface, but that does not yet seem to have been demonstrated.

In the **Polytrichaceae**, waxes may serve a different function. Rather than keeping water in, the leaves of these species must keep water out to permit maximum photosynthesis (Figure 65) (Clayton-Greene *et al.* 1985). Their lamellae provide extra photosynthetic tissue, but water can become trapped there due to the capillary spaces. This protection from water is further enhanced by the rolled margins (Figure 66) of species like *Polytrichum juniperinum* (Figure 67).

Pores

The wonderful ventral efficiency of rhizoids and scales is often challenged by a dorsal (upper) surface that does little to conserve water. In fact, this dorsal surface water loss may facilitate the movement of water and nutrients through the plant, as it does in leafy tracheophytes. The pores on the dorsal surface function much as do the stomata of tracheophyte leaves in losing water (Figure 55, Figure 73). Maier-Maercker (1982) found that *Conocephalum conicum* (Figure 36) loses water through transpiration from these dorsal thallus pores (Figure 68), accumulating radioactively labelled ions in the cells surrounding the air pores.

Figure 68. *Conocephalum conicum* pore section. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

The single-layered leaves of leafy liverworts and most mosses preclude the presence of stomata there as they would provide only a hole through the leaf, hardly a useful character. Even multicellular layers of moss leaves have no use for stomata because there is no chamber where the gases may gather. But thallose liverworts meet those two requisites – multiple cell layers (Figure 69) and chambers internally (Figure 70). Furthermore, as mentioned above for *Marchantia polymorpha* (Figure 34), the thallus has a cuticle that can at least to some degree repel water. Hence we might presume that it likewise is somewhat resistant to gas exchange, creating a problem for photosynthesis.

Raven (2002) provided evidence that stomata evolved from pores of an epidermis over plant organs at least three cell layers thick, with intercellular gas chambers, and with a cuticle. In this anatomical arrangement, the presence of pores most likely confers an adaptive advantage for photosynthesis.

Figure 69. *Conocephalum conicum* photosynthetic cells under epidermis, showing thallus that is more than three cell layers thick. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Figure 70. *Marchantia polymorpha* thallus pore in longitudinal section, showing cuticular ridge. Cells stained with purple are photosynthetic cells. Note the chamber beneath the pore. Photo by George Shepherd, through Creative Commons.

In some cases, thalloid liverworts seem to lose great quantities of water, 2-3 times that of leaves of the weeping birch tree *Betula pendula* (McConaha 1941). Under extreme conditions, they transpire equivalent to their total content of water in an hour. One reason for this rapid transpiration rate is the areolation of the thallus that creates a large surface area where water can be lost. The pores in these thalli (Figure 71), permitting contact between outside air and internal moisture, have only limited ability to close, thus being a major source of water loss. McConaha (1941) claims that the ventral specializations compensate for the losses from dorsal areolation and pores. Proctor (1980) found that these areolate thalli have internal resistances similar to those of mesophytic leaves of flowering plants (Proctor 1980). As in the flowering plants, the water loss is correlated with pore size and density.

Figure 71. *Marchantia chenopoda* pores showing rim of cuticle projecting into the pore opening. The polygons outline the internal chambers that create the areolation. Photo by George Shepherd, through Creative Commons.

But the photosynthetic cells project into these chambers beneath the pores (Figure 70), and flooded cells cannot exchange gases freely. It should be no surprise then that the openings themselves prevent the entrance of water into the chamber. Their small size (Figure 71) contributes to this. In the absence of a wetting agent, the cohesive forces of water make the aggregation of water molecules too large to enter the holes. This smallness of the hole is further enhanced by the presence of a **cuticular ridge** (Figure 71-Figure 74) that not only narrows the entrance, but that also repels the water, *i.e.* is **hydrophobic**.

Figure 72. *Marchantia polymorpha* pore in longitudinal section. Photo by Walter Obermayer, with permission.

Figure 74. *Conocephalum conicum* pore longitudinal section showing the cuticular ridge. Photo by Ralf Wagner at <www.dr-ralf-wagner.de>, with permission.

Schönherr and Ziegler (1975) found that of the fourteen thallose liverwort species they studied, twelve of them have such **hydrophobic** (repelling water) ridges, and that **cutin** is present in these ridges. Furthermore, the researchers considered the pores in these species to be "perfect" in keeping water out of the thallus. *Plagiochasma rupestre* (Figure 75) and *P. peruvianum*, on the other hand, lack such ridges and liquids are able to enter the thallus through the pores. While the waxes and small size of the holes keep water out, the water in vapor form within the thallus is able to escape through the pores, along with oxygen, while CO₂ enters. Therefore, the openings must maximize carbon gain per unit water loss (Raven 2002).

Figure 75. *Plagiochasma rupestre*, a thallose liverwort with no cuticular ridge on its pores, but with a waxy cuticle on the thallus. Photo by Michael Lüth, with permission.

While these pores are an advantage for a hydrated, photosynthesizing thallus, they are a liability for a drying thallus due to the loss of water vapor. But at least some of

the liverworts seem to be able to partially control the opening. This is accomplished by curving of the stack of cells surrounding the opening, creating partial closure. In *Preissia* (Figure 76-Figure 77, Figure 39), the barrel-shaped pores (Figure 77) change shape to accomplish control of water loss (Lepp 2008). When turgid with water, the cells at the bottom of the barrel keep the pore open, but when the conditions are dry, the cells lose their turgor and collapse, narrowing the opening at the bottom of this barrel. Those in *Marchantia* (Figure 70-Figure 72) behave similarly (Raven *et al.* 2005). A further aid, presumably, is the ability to fold the upper side of the thallus inward, as discussed above, creating a less exposed surface and slowing the rate of water loss.

Archegoniophores and Antheridiophores

In thallose liverworts, the horizontal orientation cannot serve as a model for water movement in the vertical **archegoniophore**. As determined by Duckett *et al.* (2013), the archegoniophore has more efficient water movement than the stems of mosses. They attribute this to the efficiency of movement through the rhizoids and capillary spaces among them, as well as the hydrophobic nature of the thallus surface surrounding these rhizoids (Figure 78).

Figure 78. *Marchantia polymorpha* antheridial head showing location of rhizoids within the antheridiophore. Photo from Botany website of the University of British Columbia, BC, Canada, with permission.

The importance of this rhizoid-thallus combination for the archegoniophore is suggested by comparing its response to drought with that in mosses. For example, *Marchantia* (Figure 79) archegoniophores and heads can remain fully hydrated for several hours in full sunlight at 20-30°C while the shoots of neighboring *Polytrichum commune* (Figure 80) with their bases in standing water become wilted and must have added rainwater to recover (Duckett *et al.* 2013), suggesting an efficient system of transport in the archegoniophore.

Figure 79. *Marchantia polymorpha* archegoniophore and archegonial head. Note rhizoids along stalk (archegoniophore) where they emerge from the folded thallus that makes the stalk. Photo by George Shepherd, through Creative Commons.

Figure 80. *Polytrichum commune*, a moss that wilts in full sun despite its wet substrate and colonial habit. Photo by Michael Lüth, with permission.

Duckett *et al.* (2013) suggest that the length of the archegoniophore is limited to a maximum of 7-10 cm (in *Conocephalum*; Figure 81) because of the problems of air bubbles in the mucilaginous matrix surrounding the pegged rhizoids in the grooves of the archegoniophore, a condition analogous to an embolism in the vessels of tracheophytes (see Canny 2001 a, b).

Figure 81. *Conocephalum conicum* with tall archegoniophore. Photo by Adolf Ceska, with permission.

Antheridiophores provide yet a different mechanism (Duckett & Pressel 2009). Present only in the genus *Marchantia*, they present an antheridial head (Figure 82) on a stalk that is much shorter than that of the mature archegoniophore, rarely exceeding 30 mm. Rather than being hydrophobic, the heads are highly hydrophilic and absorb raindrops much like a sponge. Whereas upward flow occurs in the stalk during dry periods, downward flow carries the motile sperm toward the archegonia on immature (shorter) archegoniophores (Figure 83) during rainfall.

Figure 82. *Marchantia polymorpha* with antheridial heads where water is absorbed like a sponge. Photo by Rudolf Macek, with permission.

Dormancy

Volk (1984) found that when *Riccia* (Figure 84-Figure 85) has less than 150 mm of rainfall per year, it requires other means to survive, and it seems that dehydration/dormancy is the solution (Figure 84-Figure 85). Some thallose *Riccia* species are able to survive up to 7 years in this dehydrated state, enduring temperatures up to 80°C. The annual species compensate for this water loss by producing huge numbers of spores, taking advantage of their ornamentation for distribution by animals.

Mosses and Leafy Liverworts

We typically think first about structural adaptations for water retention, so we will start there. Sarafis (1971) considered that *Polytrichum commune* (Figure 80) had four ways of controlling water loss:

1. Community level – gregariousness
2. Plant level – leaf density & size, plant height
3. Organ level – leaf movement and inrolling
4. Molecular level – wax on leaf surface

These all relate to structure, but internal structure and cellular level physiology are additionally important.

Vitt *et al.* (2014) consider the avoidance strategies of mosses to differ somewhat from those of liverworts and hornworts. Leaf arrangement has greater variation in mosses. Xerophytic leaves and stems often possess large **trigones** (thickenings in corners of cell walls; Figure 86) and nodular intermediate thickenings on interior walls, forming branched **vittae** (like costa, but 1 cell thick) in the lamina of leaves such as those of *Herbertus aduncus* (Figure 87-Figure 88) that enhance water uptake and storage, often with protruding **papillae** on their dorsally exposed, superficial walls. Xerophytic stem cells are thick-walled. These wall adaptations consist mostly of hemicelluloses, pectins, and cellulose, substances that would facilitate apoplastic water uptake, movement, and retention (Proctor 1979a). Water spreads over the leaves that have papillae, filling the spaces next to the leaf surface, but leaving the tips of the papillae dry to facilitate gas exchange. In taxa from moist but intermittently dry habitats, the outer cell walls are typically exposed but water-repellent. In *Nowellia* (Figure 89), *Marsupella* (Figure 90), and *Solenostoma* (Figure 91) with concave, overlapping leaves, surface tension may account for this repellent property (Proctor, 2009), but in other cases, thin coats of epicuticular waxes are hydrophobic (Duckett & Soni 1972; Heinrichs *et al.* 2000). And what is the function of the pore-like connections between cells (Figure 92) in more mesic mosses like *Dicranum scoparium*?

Figure 92. *Dicranum scoparium* cells showing pore-like connections between cells. Photo from Botany website, UBC, with permission.

Bayfield (1973) considered that water loss in endohydric *Polytrichum commune* (Figure 80) to be controlled by its leaf arrangement changes. This was accompanied by changes in water potential deficit of the shoots, with conduction being primarily internal under high evaporative flux and external under moderate flux. The ectohydric *Racomitrium lanuginosum* (Figure 93), by contrast, has little control over its water loss.

After examining 439 taxa of pleurocarpous mosses, Hedenäs (2001) reported that most differences in taxonomic character states between environments relate to two functions: 1) water conduction and retention; 2) dispersal. Those morphological characters that seem important for water relations relate to **stem central strand** (Figure 94-Figure 95), **leaf costa type** (Figure 96-Figure 97), **paraphyllia** (Figure 98), **pseudoparaphyllia** (Figure 99), **alar cells** (Figure 96), and **leaf orientation** (Figure 20-Figure 24, Figure 100-Figure 102). The latter two also relate to the **ability to change leaf orientation during drying** (Figure 103-Figure 105). But if acrocarpous mosses (upright mosses with terminal sporophytes) had been included, surely many more characters might be added, as it is mostly acrocarpous mosses that occupy the most xeric of habitats.

One feature of structural adaptations is that many are **plastic**, *i.e.* they can change depending on their growing conditions (Buryová & Shaw 2005). For example, **conducting strands** are absent in the liverworts *Moerckia flotoviana* (Figure 106) and *Haplomitrium hookeri* (Figure 94, Figure 107) under high humidity or liquid culture (Héban 1977). **Hair points** (colorless, hair-like extensions at leaf tip) of *Schistidium apocarpum* (Figure 108) likewise are absent in humid conditions (Figure 109).

Figure 106. *Moerckia blyttii*, a thallose liverwort that doesn't develop conducting cells in wet habitats. Photo by Michael Lüth, with permission.

Figure 107. *Haplomitrium hookeri*, a liverwort that doesn't develop its central strand in wet habitats. Photo by Des Callaghan, with permission.

Figure 109. *Schistidium apocarpum* without hyaline hair points, growing in a more shaded or moist environment. Photo by Jan-Peter Frahm, with permission.

Rhizoids are less well developed or absent in wet conditions (Smith 1988), even in the same species. In *Andreaea blyttii* (Figure 110), increased moisture results in longer, wider leaves that are more curved with longer cells in the basal margin, wider **costae** (midrib of leaf), and longer stems, but with a decrease in number of leaves per stem (Heegaard 1997). Even in typically aquatic taxa such as *Drepanocladus* (*sensu lato*), leaves become longer, and falcation (leaf curvature) is lost in submersed leaves (Figure 111) compared to those grown out of water (Figure 112), and the reduced light in submersed conditions results in greater **internode** distances (distances between leaf insertions) (Lodge 1959). A similar response is seen in *Fontinalis* (Figure 113). It is interesting that increases in

salt concentration increase cell length in this genus. Plasticity itself is an important adaptation.

Proctor (2010) reminds us that adaptations are subject to phylogenetic constraints and that entire clades may represent adaptations to desiccation. All plants must obtain water and CO₂, but there are multiple ways that this can be achieved.

Growth Form

Growth form is important both for obtaining and retaining water. For example, *Grimmia pulvinata* (Figure 115) forms cushions. In this moss, and most likely others with this growth form, size matters. As the clump grows larger, the surface to volume ratio decreases as the larger cushion is accompanied by greater height in the center. This reduces exposed area for gas exchange, but it also reduces the portion exposed to the atmosphere for water loss. In *Grimmia pulvinata* the larger cushions have lower area-based evapotranspiration rates due to a higher boundary-layer resistance, but the relative water storage capacity per dry weight does not change (Zotz *et al.* 2000). Consequently, the hydrated period is considerably longer in larger cushions. And as predicted, the CO₂ exchange rate decreases with increasing size of the cushion, with both net photosynthesis and dark respiration decreasing.

Figure 115. *Grimmia pulvinata* showing cushion form that conserves water. Photo by Michael Lüth, with permission.

Living in **clumps** affects the ability to gain and to retain moisture. The cushion growth form decreases the

surface to volume ratio, thus reducing surface water loss. Clump shape is important in this relationship, particularly in ameliorating wind effects (Proctor 1981; Zotz *et al.* 2000; Rice *et al.* 2001; Rice & Schneider 2004; Rice 2012). But for this system to work, the surface must be as smooth as possible. Greater roughness, resulting from protruding shoots, increases the turbulent air flow, thus increasing evaporation (Proctor 1981; Rice & Schneider 2004). A consequent advantage to the cushion growth form and its retention of water is the slowing of the drying rate (Sand-Jensen & Hammer 2012).

Fortunately, this is a self-regulating condition. As a shoot emerges from the surface, the greater exposure and greater evaporation cause its growth to attenuate. Even herbivores might contribute to this evening, choosing the protruding branch because it is easier to munch on. Hence, the surrounding mosses are able to catch up in length, returning the clump to its smooth structure. Thus, moisture limitations create a more matted clump with a smoother surface, limiting turbulent flow and wind penetration into the clump (Longton 1979; Guerra *et al.* 1992; Nakatsubo 1994).

Nakatsubo (1994) examined the importance of the growth form of sub-alpine mosses in controlling their evaporative water loss. The xerophytic species were comprised of large cushions and compact mats. Mesophytic species from the coniferous forest floor were represented by smooth mats, wefts, and tall turfs. The evaporation rate per dry weight was much less in the xerophytic species than in the mesophytic species. However, when compared on a basal area, the evaporation rates were similar. One advantage of the xerophytic species was their ability to increase weight per basal area without increasing roughness.

The density of the clumps seems to be a plastic character that can be modified by the environment (Gimingham & Birse 1957; LaFarge-England 1996; Bates 1998; Rossi *et al.* 2001). For example, the endohydric *Polytrichum juniperinum* var. *alpestre* (Figure 116), when in humid habitats, forms a looser clump structure with greater roughness than when in drier habitats (Birse 1957).

Figure 116. *Polytrichum juniperinum* var. *alpestre* showing contacting leaves of adjoining shoots in moist habitat. Photo by Des Callaghan, with permission.

Elumeeva *et al.* (2011) set out to determine the important characters that maintained moisture in sub-Arctic bryophytes. They found that individual shoot properties seemed to have little effect on colony water retention capacity. That is, leaf cell wall properties, water retention capacity, and desiccation rate of shoots made little difference in the water relations of the colony. Rather, the colony desiccation rate was determined by the density of the water-saturated colony. The desiccation rate of the individual shoot had a marginally significant negative effect on the colony rate.

In *Polytrichastrum formosum* (Figure 102), the plants are relatively tall and arranged in loose clumps. Nevertheless, the leaves of adjoining shoots touch, permitting water drops to be trapped by the resulting web. Drop size is an important consideration in conducting experiments using artificial rain. Raindrops usually range 0.5 mm (light rain) to 5 mm (heavy rain) (Best 1950; Brandt 1989; Yakubu *et al.* 2016). Using this size range, Zajaczkowska *et al.* (2016) determined that clumps of *P. formosum* were able to retain almost 60% of the applied water. When water was applied to the tips, water ran down the shoots and continued to run down until about 2 minutes after the water application ceased. When a drop lands on a leaf, it is more likely to be trapped by the leaf axil or by a leaf. Thus these clumps are benefitted by the catchment web formed by the overlapping leaves.

With these clump advantages, we might ask why so many mosses use other growth forms that are less compact. But moisture is not the only need for the mosses. A compact nature reduces light penetration, reduces CO₂ diffusion into the clump, and increases shoot-to-shoot competition for nutrients (Bates 1989; Rice 2012).

Mulder *et al.* (2001) explored the role of species richness on biomass, then compared it when these communities were exposed to experimental drought. They found that under drought conditions biomass increased with greater species richness. They determined that the interaction was facilitative rather than niche complementarity or the result of sampling effects. Survivorship increased for almost all species as richness increased, with the least drought-resistant species receiving the most benefit in biomass. Rixen and Mulder (2005) found similar results in the Arctic tundra.

Stems and Branches

Most stem and branch arrangements relate to growth form or life form (see Chapter 4-5 of this volume). However, in some cases there is internal or structural modification, exemplifying the plasticity of some bryophytes. For example, *Philonotis fontana* (Figure 117- Figure 118) exhibits variation among populations in leaf dimensions, whereas their cell dimensions show little response to differences in water regime or light level (Buryová & Shaw 2005).

Figure 117. *Philonotis fontana*, a species whose leaf dimensions vary with habitat. Photo by Des Callaghan, with permission.

Figure 118. *Philonotis fontana* leaf lamina showing cells. These cells vary little in dimensions in different water or light regimes. Photo by Kristian Peters, through Creative Commons.

Overlapping leaves from neighboring shoots help in the support of the mosses in a clump. In stems, the alternating layers of stiff and soft structures, such as those of the **Polytrichaceae**, the strength benefits from the **periodic component materials** (Vincent 2012) that occur in many biological structures and provide stronger mechanical features (Dunlop *et al.* 2011; Fratzl *et al.* 2016). This layering provides the stem with both supportive strength and flexibility that prevents breakage. In *Polytrichastrum* (Figure 102) and other members of the **Polytrichaceae**, the thicker cell walls surrounding the stem provide a higher bending strength (Niklas 1992), much like a paper straw compared with a paper lollipop stick (the former bends; the latter breaks). We also know that a lollipop stick made with twisted paper threads is stronger than a solid, non-twisted one, and that many trees likewise gain strength this way. This possibility needs to be explored in bryophytes.

Schröder (1886) considered the ability of moss stems to resprout from a dormant stem to be one method for withstanding prolonged drought. I had a similar experience with the aquatic moss *Fontinalis dalecarlica* (Figure 119). In this case, the moss was boiled for 14 hours a day for two

weeks in the lab, then returned to the stream. One year later, new growth was present on this moss that was still attached to the numbered rock used in the boiling treatment. Such ability of stem tips to recover from environmental stresses have been largely overlooked.

Figure 119. *Fontinalis dalecarlica* with from Fox Run, New Hampshire, USA, where a plant similar to this produced a green leaf one year after being boiled for 14 hours a day for two weeks. Photo by Janice Glime.

Sphagnum: Li and coworkers (1992) examined the responses of two closely related *Sphagnum* hummock species, *S. magellanicum* (Figure 120) and *S. papillosum* (Figure 121), to distance from water surface and related these responses to structural and physiological adaptations of the two species. They found that both species increase growth in length as water becomes more available, *i.e.* as the distance from water level decreases. Likewise, dry mass is maximal under wet conditions, with new branches being a major mass contributor, especially in *S. papillosum*. Furthermore, while experimenting with effects of distance from water on *S. magellanicum* and *S. papillosum*, Li and coworkers found that dry conditions result in wider stems (Figure 122), with thicker hyaline layers (Figure 123-Figure 124), than stems with apical capitula near the water surface (Figure 132), presumably increasing both absorption and water-holding ability.

Figure 120. *Sphagnum magellanicum*, a hummock species with efficient water movement. Photo by Michael Lüth, with permission.

Figure 124. *Sphagnum magellanicum* stem at level 3 above water surface. Photo courtesy of Yenhung Li.

Sphagnum has pores in its stem (Figure 125), in most species, and has very rapid movement of water externally up the stem by capillary action, adapting it for its annual cycle of being stranded well above water level in many species. Some species of *Sphagnum* have special **retort cells** (Figure 126) on the stems for absorbing water.

Figure 125. *Sphagnum papillosum* stem showing pores. The spiral thickenings of stem cells are unique in this moss. Photo from Botany website, University of British Columbia, BC, Canada, with permission.

Daniels (1989) found that while there is little differentiation between **spreading** and **pendant** branches (Figure 127-Figure 128) among *Sphagnum* plants growing in pools, hummock plants have more closely spaced **fascicles** (groups of branches), comparatively short spreading branches, and thin, closely appressed pendant branches (Figure 128). Pendant branches help to preserve stem water and maintain the wick effect as water level drops. Daniels determined that leaves of pendant branches on submerged plants photosynthesize actively, while those of hummock plants do not. He found that the two species growing in wet hollows (*Sphagnum cuspidatum*; Figure

129) or as wet carpets (*Sphagnum recurvum*; Figure 130) had the highest percentage of unbranched stems. The low hummock species *Sphagnum papillosum*, on the other hand, had up to six **capitula** (terminal clump of branches; Figure 131) per stem; the two species growing in the high-humidity, shaded wet woodland exhibited intermediate degrees of branching.

Figure 131. *Sphagnum papillosum* with branched capitula. Photo by J. C. Schou, with permission.

Sphagnum magellanicum (Figure 120) has greater ability to move and hold water than does *S. papillosum* (Figure 121) (Li *et al.* 1992). Therefore, when they grow together in the same hummock, *S. magellanicum* will not only stay wet longer, but if it is dominant it will keep *S.*

papillosum wet (Figure 132). However, it will fail to do so if *S. papillosum* is dominant (Figure 132). This is further supported by lab experiments in which *S. magellanicum* moved water farther externally in 20 hours than did *S. papillosum* (Figure 133; Figure 134).

Figure 132. Predominately *Sphagnum papillosum* (olive colored) lower on the hummock (left side of picture) causes both species to be dry, whereas predominately *S. magellanicum* (red) higher on the hummock (upper right side of picture) keeps both species wet. Photo by Janice Glime.

Central Strand

In addition to the structural adaptations of stems and branches already described, the vascular system itself may be modified. The **central strand** (Figure 135) is typically composed of hydroids that are elongated and impose fewer cell end walls through which water must travel. Héban (1973) found that variation occurred in the vascular elements, particularly in length and diameter, degree of inclination of end walls, and structure of the walls themselves. For example, whereas walls of hydroids are usually thin, they can be very thick, as in the swollen walls of hydroids in the setae of *Dicranum scoparium* (Figure 136) or the lateral walls of hydroids in the gametophyte central strand of the **Polytrichales** (Figure 137). But insufficient data exist to relate these variations to adaptive function.

Figure 135. Stem cross section of *Rhizogonium* showing narrow cells of central strand. Photo courtesy of Isawo Kawai.

Figure 136. *Dicranum scoparium* seta cross section showing hydroids. Photo from Botany website, University of British Columbia, BC, Canada, with permission.

Figure 137. *Polytrichum commune* stem cross section showing central strand. Photo from Botany website, University of British Columbia, BC, Canada, with permission.

Using several references for comparison, Héban (1977) showed that the number of hydroids within the *Polytrichum commune* (Figure 80) central strand (Figure 137) can vary with habitat, following an apparent moisture gradient. In a pseudo-alpine grassland he reports 900 hydroids in the central strand, peat bog 400, cultivated in artificial peat 280, and cultivated under water 70. There is no clear indication as to how these numbers affect the rate of conduction, but one would presume that more hydroids conduct more water.

Although in general, leafy liverworts lack conducting tissues in both leaves and stems (Crandall-Stotler 2014), *Haplomitrium* seems to be an exception. At least it possesses a differentiated central strand (Figure 94). But there seem to be no experiments to demonstrate how well this actually serves as conducting tissue.

Rhizoids and Tomentum

Rhizoids and **tomentum** (layer of matted woolly down on surface of plant; Figure 138) are adapted for water uptake. Pressel and Duckett (2011) found that rhizoids of all representatives they tested in **Polytrichales**, **Dicranales**, and **Bryales** (Figure 139) were **hydrophilic** (tendency to be wetted by water). For example, there is a sharp contrast between the leaves with a waxy cuticle in **Bartramiaceae** (Figure 140) and the highly hydrophilic tomentum-forming rhizoids (Figure 140) with papillae.

Figure 138. *Rhizomnium magnifolium* showing dense brown rhizoidal tomentum on lower half of stem. Photo by Michael Lüth, with permission.

Figure 139. *Bryum pseudotriquetrum* (Bryales) showing dense rhizoidal tomentum along stem. Photo by Misha Ignatov, with permission.

Figure 140. *Breutelia chrysocoma* (Bartramiaceae) showing rhizoidal tomentum. Photo by Michael Lüth, with permission.

Mosses with dense rhizoids or **tomentum** (Figure 138–Figure 140) seem to be well equipped to retain and conduct water by capillary action. Smith (1988) found that *Bryum pseudotriquetrum* (= *Bryum algens*; Figure 139), with a dense rhizoidal tomentum (Figure 139), held significantly more water than colonies with sparse rhizoids. But the tomentose form lost water more rapidly per unit dry mass than did the ones with sparse rhizoids. Could this be attributed mostly to loss of water from the tomentum? In *Schistidium antarctici* (Figure 141), the xeric form has less densely packed shoots and thicker cell walls that maintain

lower water content than the high-water-holding-capacity hydric turf form. Mosses in Smith's study took several times longer to drop to minimal water contents than did lichens in the same conditions.

Figure 141. *Schistidium antarctici*, a moss that becomes morphologically modified by moisture conditions. Photo courtesy of Rod Seppelt.

In acrocarpous mosses, rhizoids are produced all the way around the base of the stem, serving on the lower parts for anchorage, and in mosses like the **Polytrichaceae**, for limited conduction (Odu 1978). Rhizoids further up the stem provide capillary spaces that can both store water and facilitate movement. In pleurocarpous mosses, rhizoids appear only on the side of the stem (Figure 142) toward the substrate (Odu 1978), except in the case of those in flowing water (Glime 1987). In *Fontinalis* (Figure 143), where rhizoids have a critical function in anchorage and this aquatic moss may encounter its substrate in any direction from the stem, the individual rhizoids grow in a spiral (Figure 144) until they encounter the substrate, then form multiple branches (Figure 145) in a small space and cement themselves to the substrate, presumably offering no function of water movement (Glime 1987).

Figure 142. *Hygroamblystegium fluviatile* rhizoids on one side of stem. Photo by Janice Glime.

Figure 145. *Fontinalis squamosa* rhizoid tips branching when they encounter a paper towel substrate. Photo by Janice Glime.

Higuchi and Imura (1987) cultured three moss species to determine the effects of submersion on the rhizoid characters. The thickness, surface decorations, and positions where the rhizoids arise appear to be stable in altered moisture conditions, but in *Macromitrium gymnostomum* the mucilage that is present in terrestrial cultures is lost in water culture. Rhizoids generally are not produced on submersed mosses in standing water (Odu 1978). Could it be that ethylene, which inhibits their development, cannot escape easily? This conserves energy, because it would seem that they are needed neither for anchorage nor absorption and conduction. In flowing water they need anchorage and the flow would prevent ethylene from accumulating, if that is the mechanism.

Surprisingly, Trachtenberg and Zamski (1979) found a cuticle on the rhizoids of *Polytrichum juniperinum* (Figure 146), sharply contrasting with roots and root hairs of tracheophytes, which serve as absorbing organs and have no waxy cuticle. This suggests that they may play little role in water uptake, but rather prevent water loss to the substratum. This raises questions about how widespread this cuticle is on rhizoids of other taxa and how it affects the capillary action they might otherwise afford. Perhaps they play only a role in conservation of water and not in its uptake. Or are these cuticles designed to provide capillary spaces that hold water around the rhizoids and facilitate uptake?

Figure 146. *Polytrichum juniperinum* males, a moss that has a cuticle on its rhizoids. Photo by Jan-Peter Frahm, with permission.

It is noteworthy that the leafy liverwort *Haplomitrium* (Figure 94, Figure 107, Figure 153) lacks rhizoids (Duckett *et al.* 2013). On the other hand, *Treubia* (Figure 147- Figure 148) appears to possess rhizoids that facilitate nutrient uptake (Field *et al.* 2014). These unusual liverworts have leaves in three equal ranks and use underground stems (**rhizomes**) for anchorage and for fungal associations. All other liverworts produce **unicellular** (having only one cell) rhizoids (Figure 149). But only the thallose liverworts produce two types. Mosses, on the other hand, have multicellular rhizoids that can branch (Figure 150).

Mucilage

Stem apices are protected by mucilage secreted by specialized hairs (Berthier *et al.* 1974). This mucilage seems to play a strong role in protecting the actively dividing tissue, permitting fragments to survive long periods of desiccation until they are able to grow again, and most likely playing a role in water retention, especially for the critical apical cells.

In liverworts and the moss *Takakia* (Figure 151) there are **slime papillae** (Figure 152) that may serve a water absorption/retention function as well. The leafy liverwort *Haplomitrium* (Figure 153) produces extensive mucilage on its rhizomes (Figure 153-Figure 154). It is interesting that these slime papillae appear in the green alga *Coleochaete* (Figure 155), the genus that seems most closely related to embryophytes, causing one to wonder if slime papillae may have been a prerequisite for land adaptation in early plants.

Figure 154. *Haplomitrium gibbsiae* rhizome with mucous. Photo courtesy of Jeff Duckett and Silvia Pressel.

The thallose liverwort *Conocephalum conicum* (Figure 27, Figure 36, Figure 68) has mucilage ducts in its thallus. Clee (1943) suggests that these may aid in water retention.

Cuticles and Waxes

Bryophyte leaves have frequently been described as lacking a cuticle. However, this ancient concept has proven to be false. Even leafy liverworts can have a cuticle. The details of the leaf cuticle will be discussed in the next subchapter, but we need to consider how such a cuticle might affect the whole plant water movement. Loss of water from leaves can create a transpiration stream that draws water upward, but in most bryophytes the greater movement of water is external. Hence, it is not surprising that little is known of the effects of a transpiration stream on water movement in bryophytes. It would be interesting to know if stems have a cuticle, but I am aware of no studies that isolated the stems to look for it. For now, we will concentrate on other aspects of water movement.

Capillary Spaces

Although several adaptations to holding water seem to exist [porose leaf cells, ridges, folds, sheathing leaf bases (Figure 156), rhizoids, tomentum], Proctor (1979a) contends that most of the water is held in the larger capillary spaces between the moss shoots. Small amounts of dew that accumulate at the moss tip (Figure 157), *i.e.* the growing region, may be critical to survival (Lange 1969; Kappen *et al.* 1979). Hair points that wrap around the succeeding leaves above (Figure 158) help to deflect light and reduce evaporative loss by creating a diversion for air currents. Proctor (1980) experimented by removing hair points and found that when present they reduced water loss by 35% in *Grimmia pulvinata* (Figure 115) and *Syntrichia montana* (= *S. intermedia*; Figure 159). Thus far, it has been difficult to demonstrate that papillae afford any such advantage (Frey & Kürschner 1991). Nevertheless, in leaves they can act as a rapid capillary water movement system (Proctor 1979a; Longton 1988; Pressel & Duckett 2011).

Figure 160. *Trichocolea tomentella* dry, a leafy liverwort with finely divided leaves and paraphyllia. Photo by Hermann Schachner, through Creative Commons.

The leafy liverwort *Trichocolea* (Figure 160-Figure 162) is highly adapted to take advantage of capillary action. Its leaves are highly dissected and **paraphyllia** (leaflike appendages between the leaves; see Figure 163) are abundant, permitting this species to act like a sponge. Zehr (1979) observed that it experienced only short-term vapor deficits in its moist habitat and thus was able to grow anytime temperatures were above freezing. Paraphyllia such as those in *Hylocomium splendens* (Figure 164-Figure 165) and *Thuidium tamariscinum* (Figure 166) create capillary spaces much like a tomentum. Other mosses such as **Mniaceae** utilize **paraphyses** (Figure 167) among the archegonia and antheridia to conserve water, using the same capillary principle.

Cellular Structure

Sun-exposed rock surfaces and similar habitats require the greatest degree of desiccation tolerance. One such desiccation-tolerant species is *Andreaea rothii* (Figure 168-Figure 170), a small, blackish cushion moss that grows on hard, acidic mountain rocks. It is able to recover and photosynthesize after 12 months of desiccation at 32% relative humidity at 20°C (Proctor & Tuba 2002). Similar tolerance is exhibited by the small cushions of *Grimmia pulvinata* (Figure 171-Figure 172) on dry wall tops, *Racomitrium lanuginosum* (Figure 93; Figure 173-Figure 175) of mountain and subarctic fellfields (Figure 173), and *Syntrichia ruralis* (Figure 176-Figure 177) of dry sand dunes and steppe grasslands. A common characteristic among these and other tolerant mosses is their small or narrow cells with dense contents and small vacuoles. Their leaf surfaces are readily wetted and the leaves quickly expand within minutes of rewetting.

Liverworts in general are less desiccation tolerant than mosses, but some are able to survive frequently dry habitats (Clausen 1952). The leafy liverwort *Porella platyphylla* (Figure 178-Figure 182) grows in dry but shaded habitats on dry calcareous rock or base-rich bark. It recovers completely after 60 days of desiccation at 50% relative humidity (Hinshiri & Proctor 1971). Other leafy liverworts such as *Frullania dilatata* (Figure 183-Figure 185) and *Gymnomitrium* spp. (Figure 186-Figure 187) grow on sun-exposed rocks. But the leafy liverwort *Porella platyphylla* has moderate cell size and large vacuoles, contrasting with what seems to be typical in DT mosses (Marshall *et al.* 1998).

Figure 187. *Gymnomitrium concinnatum* leaf cells with oil bodies. The cell walls have adequate spaces and **trigones** for water storage. Photo by Hugues Tinguy, with permission.

Although 50% relative humidity seems to be the level commonly used for determining desiccation tolerance, some structures, and possibly some species, can tolerate even lower levels.

Fungal Partners

Fungal partners associated with roots have been termed **mycorrhizae**, and the same term is applied to fungi that serve as fungal partners to bryophytes. The existence

of these relationships has been mostly overlooked until recently, although we have recognized for quite some time that many bryophytes had fungi associated with them. Hence, our knowledge of their importance to the bryophyte is meager. It is likely that they serve a similar role to that in tree roots in scavenging a wide area for water, minerals, and perhaps organic nutrients. But I would also consider it likely that at least some of them play a role similar to that in the **hemiparasites** such as Indian pipe (*Monotropa uniflora*). That is, for those bryophytes living in dense shade, they could find a third partner that has more access to light – a leafy tracheophyte – that provides photosynthate that can be transferred from the tracheophyte, by way of the fungus, to the bryophyte. I am afraid I can see no substance that is likely to be produced by the bryophyte that is useful to the tracheophyte, making the bryophyte also a hemiparasite. Nevertheless, such a 3-way linkage remains to be demonstrated.

In an attempt to unravel the evolution of the fungal symbioses of bryophytes, Pressel *et al.* (2010) examined the ancient basal bryophytes *Treubia* (Figure 147-Figure 148) and *Haplomitrium* (Figure 153-Figure 154). In these liverworts they found intracellular fungal lumps, inter cellular hyphae, and thick-walled spores. Unlike the well known glomerophytes found as symbionts in thallose liverworts and lower tracheophytes, these were more ancient fungi (Figure 188-Figure 189).

In leafy liverwort families sister to the **Schistochilaceae**, the Ascomycete fungus *Rhizoscyphus ericae* occurs in the rhizoids (Pressel *et al.* 2010). This fungus has a wide range of hosts, including flowering plants in the Ericales (includes blueberries and heath plants) and an Antarctic species of the leafy liverwort *Cephaloziella* (Figure 190). Figure 191 shows a member of the **Ascomycota** inhabiting the leafy liverwort *Mylia anomala*. In the **Basidiomycota**, the genus *Sebacina* (Figure 192) is associated with leafy liverworts, but this fungus is host specific. Neither of these liverwort fungi seems to digest its host, whereas the **Basidiomycota** in the thallose liverworts of **Aneuraceae** have regular colonization and digestion cycles. The hornworts also demonstrate mycorrhizal relationships with fungi, but thus far there is no evidence that such a mycorrhizal relationship exists in mosses. It might be worth looking for it in **Polytrichaceae** and **Sphagnaceae**.

Figure 192. *Sebacina incrustans*, member of a genus of basidiomycete fungi that is associated with leafy liverworts. Photo by James K. Lindsey, with permission.

We are at a very early stage in our understanding of mycorrhizae in bryophytes. In tracheophytes these associations permit the host plant to gain water and nutrients from a much wider area by accepting these from a fungus that has grown over a wide area, as much as 15 hectares, weighing 10,000 kg (Smith *et al.* 1992). Their role in bryophytes is less clear, but the ancient origin of this association suggests that by now it could be quite sophisticated and beneficial.

Protonema

The protonema stage of mosses is a delicate threadlike stage in which every cell is surrounded by air with the potential for creating desiccation. But is it really so delicate?

In experiments, Pressel and Duckett (2010) demonstrated that protonemata can survive slow drying but not fast drying. This suggests that during slow drying there is time to manufacture something that protects the cells from the effects of desiccation. Indeed, pre-treatment with abscisic acid permits the protonemata to survive fast drying as well. During slow dehydration the cells undergo profound changes, including vacuolar fragmentation, reorganization of endomembrane domains, changes in cell wall thickness, changes in plastid morphology, changes in mitochondria morphology, and a controlled dismantling of the cytoskeleton. During fast drying, these events do not occur or are incomplete. The abscisic acid permits the rapidly drying cells to partially mimic their behavior during slow drying, permitting them to survive.

Leafy Liverwort Gemmae

Liverworts have leaf gemmae that are usually small structures along the leaf margins. Germination on the leaf is not desirable, so it is no surprise that they have a means of preventing it. This prevention may relate to their hydrophobic surface (Duckett & Ligrone 1995). In *Odontoschisma denudatum* (Figure 193), the wall

chemistry changes during maturation, with an increase in electron-opacity.

Figure 193. *Odontoschisma denudatum* with gemmae on apical leaves (yellowish). Photo by Jan-Peter Frahm, with permission.

Sporophyte

When we examine mature sporophytes with their capsules and spores, we don't give a second thought to the dangers of drying out. But we are misled by this resistant mature sporophyte. Rather, based on studies of field-collected gametophytes of *Microbryum starckeanum* (Figure 194) and *Tortula inermis* (Figure 195) (both species of dry habitats) with immature sporophytes, McLetchie and coworkers found that the sporophyte generation is more sensitive to desiccation and thermal stress than is the leafy gametophyte (McLetchie & Stark 2006; Stark *et al.* 2007). This may of course differ in species with a different phenology in different environmental conditions, but it bears questioning our perception of the importance of desiccation during sporophyte development. This need for desiccation tolerance of the sporophyte may be especially important for species like those of *Polytrichum* (Figure 80) that require as much as 20 months for sporophyte development and span an entire year of weather conditions (Arnell 1905; Longton 1972).

Figure 194. *Microbryum starckeanum*, a species in which the sporophyte is more sensitive to desiccation than is the gametophyte. Photo from BBS website, with permission.

Figure 195. *Tortula inermis* dry leaves and immature capsules, a species in which the young capsules are more sensitive to desiccation than are the gametophytes. Photo by Michael Lüth, with permission.

It appears that the embryonic sporophytes are the stage most susceptible to desiccation stress (Stark 2002, 2005). Nevertheless, some desert mosses have embryonic sporophytes that can tolerate desiccation for long periods, most likely benefitting from **desiccation hardening** (development of resistance to desiccation) (Stark *et al.* 2014). Several examples exist from non-desert mosses, although the tie to desiccation is unclear. In the boreal forest moss *Hylocomium splendens* (Figure 164-Figure 165) (Callaghan *et al.* 1978) and desert moss *Syntrichia caninervis* (Figure 25) (Stark *et al.* 2000), the number of aborted sporophytes outnumbers that of mature sporophytes. Similarly, in the boreal forest moss *Pleurozium schreberi* (Figure 196) 38% of the sporophytes aborted (Longton & Greene 1969).

Figure 196. *Pleurozium schreberi*, a boreal forest moss with a high percent of abortions. Photo by Michael Lüth, with permission.

Calyptra Protection

If we imagine the hairy calyptrae of such mosses as *Polytrichum* (Figure 197), we must ask ourselves how the calyptra avoids absorbing water and holding it against the capsule, creating water logging, or contrarily, draws water from the capsule due to capillary spaces created by the hairs. In other words, why doesn't it behave like a bath towel? To answer this question, we will look at calyptra development, timing, structure, and its ultimate role.

Figure 197. Hairy calyptra on capsule of *Polytrichum juniperinum*. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

The **calyptra** develops from the archegonium, which expands as the embryo develops. In some cases, the calyptra falls early in capsule expansion, but in others, such as *Polytrichum* (Figure 197), it may remain until the spores are ready for dispersal. One might then question the role of the calyptra in protecting the embryo through to development of spores. Budke *et al.* (2012) demonstrated that the maternal calyptra provides protection of early post-embryonic sporophytes against desiccation, but that later development of the capsule may incur cuticle development that protects as the capsule emerges from the calyptra. This demonstrates that the calyptra cannot be considered a vestigial structure, but rather that it is essential in preventing desiccation. Haig (2013) agrees that the presence of the calyptra delays the onset of transpiration. Hence, it is prudent to examine the calyptra characters that may provide this desiccation protection.

Cuticle: In *Funaria hygrometrica* there is a 4-layered cuticle on the calyptra for its duration (Figure 198) (Budke *et al.* 2012). Budke *et al.* (2011, 2012, 2013) demonstrated that the cuticle on this calyptra conferred significant protection to the developing sporophyte.

Figure 198. *Funaria hygrometrica* showing calyptra that has a 4-layered cuticle. Photo by Fred Essig, with permission.

Hairs: There appear to be two kinds of hairs on calyptrae, "true" hairs (Figure 197) and undeveloped archegonia. In *Fontinalis*, the calyptral hairs develop from aborted archegonia whose eggs (Figure 199) were presumably not fertilized (Glime unpubl.). This results in a small number of "hairs" near the base of the calyptra.

Figure 199. *Fontinalis squamosa* calyptra with young archegonium SEM. Photo by Janice Glime.

The hairs on the calyptrae in taxa such as *Polytrichum* (Figure 197) and *Orthotrichum* (Figure 200) could

function to prevent desiccation during early development or to deter herbivory both early and late in development, but earlier in development they could also serve important functions for the archegonium, helping to conserve moisture to protect the egg or other uses we haven't considered. I haven't followed the development in taxa other than *Fontinalis* (Figure 199), but the hairs seem too large and numerous in most taxa to be just a lingering of the archegonia or associated paraphyses. If they continue to elongate as the calyptra develops, then there may be some advantage that would favor that prolonged use of energy for their development.

Figure 200. *Orthotrichum stramineum* with calyptra showing long hairs. Photo by Des Callaghan, with permission.

Cuticle

It is likely that many bryophyte sporophytes have a **cuticle**. For example, the large, waxy-looking capsule of *Buxbaumia viridis* (Figure 201), and most likely the other members of the genus, has a layered cuticle (Koch *et al.* 2009). And in *B. viridis* this cuticle is waxy with massive wax layers having small embedded and superimposed platelets and granules on top of this complex. Although until recently the only documented sporophyte cuticles had been those of the **Polytrichales**, this complex of cuticle components is common in various groups of tracheophytes.

Figure 201. *Buxbaumia viridis* capsule showing shiny, waxy cuticle. Photo by Bernd Haynold, through Wikimedia Commons.

Pressel and Duckett (2011), suspecting that capsule waxes were more common than those of these two groups, examined a wider array of taxa, particularly those with shiny surfaces. They demonstrated that *Bartramia* (Figure 202), *Plagiopus* (Figure 203-Figure 204), and *Mnium* (Figure 205-Figure 207) invested as much in surface waxes of the capsule as did *Polytrichum* (Figure 197). They interpreted these waxes as having a role in preventing accumulated water from depressing gas exchange in the capsules, that is, prevention of water logging.

Figure 202. *Bartramia pomiformis* capsule showing waxy surface. Photo by Walter Obermayer, with permission.

Figure 203. *Plagiopus oederiana* with capsules showing waxy surface. Photo by Michael Lüth, with permission.

Figure 204. *Plagiopus oederiana* waxy capsule with calyptra at near maturity. In this case, the calyptra does little to protect the nearly mature capsule, most likely making the cuticle more important. Photo by Janice Glime.

Figure 206. *Orthotrichum pusillum* immersed stoma on calyptra. Photo by Bob Klips, with permission.

Figure 207. *Mnium hornum* with capsule showing waxy surface. Photo by J. C. Schou, with permission.

In the moss genus *Orthotrichum* (Figure 200) many species have immersed stomata (Figure 206). These openings are surrounded by protruding cells that maintain an air space between the capsules and the calyptra (which remains attached and covers most of the capsule until the spores are ripe; Figure 200) (Pressel & Duckett 2011). The waxes repel the water on the capsule and prevent it from being drawn under the calyptra by capillary action. That is, a primary role for these surface waxes may be to prevent water logging in this and other species.

But this cuticle story apparently does not begin with the capsule. The young sporophyte is covered by a calyptra. And as noted earlier, in *Funaria hygrometrica* (Figure 198, Figure 208-Figure 211) this calyptra is covered by a waxy cuticle four layers thick at all stages, hence providing protection long before the developing sporophyte develops its own cuticle that ultimately arises on the sporangium (Budke *et al.* 2012). When the calyptra cuticle is removed during periods of low moisture, the sporophyte suffers significant damage, including decreased survival, increased tissue damage, incomplete sporophyte development, more peristome malformations, and decreased reproductive output (Budke *et al.* 2013). This is in contrast to the conclusion of Pressel and Duckett (2011) that the cuticles function primarily to prevent water logging. I have for my entire career as an ecologist failed to understand why ecologists get into so many arguments over two or more different explanations for the same thing, in this case the presence of stomata. There seems to me to be no evolutionary argument against multiple functions for the same thing, at the same or at different times. Just consider the many functions of our brains, or the many uses for fingernails.

Budke *et al.* (2012) examined the development of the cuticle on both the calyptra and the capsule, using *Funaria hygrometrica* (Figure 198, Figure 208-Figure 211) as a model organism. These researchers found that the sporophyte cuticle does not mature until the formation of the capsule.

Figure 208. *Funaria hygrometrica* with expanding archegonia (now calyptrae) with young sporophytes still mostly protected within the perichaetial leaves. Photo by Andrew Spink, with permission.

Figure 209. *Funaria hygrometrica* young sporophytes and calyptrae emerging from the protection of the perichaetial leaves. Photo by Michael Lüth, with permission.

Figure 211. *Funaria hygrometrica* mature capsule showing waxy surface. Photo by Sarah Gregg, with permission.

As among leaves, the capsule waxes vary in structure. In *Tetradontium brownianum* (Figure 212), there are fine rods around the stomata, whereas in *Pylaisia polyantha* (Figure 213) there are both rods and fine whorls (Pressel & Duckett 2011).

Figure 213. *Pylaisia polyantha* capsule, a species with both rods and fine whorls in the cuticle around the stomata. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Peristome: Peristome teeth likewise have cuticles, with differences related to habitat conditions at the time of spore discharge (Pressel & Duckett 2011). In *Polytrichales*, the spores are dispersed when raindrops pounce on the diaphragm (**epiphragm**; Figure 214) that connects the teeth (Watson 1971). For this mechanism to work, the teeth must not only remain dry, but must repel water so that it does not block the small openings between the teeth where spores must exit (Pressel & Duckett 2011).

Figure 214. Top view of *Polytrichum* epiphragm showing the 64 adherent teeth. Water splashing on the membranous epiphragm (like a child on a trampoline) disperses the spores. Photo by George Shepherd, through Creative Commons.

On the other hand, most mosses disperse their spores when it is dry. Water is taken up and lost rapidly from between the ornamentation on these peristomes (Pressel & Duckett 2011). These include all **Bryopsida** they tested: *Amblystegium* (Figure 215), *Bryum* (Figure 139), *Coscinodon* (Figure 216), *Dicranella* (Figure 217), *Didymodon* (Figure 218), *Fissidens* (Figure 219), *Funaria* (Figure 220), *Grimmia* (Figure 115), *Hypnum* (Figure 221), *Mnium* (Figure 205-Figure 207), *Rhynchostegium* (Figure 222), *Schistidium* (Figure 109), *Syntrichia* (Figure 25), *Tortula* (Figure 1, Figure 195). These water gains and losses permit rapid closure in wet conditions and accelerate opening under dry conditions.

But what happens in capsules with no teeth or only rudimentary peristomes? As an example, in *Weissia* (Figure 223) water is prevented from entering the capsule by a highly water-repellent capsule rim (Figure 223). If water entered the capsule, it could cause premature germination or interfere with ultimate dispersal.

Guard Cells and Stomata

Capsules of many (most?) mosses have guard cells and stomata. The guard cells usually resemble those of tracheophytes, having a doughnut shape, and surrounding the **stoma** (opening; Figure 206, Figure 224). These are mostly located at the base of the capsule. In addition to the cuticle, we might expect the **guard cells** to play a role in water relations of the capsule. After all, the stomata and guard cells have existed through 400 million years of land plant evolution (Chater *et al.* 2011).

Figure 224. *Polytrichum* stomata on capsule base. Photo by George J. Shepherd, through Creative Commons.

Like the cuticle, the role of the pores and stomata has been overlooked in bryophytes. Although we have known about the stomata in moss capsules for a long time, and used them as taxonomic characters in genera such as *Orthotrichum*, we have largely ignored their function, failing even to ask what it might be.

When thinking about adaptations to drought, we usually think of the survival of the gametophyte. What danger could there be to a dry capsule full of spores, right? But before that capsule is full of spores, it is a photosynthetic body in need of water. Perhaps the young seta with no capsule has little problem, but once the capsule starts to differentiate, water needs most likely increase dramatically. And once meiosis begins, water needs are critical. An interruption during meiosis could lead to a variety of anomalies, many of which could cause spore death.

Paton and Pearce (1957) reviewed the early literature on stomata in bryophytes, pointing out that in *Sphagnum* they do not mature. In fact, the capsule pores of *Sphagnum* are considered **pseudostomata** (Figure 225-Figure 227). Their function seems to be limited, facilitating capsule dehydration, shape change, and dehiscence (Duckett *et al.* 2009; Merced 2015). This is not surprising, because in *Sphagnum*, the seta is only a few cells high (Figure 228). Instead, the capsule is elevated on a **pseudopodium** (Figure 228-Figure 229) that is developed from the gametophyte. This pseudopodium does not extend until the capsule is mature. Hence, the role of the pseudostomata to create a transpiration stream for nutrient transport would seem futile. Rather, Duckett and coworkers (2009) provide evidence that the pseudostomata remain open when the capsule is mature, causing the capsule to dry and shrink, forcing the spores out.

Stomata also are absent in the liverworts (but can have thallus pores), present in at least some hornworts (Figure 238-Figure 241), and absent in the moss order **Andreaeales** (Figure 230-Figure 231) (Paton & Pearce 1957). As in the tracheophytes, the number of guard cells associated with a stoma is usually two (Figure 224-**Error! Reference source not found.**). Known exceptions (single circular guard cells) occur in **Funariaceae** (Figure 198, Figure 208-Figure 211, Figure 232) and *Buxbaumia aphylla* (Figure 233). Larger numbers of guard cells (3-4) occur but do not seem to be consistent in any single taxon and are thus considered an anomaly.

Figure 233. *Buxbaumia aphylla* capsules, a species with single circular guard cells. Photo by Štěpán Koval, with permission.

The walls of the guard cells are strongly cuticularized (Paton & Pearce 1957). The number of stomata in capsules that have been examined varies from 4 to over 200. Species with a long seta generally have more stomata than species with a short seta or immersed capsules. This supports the hypothesis that they are needed to provide an adequate transpiration stream to transport nutrients from the leafy gametophyte to the sporophyte capsule (Haig 2013), but both are adaptations that would support wind dispersal.

Guard cells are usually located at the base of the capsule. In reality, they tend to be located below the area covered by the calyptra, where gas exchange and water loss are possible. This is consistent with a role to permit water loss, but could they also serve in gas exchange? It appeared that the capsule guard cells did not respond to changes in humidity (Copeland 1902). Rather, they are only able to close when the sporophyte is dehydrated or reopen when it is remoistened. This is consistent with their potential role in bringing nutrients upward.

In the moss *Physcomitrella patens* (Figure 234-Figure 236), the stomata of the sporophytes do indeed respond to environmental signals with the hormone abscisic acid (ABA) serving as a signalling component. In fact, the genes controlling ABA in *P. patens* can be moved to mutant *Arabidopsis thaliana* (flowering plant) that has lost its ABA-regulatory gene and cause stomata in that plant to behave normally. When *P. patens* mutants lack the ABA regulatory gene, the response to ABA is greatly reduced.

But wait! While ABA may affect guard cell closure in *Physcomitrella patens* (Figure 234-Figure 236), it appears that the guard cells in mosses have a somewhat different mechanism to function. First of all, there seems to be no potassium-regulating mechanism (Duckett *et al.* 2010a). Instead, their primary role seems to be to permit water to escape when the capsule is mature (Boudier 1988; Beerling & Franks 2009; Duckett *et al.* 2009, 2010b). This loss of water causes the capsule to become distorted enough to force the rather stiff circular cap (**operculum**) to pop off, exposing the spores (Figure 237).

Figure 237. *Physcomitrella patens* with open capsules. Photo by Hermann Schachner, through Creative Commons.

It appears that the stomata endow the capsule with multiple advantages. Loss of water during development could be important to create a transpiration stream that moves nutrients upward from the gametophyte to the capsule of the sporophyte, especially in mosses (Haig 2013). If this interpretation is correct, the water loss is essential to maintain continuous movement of water and associated nutrients upward. In fact, Haig interprets the elevation of the capsule on an elongated seta to be an adaptation that increases the movement of water by placing the capsule into the zone of turbulent air above the quiet boundary layer. The placement of the stomata at the base of the capsule gives them exposure while the calyptra reduces water loss from the part of the capsule where spores are developing.

Ziegler (1987) pointed out that in some mosses the sporophyte guard cells have thick walls and do not open and close. This type of guard cell occurs in species that have reduced photosynthetic tissue in the capsule and have been considered evolutionarily reduced. Bryophyte guard cells also differ from those of tracheophytes in that they are larger than the surrounding cells, whereas in tracheophytes they are smaller.

Paton and Pearce (1957) found that the stomata become functionless at a relatively early stage in capsule development, suggesting that this loss in function protects the developing spores against desiccation. They were able to demonstrate this early loss of function in the hornwort *Anthoceros* (Figure 238-Figure 239) and in mosses in the *Bryales*. Based on their studies on the hornwort *Phaeoceros* (Figure 240), Duckett and Ligrone (2003) say no to the function of capsule guard cells in gas exchange, at least in hornworts; they could find no response to moisture changes or to ABA in the hornwort *Phaeoceros* stomata (Figure 241). But if providing a nutrient stream through water transport is to be ruled out, we need experiments that block the stomata to compare with development in capsules that have not had them blocked.

Figure 241. *Phaeoceros laevis*, open stoma flanked by desiccated and shrunken epidermal cells well above dehiscence point. Photo courtesy of Jeff Duckett, Ken P'ng, Karen Renzaglia, and Silvia Pressel.

On the other hand, in greenhouse-grown *Funaria hygrometrica* (Figure 242) the stomata (Figure 232) open on the fourth day of capsule expansion (Garner & Paolillo 1973). By the fifth day, continuing through the tenth day, they close in darkness and reopen in light. They also can be closed by the application of abscisic acid (ABA) (Garner & Paolillo 1973; Chater *et al.* 2011). Thus far we have no evidence to demonstrate the usefulness of this opening and closing. It could enhance gas exchange; it could control water loss during the critical stages of meiosis; and it could serve as a transpiration stream to bring nutrients from the gametophyte. And the function could change or disappear at maturity.

Figure 242. *Funaria hygrometrica* capsules. Photo by Li Zhang, with permission.

Indeed it appears that the function changes as the *Funaria hygrometrica* (Figure 232, Figure 242) capsule ripens. As maturity approaches, the stomatal responsiveness declines and about half the stomata remain open day and night (Garner & Paolillo 1973)! Furthermore, more stomata become exposed when the calyptra is shed (Duckett *et al.* 2009, 2010a). The stomata no longer provide a mechanism to conserve water.

Further complicating our interpretation of stomatal function during capsule development is the apparent lack of relationship between the presence of stomata and habitat. In the liverworts, stomata are totally absent. But liverworts produce mature capsules before elongation of the stalk occurs, negating the necessity for long distance translocation of nutrients and being consistent with the observations of Paton and Pearce (1957) that fewer stomata occurred on moss capsules with short or absent setae than on those with emergent, longer setae. The widespread absence of stomata in at least some species among so many moss taxa [*e.g.* *Atrichum* (Figure 243), *Pogonatum* (Figure 244), *Acaulon* (Figure 245), *Campylopus* (Figure 246), *Leucobryum* (Figure 247), *Cinclidotus* (Figure 248), *Discelium* (Figure 249), *Nanomitrium*, *Fontinalis* (Figure 250), *Tetraphis* (Figure 251), *Catoscopium* (Figure 252), *Cyclodictyon* (Figure 253), *Leucodon* (Figure 254) (Paton & Pearce 1957)] suggests they are not essential for gas exchange. Furthermore, since most of these genera have long setae, one could argue against their function in creating a transpiration stream for nutrient transport. One might also argue that the well developed vascular tissue in both gametophytes and sporophyte setae of the **Polytrichaceae** makes the presence of stomata to create a transpiration stream unnecessary for nutrient transport, yet some members of the family have stomata and guard cells. And the stomata in tracheophytes are certainly necessary to maintain function of the xylem tissue in these larger plants. But there is no rule that says they can't serve different functions at different times or in different species.

Merced and Renzaglia (2013) demonstrated the remarkable similarity between stomata in the highly developed *Oedipodium* (Figure 255) and the very reduced *Ephemerum* (Figure 256) capsules. The capsule structure differs, with *Oedipodium* having extensive spongy tissue along the capsule apophysis where stomata are concentrated and *Ephemerum* lacks such tissue but has minimal substomatal cavities. Although *Oedipodium* (Figure 255) has numerous long-pored stomata and *Ephemerum* has few round-pored stomata, the stomatal ultrastructure and wall thickenings of these two taxa are quite similar. Both have sporophytes with a cuticle that is thicker on the guard cells and extends on the walls surrounding the stomata. When the capsules are older, epicuticular waxes and pectin clog the pores, closing them much like the stomata of fir trees in winter. Merced and Renzaglia argue that the cuticle, water-conducting cells, and spongy tissues of *Oedipodium* all support the role of stomata in facilitating gas exchange and water transport as the sporophyte develops. They also contend that the existence of stomata exclusively on capsules may indicate a function in drying and dispersal of spores.

Figure 255. *Oedipodium griffithianum* with young capsules, a species with a well developed spongy apophysis and many stomata. Photo by Des Callaghan, with permission.

Figure 256. *Ephemerum recurvifolium* with capsules, a moss that lacks a spongy apophysis and has few stomata. Photo by Tomas Hallingback, with permission.

Hence, we have four potential functions for the stomata of capsules. These include a role in creating a transpiration stream to aid in nutrient transport, prevention of water logging that inhibits gas exchange, regulation of gas exchange, and drying that contracts the capsule and aids in spore expulsion.

Spores

Spore physiological adaptations are seldom discussed. Fan *et al.* (2023) have just published a study that compares spore germination of six peatland bryophytes under various water regimes. They found that frequent dry-wet cycling reduced spore germination more than less frequent cycling. And habitat mattered. Hummock species such as *Sphagnum capillifolium* (Figure 257) and *S. fuscum* (Figure 258) had a greater spore germination percentage after continuous dry treatment, whereas the hollow species [*S. angustifolium* (Figure 259), *S. squarrosum* (Figure 260), *S. subsecundum* (Figure 261)], had the opposite response, with highest germination following the wet treatment. Both hummock and hollow species exhibited the greatest spore viability after the dry treatment, and viability gradually decreased with the increased frequency of dry-wet cycling. Hummock species had greater %germination than did hollow species (Figure 262).

Figure 261. *Sphagnum subsecundum*, a species of hollows. Photo by Mark Rahill, with permission.

Figure 262. Mean spore viability + standard error following different wet-dry cycle regimes of six peatland *Sphagnum* species. 3:1, 1:1, and 1:3 respectively represent the ratio of days of dry and wet treatment in dry-wet cycling. $n=5$. Image modified from Fan *et al.* 2023.

Hummock vs hollow species seem to have evolved different responses to wetting. Hummocks that have sufficient oxygen and intermittent flooding are more suitable for high spore germination percentage of *Sphagnum* spores than the continuously waterlogged hollows (Sunberg & Rydin 2000). But Feng *et al.* (2017) found that in *S. fallax*, (Figure 263) more wet-dry cycling promoted higher spore germination rates. Furthermore, Feng and coworkers suggested that the strong microbial activity of the intermittently flooded environments could facilitate spore germination by breaking down the spore wall.

Figure 263. *Sphagnum fallax*, a species in which spore germination rates benefit by frequent wet-dry cycles. Photo by Hermann Schachner, through Creative Commons.

It appears that the **Gaia hypothesis** may be operating at many levels in the ecosystem, and that the bryophytes are no exception. Their behavior with such companion

species as bacteria permits the combination to act as a super organism.

Summary

Poikilohydric bryophytes depend on desiccation tolerance (**DT**), becoming dormant when desiccated. Bryophytes gain water in their cells both through external (**ectohydric**) capillary movement and internal (**endohydric**) transport. When fully hydrated, their water content is typically high, up to more than 1200% of their dry mass. When dry, they can survive months to many years. Structural adaptations of stems and whole plants such as **growth form, branch and leaf arrangements, rhizoidal tomentum, mucilage, central strand, hydroids, paraphyllia, ventral scales, cuticles, and stomata** aid in moving water, facilitating entry, or reducing loss.

In xerophytic bryophytes, leaves and stems often possess large **trigones** and **nodular intermediate thickenings** on interior walls. Some liverworts have branched **vittae** such as those of *Herbertus aduncus* that enhance water uptake and storage. **Papillae** create capillary spaces to hold water on leaf surfaces. Leaf cells are usually small and basal **alar cells** help the leaf change positions to be near the stem upon drying. Xerophytic stem cells are thick-walled. These wall adaptations consist mostly of hemicelluloses, pectins, and cellulose, substances that would facilitate apoplastic water uptake, movement, and retention.

Thallose liverworts benefit from ventral transport by **rhizoids** and **scales**. The dorsal surface is covered by a **cuticle** but gas exchange may occur through pores overlying photosynthetic chambers. The pores are ringed by cells with cuticular ridges that prevent water drops from entering but that allow water vapor to escape, as well as admitting CO₂ and expelling O₂. Midribs may help to gather and direct water both externally and internally. Some have **ballooning cells** on the epidermis. For many taxa, dormancy is a "last resort" to avoid the effects of desiccation.

Fungal partners occur in both thallose and leafy liverworts, but their role is not known. Smooth rhizoids facilitate fungal entry; pegged rhizoids transport water and the pegs prevent collapse upon drying.

In mosses and leafy liverworts, **growth form** can help in both movement and conservation of water. Clumps reduce transpiration and provide additional capillary spaces. **Mixed species** can help each other, especially if one is good at moving water and one is good at retaining it. Mosses may have a **central strand** where water moves, but this is apparently absent in all liverworts except the **Haplomitriopsida**. **Leaf cuticles** occur in both mosses and liverworts and may repel water to avoid water logging or reduce loss by transpiration. **Rhizoids** and **tomentum** help in the movement of water upward. **Mucilage** in some liverworts, especially **Haplomitriopsida**, can be of great value in holding water about the plants.

The **protonema** can usually withstand slow drying. Like the guard cells in some stomata, it is responsive to **ABA**. ABA may be linked to **inducible desiccation**

tolerance in the gametophores. **Constitutive desiccation tolerance** is the most common form of desiccation tolerance in bryophytes, but as the plants age they may switch to inducible desiccation tolerance. **Hardening** can occur following slow drying and may last more than a few days.

The sporophyte and calyptra both have **cuticles**, and at least in *Funaria hygrometrica*, the cuticle in the calyptra matures first, helping the calyptra to protect the young embryo. Calyptra hairs, thallus hairs, paraphyllia, and paraphyses all function to help in movement of water and reduce rate of drying. Capillary spaces provided by these can further facilitate absorbing and holding water, bathing the tissues in water and reducing water loss.

The sporophytes of most(?) mosses and hornworts have **guard cells** and **stomata** that cease to open and close at sporophyte maturity. Their function(s) are ambiguous, but they may contribute to creating a transpiration stream to move nutrients upward, regulating capsule hydration during development, and drying the capsule prior to dehiscence and dispersal.

Acknowledgments

An earlier version of this chapter benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me explain things without leaving too much to one's imagination, but at the same time not repeating myself. In an earlier version Linda Luster checked the literature citations, proofread, and made glossary suggestions from a layperson's perspective.

CHAPTER 7-4a

WATER RELATIONS: LEAF STRATEGIES – STRUCTURAL

Figure 1. *Campylopus introflexus* demonstrating the ability of water to cling and collect on the thin, wiry leaves. Photo by Michael Lüth, with permission.

Much of what we know about water uptake by bryophytes has been through observation. While the observations are probably valid, broad generalizations have emerged and these have been applied to all mosses, especially by non-bryologists, and can lead to inappropriate experiments and conclusions.

Larson (1981) experimented with three species of bryophytes (and 8 lichens) using a "raining" wind tunnel environment to determine the effects of various structures on water uptake and storage. Larson found that the time required to reach saturation did not differ between lichens and mosses, varying from three minutes in the moss *Polytrichum juniperinum* (Figure 2) to over 300 minutes in the lichen *Stereocaulon saxatile*. The rate of absorption increases with the ratio of surface area to weight, making it extremely rapid in finely divided plants. Hence, comparison of leaf structure and plant form become important in considering the role of bryophytes in the water cycling of an ecosystem (Proctor *et al.* 1998; Wu *et al.* 2007).

Schofield (1981) considered leaf shape, arrangement, orientation, surface ornamentation, and detailed anatomy to

be important in influencing water movement. These adaptations are complemented by branch arrangement, stem cortical cells, rhizoid structure, and presence of paraphyllia.

Figure 2. *Polytrichum juniperinum* hydrated (left) and dry (right) showing change in leaf position to wrap around stem. Photo by Michael Lüth, with permission.

Bryophytes hold their water in three ways (Proctor *et al.* 1998): **apoplastic** water in cell-wall capillary spaces and held by matric forces; **symplastic** (internal osmotic) water; external capillary water. For many bryophytes, the external capillary water is a highly important, albeit variable, component. This external water complicates any measurements of relative water content (RWC) because it makes measurement of the bryophyte at full turgor a difficult endeavor. Proctor *et al.* found that full-turgor water ranged from 110% dry weight (dw) in *Syntrichia ruralis* (Figure 3) and *Andreaea alpina* (Figure 4) to 1400% dw or more in *Dumortiera hirsuta* (Figure 5) and *Conocephalum conicum* (Figure 6-Figure 7). Most species had an osmotic potential ($\Psi\pi$) at full turgor of -1.0 to -2.0 MPa, but thallose liverworts had values that were much less negative (-0.35 to -0.64 MPa).

Figure 7. *Conocephalum conicum* thallus section with pore. From website of the Botany Department, University of British Columbia, with permission.

Pressel *et al.* (2009) pointed out that despite the ancient history of liverworts, we know little about the physiology of their desiccation tolerance. Desiccation causes a number of cytological changes in liverworts, including fragmentation of the vacuole, rounding of the chloroplasts and mitochondria with thylakoids, and cristae becoming rearranged but remaining undamaged, all responses that are similar to those of mosses and **tracheophytes** (non-bryophyte plants; plants with lignified vascular tissue). Furthermore, chlorophyll fluorescence shows half-recovery within minutes to 2 hours, but requires 24-48 hours to reach normal, unstressed values. And like desiccation tolerance in mosses, the de- and repolymerization of the cortical microtubule cytoskeleton

are associated with de- and rehydration. But liverworts have oil bodies, and these play a role unknown in mosses, as will be seen below.

Guerra *et al.* (1992) described the adaptations of xeric mosses in the gypsiferous zones of the southeast Iberian Peninsula, listing 15 modifications for conserving water. I have included these and some of my own observations here.

Overlapping Leaves

Most bryophytes have their leaves inserted at angles on the stem. In some cases, especially leafy liverworts (Figure 8), these are **incubous** in arrangement [leaves overlapping from base to tip like shingles on a roof, with the part of the leaf closer to the stem base being nearer the substrate (ventral) and the more apical side emerging on the upper (dorsal) side of the stem], whereas others are **succubous** [basal edge dorsal, apical edge ventral – the leaf succumbs to the leaf above it].

Figure 8. Succubous leaf arrangement of liverworts such as *Jungermannia* (left) and incubous arrangement of those such as *Calypogeja* (right). Note the decurrent leaf bases in the liverwort on the left. Redrawn by Margaret Minahan from Iwatsuki.

Clee (1937) found that in the succubous *Plagiochila asplenioides* var. *major* (Figure 9), water could move up to 3.7 cm in one minute. However, with the incubous arrangement, water moved less than 1 cm per minute. On the other hand, Basile and Basile (1987) questioned the role of the incubous vs. succubous leaf orientation in water conduction. They found that conduction proceeds equally in both orientations and that there is no correlation between the direction of leaf overlap and the angle of the substrate slope where they commonly grow. This seems reasonable since water coming from the top in rainfall would be presented with the opposite direction from water coming from beneath the branch. Hence, we could consider the branches in Figure 8 to be the above and below presentations of the same plant. Certainly if water is available from both above and below, it should make little difference if the plant is succubous or incubous. We need experiments to compare the effect on liverworts that form protruding shelves, those that are growing upright from a substrate, those that are adnate to a vertical surface, and

those that grow horizontally adnate to a substrate. Then we need to compare the direction of the water source – base or tip of plant, dorsal or ventral surface.

Figure 9. *Plagiochila asplenioides* with overlapping, succubous leaves. Photo by Michael Lüth, with permission.

Among mosses, Bowen (1933) considered the erect habit of leaves to hold and conduct more water than spreading leaves. This effect is enhanced if the leaves have **decurrent** bases (extensions of the leaf base down the stem; Figure 8).

Bayfield (1973) found that as water content declined in *Polytrichum commune* (Figure 10), the leaf arrangement changed (see also changes in *Polytrichum juniperinum* Figure 2). As the moisture decreased, the leaves wrapped closer around the stem, seemingly increasing moisture retention, a phenomenon that makes *Hedwigia ciliata* (Figure 11) almost unrecognizable when wet if one is only familiar with the dry state. Bayfield also found that external conduction is possible in the capillary spaces between the stem and the overlapping leaf bases. In the endohydric *Polytrichum* species, the loss of water is controlled by a complex series of changes in the leaf arrangement, whereas in the ectohydric *Racomitrium lanuginosum* (Figure 12-Figure 13), little or no mechanical control is exercised over water loss. It is likely that all *Polytrichum* (Figure 2, Figure 10) species benefit from this movement of the leaves upon drying.

Figure 10. *Polytrichum commune* showing the dry lower leaves that are beginning to wrap around the stem compared to the wide-spreading upper leaves that are well hydrated. Photo by Michael Lüth, with permission.

Leaves Curving or Twisting upon Drying

Many species have leaves that curve or twist when they dry, particularly those in xeric habitats. These leaves curve toward the stem and thus reduce the exposed surface area. Among these are *Campylostelium pitardii* (Figure 14), *Phascum cuynetii*, and *Pterygoneurum sampaianum*.

Thickened Leaf

Many leaves partially protect themselves from water loss by having all or part of the leaf more than one cell thick. This is a common character for the borders and costa, where it most likely serves for support and possibly water movement, but in the leaf **lamina**, this reduces the exposed surface area (Figure 17).

Some leaves are **bistratose** in the upper part of the leaf, *i.e.* the part most exposed when the plant is dry. Among these are the xerophytic species *Syntrichia caninervis* (Figure 115) subsp. *spuria*, *Dicranella varia* (Figure 15), and *Didymodon australasiae* (Figure 16) (Guerra *et al.* 1992).

Figure 15. *Dicranella varia*. Note the twisted leaves on the dry mosses in the foreground. Photo by J. C. Schou, with permission.

Figure 16. *Didymodon australasiae* showing leaves curved around the stem in this dry state. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Some species protect the photosynthetic cells with hyaline cells, as in *Leucobryum* (Figure 18) and *Octoblepharum* (Figure 19). *Fissidens grandifrons* (Figure 20) differs from most other members of the genus *Fissidens* by having leaves that are multiple cell layers thick, most likely an adaptation to its habitat in fast-flowing water of streams and waterfalls. *Fissidens* accomplishes a degree of protection and provides capillary water-holding spaces by creating a pocket (Figure 21-Figure 24), giving this region a thickness of two layers of cells; the next leaf toward the apex often fits into this pocket. But this flattened moss nevertheless moves water slowly through its external surface (Table 1).

Concave Leaves

Proctor (1979a) found that many taxa of ectohydric mosses have concave leaves (e.g. Figure 25-Figure 26). When examined in moist weather, the concavities on the upper sides of the leaves will generally be full of water. This helps to solve the problem of gas exchange by exposing one surface to the atmosphere while keeping the other surface bathed in water. And most of the CO₂ needed for photosynthesis comes from respiration in the soil and litter. Gas diffusion in air is about 10⁴ times faster than in water (Proctor 1982). Other mosses, like *Campylopus* (Figure 1) and *Polytrichum* (Figure 2, Figure 10), are able to roll their leaves, like some grasses, when they are dry. In this mode, mosses like *Syntrichia ruralis* (Figure 28) can look much darker and expose less surface area to the atmosphere, whereas the wet cells change the optical properties, making the cell walls more translucent (Glime & Church, unpubl.).

Figure 25. The moss *Scleropodium touretii* illustrating deeply concave leaves. Photo by Michael Lüth.

Figure 27. *Syntrichia ruralis* dry. Photo by Janice Glime.

Figure 28. *Syntrichia ruralis* wet. Photo by Janice Glime.

Leaf spreading upon re-moistening is rapid in most bryophytes. Yenhung Li (unpublished data) found that in *Sphagnum* sp., *Ptilium crista-castrensis* (Figure 29), *Pleurozium schreberi* (Figure 30), and *Dicranum polysetum* (Figure 32), the first leaves spread within 1.5 to 2 seconds of receiving water (Table 1). To wet all the leaves in pieces 0.7 cm long required less than 2 minutes for most taxa, but required 24 minutes in *Rhodobryum ontariense* (Figure 31). The highest rate of conduction among the 15 taxa was in *Pleurozium schreberi* (140 mm min⁻¹).

<i>Fissidens adianthoides</i>	284	0.08
<i>Rhodobryum ontariense</i>	1421	0.06

Li found some indication that small leaves can spread more quickly than large ones, at least in *Fontinalis*. *Fontinalis duriaei* (Figure 33) has smaller and thinner leaves than does *F. antipyretica* var. *gigantea* (Figure 34-Figure 35), and *F. duriaei* can spread its leaves in 1/3 the time required for *F. antipyretica* var. *gigantea*. However, the difference may be due to the stiffness of the keel (leaf fold; Figure 35) in *F. antipyretica* var. *gigantea*, whereas *F. duriaei* has flat leaves.

Figure 33. *Fontinalis duriaei*, a species with flat, relatively narrow leaves that spread more quickly than larger leaves with a keel in *Fontinalis antipyretica* var. *gigantea*. Photo by Janice Glime.

Among the slowest species to re-wet in Li's study were *Fissidens adianthoides* (Figure 36) and *Rhodobryum ontariense* (Figure 31), both for rate of conduction and leaf wetting. *Fissidens adianthoides* has leaves that are large and partly two-layered. There is little overlap between the leaves in this genus except at the two-layered pocket (Figure 37), and Church and Nelson (unpubl data) noted that when the leaves of *F. adianthoides* are dry there is little or no overlap even at the pocket. Therefore, lack of capillary space may account for its slow response. The slowness of *Rhodobryum ontariense*, which has all its leaves crowded at the top of the stem like a palm tree (Figure 31), may likewise be explained by lack of capillary spaces (Figure 38). Below the crowded rosette of leaves at the apex are very reduced scale-like leaves along the stem, providing little capillary space and rendering it the slowest among the 15 species observed by Li. It required 123 minutes for the water to travel 0.7 cm up the stem! Although Li's data indicate a slight trend for rapid conduction to be coupled with rapid leaf spreading, there are enough exceptions to indicate that the relationship is not so simple.

Cucullate Leaves

Cucullate is hooded or boat-shaped, referring to the apex of leaves in this case. The cavity created by this leaf form is able to hold water, in part due to surface tension. An example of this is the moss *Phascum cuynetii*; some *Sphagnum* (Figure 39) species also have cucullate leaves.

Figure 39. *Sphagnum* sp. from the Neotropics showing cucullate leaves. Photo by Michael Lüth, with permission.

Plications

Plications, or Japanese fanfolds, in the leaf may reduce evaporation by reducing the exposed area and creating nearly dead space between the folds. On the other hand, it might simply be a means of neatly folding the leaf as it dries and loses the turgidity that kept it concave. These plications are present in *Brachythecium* (Figure 40), *Coscinodon* (Figure 41-Figure 43), and *Hamatocaulis vernicosus* (= *Drepanocladus vernicosus*; Figure 44), among others. Some taxa exhibit these only as they are drying or dry, so the system is responsive to water loss. When it is rehydrated, the plications permit the leaf to expand.

Revolute and Involute Margins

Just as elongate cells of the border permit leaves to become contorted as they dry, the involute (Figure 45-Figure 48) and revolute (Figure 49-Figure 50) margins add structural support to the margin that causes contortions when the leaf dries (Figure 50). This contorted condition is known as **crispate**.

Figure 45. *Weissia controversa* that has recently been wet, showing **involute** leaf margins. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 50. *Bryoerythrophyllum recurvirostrum* leaf showing strong costa and **revolute** leaf margin that cause its **crispate** appearance when dry. Photo by Michael Lüth, with permission.

Both **Pottiaceae** and **Grimmiaceae** exhibit crisp, contorted leaves where the lamina is able to shrink and the leaf can roll with marginal rolling increasing as the plants dry (Kürschner 2004). The leaves wind spirally around the stem as they dry, reducing water loss and protecting the chlorophyll and DNA from excessive sunlight. The untwisting of the leaves provides another service – removal of trapped sand particles and other particles held by the leaves. When the lamina folds inward, it reduces desiccation. Kürschner suggests that the shiny costa may increase reflection of sunlight, further reducing desiccation. In these two families that occupy dry, open habitats, parallel evolution has adapted them to their similarly dry niches.

Borders

Borders are usually elongate cells that may be light in color or heavily pigmented. But in some species, the leaf margin may be heavily pigmented with chlorophyll in multiple cell layers. Such is the case in species of *Pseudocrossidium* (Figure 51-Figure 54) (Kürschner 2004). These species have marginal cells that form a well developed chlorophyllous region (Figure 52). They are protected by the **revolute** (rolled under; Figure 52-Figure 53) leaf margin that helps to maintain their hydration (Herzog 1926; Kürschner 2004).

So if the costa conducting cells all have protoplasm (**leptoids**), this leaves us with the question of water transport within the leaf. **Leaf borders** with elongate cells such as those in *Atrichum* (Figure 55) and the **Mniaceae** (Figure 56) provide benefits similar to those of the costa and seem to speed the movement of water from the base of the leaf to more distal parts, or in some cases from the tip toward the middle, but unfortunately, I have been unable to find any published study to verify this memory. Other roles are discussed in Chapter 7-4.

Figure 56. *Plagiomnium affine* leaf border showing elongate cells compared to wider but shorter leaf lamina cells. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

It appears that long border cells (Figure 56) are able to move water and facilitate uptake. But they may provide an additional role in the wet to dry state transition of the leaf in at least some taxa (Lowell 1998). When the leaf of *Atrichum undulatum* (Figure 57) is wet, the elongate cells of the border are turgid and extend the leaf lamina out into a nearly straight surface. But as the leaf dries, the opposing forces of the drying leaf cells and the border result in the contorted leaf shape that is exhibited by the dry *Atrichum undulatum* leaf (Figure 57). The margins roll toward each other and the tip rolls toward the base, creating a "boat" shape. The border acts much like a wire sewn into the edges of a cloth ribbon, but somewhat more flexible.

In *Atrichum* (Figure 57) the leaf is **prestressed**; that is, it has a natural dry state that is highly convoluted, but when wet the turgor forces it to become straight (Lowell 1998). Thus, when the leaf dries, the leaf itself contorts into a form that is able to trap and hold water next to the leaf and stem surface. As Lowell describes it, the border is like the party toy that you blow into and it extends straight out, but when it is relaxed, it forms a coil. Species of **Mniaceae** (Figure 58) with borders seem to have similar responses, with the borders causing the leaf margins to curl

Figure 58. *Plagiomnium* branch with contorted leaves due to drying. Although this moss has been rewet, it is slow to hydrate and regain its shape. Photo source unknown.

A similar adaptation appears in **Lejeuneaceae** and *Porella*, where a hyaline row of marginal leaf cells function in water storage (Daniels 1998). Perhaps the same function occurs in some of the mosses such as some *Fissidens* (Figure 59-Figure 60) or *Plagiomnium* (Figure 56) with well-developed borders. Because of their elongate structure, water can be expected to move more quickly along the border because of fewer end walls to traverse. Yet there seems to be little experimentation to demonstrate that these cells are of any advantage in gaining or moving water to vital parts, or holding water.

Leaf Teeth

Lots of ideas have been presented to suggest the evolutionary significance of teeth in tracheophytes, from deterrents to insects (making the leaf look like something has eaten it, stimulating production of antiherbivore compounds or being spiny) to dripping points for water to help reduce growth of fungi and epiphytes. But what might their value be to bryophytes (Figure 61-Figure 62)?

One interesting observation is that teeth and lobed leaves of deciduous trees are more common in deciduous forests, but they are rare in tropical forests (Baker-Brosh & Peet 1997). Baker-Brosh and Peet hypothesized that they might provide sites for early season photosynthesis. They found that eight species with prominent teeth or lobes did indeed have early season photosynthesis on the margins of the leaves, but not in seven others and none in the four entire-leafed species in the experiments.

Figure 61. *Mnium spinosum* leaf showing small, nearly rounded lamina cells compared to the elongate border cells and prominent paired teeth. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Royer and Wilf (2006) noted that toothed leaves of tracheophytes were common in cold climates and that the percentage of toothed leaves correlated negatively with temperature in **mesic** (containing a moderate amount of moisture) environments. They conducted experiments in Pennsylvania and North Carolina, USA, to determine the

advantages of the teeth. They found that the physiological activity at the leaf margins was greatest early in the first 30 days of the growing season. And toothed margins were more active in photosynthesis and transpiration than were those of untoothed leaves. They supported the observations of Baker-Brosh and Peet 1997, showing that the leaf margins were more active in leaves from Pennsylvania, which was colder, than those of the California leaves. This strategy maximizes carbon gain during the season when the temperature is limiting but moisture and nutrients are not limiting.

Figure 62. *Atrichum undulatum* leaf cells and border showing enlarged tooth with chlorophyll. Photo by Walter Obermayer, with permission.

Obeso (1997) found that spines on the European holly (*Ilex aquifolium*) deterred browsing by ungulates, and that the spines were inducible, decreasing significantly when browsing was prevented for one year.

Another possibility for the adaptive value of teeth is their bearing on water relations. Royer *et al.* (2009) found that among the 227 sites they studied in the Australian subtropical rainforest, both the percentage of species and abundance of toothed species declined from **riparian** (wetlands adjacent to rivers or streams) habitats to ridge-top habitats. Hence, we can rule out any protective value that teeth might have against desiccation. On the contrary, this correlation suggests that teeth could have a role in reducing water in saturated leaves.

Do these tracheophyte models help us to suggest roles for teeth in bryophytes, or are they simply not a detriment to the mosses and liverworts that have them? Do leaf teeth suggest that something has eaten the leaves? We don't know if antiherbivore compounds are inducible in bryophytes, so there may be no disadvantage to having teeth as a warning unless most of the leaves with teeth do have antiherbivore compounds, inducible or not. It seems unlikely that the teeth have any painful effect to deter browsers. And we don't even understand how deciduous tree leaves benefit from teeth in more moist climates.

It is possible that the bryophyte teeth do have a photosynthetic role in spring when new leaves are forming. The apex, especially of acrocarpous mosses, has the most exposure to light, and the marginal parts of the leaves will have the most exposure, so it is possible that they have such a role. But experiments to demonstrate such a benefit are lacking.

Teniolae

The **teniola** is a border-like row of differentiated cells (Figure 63), differing from a true border by being intramarginal (*i.e.* not at the margin). They are more than one cell thick and this condition may extend also throughout the blade portion. These are found in *Calymperes* (Figure 64) and function for support, but may also provide water transport (Reese 1993).

Figure 63. Portion of leaf showing the intramarginal border, the **teniola**. Drawing by Janice Glime.

Figure 64. *Calymperes motleyi*, member of a genus that has **teniolae**. Photo by Jan-Peter Frahm, with permission.

Costa

The **costa** is the supporting structure for many moss leaves, often also providing an avenue of water transport (Frahm 1985) (Figure 65-Figure 66). It resembles a midrib both in appearance and function (Figure 67). Habitat

seems to play some role in its development, although its predisposition to presence or absence is usually genetically determined.

Figure 65. *Mnium hornum* showing distinct costa and teeth. Photo by Bob Klips, with permission.

Figure 66. *Mnium hornum* leaf showing elongate cells of costa and border. Photo by Bob Klips, with permission.

Figure 67. Cross section of *Trichodon cylindricus* showing costa. Photo by Janice Glime.

The costa of some species may be shorter, thinner, and even disappear when it develops in water (Zastrow 1934). For example, the submerged forms of *Warnstorfia exannulata* (= *Drepanocladus exannulatus*) (Figure 68-Figure 69) have a costa that only reaches midleaf, whereas the terrestrial forms have a strong costa; similarly, *Cinclidium stygium* (Figure 70) normally has a strong costa above water, but when grown submerged it becomes thin and small (Zastrow 1934). When cultured in artificial streams where the leaves were exposed to air, *Fontinalis novae-angliae* developed short double costae, although

these are normally absent when it grows submersed (Glime, unpubl.). The broad costa in *Campylopus* (Figure 71-Figure 72) not only serves as the photosynthetic organ, but as a water reservoir as well, adding to the possible advantages of growing a costa above water.

Figure 72. Leaf cross section of *Campylopus flexuosus* showing broad costa with cells that have water-holding capacity as well as photosynthetic capacity. Photo by Michael Lüth, with permission.

Guerra *et al.* (1992) considered **nerve enlargement** to be an adaptation to the xeric environment, providing stiffening that supports the leaf during desiccation. Bell (1982) suggested that it also might retain water.

Stereids

In the stem, **stereids** are thick-walled cells that contain living protoplasm and have been compared to xylem parenchyma cells (Héban 1970). In leaves, they form ribs on one or both sides of the costa (Figure 73) and may function as protection against desiccation (Frahm 1985). They occur in a variety of families, including **Dicranaceae** (Figure 74) and **Pottiaceae** (Figure 75-Figure 76).

Figure 73. *Trichostomum tenuirostre* (moss) leaf cross section showing stereids. Photo by Janice Glime.

Figure 74. *Dicranum scoparium* (Dicranaceae) leaf cross section. This leaf has few sclereids but has relatively large conducting cells, in this case smaller than the leaf lamina cells. Photo from Botany website, University of British Columbia, Canada.

Figure 75. *Syntrichia inermis* (Pottiaceae) leaf cross section. Note the enlarged costa with stereid cells on the bottom and conducting cells near the top. In this case, the lamina cells are covered with papillae that may help in water intake, a function thus far demonstrated for only one species. More likely they channel the water. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 76. *Syntrichia princeps* (Pottiaceae) leaf cross section showing costa with stereids (pinkish color on lower portion) and large leptoids. Photo by Paul S. Wilson.

It appears that the structure of the costa can have adaptive value relating to moisture conditions. Those *Campylopus* taxa surviving habitats with changeable conditions have well-developed costal stereids (Frahm 1985). Frahm found that dorsal costal **lamellae** (Figure 95) aid in water uptake, whereas the ventral costal stereids (Figure 77) common among *Campylopus* species help to reduce desiccation. *Campylopus savannarum* survives its savannah habitat with the aid of such stereids, whereas *Campylopus* taxa occurring on wet cliffs, dripping rocks, and swamps lack stereids (Figure 78).

Figure 78. *Campylopus tallulensis* leaf cross section showing thin-walled ventral costal cells typical of the more humid mountainous regions. Photo by Amelia Merced, with permission.

Lamellae

The term **lamella** shares the same root word as laminate and refers to layers, in this case vertical stacks of cells that form rows, often reaching the length of the leaf (Figure 82, Figure 83). They may cover the costa, the blade, or a liverwort thallus. These rows are arranged in such a way that they somewhat resemble a book that has just been opened and laid to rest, with its pages still parting and standing upward from the middle. Some of the most **xerophytic** (referring to plants of dry habitats) mosses, such as *Aloina* (Figure 79), have branched filaments over the costa, giving it a **succulent** (fleshy) appearance; *Crossidium* (Figure 80-Figure 81) achieves a similar effect with dense filamentous outgrowths from the costa in the upper half of the leaf.

Figure 79. *Aloiina brevirostris*, illustrating the succulent appearance caused by the numerous filaments on the costa. Photo by Michael Lüth, with permission.

Figure 80. *Crossidium crassinerve* with filaments on leaf costae. Photo by Michael Lüth, with permission.

Figure 81. *Crossidium aberrans* leaf showing filaments on costa. Photo by Michael Lüth, with permission.

Members of the **Polytrichaceae**, such as *Polytrichum* and *Dawsonia*, which are all **endohydric** (having internal water transport), have vertical lamellae (Figure 82, on their leaves that provide capillary spaces and create dead air spaces that can reduce water loss across the broad surface of these atypically large moss leaves (Figure 82-Figure 85). In addition, some species [*Polytrichum hyperboreum* (Figure 86-Figure 87), *P. piliferum* (Figure 88-Figure 89), *P. juniperinum* (Figure 90-Figure 91)] have the edge of the

leaf **lamina** (flattened part of leaf not including costa or border) rolled over the lamellae, creating an internal structure somewhat like the **palisade mesophyll** (columnar cells of inner leaf tissue) of a flowering plant, with the lamina behaving in some ways like an epidermis. The leaves have the additional ability to flex like a hinge when water fills the thin-walled leaf base cells (van Zanten 1975), causing the leaves to be spread lengthwise away from the stem under moist conditions but be straight or curved around the stem when dry (Figure 2). Such behavior retards water loss and protects the chlorophyll during dry periods, while permitting maximum use of light during wet periods.

In *Pilopogon laevis* (Figure 92) the costa is ribbed on the back of the leaf; in *P. peruvianus* (Figure 93-Figure 94) it has 3-4-cell-high lamellae on the back of the leaf, adapting this species to its dry coastal desert habitat. Likewise, *Campylopus pilifer* (Figure 95) has similar lamellae and prefers such dry habitats as rocks, soil-covered boulders, and gravel. On the other hand, *C. introflexus* (Figure 96) has only 1-2-cell-high lamellae and lives on humus, wet sand, and peat.

Figure 96. *Campylopus introflexus*, a plant of humus, wet sand, and peat, leaf cross section showing shallow lamellae. Photo by Gilles Bailly, through Creative Commons.

Although Frey and Kürschner (1991) found a correlation between costal lamellae and increasing aridity, the lamellae of *Polytrichum* seem not to be so much an adaptation to prevent water loss as to provide for additional surface area [2.4-fold in *Polytrichum commune* (Figure 97-Figure 98)] and gas exchange during photosynthesis (Thomas *et al.* 1996). Proctor (1979a, b) and Thomas *et al.* (1996) described wax on the terminal cells of the lamellae of *Polytrichum* and attributed to this wax the repulsion of water, preventing it from entering between the lamellae. Perhaps lamellae are adapted to increasing gas exchange and are more important in water retention or repulsion than in absorption, at least in some species.

Figure 97. *Polytrichum commune* leaves with waxy surface that keeps water out of the lamellae. Photo by James K. Lindsey, with permission.

The genus *Atrichum* (Polytrichaceae) also has shallow to deep lamellae, and these have been used to justify separation into different species. The lamellae shown in Figure 99-Figure 101 fall within *Atrichum undulatum* var. *undulatum*, but any lamellae more than 4 cells high would indicate a different variety (Crum 1983), or species (The Plant List 2010).

Lobules and Storage Organs

Liverworts have an evolutionary history that separates some of the major groups by their water relations (Heinrichs *et al.* 2005). In the **Jungermannniidae**, two clades split. The **Porellales** are predominantly epiphytes that have specialized **lobules** (Figure 102) or water sacs and **endosporous** protonemata. The **Jungermanniales** (Figure 103) are frequently terrestrial, lack water sacs, and normally develop **exosporous** protonemata.

Figure 102. Ventral side of *Porella platyphylla* showing underleaves along stem and lobules on each side of them. Photo by Paul Davison, with permission.

Figure 103. *Lophozia wenzelii*, a member of the **Jungermanniales**, showing the absence of lobules. Photo by Des Callaghan, with permission.

Daniels (1998) has compared leafy liverworts growing in a variety of habitats. **Xerophytic** (dry habitat adapted) taxa such as *Frullania* (Figure 104) have helmet-shaped leaf **lobules** and *Radula* (Figure 105) has a saccate lobule, both functioning for water storage. *Porella* (Figure 102), capable of both an **epiphytic** (living on plants) and a **saxicolous** (living on rock) habit, has leaf folds underneath (lobules) and large underleaves. Liverwort plants in the humid rainforests such as those in the **Lejeuneaceae** (Figure 106-Figure 108) have smaller lobules than those growing in drier, more exposed habitats (Cornelissen & ter Steege 1989; Gradstein 1995). Such structures help to hold water in capillary spaces in the absence of multiple rows of leaves. Some aquatic invertebrates, especially rotifers, live in these watery lobules (see Volume 2, Chapter 4-5 on Rotifers). It is likely that the pockets of *Fissidens* (Figure 21-Figure 24, Figure 37) may have similar water-holding functions.

Hair Points

Hair points are common on leaves of xerophytic mosses, including species of *Campylopus* (Figure 109- Figure 110), *Grimmia* (Figure 111), *Schistidium* (Figure

112-Figure 113), *Hedwigia* (Figure 134), and *Syntrichia* (Figure 114). As discussed earlier, Loeske, in 1930, demonstrated that in *Schistidium apocarpum* (Figure 112-Figure 113) hair points are actually lost when the mosses are kept in damp air or deep shade. Proctor (1979a) and Kürschner (2004) consider these hairs to be organs that reflect some of the solar radiation, thus reducing energy absorption, temperature, and evaporation. But they reduce water loss more directly as well; hair points on *Syntrichia intermedia* (Figure 114) and *Grimmia pulvinata* (Figure 111) reduce the boundary layer conductance by about 20-35% in experiments (Proctor 1980). Not only does this thicker boundary layer trap stagnant air, thus reducing evaporation loss, but it increases the distance from the leaf surface to the surrounding air, thus decreasing the diffusion gradient (Proctor 1982).

Figure 113. *Schistidium apocarpum* exhibiting the leaf hair points that develop when the plants are in dry areas. Photo by Christophe Quintin, through Creative Commons.

Hair points may also help in trapping and absorption of water vapor from fog and dew (Figure 109-Figure 110). Dry tips can reflect sunlight (Figure 109), reducing water loss (Kürschner 2004).

Figure 114. *Syntrichia intermedia* demonstrating prominent hair points. Photo by Jan-Peter Frahm, with permission.

As suggested by the example of *Campylopus introflexus* (Figure 109-Figure 110), hair points can help in collecting moisture from the air as well (Figure 110). Shaun Russell has described to me that in African highlands the mosses act as tiny collectors that trap moisture from the fog. This is often their only source of water for an entire year. Chang and coworkers (2002) have measured the water available to epiphytes in fog (Table 2) and in precipitation in a subtropical montane forest in Taiwan. In a one-year study, they found that the fog endured for a mean of 4.7 hours per day at its low in the summer to 11 hours per day the rest of the year, reaching nearly 15 hours per day in November. Furthermore, it contributed more than 50% of the nutrient ions reaching the bryophytes.

Table 2. Absorption rate of fog in dominant epiphytes during a single dense fog event on 24 February 2001 at Yuanyang Lake, Taiwan. From Chang *et al.* (2002).

Species	absorption rate g H ₂ O gdw ⁻¹ h ⁻¹
<i>Bazzania fauriana</i>	1.28
<i>Bazzania</i> sp. 2	0.90
<i>Pleurozia acinosa</i>	0.67
<i>Mastigophora diclados</i>	0.59
<i>Schistochila acuminata</i>	0.58
<i>Dicranoloma blumii</i>	0.42
<i>Scapania</i> sp. 1	0.38
<i>Bazzania</i> sp. 1	0.23

Zhang *et al.* (2009) considered the effect of dew as an important moisture source in the Gurbantunggut Desert, Northwestern China. They measured dew quantities with micro-lysimeters and demonstrated the increase in dew deposition as the crust grew larger. Mosses had the highest deposition compared to that of lichen crusts, cyanobacterial crusts, and bare sand ($p < 0.05$). Interestingly, the retention time for the moisture gained from dew did not follow this pattern. Instead, it was held longest by sand, followed by the cyanobacterial crust, moss crust, and lichen crust, in that order.

Tao and Zhang (2012) further examined the function of hair points in the desert moss *Syntrichia caninervis* (Figure 115). The hair points in this case comprised only about 4.8% of the shoot weight, but they were able to increase the absolute water content by 24.9%. And, during dehydration, those moss samples with hair points always

had a higher water content than did those without. Furthermore, the shoots with hair points took 20 minutes longer to become completely dehydrated. And of course there was greater dew accumulation on the shoots with leaf hair points, increasing the dew on the crusts by 10.3%. Following short simulated rainfall events, the evaporation of water from the crusts was always slower when the leaves had hair points in contrast to the rapid loss of water trapped from dew (Zhang *et al.* 2009).

Yuan Ming Zhang's research team filmed the events following application of a drop of water on the hair points of *Syntrichia caninervis* (Figure 115). The water moved quickly down the hair point and was absorbed by the leaves within seconds. Like a fine wire, the hair tips serve as a conduit for the water. This mechanism permits these mosses to extract water from dew or fog, and to benefit from rapid absorption of the first few drops of rain, maximizing its period of hydration. Zhang *et al.* (2011) supported the significance of this rapid rewetting. In lab experiments they showed that within the first minute the photosynthetic yield (F_v/F_m) recovered to 90% of its rate after 30 minutes. Cytological changes occurred rapidly, indicating no damage to membranes or organelles. This rapid recovery makes it possible for it to use the water collected by the hair points from fog, dew, rain, and melting snow for immediate recovery, making it possible to attain positive photosynthetic gain in its desert ecosystem.

Figure 116. *Syntrichia caninervis* leaf showing awn. Photo by Yuan Ming Zhang.

Duration of the rainfall or dew fall event is important. Proctor (2004) found that in *Grimmia pulvinata* (Figure 111), dew fall did not enter the moss sufficiently to rehydrate it. Could these hair points prevent wetting and drying cycles that are too frequent for adequate repair of dehydration damage in mosses regularly subjected to hot, dry days? Is this a mechanism to prevent the leaf from becoming hydrated at a time when it will dehydrate again within hours? This is reminiscent of the dormancy mechanism in desert seeds wherein a chemical must be washed off before the seed will germinate. This keeps the seed from germinating unless there is enough rainfall to sustain the young seedling until it reaches a size where it can survive. In these mosses, it requires a rainfall that will hydrate the moss long enough for it to repair the damage of desiccation and make a positive photosynthetic gain before becoming dehydrated again.

Nucleation

It appears that bryophytes are good nucleators. This is a phenomenon in which a small object, known best from bacteria and proteins, causes the formation of ice around itself. Moffett *et al.* (2009) suggest that this phenomenon is widespread among bryophytes. Nucleation occurs when the difference in vapor pressure over ice and water is at or close to the maximum. At these temperatures, typically -8 to -18°C, ice grows at the expense of supercooled water. Moffett *et al.* suggest that the nucleation ability permits the bryophytes to collect water from fog, dew, and cloud water. It is interesting to note that airborne bryophytes may use this nucleation to initiate precipitation.

Papillae

Papillae in bryophytes are small projections from cells, especially common in the **Pottiaceae** (Figure 117-Figure 118). Kou *et al.* (2014) attempted to limit the confusion of many terms in their descriptions by providing four terms to describe them: simple, forked, branched, and pedicellate.

Papillae can both facilitate rapid water uptake (Proctor 1979a; Longton 1988; Kürschner 2004) and accelerate water loss (Pressel *et al.* 2010). Species that benefit from these papillae must, as a consequence, shut down under drying conditions. This is consistent with the role of surface waxes (discussed in Chapter 7-4b of this volume). The thick surface waxes of tracheophytes are usually associated with conditions of drying. In bryophytes, however, they are often characteristic of species from constantly flowing aerated water or other places where water logging depresses gas exchange (Pressel *et al.* 2010). In other words, often they are important for their **hydrophobic** (water-repelling) nature.

The role of papillae, those little bumps and extensions on cell walls (Figure 118), has been controversial for a long time, but their common appearance on bryophytes of dry habitats cannot be ignored. Nevertheless, Loeske (1926) points out that papillae are also found in a number of wetland and aquatic taxa, including *Dichodontium pellucidum* (Figure 119-Figure 120), *Philonotis* (actually **prostrate** cells – end walls overlap and protrude; Figure 121-Figure 122), *Aulacomnium palustre* (Figure 123-Figure 124), *Helodium blandowii* (Figure 125-Figure 126), and *Paludella* (Figure 127). Loeske observed that the papillae

are maintained in a number of species through a wide range of wet to dry habitats. On the other hand, these taxa are common in wet meadows, lake shores, and other wet habitats where they may periodically be dry while being exposed to high sunlight, suggesting that the papillae may be of value under those exposed conditions.

Some papillae are quite decorative, adorning species that typically live on limestone rocks or other highly desiccating habitats. *Encalypta ciliata* (Figure 128-Figure 130) has branched papillae and lives on limestone rocks and other dry locations.

Figure 128. *Encalypta ciliata* in a hydrated state, showing the nearly translucent appearance of the leaves. Photo by Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 130. *Encalypta ciliata* leaf cells with multiple papillae. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Proctor (1979a, 1984, also Longton 1988) described the interstitial spaces between papillae as forming a capillary conducting system that is capable of rapid water movement, as we might expect in *Tortula muralis* (Figure 131-Figure 132). (See also the chapter on Leaf Strategies – Cuticles and Waxes in this volume.) But papillae may be most important in altering the boundary layer and creating a dead space that reduces water loss. Both of these ideas, as well as their role in deflecting UV light, remain to be tested.

Figure 131. *Tortula muralis* leaf cross section showing the multiple papillae on each cell. Photo from Botany Department website, University of British Columbia, with permission.

Hedwigia ciliata (Figure 133-Figure 134) is a moss that has white tips on its leaves, presumably protecting the underlying leaves from sun damage. But we need to examine the role of these tips in water uptake as well. The leaf and awn cells are heavily endowed with papillae that give the leaves a waxy appearance despite the absence of waxes.

Figure 133. *Hedwigia ciliata* with hyaline tips and awns on leaves. Photo by Michael Lüth, with permission.

Figure 134. Hyaline hair tip on the leaf of *Hedwigia ciliata*. Note the numerous papillae on these **awn** (hair tip) cells as well as on the **lamina** cells. Photo by Janice Glime.

At least some leaf papillae (*Andreaeobryum macrosporum*, Figure 135) are constructed in such a way that they provide a channel for the uptake of water (Crandall-Stotler & Bozzola 1990, 1991). This channel is within each papilla and is different from the channels formed between the papillae (*cf.* Proctor 1984). SEM observations indicate the channel within the papilla facilitates the rapid uptake of water during rehydration (Crandall-Stotler & Bozzola 1990, 1991). So far, this channel has not been demonstrated in any other species.

So how can papillae function both for water absorption and water loss, and why would evolution tolerate such a seeming contradiction? Pressel *et al.* (2010) may have answered this question. They found that in *Rhacocarpus purpurascens* (Figure 136), the **trilamellate** (having 3 layers) walls have a porous outer layer that permits rapid uptake of water, whereas its cuticle-like layer is highly hydrophobic and prevents water-logging. Could it be that the papillae of bryophytes create that space needed to prevent water-logging? But Pressel and coworkers contend that papillae in *R. purpurascens* accelerate water loss,

resulting in a metabolic shutdown when the plants are water-stressed. With the wide variety of shapes, sizes, and density of papillae among the bryophytes, it is still possible that some have the ability to prevent water-logging during the critical periods when the plants are wet in normally dry habitats. If this ability exists, it may be of considerable importance in at least some cases.

Figure 136. *Rhacocarpus purpurascens* showing shiny leaves. Photo by Michael Lüth, with permission.

One such species is the desert moss, *Syntrichia caninervis* (Figure 115, Figure 137-Figure 139). When Wu *et al.* (2014) compared absorption of rhizoids to that of leaves, the leaves were clearly the greater absorptive organs. They tested absorption by dropping water onto the upper and lower leaf surfaces, both of which have C-shaped papillae (Figure 137) (Zheng *et al.* 2010). Wu and coworkers found that the adsorption by the papillae is so rapid that they could not determine the leaf angles. They concluded that in this case the papillae are **superhydrophilic** (having a highly efficient water absorption mechanism). The spaces between the papillae form microcapillary spaces that serve as an efficient conducting system (see also Koch *et al.* 2008).

Figure 139. *Syntrichia caninervis* var. *caninervis* showing long papillae on costa and smaller ones on cells. Photo by M. T. Gallego.

The only thing that seems clear about papillae is that our understanding of them is not clear. It is likely that papillae cannot be lumped into one function, but that shapes, structure, and arrangement may create different capabilities, and these must coordinate in various ways with surface waxes, cell wall components, and other leaf surface features to optimize their role in the climates where the bryophytes live.

Figure 142. Leaf of *Calliergon giganteum* showing costa and enlarged **alar cells** at leaf base. Photo by Michael Lüth, with permission.

Leaf Bases and Alar Cells

Many mosses have the advantage of enlarged, thin-walled cells at the base of the leaf (**alar cells**) (Figure 141- Figure 142). These serve as entry points for water into the leaf and stem, but in many species their enlargement when fully hydrated also forces the leaf away from the stem, exposing greater surface area for photosynthesis, and perhaps even for water capture.

Figure 141. *Tortella tortuosa* leaf base showing enlarged hyaline cells where water can enter and cells can swell. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Those alar cells that are thin-walled shrink upon drying and readily gain water as it moves along external capillary spaces. Tucker and coworkers (1975) describe shrinkage of the basal cell cytoplasm during dehydration, creating gas pockets. Upon rehydration, the pockets of gas shrink and disappear within 10-30 seconds and the cytoplasm expands to fill the entire cell. This can explain the rapid unfolding of leaves upon rewetting in many taxa of bryophytes, with alar cells acting like the bulliform (expansion) cells of grasses.

Wu *et al.* (2014) demonstrated the importance of adjusting the leaf angle in the desert moss *Syntrichia caninervis* (Figure 115, Figure 144). Although this moss is extremely desiccation tolerant, it must balance the need for water conservation with the need for light for photosynthesis when it is hydrated. This is accomplished by the movement of the leaves in response to moisture changes. As leaves become hydrated, they can move from a steep angle of 69-84° with the horizontal axis (Figure 144) to one of only 30° (Figure 115) within 7 seconds of becoming hydrated, with the first leaves moving within 1 second. They are able to obtain maximum net photosynthetic gain at a shoot relative water content of only 60%. The hyaline cells at the leaf base facilitate the rapid absorption of water, but they also swell and force the leaf away from the stem mechanically. It is interesting that the loss of leaf hair retards the leaf angle adjustment. When water was added to the soil instead of being added as an aerial source of water, the absorption rate was reduced, indicating that most water absorption is through the leaves.

Leaf Cell Shape

Bill Buck once asked me what I thought about the elongate cells in mosses such as *Fontinalis* and what the significance of such elongate cells might be, predominant in pleurocarpous mosses but rare in acrocarpous ones. I don't know that either of us has a better answer than we did then, but long, narrow cells should have an advantage in water movement. Elongate cells mean that fewer end walls must be crossed for water and other substances to traverse the interior of the leaf from tip to base or vice versa. The split between acrocarpous and pleurocarpous mosses suggests to me that the innovation of elongate cells, perhaps unnecessary in aquatic ancestors, occurred early in the evolution of pleurocarpous mosses and was rarely achieved among the acrocarpous species.

In the acrocarpous moss *Bryum pseudotriquetrum*, this elongation is partially achieved (Figure 145). This is a moss of wet habitats that dries out. The leaves are usually out of the water, and having somewhat elongated cells should improve transport.

Figure 145. *Bryum pseudotriquetrum* leaf showing somewhat elongate cells, bordered by longer cells. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

It is interesting that many acrocarpous mosses have short leaf cells and tend to be more endohydric, whereas

the pleurocarpous mosses, largely lacking a central strand and endohydric conduction, have mostly elongate leaf cells. Although these elongate cells would seemingly facilitate conduction between cells and from the leaf surface to the stem, we lack experimental evidence to support this.

Porose Cells

Porose cells provide more cause for speculation. These cells, uncommon among bryophytes, would seem to provide linkages to adjoining cells while permitting the cells to have otherwise thick walls. Such porosity is easily seen in *Dicranum polysetum* (Figure 146). I am unaware of any experiments to demonstrate that this is actually true or to compare the rate of transport in leaves with such cells to those in leaves with non-porose cell walls.

Figure 146. *Dicranum polysetum* leaf cell wall structure. Photo by Walter Obermayer, with permission.

Hyalocysts

Colorless or **hyaline** cells (Figure 147) are typical of leaves of *Sphagnum* (Figure 148) and *Hedwigia* (Figure 134), and the awns of numerous xerophytes. Frahm (1985) examined the correlation between **hyalocysts** and habitat in *Campylopus* (Figure 149). *Campylopus shawii* occurs in wet swamps where it can obtain and store water easily; it has large ventral hyalocysts. *Campylopus setifolius*, on the other hand, grows on wet, dripping rocks that dry out occasionally; it has smaller hyalocysts, presumably to reduce the water loss to evaporation from these cells. The presence of ventral hyalocysts in *C. flagelliferus* (Figure 149) seem to adapt it to its life restricted to the bark of living trees where it needs a means of rapid water uptake.

Figure 147. Leaf of *Tortula vahlana* showing hyalocysts in basal half of leaf. Photo by Michael Lüth, with permission.

Figure 148. *Sphagnum papillosum* leaf cells showing large hyaline cells with fibrils and green photosynthetic cells. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Figure 149. *Campylopus flagelliferus*, an epiphyte with ventral hyalocysts. Photo by Jan-Peter Frahm, with permission.

Species of the cushion moss, *Leucobryum* (Figure 18, Figure 150), appear very succulent because of the hyalocysts among the photosynthetic cells. In this case, the leaf is several cells thick and the hyalocysts give them a whitish appearance. *Leucophanes* (Figure 151-Figure 152) has two different types of hyalocysts. The base of the leaf has a V-shaped arrangement of hyaline cells and the leaf lamina has an upper and lower layer of hyaline cells surrounding the photosynthetic cells.

Sphagnum species are considered xerophytic hydrophytes with many adaptations to deal with periodic drought (Andrus 1986). Living in a watery mire for most of the year, this genus has no internal conducting system and must face a severe threat of drying in the full sun of the summer when the water table is low. The ectohydric *Sphagnum* is a poor drought tolerator, but a relatively good drought avoider (Li *et al.* 1992). It has two types of leaf cells, small photosynthetic cells and large hyaline cells (Figure 153).

Figure 153. *Sphagnum* leaf cell types and pores. **Left:** *Sphagnum* leaf cells stained with crystal violet. Photo by Janice . Glime. **Right:** *Sphagnum palustre* photosynthetic and hyaline cells as seen in cross section (**upper**) and flat (**lower**). Drawings by Margaret Minahan.

Hyaline cells bathe the photosynthetic cells in water by providing a reservoir. Since the hyaline cell is a dead cell, its sole purpose seems to be to supply water to the photosynthetic portion of the leaf. These cells give some species of *Sphagnum* (Figure 153-Figure 154) the ability to hold up to 25 times their own mass in water (Andrus 1986).

Figure 154. *Sphagnum fallax* leaf cells under normal nutrient conditions. Hyaline cells disappear under certain high N or low carbohydrate conditions in culture. Photo by Kristian Peters, with permission.

Transplant studies indicate that species of *Sphagnum* differ in abilities to inhabit different heights above the water level, and these differences seem to correlate with the positions they occupy in the field (See Li *et al.* 1992, Rydin 1993, and discussion in competition chapter). Studies by Hintikka (1972) hint that the mechanism for some of these adaptive differences may not relate to water, but to other factors associated with submersion. When grown in sterile culture, *S. fallax* (Figure 154) produced no hyaline cells in the presence of high ammonium, high organic nitrogen, or low carbohydrates. In nature, ammonia from decomposing plant matter would be greater under water than around emergent plants, quickly diffusing away in the atmosphere. Likewise, amino acids from organic decomposition would be present only in submersion water, not in rainfall. Response to low carbohydrates may be a limit in carbon available for making additional cell wall tissue, a need for an energy source, or it could relate to CO₂ from decomposing plant material in interstitial bog or fen waters.

Sphagnum seems to require a tremendous water content to achieve its maximal net photosynthesis, probably supplied by the large reservoir of water in its non-photosynthetic hyaline cells. In *S. fuscum* (Figure 155), a hummock top species, 600-1000% saturation was optimal, whereas in *S. angustifolium* (Figure 156), which tends to occur somewhat closer to the water surface, 900-1300% was optimal (Silvola & Aaltonen 1984), indicating the greater need for water in species that live closer to the water level. The photosynthetic decrease with water reduction was steeper for *S. fuscum*, and plants in the field generally occurred where their water content was within this 600-1000% range. In *S. angustifolium*, however, plants often occurred where their water content was outside their optimum range, thus defining narrow and broad relative niches.

Sphagnum is well known for its morphological plasticity in response to water availability (Miller 1991). For example, *Sphagnum magellanicum* (Figure 157) and *S. papillosum* (Figure 158) in dry conditions produce leaves that are longer (Figure 159) with more pores per cell (Figure 160). Li and coworkers (1992) suggest that these modifications may promote water-holding and absorbing properties.

Figure 155. *Sphagnum fuscum* in its typical position atop a hummock. Photo by Michael Lüth, with permission.

Figure 156. *Sphagnum angustifolium*, a species that lives low on a hummock. Photo by Michael Lüth, with permission.

Figure 157. *Sphagnum magellanicum*, a species that makes longer leaves under dry conditions. Photo by Janice Glime.

Figure 158. *Sphagnum papillosum*, a species that makes longer leaves under dry conditions. Photo by Michael Lüth, with permission.

Figure 159. Comparison of leaf dimensions in *Sphagnum magellanicum*, a drought-resistant species, and *S. papillosum*, a more drought-tolerant species. Based on Li *et al.* (1992).

Yet, these two species also differ in their water relations (Li *et al.* 1992). *Sphagnum magellanicum* (Figure 157) seems to be a better competitor for water than is *S. papillosum* (Figure 158) under dry conditions. This is exhibited by its better water transport ability and greater water content under the same atmospheric moisture conditions (Figure 161). This greater ability may be facilitated by its greater stem diameter due to larger hyaline cells, greater pore number, and smaller leaf size. On the other hand, *S. papillosum* (Figure 158) seems to be a better drought tolerator, having a higher survivorship following severe drought conditions.

Figure 160. Comparison of number of pores per leaf cell in *Sphagnum magellanicum*, a more drought-resistant species, and *S. papillosum*, a more drought-tolerant species. Based on Li *et al.* 1992.

Superiority in water transport permits *S. magellanicum* (Figure 157) to occupy a higher position in the hummock than does *S. papillosum* (Figure 158). Li and coworkers (1992) found that when the two species grow intermixed in the higher hummock positions, both species grow better than if either is alone, provided at least half the plants are *S. magellanicum*. They suggest that lateral transport among stems may occur to facilitate this, with *S. magellanicum* providing water for both species. If

S. papillosum is dominant, even at somewhat lower positions in the hummock, both dry out more quickly.

Cancellinae

The **cancellinae** (sing. cancellina) occur in few bryophytes, but especially in the **Calymperaceae**, **Pottiaceae**, **Encalypta** (Figure 163-Figure 164), and some species of **Leptodontium** (Figure 162). They are large, empty basal leaf cells, usually hyaline, that form a lattice. In the **Calymperaceae**, these are porate (having pores), and may serve as water storage cells.

Cell Structure

Cells structures can differ in a variety of ways that can affect water uptake, movement, and conservation. These differences include cell wall thickness, cell wall components, pores in the walls, internal papillae, presence of oil bodies, and vacuole size. These differences have the potential to alter the water relations of the leaves.

Cell Walls

Guerra *et al.* (1992) included **incrassate** cell walls among the adaptations of xerophytic mosses. Examples of these include *Aloina aloides* (Figure 165-Figure 166) and *Didymodon fallax*. (Figure 167-Figure 168).

Figure 165. *Aloina aloides*, a dry habitat moss with incrassate leaf cell walls. Photo by Michael Lüth, with permission.

Figure 168. *Didymodon fallax* with incrassate leaf cell walls. Photo by Hermann Schachner, through Creative Commons.

Proctor (1979a) contends that coarse leaf cell walls (Figure 169) seem to aid water movement, possibly creating more internal capillary spaces among the fibrils of the cell wall (Proctor 1982). Proctor (1984) noted that mosses of dry habitats tend to have thick cell walls that can occupy more than half the cross section of the leaf. Fajuke (2010) further found that six mosses from Nigeria had thick cell walls that helped them survive desiccation.

Figure 169. Leaf of *Zygodon dentatus* showing thick cell walls and papillae. Photo by Michael Lüth, with permission.

On the other hand, Frey and Kürschner (1991) could find no correlation between thickened cell walls and increasing aridity. Proctor (1982) also pointed out that such xerophytic mosses as *Syntrichia* (Figure 170-Figure 171), *Encalypta* (Figure 172-Figure 173), and *Anomodon viticulosus* (Figure 174-Figure 175) have quite thin walls and external conduction, suggesting that the thick walls are associated with species having internal conduction.

Figure 175. *Anomodon viticulosus* leaf cells and papillae. Proctor (1982) considered this species to have thin cell walls, but that does not appear to be the case in this example. Photo by Walter Obermayer, with permission.

The moss *Rhacocarpus purpurascens* (Figure 136) appears to have a unique means of facilitating rapid absorption of fog, dew, and rain (Barthlott & Schultze-Motel 1981; Edelmann *et al.* 1998). It has four layers of cell wall with a "peculiar architecture," forming cavities within the wall.

Flexibility of the cell wall is undoubtedly an aid to cell survival. This permits the cells to shrink upon dehydration, up to 50-70% in *Syntrichia ruralis* (Figure 176), without allowing for air to enter the drying cells (Moore *et al.* 1982).

Figure 176. *Syntrichia ruralis* leaf cells with c-shaped papillae and thin walls. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Popper and Fry (2003) suggest that the addition of **xyloglucans** to the cell wall components may have been an important contribution to the ability of bryophytes to invade land. The presence of high concentrations of uronic acids would have permitted these plants to hold nutrient ions until such time as water was available for transport.

Cell walls seem like the first line of defense against desiccation. Autofluorescing compounds that can strengthen these walls are present in sporangial epidermis, spiral thickenings of elaters, and rhizoids, and leaf cells in the special case of *Sphagnum* (Figure 177) Krokken *et al.* (1996). In charophytes, these resistant compounds have multiple functions that include desiccation resistance and microbial resistance in lower charophytes, a role in embryogenesis in *Coleochaete* (Figure 178) and embryophytes, and decay resistance in structures that characterize bryophytes, such as rhizoids, sporangial epidermis, and elaters.

Figure 178. *Coleochaete*, an alga with slime papillae and other characters that are more common among bryophytes. Photo by Yuuji Tsukii <<http://protist.i.hosei.ac.jp/>>, with permission.

It appears that the resistance of cell walls to desiccation is an ancient trait, already present in the green alga *Coleochaete* (Figure 178) (Krokken *et al.* 1996). In fact, it seems to be unique to *Coleochaete* among the charophytes and the resistance is produced in response to desiccation stress.

But bryophytes also have this ability – sexual reproduction induces autofluorescence in the cell walls of well-hydrated tissues at the placental junction, suggesting that these cell walls are endowed with compounds (phenols?) that endow them with desiccation resistance (Krokken *et al.* 1996). A similar phenomenon occurs in the gametophyte tissue at the apical end of the **pseudopodium** (gametophyte stalk that suspends the *Sphagnum* capsule away from the plant; Figure 179), suggesting a similar role to that of other bryophytes and even *Coleochaete* (Figure 178).

Figure 179. *Sphagnum* pseudopodia supporting capsules. The swollen upper end is desiccation tolerant and houses the foot of the sporophyte. Photo by Joan Edwards, with permission.

Lignin: The presence of lignin in bryophytes has been a controversial topic for ages. Lignins are present in xylem and sclerenchyma cells of tracheophytes. To demonstrate whether these substances might be present in bryophyte and charophyte cell walls, Ligrone *et al.* (2008) examined the charophyte *Nitella* and a number of bryophytes. Using polyclonal antibodies that labelled lignified walls in tracheophytes, they found that these also bound to the cell walls of bryophytes. But rather than the specific locations found in tracheophytes, the locations in mosses and liverworts were not tissue-specific. Hornworts (*Megaceros flagellaris* and *M. fuegiensis*; Figure 180) differed somewhat in that labelling was stronger in pseudoelaters and spores than in other cell types. Cell walls were likewise labelled in the charophyte *Nitella*, but a lack of binding suggested that lignins or lignin-like substances were absent in *Coleochaete*.

Oil Bodies

Oil bodies are common in the leaf cells of leafy liverworts (Pfeffer 1874; Garjeanne 1903; Müller 1905, 1939; Schuster & Hattori 1954; Pihakaski 1972a, b; Stewart 1978; Schuster 1992; Asakawa 2004), but similar structures are generally absent in mosses. Kronstedt (1983) found that they had seasonal variability in the nature of the matrix and the amount of lipophilic material in the floating liverwort *Ricciocarpus natans* (Figure 181). The globules can coalesce to form larger units. Their role has remained a mystery (He *et al.* 2013), but recently several researchers have provided evidence that they may have a crucial role in desiccation tolerance.

Oil bodies seem to have different developmental pathways in different species. Pihakaski (1966, 1968, 1972a) compared their development in two leafy liverworts – *Bazzania trilobata* (Figure 182-Figure 183) and *Lophozia ventricosa* (see Figure 184). The component parts are the same in both species: an outer membrane that envelops the whole oil body, a granular stroma layer that varies in size and thickness, specific globules enveloped by the stroma layer, and a thin inner membrane that surrounds the specific globules. But the oil bodies in these two species develop in different ways. In *B. trilobata*, they develop from vacuole-like formations in the shoot apex or in leaf primordia where certain substances segregate. In this species, granular dense bodies are visible in the cells of

the shoot apex, but these shrink in size as oil bodies develop and are absent in the mature leaf cells. In *L. ventricosa* they originate by aggregation and fusion of lipid bodies.

Figure 183. Oil bodies (transparent) in leaf cells of *Bazzania trilobata*. Photo by Walter Obermayer, with permission.

Figure 184. *Lophozia incisa* leaf cells with oil bodies. Photo by Walter Obermayer, with permission.

Duckett and Ligrone (1995) followed the development of oil bodies in gemmae of *Odontoschisma denudatum* (Figure 185). They appear suddenly early in development, forming flat structures associated with the endoplasmic reticulum. Suire (2000) provided evidence that liverwort oil bodies are secretory cell compartments that originate from the endoplasmic reticulum. The oil bodies remain closely associated with the cytoplasmic lipid bodies throughout development but do not fuse with them. Finally they take on their ultimate shape and become suspended by fine cytoplasmic bridges within the vacuoles.

Oil bodies are notorious for disappearing in herbarium specimens. Pressel *et al.* (2009) described this behavior for desiccation-tolerant liverworts. They found that while they are dry, they remain substantially unchanged, but when they are rewet, they initially change drastically, becoming flattened. It requires up to 48 hours for them to regain their normal shapes. However, if the liverworts are dried faster than would typically happen in nature, they, and other organelles, disintegrate when the liverwort is rewet. Pressel *et al.* suggested that loss of shape upon normal rewetting could be evidence of a shift in soluble carbohydrates or other substances into the cytosol, indicating that the oil bodies may be critical to the desiccation tolerance of liverworts.

Figure 185. *Odontoschisma denudatum* "cuticular" papillae (see leaf edge), leaf cells, and oil bodies. Photo by Kristian Peters, with permission.

Galatis *et al.* (1978) found phenolic and "polysaccharidic" compounds but no protein in the oil bodies of *Marchantia palacea* (Figure 186). On the other hand, He *et al.* (2013) reported that in *Marchantia polymorpha* (Figure 187) the oil bodies (Figure 188) contain a protein complex that is immunologically related to plastid and cytoplasm enzymes of the **isoprenoid** synthesis (isoprenoids belong to a class of organic compounds composed of two or more units of hydrocarbons, with each unit consisting of five carbon atoms in a specific pattern; they have a wide range of roles in physiological processes of plants and animals). Suire *et al.* (2000) similarly found isoprenoid biosynthetic enzymes similar to those found in plastids and the cytosol of *Marchantia polymorpha*. The suggested paucity of protein in the oil droplets of liverworts (Galatis *et al.* 1978) is likewise in sharp contrast with that found in the green alga *Chlamydomonas reinhardtii* (Moellering & Benning 2010). In this alga, 259 proteins were associated with lipid droplets.

Oil bodies of liverworts produce mono-, sesqui-, and diterpenoids, aromatic compounds such as bibenzyl, bis-bibenzyls, and acetogenins (Asakawa 2008; Asakawa *et al.* 2013). These often aromatic compounds have such activities as causing allergenic contact dermatitis, antimicrobial action, antifungal and antiviral action, cytotoxicity, insecticidal action, insect antifeedant, superoxide anion radical release, 5-lipoxygenase, calmodulin, hyaluronidase, cyclooxygenase, DNA polymerase β , and α -glucosidase and NO production inhibition, antioxidant, piscicidal, neurotrophic, and muscle relaxation. But these are mostly uses of interest to humans and do little to tell us how the liverwort benefits from them.

It appears that mosses do have their own version of oil bodies. Huang *et al.* (2009) reported abundant oil bodies in the photosynthetic gametophyte and the spores of *Physcomitrella patens* (Figure 189-Figure 190). These researchers found that neutral lipids in these oil bodies in the gametophyte were largely steryl esters and triacylglycerols, and unlike some reports on the liverwort oil bodies, they had proteins. These proteins were programmed by three oleosin genes. The expression of these oleosin genes were tissue specific. Structural proteins cover the surfaces of the lipid droplets and prevent them from coalescing during desiccation (Huang *et al.* 2009; He *et al.* 2013).

The number of oil bodies in apical gametophyte tissue decreases during the production of sex organs in *Physcomitrella patens* (Figure 189-Figure 190) (Huang *et al.* 2009). In spores, the oil bodies serve as food reserves for **gluconeogenesis** (formation of glucose from smaller molecules) and are equivalent to those of seed oil bodies. It appears that these oil bodies have an energy function for reproduction, but could they be important in providing the energy needed during rehydration as well?

It seems surprising to me that we know so little about the functioning of oil bodies, especially in liverwort leaf cells. We cannot discount them as a non-functioning structure that happened and wasn't eliminated because they are so widespread. And they have tremendous variability, both in morphology and in chemical constituents. More than 1600 lipophilic compounds have been extracted from liverworts (Ludwiczuk & Asakawa 2019)!

Hieronymus (1892) suggested that oil bodies protected against UV light stress. Schuster (1966) suggested that they help maintain the liverworts through cold, drought, and osmotic stress.

Early experiments demonstrate a role in antiherbivory, with snails preferring species with fewer oil bodies (Stahl 1888). And when oil bodies were leached from some of the liverworts, those were preferred over the non-leached ones. Further support of the antiherbivory hypothesis was demonstrated by genetic manipulation of *Marchantia* (Figure 187-Figure 188). Those plants defective in oil bodies were more likely to be eaten than were the normal populations (Kanazawa *et al.* 2020; Romani *et al.* 2020). Likewise in *Marchantia*, Peñuelas *et al.* (2019) demonstrated that mutant plants with reduced sesquiterpenes experienced greater foraging by *Spodoptera littoralis* caterpillars (Figure 191).

Figure 191. *Spodoptera littoralis* larva, a species that responds to reduced sesquiterpenes in *Marchantia* by eating more of it. Photo by Ishbb, through Creative Commons.

We know that essential oils extracted from liverworts serve as antibiotics against a wide range of organisms (Asakawa & Ludwiczuk 2018). Furthermore, we know that extracts from plants that have reduced oil bodies also have reduced antibiotic activity against bacteria and fungi (Romani *et al.* 2020).

One of the functions of oil bodies is that they enclose vast quantities of sesquiterpenoids and other compounds, meanwhile protecting the cells from the toxicity of these chemicals (Tanaka *et al.* 2016; Romani *et al.* 2022). Mapping of oil body types suggests that they were present in the most recent common ancestor of liverworts and were probably the first secretory structure in land plants.

Tanaka *et al.* (2016) found that nutrient starvation and non-axenic growth in *Marchantia* greatly increases the number of oil bodies, suggesting a possible role in maintaining nutrient reserves. This notion is supported by the chemical properties of the carbohydrates present and the maintenance of turgidity after dehydration (Pressel *et al.* 2009).

To protect the cells from the toxic nature of the specialized compounds, the oil bodies not only compartmentalize the compounds, but also the enzymes needed to make them (Tissier 2018; Suire *et al.* 2000). Hence, the cells are completely protected from these toxic substances. Furthermore, the substances are typically volatile and the oil bodies prevent them from evaporating too quickly. This explains the various aromas one can smell when the tissues are crushed.

Vacuoles

Bryophytes, for some reason, were long thought to lack vacuoles. However, this is not the case, as demonstrated in the liverwort *Lunularia cruciata* (Figure 192) (Carginale *et al.* 2004), the mosses *Physcomitrella patens* (Figure 189) (Nagao *et al.* 2005), *Ephemerum cohaerens* (Figure 193) (Kwok & Rushing 1999), and *Fontinalis antipyretica* (Figure 194) (Bruns 1998). In fact, the vacuoles can be quite large, as witnessed by the chloroplasts crowded around the periphery of the cell in many species. But there has been no systematic study to indicate which bryophytes have vacuoles and which do not. We might ask if there is some correlation between the ability to withstand drought or to take up water, or even to hold on to cellular water as the environment dries and the presence of one or more vacuoles.

Vacuoles are known in plants to contain solutes that control the water uptake by the vacuole (Taiz & Zeiger

1991). In bryophytes, Nagao *et al.* (2005) have demonstrated that ABA affected the appearance of vacuoles during treatment with freezing. Since ABA is also involved in drought tolerance and has resulted in the increased osmotic concentration of protonemal cells, this mechanism of vacuolar preparation should be explored for possible relationships to drought tolerance in various bryophytes. Could presence of a vacuole help the cell take in water more quickly by storing solutes that create an osmotic gradient, yet are safely out of the way of cellular metabolism? Could it also have a role in the ability of the cells to shrink as they dry and expand when wet?

Slime Papillae

In leafy liverworts, **slime papillae** on marginal leaf cells can help to absorb and hold water, as in the leaf margins of *Porella* (Figure 195) and *Heteroscyphus* (Figure 196) (Daniels 1998). The presence of slime papillae in *Takakia* (Figure 197) was among the reasons why several bryologists originally considered that genus to be a liverwort, but capsule structure confirmed its similarity to mosses.

Summary

Bryophytes gain water in their cells both through external (**ectohydric**) capillary movement and internal (**endohydric**) transport. Structural adaptations such as **overlapping leaves**, **concave leaves**, **crispate leaves**, **plications**, **revolute** or **involute margins**, **lamellae**, **multi-layered leaves**, **lobules**, **hair points**, **papillae**, **costae**, **stereids**, **borders**, **leaf teeth**, **tenirolae**, **alar cells**, **hyaline cells**, **cancellinae**, **resistant cell walls**, **oil bodies**, and **vacuoles**, aid in moving water, facilitating entry, or reducing loss. In areas with high fog occurrence and little or no rainfall, fog can be a major contributor to the bryophyte water budget.

Overlapping leaves, **concave leaves**, **revolute margins**, and **involute margins** help to hold water in capillary spaces. **Alar cells** provide a point of entry through thin walls that balloon up and mechanically spread the leaves. The **costa** and **border** cells may move water more quickly because the cells are long and have fewer end walls to be crossed. **Plications** permit leaf expansion in hydrated leaves and conserve moisture in drying conditions, as do **twisting** and **contorted** leaves. **Hair points** collect water from fog and dew and slow down drying by reducing exposed surface area of the leaf above. In leafy liverworts, **lobules** retain water for species of dry habitats. **Lamellae** may repel water and prevent water logging in some species, but hold water in capillary spaces in others.

Cell walls may contain **phenols** and other fluorescing materials similar to lignin to resist water loss. **Oil bodies** may provide rehydration energy, but their role in water relations is still poorly understood. **Vacuoles** hold water within the cell and permit expansion and contraction of the cell. **Slime Papillae** may contribute to absorption and holding of water.

Acknowledgments

An earlier version of this chapter benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me tow the line in explaining things without leaving too much to one's imagination, but at the same time not repeating myself. Ron Gratz translated part of the work by Loeske. Linda Luster checked the literature citations, proofread, and made glossary suggestions from a layperson's perspective. I was fortunate to have Ken Kellman ask on Bryonet for examples of bryophytes with a demonstrated cuticle; he was kind enough to share his collected references with me. Thank you to Noris Salazar Allen for sending me the leaf images of *Leucophanes*.

CHAPTER 7-4b

WATER RELATIONS: LEAF STRATEGIES – CUTICLES AND WAXES

Figure 1. *Pohlia wahlenbergii* var. *glacialis* in Norway. The drops of water on the surface are being repelled by hydrophobic surface waxes, preventing water logging. Photo by Michael Lüth, with permission.

Bryophytes Do Have Cuticles

Anyone who has observed the speed with which many mosses and leafy liverworts absorb water would assume that they lack waxes. But as we examine these bryophytes with chemical and SEM methods, we find that this assumption is not reliable (Buda *et al.* 2013). For example, the simple moss *Physcomitrella patens* (Figure 2) has a cuticle with a chemical composition and structure similar to that of flowering plants. It is likely that the cuticle was a necessary factor in the evolution to land, regulating water status and providing protection from biotic and abiotic stresses. Using knockout genes to create mutant plants that were "severely deficient in cuticular wax accumulation" Buda *et al.* found that these plants also had reduced desiccation tolerance. The gene responsible for the cuticle wax formation in *Physcomitrella patens* is the same one as that in *Arabidopsis thaliana*, indicating its evolution early in the invasion of land.

Figure 2. *Physcomitrella patens*, a moss from which the cuticular wax gene has been isolated. Photo by Janice Glime.

Although thickened waxy cuticles seem to be rare in moss gametophytes, various mosses have some sort of cuticular covering. In some mosses, this is expressed as granules, platelets, or ribbons that are soluble in chloroform (Proctor 1982), satisfying the test for cuticular wax in tracheophytes. This type of cuticle endows *Pohlia cruda* (Figure 3), *P. wahlenbergii* (= *P. albicans*; Figure 4), *Saelania glaucescens* (Figure 55), *Schistostega pennata* (Figure 5), *Pogonatum urnigerum* (Figure 6), and many **Bartramiaceae** with their **glaucous** (whitish) appearance (Proctor 1982). We shouldn't be surprised that *Pogonatum urnigerum* has surface waxes similar to those of tracheophytes, but even primitive mosses such as *Andreaea rupestris* (Figure 7) have surface waxes that are similar to the epicuticular waxes of tracheophytes (Haas 1982).

Figure 7. *Andreaea rupestris* showing slightly glaucous appearance. Photo by Janice Glime.

In addition to most of the species already named, Stránský *et al.* 1967) found n-alkanes (19-33 carbon atom chains) in *Leucobryum glaucum* (Figure 8), *Rhytidiadelphus triquetrus* (Figure 9), *Conocephalum conicum* (Figure 10), *Porella platyphylla* (Figure 11), *Pellia fabbronia* (Figure 12), and *Pellia epiphylla* (Figure 13). Even *Sphagnum* is known to have waxes (lignoceryl alcohol) in *S. capillaceum* (*S. nemoreum*; Figure 59), *S. fuscum* (Figure 60), and *S. magellanicum* (Figure 61) (Ives & Neill 1958).

The documentation of cuticle in bryophyte leaves is somewhat scant. Nevertheless, Proctor (1979b) examined 43 species of mosses and determined that 12 of these have a well developed surface wax on the leaves that is comparable to that of flowering plants. Eight more have traces of wax. Not surprisingly, all of these species are **endohydric** (have internal conduction). If a moss has a waxy or glaucous look, it most likely has surface wax. A good example of this is the leaves of *Polytrichum* (Figure 14-Figure 18). On the other hand, *Atrichum undulatum* (Figure 19-Figure 21), in the same family (**Polytrichaceae**), has no discernable wax and lacks the waxy appearance. Instead of having leaves that curl inward and wrap around the stem upon drying, members of *Atrichum* have wavy leaf surfaces and become contorted when they dry (Figure 22-Figure 23).

The array of species with demonstrated waxes is a mixed group of xerophytes and hydrophytes (Proctor 1979b, 1982). *Pohlia wahlenbergii* (Figure 24-Figure 26), a glaucous moss of wet habitats, has a high content of wax, whereas *Pohlia nutans* (Figure 27-Figure 28), a ubiquitous moss often found in dry habitats, has little wax. *Pohlia cruda* (Figure 29-Figure 31), a species of moist places, has a high content like that of *P. wahlenbergii*. It appears that the wax in these species is important to prevent water logging, allowing for gas exchange for photosynthesis.

Bartramia pomiformis (Figure 32-Figure 34) has a whitish appearance and has a high degree of wax covering (Figure 34) (Proctor 1979b). In the same family, *Conostomum tetragonum* (Figure 35) has an intriguing 3-d mesh of wax (Figure 36).

Xu *et al.* (2009) found surface wax on the leaves of the desert moss *Syntrichia caninervis* (Figure 37). These waxes were comprised of fatty acids, alcohols and alkanes. In this species, the wax crystals shift as the leaf ages, increasing the percentage and weight (13.6%; 1150 $\mu\text{g g}^{-1}$ DW) of very long-chain components in young leaves to 37.2% and 2640 $\mu\text{g g}^{-1}$ in older leaves. Furthermore, when juvenile leaves experienced dehydration followed by rehydration the wax content of juvenile leaves increased by 35.17%. In lab-cultivated leaves subjected to three wet/dry cycles, the wax content increased by 1900%.

Figure 37. *Syntrichia caninervis*, a desert moss with a cuticle comprised of fatty acids, alcohols, and alkanes. Photo by John Game, with permission.

Some bryophytes are puzzling at first glance. For example, *Hedwigia* (Figure 38-Figure 40) species appear to be waxy, yet absorb water rapidly. But members of the **Hedwigiales** lack waxes (Pressel & Duckett 2011). This puzzle unravels when we understand the role of the papillae (which typically make leaves look whitish) on the leaves of **Andreaeales**, **Grimmiales** (Figure 41-Figure 42), **Pottiales** (Figure 43-Figure 46), **Hedwigiales**, and **Orthotrichales**. Based on experiments by Proctor (1979a) and confirmed by Pressel and Duckett (2011), the water enters these leaves by flowing within channels in the **striated** (having linear marks, slight ridges, or grooves on surface, often one of number of similar parallel features) cell walls and between the papillae, causing rapid uptake of water through the leaf surface between the papillae. These taxa lack waxes.

In genera such as *Aloina* (Figure 47), *Crossidium* (Figure 48-Figure 49), and *Pterygoneurum*, (Figure 50-Figure 52) the water enters between the leaf lamellae (Figure 51-Figure 52) (Proctor 1979a; Pressel & Duckett 2011). All these taxa grow in habitats where intermittent dehydration/rehydration, often in rapid sequence, is common. However, in the **Polytrichaceae** (Figure 14-Figure 18), water logging between the lamellae is an issue, depressing gas exchange needed for photosynthesis (Proctor 1979a, 1982, 1984). These leaves are protected by abundant waxes that prevent water from entering the spaces between the leaf lamellae. Instead, air bubbles are trapped in these spaces.

One of the problems that bryophytes must face is having ice or ice crystals on their surfaces (Figure 53- Figure 54). These crystals are very hygroscopic, potentially causing the kind of dehydration that can occur to your meat in the freezer. A waxy cuticle could serve like a plastic freezer bag, in this case preventing the water from being drawn from the cells. This role for the wax, if present, remains to be tested.

Figure 53. *Polytrichum* sp. with frost, a condition that could draw water out of unprotected cells. Photo by Allan Water.

Figure 54. *Hedwigia ciliata* in ice, a frequent condition for this rock dweller. The ice, like freezer ice, draws water out of plant cells. Photo by Michael Lüth, with permission.

The presence of a white flocculent material on the moss *Saelania glaucescens* (Figure 55-Figure 57) is widely known. *Saelania glaucescens* has been a puzzle to bryologists and biochemists. Its whitish covering is predominantly on the backs of the leaves and takes the form of a hoary appearance, not a smooth or shiny surface. Although this material has been identified as kauranol plus several minor waxes (Nilsson & Mårtensson 1971), the reason for the peculiar arrangement that looks like a thin layer of minute angel hair remains a mystery. Bryologists have suggested that it might be caused by parasitic fungi or bacteria, but there is no evidence to support these ideas (Mårtensson & Nilsson 1974). Likewise, it does not seem to be the result of any normal metabolic product. Proctor's (1979b) analysis demonstrates that this is a heavy coating of waxes with weblike ridges covered by a fine, cobwebby matrix of wax.

Sphagnum

Sphagnum fimbriatum (Figure 58-Figure 62), a peatmoss of wet habitats, has an osmiophilic layer (one that stains with osmium tetroxide, indicating wax) that resembles the early developmental stage of tracheophyte cuticle (Cook & Graham 1998). One might think that a wet habitat moss would not need such protection, but in summer these peatmosses can become quite dry, so such a layer may help to reduce desiccation. On the other hand, this layer may prevent water logging at times when this moss is submersed (*cf.* Pressel & Duckett 2011). The cuticle in *S. fimbriatum* is sheetlike with regular ridges that run parallel to the edges of the "thalli." Our next question is how can a leaf with a cuticle use it for protection from desiccation and yet be able to absorb water. In *Sphagnum*, this may be facilitated by the pores, but might the structure of the cuticle play a role?

Leafy Liverworts

Even the leafy liverworts can have waxes. Heinrichs *et al.* (2000) support the contention of Cook and Graham (1998) that this innovation occurred prior to the evolution of bryophytes from their algal ancestor. Although only six (5 of *Plagiochila* plus *Plagiochilium mayebarae*) of the 81 species of *Plagiochilaceae* in the study had surface waxes on their leaves (Heinrichs *et al.* 2000), this is a family with

many members in damp or wet, even submersed, habitats. They found that *P. tabinensis* contains 1.4% of its dry weight as surface waxes. These are comprised of steryl esters, triacylglycerols, and free fatty acids.

By using the electron microscope, Heinrichs and Reiner-Drehwald (2012) found surface wax in the leafy liverworts *Lejeunea flava* (Figure 63), *Mytilopsis albifrons*, *Dinckleria pleurata*, and *D. fruticella*, representing the families *Lejeuneaceae*, *Lepidoziaceae*, and *Plagiochilaceae*, respectively.

Admissibility of Water

If leaves of bryophytes are covered with waxes, how does water enter these largely ectohydric plants? One suggestion is that the bases of the leaves may lack a cuticle, but that would seem to slow down water entry and be maladaptive for gathering dew or taking advantage of short desert rainfall events. But the structure of the wax itself may solve this problem. Shepherd and Wynne Griffiths (2006) describe the layered sheets of wax as probably discontinuous and surrounded by further solid amorphous regions. The crystalline regions are considered impermeable, but water and solutes are able to diffuse through the cuticular wax by way of the amorphous zones. This requires a greater travel distance than a straight path through the surface, but it seems a better route than travelling to the leaf base, then travelling internally through cell contents and cell walls to reach the tip of the leaf.

Multiple Forms – Multiple Roles

The cuticle, like many plant features, can serve multiple advantages for plants. In tracheophytes it is able to reduce water loss, prevent water logging, protect against high light intensity, reduce the temperature, reduce osmotic stress, prevent physical damage, protect against altitudinal stresses (light, extreme temperatures, wind), and protect against pollution (Shepherd & Wynne Griffiths 2006).

In tracheophytes, waxes exist in several forms, including rods, ribbons, filaments, tubes, and plates (Shepherd & Wynne Griffiths 2006). Among the bryophytes, for five *Plagiochila* (leafy liverwort) species studied, two exhibited wax platelets and three exhibited wax rodlets (Heinrichs *et al.* 2000). Proctor (1979b)

demonstrated several forms among mosses (Figure 31, Figure 34, Figure 36, Figure 57).

Among the tracheophyte forms, wax tubes are associated with mid-chain oxy-substituents, such as β -diketones, hydroxy- β -diketones, diols, and secondary alcohols (Shepherd & Wynne Griffiths 2006). Platelets are associated with primary alcohols with a terminal oxy-substituent. Are these same factors influential in bryophyte wax morphology? If so, is there any adaptive significance for these differences?

Temperature

We know that in tracheophytes temperature, light intensity, and humidity influence the wax morphology, but since these three factors typically act together, it is often difficult to tease out cause and effect (Shepherd & Wynne Griffiths 2006). For example, in *Citrus aurantium*, a higher daytime temperature during leaf development reduces the quantities of alkanes, primary alcohols, fatty acids, and alkyl esters per unit area (Riederer & Schneider 1990). But except for the esters, the amounts of these same compounds increase with higher night-time temperatures.

At higher temperatures, the waxes are more likely to form plates and flakes, whereas at lower temperatures they are more likely to form vertical structures such as rods and tubes (Shepherd & Wynne Griffiths 2006). But waxes at higher temperatures also often form complex dendritic shapes. Tubular forms of waxes are thermodynamically unstable due to their high surface area to volume ratio, so an input of energy, typically heat, can transform them into compact planar forms that are thermodynamically more stable. And tubes can turn into dendrites when the temperature is raised. On the other hand, rapid cooling can also favor dendrite formation. Furthermore, more waxes are produced at lower temperatures.

Light

Shorter, less elaborate wax structures are often associated with greater illumination (Shepherd & Wynne Griffiths 2006). Thick waxes such as those in *Eucalyptus* leaves increase reflectance and reduce photosynthesis, but in "non-waxy" leaves (*i.e.* not appearing waxy or glaucous), there is no effect. In wheat, reflectance is proportional to the amount of wax present, with higher reflectance reducing light transmission to underlying mesophyll cells (Johnson *et al.* 1983). Higher radiation levels can cause an increase in wax thickness in many plants, suggesting an inducible mechanism to protect the cells (Baker 1974; Giese 1975; Reed & Tukey 1982; Shepherd *et al.* 1995).

But it seems unlikely that the thin cuticle of bryophytes has much of an effect on reflectance or photosynthesis. Nevertheless, as will be seen in the chapter on light relations, many bryophyte leaves transmit more light when wet than when dry, suggesting that papillae or other surface features may screen light, thus protecting the DNA and chlorophyll, but that when water fills in the spaces, light is transmitted rather than scattered. Are these waxes protective agents against UV radiation when the

bryophytes are dry? But UV reflectance is an uncommon adaptation among tracheophytes. It can range from <10% in most plant species, to 70% in only a few others (Caldwell *et al.* 1983; Barnes *et al.* 1996).

Waxes may play yet another role for the light-limited bryophytes. Droplets held on wettable tracheophyte leaves can focus solar radiation up to 20 times (Brewer *et al.* 1991). We might imagine that bryophyte leaves or multiple plant tips might trap water droplets that likewise focus the light in some low-light habitats. This focussing would occur at the actively growing tips in most acrocarpous mosses.

Salt Stress

Waxes also protect leaf cells from salt stress (Shepherd & Wynne Griffiths 2006). Examples from tracheophytes suggest that an increase in wax production may be an inducible response to increased salt exposure. Fujiwara *et al.* (2002) found that pre-treating cabbage seedlings with NaCl induced hardening, improving drought resistance. It would be interesting to compare wax content among bryophytes that grow within areas affected by salt spray to the same species grown away from its influence.

Contact Angles and Entry

Contact angles are important for water entry. Brewer *et al.* (1991) found that changes in the contact angle and wettability are also associated with changes in wax composition and morphology in tracheophytes. These observations present interesting questions for bryophytes. If leaves have waxes over the leaf lamina, but lack waxes at the base, water will roll to the leaf base where uptake is easy. This movement to the leaf base would further facilitate the solution of deposited nutrients and carry them to the base for absorption (Cape 1996 for tracheophytes). Because of the mode of water uptake in bryophytes, this feature is likely to be more important than it is in tracheophytes. Hence, we should expect the angle of the leaf to be important in this nutrient and water gathering. At the same time, it presents dangers for collecting deposited pollutants.

Combined Role and Water Relations

Let's continue under the assumption that at least in some cases the waxes on bryophytes may play a role in reflectance and scattering of light to a degree that can lower the temperature of the bryophyte cells they cover. This will, in turn, reduce the vapor pressure difference between the leaf tissue and the air, reducing the loss of water through transpiration. But all these assumptions remain to be tested in bryophytes.

Altitude Protection

High altitude imposes stresses that include weathering, dehydration, low temperatures, and greater UV light intensity. In conifers, a thicker wax coverage is characteristic of high altitude growth (Günthardt 1984; Riolo 1999). We need to look for a similar relationship in bryophytes.

Pollution Protection

Ozone

In tracheophytes, ozone causes a severe reduction in the formation of new wax, but it does not seem to affect existing wax (Carlsson *et al.* 1994; Hellgren *et al.* 1995). Its effect on bryophyte cuticles remains unknown, but failure to replace cuticle could have severe consequences in prevention of water logging and protection from UV radiation.

CO₂

The effects of CO₂ on tracheophytes are varied, in some cases causing an increase in waxes and in others a decrease (Shepherd & Wynne Griffiths 2006). The effect on bryophyte cuticles remains to be demonstrated.

Repelling Water

Despite all of these reports on waxes on the cuticle of bryophytes, we know little of their role. Mårtensson and Nilsson (1974) comment that not all of the aforementioned waxy species are shiny, including *Rhytidiadelphus triquetrus* (Figure 9), although I would consider it to be shiny. Others, such as *Sphagnum subnitens* (Figure 64-Figure 65) and *S. subfulvum* (Figure 66) are shiny when dry, but lose their shine when moist, suggesting that the relationship is complex and is not a matter of simple reflection. It would be interesting to determine their role in repelling water to avoid water logging vs retaining water in times of drought.

Figure 66. *Sphagnum subfulvum*, a species that is shiny when dry due to waxes. Photo by Michael Lüth, with permission.

The role of repelling water may be more important than that of retaining water. I have mentioned a potential role of repelling water, as seen in Figure 1. Gas exchange works poorly through a wet surface. Waxy or oily surfaces help to repel the water, yet allow a higher rate of gas exchange than does water. Hence it is not uncommon to find such surfaces among aquatic bryophyte taxa (Proctor 1984).

Proctor (1984) contends that the ability to shed surface water is important to bryophytes in their low-light habitats of crevices and caves or in waterside habitats of waterfalls. He cites the waxy surfaces of the tops of photosynthetic lamellae of the **Polytrichaceae** (Figure 6, Figure 14-Figure 18) as support for this contention. This might also be supported by the waxy surface of *Pohlia cruda* (Figure 29-Figure 31), a common species in crevices.

As discussed in Chapter 7-3 of this volume, the pores of *Marchantia* (Figure 67), as in the stomata of tracheophytes, have strongly water-repellent ledges (Schönherr & Ziegler 1975; Figure 68), like the waxy ridges of tracheophytes, preventing water from entering and interfering with the photosynthetic interior.

Figure 68. Section through pore of *Marchantia polymorpha*, with waxy ledge indicated by arrows. Photo by George Shepherd, through Creative Commons.

Mosses like *Plagiomnium* (Figure 69) have both upright and horizontal stems. But this genus has a different problem from most mosses in obtaining water. Its leaves repel water, as known by anyone who has tried to wet them to make a slide. It has perhaps solved this problem by its well-developed hydroids and leptoids, and even false leaf traces (Figure 70).

Figure 70. *Plagiomnium ellipticum* stem cross section. This is a moss with both upright and horizontal (plagiotropic) stems. It most likely benefits from having both hydroids and leptoids to transport substances because its leaves are very resistant to getting wet and typically repel water. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

In some cases, there are special adaptations for bringing water into the leaves while at the same time being able to prevent water loss. In *Rhacocarpus purpurascens* (Figure 71), a moss of exposed habitats that experience frequent alternation of drought and heavy precipitation, the cell walls are trilamellate (Pressel *et al.* 2010). The outer layer is porous and ensures rapid uptake of water and retention. At the same time its very hydrophobic cuticle-like layer prevents waterlogging. The middle lamellar stratum permits extension of protoplast hydration, allowing the metabolism to remain active under drying conditions. *Sphagnum*, on the other hand, can become waterlogged and experience depressed metabolism as a result.

Summary

Bryophytes gain water in their cells both through external (**ectohydric**) capillary movement and internal (**endohydric**) transport. Structural adaptations such as **overlapping leaves, concave leaves, crispate leaves, plications, revolute or involute margins, lamellae, multi-layered leaves, lobules, cuticles, hair points, papillae, costae, stereids, borders, cancellinae, teniolae, alar cells, hyaline cells, pores, oil bodies, vacuoles** aid in moving water, facilitating entry, or reducing loss. In areas with high fog occurrence and little or no rainfall, fog can be a major contributor to the bryophyte water budget.

Waxes are known from all the major groups of bryophytes, including such aquatic taxa as *Sphagnum*, and occur in a wide range of habitat moisture, but many species seem to lack them. Glaucous species may be so because of waxes or because of dense papillae. The water repellant nature of waxes keeps water from entering pores of a thallus and prevents water from remaining on plants in a way that blocks gas exchange. The presence of waxes may relate to endohydry or to living in places where water lingers on the plants. The role may be more to keep water away than to hold water in.

Waxes need to be arranged on a leaf to admit water, at least at the base, but they may have an amorphous layer that transmits water. Multiple forms

of waxes seem to be correlated with various environmental parameters such as UV light, temperature, salt stress, contact angle, and altitude, but these correlations have not been explored in bryophytes. Cuticles can offer protection from such pollutants as ozone and CO₂ and may play a role in preventing absorption of airborne pollutants that land on the surfaces of the leaves.

Acknowledgments

An earlier version of this chapter benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me tow the line in explaining things without leaving too much to one's imagination, but at the same time not repeating myself. Translation of part of the work by Loeske was by Ron Gratz. Linda Luster checked the literature citations, proofread, and made glossary suggestions from a layperson's perspective. I was fortunate to have Ken Kellman ask on Bryonet for examples of bryophytes with a demonstrated cuticle; he was kind enough to share his collected references with me and offer suggestions for improving this chapter.

CHAPTER 7-5

WATER RELATIONS: PHYSIOLOGICAL ADAPTATIONS

Figure 1. *Riccia cavernosa*, a thallose liverwort that dries out during drought and recovers in the fall when rain returns. Photo by Jan-Peter Frahm, with permission.

Water Relations on Land

Proctor (2014) points out that one of the basic needs of bryophytes is that of coping with the intermittent availability of water. To this end, poikilohydry is efficient at the small scale of a bryophyte, whereas endohydry is more beneficial for the large tracheophytes.

Physiological adaptations relate on one end to the morphology and on the other to the biochemistry. Although we have recognized morphological characters for a very long time, few have actually been tested experimentally on a large scale for their adaptive value in altering physiology. The biochemical adaptations, on the other hand, constitute a new and emerging field of bryology, one that coincides closely with physiology of tracheophytes. By using the more easily studied bryophytes, we have gained the possibility of better understanding of the physiology of tracheophytes. This unusual interest in bryophytes is largely because of the

relative ease with which genes can be moved into them or knocked out of them and their expressions be observed. And both bryophyte and fern gametophytes exhibit desiccation tolerance, whereas this ability is rare among sporophytic seed plants (Watkins *et al.* 2007). Long live the gametophytes! Even the lichens seem to have less desiccation tolerance than the bryophytes (Green *et al.* 2011).

Oliver *et al.* (2000) hypothesized that for photosynthetic plants to move onto land, desiccation tolerance was crucial. Using species of "resurrection plants" from both bryophytes and tracheophytes, Fisher (2008) concluded that desiccation tolerance arose among propagules as a means of survival. In bryophytes, nearly every part is a potential propagule in most species. For example, Maheu (1902) found that the moss *Tortula muralis* (Figure 2) would regenerate protonemata after

being stored dry for 14 years. Physiological adaptations may permit the bryophyte to retain water or to recover from loss of water, and to change its strategies with the seasons or the climate.

Figure 2. *Tortula muralis*, a moss species that can survive drought as protonemata. Photo by Christophe Quintin, through Creative Commons.

Alpert (2000) presented two main puzzles from the observed habitat patterns of desiccation-tolerant plants. "What are the mechanisms by which plants tolerate desiccation?" and "Why are desiccation-tolerant plants not more ecologically widespread?" There appear to be multiple mechanisms of tolerance, including protection from oxidants and loss of normal configuration of macromolecules during dehydration. Alpert suggests that their inability to occupy a wide ecological range is due to their inability to maintain a cumulative positive carbon balance during their repeated wet/dry cycles and the tradeoffs between desiccation tolerance and growth rate.

Drought Tolerance vs Avoidance

As clear as the two words **tolerance** and **avoidance** may seem, they can lead to confusion because of differences in perspective. During (1979) tells us that **drought tolerance** is the ability to survive and maintain activity despite a lack of water in the environment. Proctor (2000) gives a more physiological definition that considers drought-tolerant plants to be those that are able to maintain a more or less normal metabolism at lowered cell volume and water potential, while tolerating elevated ionic concentrations in the cytoplasm and external environment. This physiological type of maintenance may be in evidence for the drought-tolerant *Hedwigia ciliata* (living on exposed boulders; Figure 82) and *Grimmia pulvinata* (often living on concrete; Figure 3). During a 5-day sequence of natural field drying, they showed no sign of plants drying and both maintained their photochemical efficiency, exhibiting normal day-night patterns (Schroeter *et al.* 1999).

Plants that show **tolerance** have vegetative parts that endure the stress period as best as possible (During 1979). But where is that lack of water, in the environment, or in the plant? I prefer to clarify this and say that **drought tolerance** is the ability of the plant to survive in a **habitat** that becomes dry. **Desiccation tolerance** is the ability of the **plant** to survive periods during which the **cells** are

water-stressed and the plant itself has become dry; it suffers dehydration of all its metabolic systems. Such vegetative desiccation tolerance is rare among tracheophytes, with few species withstanding vegetative desiccation: 60-70 species of fern and fern allies and 60 species of angiosperms (Oliver *et al.* 2000). Instead, most tracheophytes survive through reproductive structures. Bryophytes (and lichens), on the other hand, exhibit vegetative desiccation tolerance as well as through reproductive structures (Kappen & Valladares 1999; Proctor *et al.* 2007).

Figure 3. *Grimmia pulvinata*, a drought tolerator growing on concrete. Photo with permission from Botany Department website, University of British Columbia, Canada, with permission.

For sake of clarity, let us consider **drought** to be a condition of the environment and **desiccation** to be a condition of the plant, in this case the bryophyte. For tracheophytes, drought in the environment nearly always causes desiccation in the plant, but for bryophytes, this may not so often be the case.

Using that terminology, **drought tolerance** can be accomplished in two ways: **desiccation tolerance** and **desiccation avoidance**. **Desiccation avoidance** is the ability to prevent desiccation from occurring within the plant or the ability to go into a **dormant stage** during periods of low water availability; it is often characterized by plants that die and leave stress-tolerant **diaspores** (any structures that become detached from parent plant and gives rise to new individuals) that will grow the next season. Note the use of the word **stage** here, not **state**. For bryophytes, spores and gemmae provide dormant **stages**, although the entire **mature** sporophyte might be considered a stage that does not require water. On the other hand, a desiccation-tolerant vegetative plant can go into a dormant **state**, where metabolic activity slows to an imperceptible level, but where this same plant stage will regain its ability to gain carbon and grow.

Using these concepts, Smith (1986) considers that true desiccation tolerance among plants is rare or non-existent. The tracheophytes may in fact never be desiccation tolerators (Larcher 1983), generally relying on avoidance by storing water or by going into a dormant life cycle stage until the return of sufficient water (Smith 1986). Bryophytes, on the other hand, can be true desiccation tolerators, and suffer relatively little damage at relative humidity levels far below those tolerated by tracheophytes (Table 1). They do this in a vegetative stage through mechanisms that avoid desiccation damage.

Desiccation resistance, the ability to maintain an adequate water supply under drought conditions, is actually **drought avoidance**. Drought avoidance also includes the

ability to revert to a dormant stage that requires no water, such as spores and tubers. Water is essential to all life, and the ability to obtain it under limiting conditions or to store it until more is available permits some organisms to live in conditions that are intolerable for others. Most perennial bryophytes do not have the option of disappearing into the soil for the winter, and in fact the period of greatest drought for many of them is in the summer. However, bryophyte growth generally ceases during this hot and often dry time and metabolic activity is slowed considerably, if not completely.

Table 1. Comparison of desiccating percent relative humidity levels tolerated by various groups of plants. Table modified from Larcher (1983).

Plant	%RH Tolerated without injury	%RH Moderate injury
Marine algae		
Deep water algae	99-97	14-41
Algae of the ebb line	95-86	69-204
Intertidal algae	86-83	204-252
Liverworts		
Hygrophytes	usually 95-90	92-90
Mesophytes	usually 92-50	90-36
Xerophytes	usually (36)-0	0
Mosses		
Water mosses and hygrophytes	95-90	69-141
Mesophytes	usually 90-50 extreme 10	
Xerophytes	usually 5	0
Fern gametophytes		
Forest ferns	>90	50-90
Rock ferns	40-60	20-30
Tracheophytes (tissue sections)		
Leaf epidermis		96-92
Mesophyll	96	95-90
Root cortex		97-95

Both desiccation avoidance and desiccation tolerance strategies are available to bryophytes (Figure 4-Figure 5). You will soon see that whereas desiccation tolerance may be unavailable to tracheophytes, it is of considerable importance for bryophytes.

Desiccation Tolerance

In 1702 Anthony von Leeuwenhoek examined dry sediment from a gutter after hydrating it for an hour, and found tiny animals swimming about (Alpert 1982, 2000). These animals, rotifers, seemingly had arisen from the dead. Leeuwenhoek followed with experiments that showed these animals could remain in this dry state for months. But he did not imagine that they had lost all moisture because they retained their normal oval shape. During the next century, experiments demonstrated that rotifers, nematodes, and tardigrades all could undergo a dry, dormant state. In fact, some organisms can survive for over ten years without water, reaching immeasurably low water potentials (Alpert 2000). In this desiccated state they can endure temperature extremes from 0272 to 100°C.

But what was this dormant state? Words such as **anabiosis** (temporary state of suspended animation or

greatly reduced metabolism), **abiosis** (absence of life), **revivification** (restoring life), and **resuscitation** (action of making something active or vigorous again), arose to describe the dry state and ability to return from it (Alpert 1982). The term **cryptobiosis**, however, seems most appropriate, avoiding the question of whether or not the organism is still alive. Instead, it refers to the state of an organism when it shows no visible sign of life, when its metabolic activity is immeasurable (hidden life).

Figure 4. Distribution of a number of genera of mosses relative to mesic and xeric conditions and their strategies of avoidance vs tolerance. Modified from Vitt *et al.* 2014.

Figure 5. Distribution of a number of genera of mosses relative to mesic and xeric conditions and their strategies of avoidance vs tolerance. Modified from Vitt *et al.* 2014.

Low temperature physics helped to clarify the issue. Recognizing absolute zero as -273°C, the temperature at which everything freezes and all molecular movement stops, Becquerel (1950a, b, c, 1951) subjected tardigrades, rotifers, algae, seeds, bacterial and fungal spores, fragments of the lichen *Xanthoria parietina*, and leaves of the mosses *Grimmia* (Figure 79-Figure 80) and *Barbula* (Figure 6) to two-hour treatments at temperatures very close to 0.0°K

(0.05-0.008°K). These organisms returned to their active state and bacteria even reproduced. *Syntrichia ruralis* (Figure 77-Figure 93) survived after 24 hours at -198°C (Bewley 1973). Based on typical reduction in metabolism of ½ for every 10°C drop in temperature, Becquerel calculated that at absolute zero metabolism would be 7.13 trillion times as slow as the normal rate at 15°C (see Alpert 2000).

Figure 6. *Barbula convoluta* var. *commutata*, a species that survives at temperatures close to 0°K. Photo by Michael Lüth, with permission.

This did not support the hypothesis that life ceased and then was reactivated. In fact, three arguments can be made against that hypothesis, some of which have been demonstrated for desiccated mosses. First, Dilks and Proctor (1976b) have demonstrated that mosses recover more slowly as duration of desiccation increases, ultimately reaching a duration from which they are unable to recover. Second, for most organisms in this cryptobiotic state, there is still a minute uptake of oxygen (Pigón & Weglarska 1955a,b), indicating retention of metabolism. Third, there is a point at which all these organisms die.

Such desiccation tolerance, a common phenomenon among bryophytes, seems to have been lost in the evolution of tracheophytes. Rather, tracheophytes have experienced increased growth rates, more structural and morphological complexity, and mechanisms for conserving water rather than recovering from its loss (Oliver *et al.* 2000). Only in their reproductive structures, particularly seeds and underground storage organs, have tracheophytes retained and diversified the strategy of desiccation tolerance.

Norris (1990) contends that four dimensions of water relations must be understood to understand the problems of bryophytes compared to tracheophytes. To this I have added the fifth as a result of more recent experiments:

1. hydration/dehydration frequency
2. hydration duration
3. dehydration duration
4. degree of water loss
5. rate of water loss.

With the need for repair whenever moss cells become dry, it is not surprising that the frequency of the wet-dry cycle and the duration of the hydration period are important in determining survival. Even in such xerophytic bryophytes as *Grimmia pulvinata* (Figure 3), living on rock walls in Britain, the median length of wet and dry periods is generally between 5 and 15 hours (Proctor 2004). The longest dry periods in early summer are typically 15-

17 days, with the longest continuously wet period lasting nearly 28 days. The moss cushions typically remain wet about 1.7 times the duration of rain. It appears that dew fall is insufficient to cause hydration in this species, perhaps because water drops are trapped by the long hairs instead of reaching the leaf lamina. Such a mechanism could protect the species against frequent (daily) wet-dry cycles in which the nightly wet period is insufficient for damage repair before the moss becomes dry again. Growth occurred primarily in autumn when the moss was wet for long periods, despite relatively low levels of irradiation.

Like others, Stark *et al.* (2013) argued that desiccation tolerance is the most important evolutionary innovation permitting plants to colonize land. They used the desert moss *Pterygoneurum lamellatum* (Figure 7) and chlorophyll fluorescence to test recovery from drying of 30 minutes to 53 hours. As in other studies, rate of drying is a major factor in recovery, with only the shoot apex escaping the severe damage of very rapid drying. Rapidly desiccated shoots have slower growth rates, fewer regenerative shoots, and a compromised photosynthetic system. The responses to differences in rate of drying indicate that this xerophytic moss has inducible desiccation tolerance, in contrast to the assumption that xerophytic bryophytes have only constitutive desiccation tolerance.

Figure 7. *Pterygoneurum lamellatum*, a desert moss with inducible desiccation tolerance. Photo by Michael Lüth, with permission.

Although *Sphagnum* (Figure 63) may not be a good model for other kinds of bryophytes, it gives us an idea of the evaporative relationships of these non-tracheophytes. *Sphagnum* in a foggy coastal blanket bog in Newfoundland demonstrated that the bog surface loses little water during foggy periods, due, in part, to absence of a vapor pressure deficit. On the other hand, during dry, clear periods the surface of the bog dries, increasing the surface resistance to evaporation (Price 1991); at the same time, higher available energy from the sun causes the rate of evaporation to be higher than on foggy days. This results in a daily evaporation rate of 1.5 mm per day on clear days, contrasting to 0.7-1.1 mm per day for foggy or rainy days.

If we put the two strategies, avoidance and tolerance, into a different perspective, we find that some species tend to avoid drought by holding water more effectively while some survive better at a lower water content. Table 2 lists the survival time of a number of bryophytes. Mechanisms

to accomplish survival vary. As we have seen already (in Chapter 7-4a & b of this volume; Li *et al.* 1992) *Sphagnum magellanicum* (Figure 8) is superior to *S. papillosum* (Figure 9) at retaining water and transporting it from lower parts of its environment, but *S. papillosum* has a greater rate of survival (95%) after laboratory drying (80% for *S. magellanicum*). Thus, *S. magellanicum* is more of a drought avoider whereas *S. papillosum* is more of a short-term drought tolerator. On the other hand, *S. papillosum* death (65%) surpasses that of *S. magellanicum* (50%) when both are dried for 30 days.

Lloyd Stark (pers. comm. 18 July 2015) found conflicting results among the publications on the duration of the dry period of *Sphagnum*. Desiccation tolerance alone did not explain the conflicting results. Sagot and Rochefort (1996) dried fragments three species of *Sphagnum* [*S. fallax* (Figure 14-Figure 16), *S. fuscum* (Figure 10), *S. magellanicum* (Figure 8)] and dried them at 60% relative humidity. These species were able to tolerate up to 14 days of desiccation under these conditions. On the other hand, when Schimperges and Rydin (1998) completely dried *S. fuscum* and *S. magellanicum*, and three other species, none of the five species survived. On the other hand, if the water content was maintained above 100% (normal hydration of *Sphagnum* is much greater than that), all the species survived 3-12 days in this "dry" condition. But with the standard water content considered to be near 10% dry weight (~equilibration with 50% relative humidity), This hardly qualifies as dry.

Hájek and Beckett (2008) likewise found that hummock species *Sphagnum magellanicum* (Figure 8) and *S. fuscum* (Figure 10) under desiccation conditions lose more water before turgor starts dropping than do other *Sphagna* from less exposed habitats (73% vs 56% on average). Nevertheless, the osmotic potentials [potentials of water molecules to move from hypotonic solution (more water, less dissolved solutes) to hypertonic solution (less water, more dissolved solutes)] across semi-permeable membrane at full turgor are similar in all species (-1.1 MPa). Unlike the desiccation-tolerant *Racomitrium lanuginosum* (Figure 78) and *Syntrichia ruralis* var. *arenicola* (Figure 77), the hummock *Sphagnum* species have more rigid cell walls than those of wet habitats. Thus, the leaves of hummock species lose turgor at higher relative water contents (0.61) than species lower in the hummock-hollow complex (0.46). Hummock species also begin a photosynthetic decline sooner during drying. On the other hand, the hummock species recover more completely after rehydration.

Hajek and Vicherova (2014) were able to harden 13 species of *Sphagnum* (Figure 8-Figure 9) to desiccation. Hardening agents included drought, slow drying, ABA application, and chilling or frost. They measured tolerance by recovery of chlorophyll fluorescence parameters after severe desiccation. The hardening was accomplished by subjecting the shoot apices to a very high relative humidity (98-99%) for seven days prior to exposing them to desiccating conditions. With that preparation, the bryophytes were able to tolerate 56% relative humidity. This indicates that in *Sphagnum* desiccation tolerance is inducible.

Despite its ability to induce desiccation tolerance, one important role of *Sphagnum* (Figure 8-Figure 9) as an ecosystem engineer is its ability to retain water (Hajek & Vicherova 2014). Its ability to survive desiccation is seasonal. Following initial dehardening in the lab, untreated shoots of *Sphagnum* lack desiccation tolerance. Nevertheless, desiccation tolerance was induced by all hardening treatments except chilling, and especially by slow drying, even in the aquatic section *Cuspidata*. Under field conditions, *Sphagnum* species in hollows and lawns developed desiccation tolerance several times during the growing season as the precipitation and lowered water table created changing conditions. On the other hand, hummock

and aquatic species responded only to frost in late autumn, becoming desiccation tolerant. The protonemata did not develop desiccation tolerance, suggesting that this may be a limiting stage in the life cycle. The desiccation avoiders do not develop desiccation tolerance and must live in compact hummocks or submerged. Thus, there seems to be a tradeoff between desiccation tolerance in species lower on the hummocks and submerged vs resources spent on water retention and desiccation avoidance at higher positions.

Figure 10. *Sphagnum fuscum*, a hummock species. Photo by Michael Lüth, with permission.

Hájek and Beckett (2008) suggest that the higher water-holding capacity of hummock *Sphagnum* (Figure 8-Figure 10) would allow them to continue their metabolism longer during desiccation, *i.e.*, they have greater desiccation avoidance. On the other hand, their faster recovery makes them desiccation tolerators. Species in lower positions suffer fewer wet-dry cycles but have more elastic cell walls, permitting them to maintain turgor through a wider range of conditions and thus continue metabolism.

Hájek and Beckett (2008) found that *Atrichum androgynum* (Figure 11), a moss of the New Zealand forest floor, behaved in a manner similar to hummock *Sphagnum* (Figure 8-Figure 10) species. Proctor (2000) suggests that it is the ability to use external water conduction that permits bryophyte leaf cells to maintain full turgor most of the time. Their carbohydrate content is similar to that of embryos in desiccation-tolerant seeds. They are furthermore able to recover rapidly without protein synthesis. As larger plants evolved, vegetative desiccation tolerance was lost; growth rates increased, structural and morphological complexity evolved (Oliver *et al.* 2000), and water conservation mechanisms were selected over rapid intake and recovery.

Oliver *et al.* (1993) noted that carbon balance, damage limitation, and cellular repair are necessary components of desiccation tolerance. Using desiccation tolerance of three desiccation-tolerant species of *Syntrichia* (Figure 12-Figure 13, Figure 77), they learned that electrolyte leakage is not an important measure of tolerance, but that differences in protein synthesis could be used to assess damage limitation. Using this assessment, they found the order of tolerance in descending order to be *Syntrichia caninervis* (Figure 12), *S. ruralis* (Figure 77), and *S. norvegica* (Figure 13). This basis of classification and

ranking correlates well with the water stress considered to be present in their natural habitat.

Figure 12. *Syntrichia caninervis*, the most desiccation-tolerant of three *Syntrichia* species on the basis of protein synthesis. Photo by Michael Lüth, with permission.

Wagner and Titus (1984) compared two *Sphagnum* species – *S. fallax* (Figure 14-Figure 16), a hollow species that lives close to the water table, and *S. capillifolium* (Figure 17-Figure 18) (= *Sphagnum nemoreum*), a hummock species. Here, the relationship is somewhat surprising. The hollow species *S. fallax* is more desiccation tolerant than the hummock dweller *S. capillifolium*. *Sphagnum fallax* not only recovers a greater proportion of its predesiccation photosynthetic rate, but it also has a higher survival rate after 5-10 days of desiccation. This relationship can be explained by events in its habitat. *Sphagnum fallax* dries more frequently and for longer periods of time than does the hummock-dwelling *S. capillifolium*. *Sphagnum capillifolium* is able to retain moisture longer in the field. Growth habit may explain this ability, with *S. fallax* being larger and having a wide-spreading head, whereas *S. capillifolium* has a compact capitulum (head) (Figure 18) and lives in tightly packed clumps (Figure 17).

Bu *et al.* (2013) consider that peatlands have hummocks with drought-tolerant species and hollows with drought-intolerant species. They found that drought reduces the biomass production, height increment, and side shoot production of both hummock species [*Sphagnum palustre* (Figure 19) and *S. capillifolium* (Figure 17-Figure

18)] and hollow species [*S. fallax* (Figure 14-Figure 15). Bu and coworkers found that the leaf hyaline cell percentage increases in the hummock species but not in the hollow species. Furthermore, the nitrogen and carbon contents of the hummock species respond more to drought than they do in the hollow species. Instead, it is the presence of neighboring species of *Sphagnum* that causes the decrease in carbon in all three species. Despite this effect, there is no change in the competition under wet or dry treatment for any of the six species combinations. Contrary to expectations, *Sphagnum fallax* exhibits a change from facilitation in wet conditions to competition under dry conditions. This suggests that hummock species can facilitate the hollow species in wet environments but can outcompete them for water under drying conditions. The inability of hollow species to grow on hummocks could be the combination of superior competitors and the greater drought.

Figure 19. *Sphagnum palustre*, a drought-tolerant hummock species. Photo by Michael Lüth, with permission.

Wood (2007) summarized vegetative desiccation tolerance of bryophytes. Defining it as the "unique ability to revive from the air-dried state," he considered desiccation-tolerant species to be those that can survive equilibration with either modestly dry air (i.e., 70-80% RH) or extremely dry air (i.e., 0-30% RH). He considered these desiccation-tolerant species to comprise seven bryological classes: **Andreaeopsida**, **Bryopsida**, **Polytrichopsida**, and **Tetraphidopsida** (mosses), **Jungermanniopsida** and **Marchantiopsida** (liverworts), and the **Anthocerotopsida**. This omits the **Andreaebryopsida** and the **Sphagnopsida**. The **Andreaebryopsida** may be omitted simply due to lack of data. The **Sphagnopsida**, on the other hand, do indeed have desiccation tolerance in at least some species. In defense of the omissions, only 210 out of ~21,000 bryophyte species (ca. 1.0%) have been experimentally determined to possess vegetative desiccation tolerance – 158 species of mosses, 51 species of liverworts, and 1 species of hornwort.

Desiccation Avoidance

Many options of desiccation avoidance are available to tracheophytes that are not available to bryophytes. Bryophytes cannot make use of deep roots or increase the length of their roots (or in bryophytes - rhizoids), as do

many tracheophytes, because this would have little effect at the scale of a bryophyte. Nor do they have large underground storage organs to permit dormancy. But many do have underground **tubers** (see Chapter 4-10 of this volume) that store significant quantities of lipids or starches (Duckett & Pressel 2003) and that seem to be an adaptation to drought avoidance (El-Saadawi & Zanaty 1990).

Bryophytes cannot conserve water by using an alternate photosynthetic pathway to store CO₂ (Rundel *et al.* 1979, James 1981) because it would provide no water conservation advantage due to their lack of leaf stomata. Their developmental structure does not permit the loss of leaves because no buds occur at the base of each leaf, and one must wonder if such a small stem could store sufficient energy to support the growth of new leaves prior to any new input from photosynthesis.

The plants protect each other from desiccation and may hide buds of younger shoots within the clump. In *Bazzania trilobata* (Figure 20), field plants are able to tolerate drying, whereas lab drying is lethal (Sollows *et al.* 2001). Field conditions do not provide the desiccation level one might suppose by measuring air moisture. But it is also likely that the drying rate is different, and the integrity of the clump may have been altered in the lab.

Figure 20. *Bazzania trilobata* illustrating overlapping leaves and layering of branches. Photo by Janice Glime.

Many bryophytes can roll their leaves, as do some vascular plants, and they have several other related options to reduce the exposed surface area. These include curling and contorting the leaves (see Chapter 7-4 in this volume), a mechanism that creates small air spaces and presumably decreases air movement across the leaf surface. Others appress their leaves closely to the stem, protecting the upper surface from exposure and overlapping leaves sufficiently to protect even portions of the back surface of the leaf from exposure. And, despite their lack of specialized energy-storing organs (with some exceptions), they do have life cycle options. Perhaps the most important of these adaptations is the ability to withdraw water from the cell and form extracellular ice, with desiccation tolerance being an important adaptation (Dilks & Proctor 1975). (See Chapter 7-9 and 7-10 for further information on effects of freezing.)

Life Cycle and Life Strategy Adaptations

Hedderson and Longton (1996) evaluated the relationship between life history traits and taxonomic group, relating these to water relationships. They found

that 40-50% of the life history variation was related to water relations. The capacity for water uptake and retention arranges species from short-lived **monoicous** (having both sexes on same plant) taxa that produce few, large spores to those **dioicous** (having separate sexes) taxa with the opposite traits. The **endo-ectohydric** (internal vs external water control) gradient similarly relates to the investment in spores as a function of life expectancy.

One way to survive dry periods is to avoid them by leaving your spores behind to carry on the species. In the Murray River Valley, Australia, where flooding occurs every spring, long dry periods ensue and many taxa such as the ephemeral mosses persist there as spores (Peintinger 1988). In such genera as *Riccia* (Figure 1), which typically inhabit seasonally dry areas, dispersal of spores by animals, aided by the ornamentation of the spore, is important (Volk 1984; see Chapter 4-8 in this volume). Survival is facilitated by the ability to endure temperatures as high as 80°C when dry, whereas temperatures higher than 50°C when wet will injure them.

Alternatively, ephemeral bryophytes such as *Riccia cavernosa* (Figure 1), *Physcomitrella patens* (Figure 21), and *Physcomitrium eurystomum* (Figure 22) are able to grow on the muddy floodplain soil (Peintinger 1988), then become dormant in the fall until water returns again.

Figure 21. *Physcomitrella patens* on wet soil after flooding recedes. Photo by Michael Lüth, with permission.

Figure 22. *Physcomitrium eurystomum*, an ephemeral bryophyte that grows on floodplains. Photo by Michael Lüth, with permission.

For some bryophytes, altering their phenology according to available water is an adaptive strategy to take advantage of water when it is available. *Octoblepharum albidum* (Figure 23) in Nigeria produces antheridia and archegonia two months earlier when watered regularly (Egunyomi 1979). In nature, they produce archegonia during the rainy season, then produce capsules and take advantage of the dry season for dispersal of spores. This moss furthermore has leaves that can regenerate after as much as 29 weeks of dry storage, permitting an alternate means of propagation in those years when weather is not favorable for sexual fertilization.

In the very hot and dry summers of Kuwait, El-Saadawi and Zanaty (1990) found that a different avoidance strategy can be used. *Bryum bicolor* (Figure 24) forms subterranean rhizoidal **tubers** (see Figure 25) (Risse 1993) and stem tubers that permit it to be dormant as an avoidance mechanism, but it also exhibits tolerance in its protonemata, main stems, and stem apices (El-Saadawi & Zanaty 1990). *Funaria hygrometrica* (Figure 26) survives only by avoidance in the same conditions, using subterranean corm-like or bulbiform bases and bulbils to span the drought period.

Figure 23. *Octoblepharum albidum* growing epiphytically in India. This moss modifies its **phenology** (timing of life cycle events) when more water becomes available. Photo by Michael Lüth, with permission.

Figure 26. *Funaria hygrometrica* with young sporophytes, growing abundantly on charcoal, where it will continue growth for several years until competition moves in. Note the bulbiform basal leaves that can protect the plant and young sporophyte during drought. Photo by Janice Glime.

Even in less xeric conditions, drought-resistant **tubers** (Figure 25) are present in such taxa as *Atrichum tenellum* (Figure 27), *A. crispum* (Figure 28) (Arts 1987), and *Fissidens cristatus* (Figure 29) (Arts 1986). In *Haplodontium notarisii* (Figure 31), tubers are viable for up to 10 years (Arts 1988).

Figure 27. *Atrichum tenellum*, a moss that can survive drought as tubers. Photo by Michael Lüth, with permission.

Figure 29. *Fissidens cristatus*, a moss that is able to survive drought and freezing as tubers. Photo by Jan-Peter Frahm, with permission.

Some bryophytes actually require a dry season. In *Orthotrichum anomalum* (Figure 30), this dry period is necessary for the **operculum** (capsule lid) to dehisce (Johnsen 1969). The leafy gametophyte grows only when it is cool and moist, but watering during the dry period is detrimental.

Figure 30. *Orthotrichum anomalum* with dehiscent capsules. Photo by Michael Lüth, with permission.

Seasonal Changes

As we have just seen, the physiological state of the bryophyte, and hence **desiccation tolerance**, varies with the **season**. Many bryophytes [e.g., *Plagiochila spinulosa*

(Figure 32), *Hylocomium splendens* (Figure 61-Figure 62), *Scorpiurium circinatum* (Figure 33), *Syntrichia ruralis* (Figure 93), *Racomitrium aquaticum* (Figure 34)] seem to be most sensitive during autumn and early winter, the times when most bryophytes resume growth after a hot summer (Dilks & Proctor 1976a). Desiccation tolerance increases from spring to a maximum in early summer, the season when many species become dormant. Some degree of acclimation may be occurring, resulting in increased tolerance as summer approaches (Richardson 1981).

Bryophytes apparently adjust their desiccation tolerance and resistance according to their experiences with the environment (Dilks & Proctor 1976a), as will be discussed in greater detail later with regard to rehydration. That is at least part of the reason for different studies showing different results, even from the same researchers. It is interesting that not all bryophytes adjust in the same way, with one group of bryophytes having their least desiccation tolerance time in autumn and winter and others in late summer in Britain (Figure 35), in this case coinciding with differences among their habitats. *Andreaea rothii* (Figure 36) seems to have no response to season.

Ochi (1952) examined the effects of season on drought tolerance and concluded that mosses with active buds at the beginning of the growing season are generally more drought resistant than in other seasons. Seemingly in contrast to this statement, Ochi showed that in Japan *Dicranum japonicum* (Figure 37) survives drought longer (28 weeks) if the plant has active buds in early January rather than in early September or April (~4 weeks),

whereas *Polytrichastrum formosum* (= *Polytrichum attenuatum*; Figure 38), when dried on the same dates, survives longest when buds become active in September (>56 weeks compared to 28 in January and 11 in April). He concluded that these seasonal strategies represent three types of seasonal fluctuations in osmotic value: higher values in summer (dry season), lower in winter (wet season); higher in winter, lower in summer; no seasonal fluctuations (those from wet habitats).

Figure 35. Relationship between season and maintenance of photosynthesis during desiccation of British bryophytes. P_{50} is the number of days (in this case) of desiccation at which photosynthesis upon rehydration is reduced to 50% its initial value. Redrawn from Dilks and Proctor (1976a).

Figure 36. *Andreaea rothii*, a season-neutral moss with respect to its desiccation tolerance. Photo by Michael Lüth, with permission.

Davey (1997) found that in Antarctic bryophytes, the photosynthetic rate following a desiccation/rehydration cycle decreased from spring to summer to autumn. The pattern was clearest in the hydric taxa, with less effect in the xeric species.

Figure 37. *Dicranum japonicum*, a moss where early January buds result in ability to survive drought longer. Photo by Li Zhang, with permission.

Figure 38. *Polytrichastrum formosum*, a moss that survived longest when buds became active in September. Photo by David T. Holyoak, with permission.

Akande (1984, 1985) likewise attributed seasonal differences in desiccation tolerance of four **epiphytic** (growing on other plants, especially trees) bryophytes to changes in osmotic values, with osmotic values increasing from wet to dry season. He found that the mosses *Entodontopsis nitens* (= *Stereophyllum nitens*) and *Calymperes palisotii* (Figure 39) had a greater osmotic potential and greater desiccation tolerance than the leafy liverworts *Mastigolejeunea florea* and *Frullania spongiosa*.

Physiological Adaptations

All of us have observed that bryophyte assemblages differ with habitats (e.g. Šinžar-Sekulić *et al.* 2005). Oliver *et al.* (2000) note that most of the desiccation-tolerant plants are bryophytes, in addition to algae and lichens. They agree that desiccation tolerance was an important step in the evolution of land plants. They suggested that such tolerance requires constitutive cellular protection coupled with active cellular repair. But as evolution progressed, plants gained structural and morphological complexity. Plants developed mechanisms that conserve water within the plant, and vegetative desiccation like that seen in bryophytes was no longer necessary.

But Alpert and Oechel (1985) contend that desiccation-tolerant plants are rarely present in the most xeric microhabitats, suggesting that in these locations they are unable to maintain a positive cumulative carbon balance. They demonstrated this in *Grimmia laevigata* (Figure 83), the dominant green plant on exposed granitic boulders in the California, USA, chaparral by measuring the response of net CO₂ flux to light, temperature, plant water content, and previous desiccation.

Among desiccation-tolerant bryophytes, rehydration is rapid, with leaves returning to normal form in as little as 2 minutes and chloroplasts returning to normal conformation in 2-5 minutes in such desiccation-tolerant mosses as *Syntrichia ruralis* (Figure 77) (Tucker *et al.* 1975; Oliver & Bewley 1984). On the other hand, following rapid drying such intolerant species as *Cratoneuron filicinum* (Figure 40) still have misshapen organelles after 24 hours, and about half the cells of slow-dried plants still contain misshapen organelles (Oliver & Bewley 1984). In slow-dried plants respiration recovers, but it does not in rapid drying of desiccation-intolerant plants.

Charron and Quatrano (2009) considered two general mechanisms for survival in the xeric aerial environment. The descendants of the early land plants evolved specialized transport tissues while the bryophytes retained and perfected their co-equilibrium of their water content with that of their surroundings, relying on cellular processes to recover from damages due to water stress.

Figure 40. *Cratoneuron filicinum*, a moss species intolerant of rapid drying. Photo by Ivanov, with permission.

Bates (1997) examined the effects of wet/dry cycles on the nutrient economy of two pleurocarpous mosses of different habitats – *Brachythecium rutabulum* (Figure 56-Figure 57; wet ground, among grasses, logs; shade or open) and *Pseudoscleropodium purum* (Figure 41; grasslands and heaths). When provided with weekly drying periods of 24 hours every week, these plants had noticeably less biomass production than those plants that were continuously hydrated. *Brachythecium rutabulum* experienced bleaching of green tissues, unlike *Pseudoscleropodium purum*. When NPK (mix of nitrogen, phosphorus, and potassium salts) was added to the growing solutions once a week, *Pseudoscleropodium purum* exhibited growth stimulation even among the weekly desiccated plants. Uptake of N was similar in both hydrated and desiccated plants of both species. P and K⁺ were considerable in *B. rutabulum*, but in desiccated plants they were greatly reduced. As with phosphorus, uptake of P and K⁺ differed little between hydrated and intermittently desiccated *Pseudoscleropodium purum*. In both species, P and K⁺ were leaked from cells during desiccation, were retained on the cells by cation exchange, and taken up again during rehydration. But even this maintenance has a cost. K⁺ and Mg⁺² intracellular levels in new growth are maintained at the expense of exchangeable cations. Uptake is greatest during the early stages of recovery, most likely due to damaged membranes, and that is when the NPK application has the greatest effect on growth. These experiments suggest that *P. purum* has a lower nutrient requirement than *B. rutabulum* and they explain why *B. rutabulum* requires a more continuous hydration to maintain its greater production. An interesting revelation is the ability of these species to initiate new growth without additional nutrient absorption.

Bohnert (2000) asked what makes desiccation tolerable. He considered that bryophytes tolerated rapid desiccation, using protective mechanisms. Most research has focussed on repair mechanisms. The photosynthetic apparatus and cell integrity are maintained during desiccation, but rehydration leads to cellular damage. Despite this damage, recovery is rapid. mRNA (messenger RNA, the molecule that carries information from DNA to the ribosome) exists in RNPs (nucleoproteins that contain RNA) before the stress conditions arise. During recovery,

non-reducing sugars, **dehydrins** (group of proteins produced in response to cold and drought stress), and **rehydrins** (transcripts used during rehydration) appear. Hoekstra (2005) reported on the importance of fatty acid saturation in membranes in imparting survival of desiccation.

Figure 41. *Pseudoscleropodium purum*, a species in which intermittent desiccation seems to have little effect on K and P uptake. Photo from Proyecto Musgo, through Creative Commons.

Yang *et al.* (2012) sought the genetic determinant(s) for stress tolerance. Using *Syntrichia caninervis* (Figure 12) they identified ScALDH21, a gene that responds to **ABA** (abscisic acid, a stress hormone; see Chapter 7-7 Water Relations – Biochemistry) and desiccation and that plays an important role in response to desiccation and salinity stresses.

When the desiccation-tolerant *Syntrichia ruralis* (Figure 77) is desiccated, it retains all its pigments, chlorophyll included, and is able to recover physiological function rapidly upon rehydration (Hamerlynck *et al.* 2002). But all is not equal among these plants of both sun and shade habitats. *Syntrichia ruralis* has lower plant mass, as well as lower tissue N, C, total photosynthetic pigment concentrations, and carbon isotope discrimination (Δ) values compared to shade plants. The ratio of carotenoid to chlorophyll in sun plants is typical of high light plants, but the ratio of chlorophyll *a* to chlorophyll *b* in these plants is lower than expected, resembling those of plants adapted to shade. As a consequence, the levels of optimal quantum efficiency of **PS II** (F_v/F_m) (= variable fluorescence / maximum fluorescence; PS II is photosystem II of photosynthesis, where oxygen is liberated from water) are lower in the sun plants. Reciprocal transplants reveal that *Syntrichia ruralis* is able to adjust to altered light levels. This is evidenced by increases in F_v/F_m , **NPQ** (non-photochemical quenching), light-adapted PSII yield (ϕ PS II) in transplanted sun plants, and concurrent decreases in sun-transplanted shade plants. Nevertheless, the transplanted sun plants did not adjust sufficiently to reach performance levels exhibited by the undisturbed shade plants. These plants demonstrate at least some ability to adjust to the loss of shade canopy or other disturbance in the light regime.

Sphagnum (Figure 8, Figure 9, Figure 14-Figure 18) has a unique cell structure (Figure 42) providing a water reservoir. We might expect that this reservoir increases the

drying time, sparing the moss from the detrimental effects of rapid drying. But differences do exist among *Sphagnum* species.

Figure 42. *Sphagnum hyaline* leaf cells and pores. Photo from Botany Department website, University of British Columbia, Canada, with permission.

In the hummock-forming *Sphagnum fuscum* (Figure 10) and *S. magellanicum* (Figure 8), desiccation results in a greater water loss before turgor sets in, compared to other non-hummock species (mean of 73% water loss vs 56%, respectively) (Hájek & Beckett 2008). The hummock species have more rigid cell walls than those of wet habitat species (ϵ = 3.55 vs 1.93 MPa, respectively). This rigidity results in loss of turgor in chlorophyllous cells at a higher relative water content in hummock species compared with species of wet habitats (0.61 vs 0.46) and at less negative osmotic potentials (-2.28 vs -3.00 MPa, respectively). Compared with other species, hummock *Sphagnum* (Figure 8, Figure 9) species that have been desiccated to -20 or -40 MPa recover more completely after rehydration. The **mesophytic** (intermediate habitat based on moisture) *Atrichum androgynum* (Figure 43) responds similarly to the hummock *Sphagnum* species.

Figure 43. *Atrichum androgynum*, a moss that behaves similarly to hummock *Sphagnum* species when it loses water. Photo by Jan-Peter Frahm, with permission.

Under a given rate of desiccation, the hummock species of *Sphagnum* (Figure 8-Figure 10), with their higher water content, continue their metabolism longer than species with lower water-holding capacities (Hájek & Beckett 2008). And these species recover faster, indicating a higher drought tolerance. These behaviors permit them to survive in the drought-exposed hummocks. The species growing in wet habitats have smaller water-holding capacities but are able to maintain turgor and have more elastic cell walls that permit them to metabolize longer during drying.

Most *Sphagnum* (Figure 8-Figure 10) species live where intermittent desiccation is inevitable. Hence, this genus appears to have inducible desiccation tolerance (Hájek & Vicharová 2013). In experiments to **harden** (process by which a plant becomes tolerant to the effects of such stresses as frost and drought) the species, Hájek and Vicharová subjected them to slow drying, ABA application, and chilling or frost. In the laboratory, *Sphagnum* species that were de-hardened and remained untreated lacked desiccation tolerance. Slow drying, ABA application, and frost induced hardening and desiccation tolerance. The section *Cuspidata* (Figure 44) – aquatic species – did not exhibit hardening. Similar hardening occurs multiple times each year among hollow and lawn species in the field. Hummock and aquatic species, on the other hand, develop their tolerance only in late autumn, a phenomenon that Hájek and Vicharová attributed to frost. Protonemata, however, did not develop desiccation tolerance under any of the hardening treatments. The hummock species exhibit a tradeoff, having greater water-holding capacity to the detriment of their physiological desiccation tolerance.

Figure 44. *Sphagnum cuspidatum*, an aquatic species that does not seem to experience hardening. Photo by Bernd Haynold, through Creative Commons.

Cratoneuron filicinum (Figure 40) demonstrates the effects of slow vs rapid drying on a semi-aquatic species (Krochko *et al.* 1978). In rapid drying, the cell contents are very disrupted and become increasingly disorganized over the next 24 hours. In slow drying, only some cells have

this appearance while others maintain their cellular integrity. The greater the rate of drying, the more protein synthesis is reduced on rehydration, but it will resume following rapid water loss down to 50% of the fresh weight. On the other hand, respiration does not resume following rapid drying and rewetting.

Mode of Conduction

Can the mode of conduction provide a beneficial edge that permits success when faced with limited water? Raven (1999) claims there is a "mechanistically mysterious size limit" for poikilohydric, desiccation-tolerant plants, suggesting an upper limit of 1 m. Anderson and Bourdeau (1955) demonstrated that external water can travel only to a "certain level." Bowen (1933c) and Mankiewicz (1983, 1984a,b, 1987a,b) remind us that this upper limit is imposed by the height to which water can rise by capillarity alone, a distance Héban (1977) considers to be only a few centimeters without the addition of other forces. As stated by Mankiewicz, "geometry of bryophytes may be constrained by the cohesive and adhesive forces of water," a statement he was able to confirm by empirical measures of flow rates through bryophyte colonies. However, we are reminded that most bryophytes receive their water from above, hence that capillary limit is of little importance for most of them. Therefore, we might ask, is the endohydric system important for the slow-growing, short bryophyte?

Bowen (1933a,b,c) compared conduction of bryophytes in wet, moist, and dry habitats. External water movement was faster than internal movement in all but two cases [*Thamnobryum alopecurum* (Figure 50) and *Plagiomnium undulatum* (Figure 52)]. *Plagiomnium undulatum* has a well-developed internal conducting system and lacks significant capillary channels externally. *Thamnobryum alopecurum*, on the other hand, typically lives where it is constantly wet from splashing or dripping water and seems to lack external conduction, perhaps due to external saturation. However, as the moisture of the habitat increases, the ability of the bryophyte plant to conduct decreases both externally and internally.

All of the taxa Bowen (1933a,b,c) studied had a **central strand** (Figure 45), varying considerably in relative size. But just how important is that strand in moving water from substrate to plant tissues? If the central strand is important in water movement, should we expect it to be most important in those mosses that suffer frequent drought conditions? In the epiphytic (but pleurocarpous) *Hypnum cupressiforme* var. *filiforme* (Figure 46-Figure 47), the central strand appears only occasionally and is absent in branches. In the boreal forest floor *Rhytidiadelphus triquetrus* (Figure 48), the cells are short with numerous transverse walls, suggesting inefficient water movement through walls. Nevertheless, in *Aulacomnium palustre* (Figure 49), internal conduction seems not to exist, despite a "relatively large central strand;" external conduction is rapid, suggesting that other factors, not the central strand, are more important in determining importance of internal versus external conduction.

Figure 47. Cross section of stem of *Hypnum* sp. showing indistinct central strand. Photo by Isawo Kawai, with permission.

Figure 49. *Aulacomnium palustre*, a moss with predominately external conduction despite its central strand. Photo by Janice Glime.

When Bowen (1933b) compared nine species of moist habitat bryophytes (Figure 53), she found that external conduction likewise predominated in all but *Rhizomnium magnifolium* (Figure 52; as *Mnium punctatum*, but based on her description most likely what is now called *Rhizomnium magnifolium*). *Thamnobryum alopecurum* (Figure 50), apparently erroneously reported in cm instead of mm in her table, has almost no water movement internally or externally (Mägdefrau 1935), but relies instead on the constant humidity of waterfalls and streamsides. Among the dry habitat mosses in the study, only *Plagiomnium undulatum* (Figure 52) exhibits more rapid internal conduction than external conduction.

Figure 50. *Thamnobryum alopecurum*, a moss of dripping habitats that seems to have little water movement internally or externally. Photo by Michael Lüth, with permission.

Based on Bowen's (1931, 1933a,b,c) comparisons, we can derive little satisfaction about the relationship between the central strand and habitat. None of the species lacking a central strand were examined, nor were any extremely xerophytic or aquatic mosses or any liverworts examined. However, external adaptations to movement of water do seem to correlate with habitat, with those mosses from wet habitats having poor conduction capability both internally and externally, relative to taxa from drier habitats (Figure 53). The central strand appears to have only a minor role in conduction, being most useful in those taxa with a well-developed central strand, such as the **Mniaceae** (Bowen 1933c), and providing almost no value in those taxa with a small strand (Mägdefrau 1935; Zacherl 1956).

Despite Bowen's (1931, 1933a,b,c) small sample size and the presentation of "representative" data rather than means, one can still infer several patterns that indicate water pathway adaptations. The **Mniaceae** are a good example (Figure 52). There is good external conduction in *Mnium hornum* (Figure 52), where the leaf insertion is relatively small, but the leaves are strongly overlapping, as are the plants. In the very tomentose *Rhizomnium magnifolium* (Figure 52), with somewhat overlapping and encircling leaves, external conduction is relatively good, but internal conduction is much better than in *Mnium hornum*. However, in *Plagiomnium undulatum* (Figure 52), where the leaves are non-overlapping and the leaf tapers to the equivalent of a petiole at insertion, external conduction is almost non-existent. It is noteworthy that members of this family are particularly difficult to rehydrate for slide preparation, presumably due to thickened cell walls and cuticular substances on the leaves. It is reasonable to expect rapid internal conduction in the

Mniaceae because these mosses have well developed central strands of conducting tissue. In *Plagiomnium undulatum* the central strand occupies up to 2/3 of the stem diameter. Members of the family **Mniaceae** and *Polytrichum commune* (Figure 54-Figure 55) are also the only ones examined that have hydroids in the leaves (Bowen 1931, 1933a,b,c). As noted in *Aulacomnium palustre* (Figure 49), factors other than the size and construction of the central strand are important in determining relative conductance.

In *Brachythecium rutabulum* (or *B. rivulare*?) (Figure 56-Figure 57), the slightly decurrent leaf bases form channels that retain capillary films of water. In *Entodon rubicundus* and *Calliergonella cuspidata* (Figure 58), internal conduction is appreciable in young tissues, becoming negligible in older stems (Mizushima 1980). Bowen (1933b) attributes this to the changes in **hypodermal tissues**, which are thin-walled in young stems, becoming thick-walled in older ones. Rather, the epidermis absorbs water and sends it cell-to-cell to the tip of the plant where the young hypodermal cells permit the water to penetrate to the center of the plant where a very thin central strand occupying about 10% of the stem exists. Entry of water into the apex is rapid, as is the external movement to the tip. *Campylopus brevipilus* (Figure 59) has a central strand of 5-15 cells in diameter. As might be expected in a genus so well adapted to dry habitats, even this more wetland species has little absorption through its stem epidermis and movement of water through the hypodermis is slow, entering primarily at the stem apex. Likewise, little conduction occurs from the base through the central strand.

Figure 51. *Entodon rubicundus* with capsules & dew drops, a species with internal conduction in young tissues. Photo by Shu Suehiro, permission pending.

Figure 53. Comparison of movement of water up the stems in wet, moist, and dry habitat mosses. Note that for *Brachythecium rutabulum*, *Hypnum cupressiforme* var. *filiforme*, and *Rhytidiadelphus triquetrus* the internal movement is for 18 hours. (Based on the description of decurrent leaf bases and habitat, *Brachythecium rutabulum* may actually have been *B. rivulare*.) For *Thuidium tamariscinum*, *Hypnum cupressiforme* var. *filiforme*, and *Dicranum scoparium*, the external water reached the tip before one hour. In *Ditrichum flexicaule* and *Anomodon viticulosus* the water reached the tip in 15 minutes. Based on Bowen (1931, 1933a,b,c).

Could it be that the central strand serves a different function? In an Alaskan black spruce forest, Skré *et al.* (1983) found that endohydric *Polytrichum commune* (Figure 54-Figure 55), which has a well-developed central strand (Figure 60) and considerable internal conduction, suffers less moisture stress than the three ectohydric mosses studied [*Hylocomium splendens* (Figure 61-Figure 62), *Pleurozium schreberi* (Figure 64), and *Sphagnum subsecundum* (Figure 63)] during the summer dry period. *Hylocomium splendens* remained below its water compensation point for nearly 50% of the July measurement period. The rates of water loss and moisture level required to reach field capacity correlate well with the moisture status observed for mosses in the field. This water retention in the endohydric *Polytrichum* supports the suggestion of Skré and coworkers that a major function of the central strand may be water storage.

Osmotic Potential and Turgor

Unlike tracheophytes, whose net photosynthesis decreases when the water potential drops below -1 to -3 bars (Busby & Whitfield 1978), drought-tolerant mosses can resume normal photosynthesis after a drop in water potential to about -1000 bars, a condition found during the dry, hot days of summer in the open (Dilks & Proctor 1979). Even in the shaded forest, the water potential of a moss can drop to -200 to -400 bars. While flowering plants and ferns may have negative photosynthesis at water potentials of -12 to -15 bars, mosses such as the woodland to semi-shaded species *Hylocomium splendens* (Figure 61-Figure 62), *Pleurozium schreberi* (Figure 64), and *Tomentypnum nitens* (Figure 65) can continue net photosynthesis until the water potential falls below -55 to -100 bars (Busby & Whitfield 1978), and *Camptothecium lutescens* (Figure 66) from the United Kingdom can maintain a net positive photosynthesis down to -150 bars (Dilks & Proctor 1979). The drought-intolerant moss *Hookeria lucens* (Figure 67), on the other hand, must maintain 100% humidity and cannot maintain positive photosynthetic gain when the water potential drops below 80 bars (Dilks & Proctor 1979). Yet this highly drought-intolerant moss, relatively speaking, has primary cell walls with **pit fields** in its stem parenchyma, structures common to tracheids and vessels and permitting lateral transport, suggesting that *Hookeria lucens* may use these cells in internal conduction (Cortella *et al.* 1994).

Figure 65. *Tomentypnum nitens*, an ectohydric moss. Note dense tomentum covering stems. Photo by Michael Lüth, with permission.

One adaptation to maintaining water is to increase the osmotic value of the cells. Ochi (1952) compared a number mosses and showed that the highest osmotic values were generally in mosses adapted to xeric conditions. He obtained high values (0.90-0.62) in such tree-trunk and sunny rock dwellers as *Hedwigia ciliata* (Figure 82), *Thamnobryum subseriatum* (= *Thamnobryum sandei* var. *cymbifolium*?) (Figure 68), *Myuroclada maximoviczii* (Figure 69), *Thuidium cymbifolium* (Figure 70), *Neckera yezoana*, and *Anomodon giraldii* (Figure 71). Intermediate values characterized those on soil (0.70-0.30), including *Dicranum japonicum* (Figure 37), *Pogonatum inflexum* (Figure 72), *Plagiomnium maximoviczii* (Figure 73), and *Plagiomnium cuspidatum* var. *trichomanes* (Figure 74). In shady, wet, forested areas, Ochi obtained the lowest value (0.26), exemplified by *Plagiomnium vesicatum* (Figure 75) and *Hookeria acutifolia* (Figure 76). Surprisingly, values were highest in older plants and mature portions, not the vital young buds.

Proctor (1999) likewise examined a number of bryophytes to determine their osmotic potential. He found that the leafy ones (mosses and leafy liverworts) have a full turgor osmotic potential of -1.0 to -1.5 MPa, whereas the multistratose thallose liverworts have -0.5 to -1.0 MPa.

The full turgor content of water varies with season, ranging 100-300% in bryophytes from well-drained habitats. But Proctor found that the highest turgor occurs in the new growth. The cell walls are highly extensible in most of the thallose liverworts and such drought-tolerant mosses as *Syntrichia ruralis* var. *arenicola* (Figure 77) and *Racomitrium lanuginosum* (Figure 78), but it is quite low in certain leafy liverworts with very rigid cell walls. Unlike Ochi (1952), Proctor found that variations in water relation parameters seem to bear little relationship to habitat for most bryophytes. He attributed this lack of relationship to the consideration that they are usually only metabolically active when they are fully hydrated.

Some bryophytes can tolerate turgor up to 1400% of their dry mass [*Dumortiera hirsuta* (Figure 79) & *Conocephalum conicum* (Figure 80)] (Proctor *et al.* 1998). On the other hand, xerophytic mosses such as *Syntrichia ruralis* (Figure 77) and *Andreaea alpina* (Figure 81) reach full turgor at only 110%.

Water Content

Given sufficient water, water content is related to the cell's osmotic potential. Low water content seems to be related to a xeric habitat (Hernández-García *et al.* 1999), suggesting tolerance rather than the avoidance that might be obtained by maintaining high osmotic potential. In the xeric and mesic pine forests of Tenerife, water content of all mosses tested was <140% of dry mass. *Hedwigia ciliata* (Figure 82), *Grimmia laevigata* (Figure 83), *G. trichophylla* (Figure 84), and *Pterogonium gracile* (Figure

85), the rock dwellers, have the lowest field water content and fastest absorption and water loss rates among the species. *Polytrichum juniperinum* (Figure 86), *Bartramia stricta* (Figure 87), and *Anacolia webbii* (Figure 88) have the highest field water content and slowest water absorption and loss rates. The highest drought tolerance occurs in *H. ciliata*, *B. stricta*, *G. laevigata*, and *G. trichophylla*.

Nevertheless, most bryophytes apparently do not exhibit the low **water capacity** (50-250%) that permits some seed plants and lichens to survive areas with very low rainfall (During 1992). Known **water capacities** (percent of wet mass relative to dry mass) in bryophytes mostly fall into the high water capacity range of 650-1700% (During 1992), except for endohydric taxa, ranging 190-577% (Coufalová 1951). For example, the damp forest leafy liverwort *Bazzania trilobata* (Figure 89) at saturation had a moisture content of 1300% of its dry mass (Sollows *et al.* 2001).

Figure 89. *Bazzania trilobata*, a damp forest species with a saturation moisture content of ~1300% dry weight. Photo by Jan-Peter Frahm, with permission.

Nichols (1918) reported that *Sphagnum* (Figure 63) pads, used for bandages in World War I, could absorb up to 22 times their mass (water capacity = 2200%), making them 5-6 times as absorptive as cotton pads. Other bryophytes, as in some South African montane areas, survive on the water they collect from early morning mist in low-lying clouds (Russell 1982), suggesting that these bryophytes may indeed have low water capacities. Furthermore, many bryophyte taxa are tolerant of very low water contents (5-10% of dry mass), resuming photosynthesis upon remoistening (Proctor 1990).

It appears that at least for some bryophytes, it is best to be wet or be very dry. Water pressure in the range of -100 to -200 MPa is best for survival in a dry state (Proctor 2001). Akande (1984, 1985) has examined the effects of the degree of dehydration on Nigerian bryophytes and found that those maintained at 0% humidity for one week and for one month both resumed respiration more quickly than those maintained for the same time period at 32% and 54% (Akande 1984). He found that the leafy liverwort *Mastigolejeunea florea* is less desiccation-tolerant than the two mosses studied, but all three taxa did have individuals that survived at 0%, 32%, and 54% relative humidity at ambient temperature (Akande 1985).

Water-logging

Despite their needs for high water content, bryophytes cannot afford to be too wet or they are unable to carry out photosynthesis. Acquiring CO₂ must occur through the leaf surface, and a continuous layer of water interferes with that transfer. Silvola (1991) found that in all the boreal forest mosses he tested except *Polytrichum commune* (Figure 54-Figure 55), photosynthesis decreased when the water content exceeded a certain optimal level (see also Williams & Flanagan 1991). It is likely that the leaf lamellae provided air spaces for CO₂ transfer in *P. commune*. Many *Sphagnum* species suffer similarly from water-logging.

Inducible vs Constitutive Desiccation Tolerance

As recently as 2011, Green *et al.* reviewed the literature and reported that bryophytes appear to all be constitutive. To support this they cite that no protein synthesis is required upon rehydration before metabolism can commence. Bryophytes furthermore appear to always be protected from desiccation mortality. Further support is the constant presence of high sucrose levels. And the cellular structure is usually maintained during desiccation.

Both **constitutive** (always present; fully desiccation tolerant) and **inducible** [produced when drying conditions occur; previously known as modified desiccation-tolerant (Oliver *et al.* 1998)] **desiccation tolerance** exist among bryophytes (Stark *et al.* 2013). Those with **constitutive desiccation tolerance (CDT)** are not dependent on the rate of drying to determine their recovery, whereas those that depend on **inducible desiccation tolerance (IDT)** are. Reduced or no desiccation tolerance following rapid drying is generally an indicator that the plants are IDT plants. Tracheophytes, with the exception of some ferns (Watkins *et al.* 2007), are IDT plants (Oliver *et al.* 1998, 2000), whereas bryophytes are mostly CDT plants (Toldi *et al.* 2009), hence their high ability to survive drying.

Those bryophytes with **constitutive desiccation tolerance (CDT)** are not dependent on the rate of drying, whereas those with only **inducible desiccation tolerance (IDT)** are. Therefore, the IDT plants, including IDT bryophytes, are likely to die when exposed to rapid drying.

But bryophytes can use both strategies. Stark and coworkers have investigated the inducible protections that permit bryophytes to survive desiccation. Those bryophytes that survive slow drying but not rapid drying provide us with evidence that something happens during that slow drying process, and that happening provides the inducible desiccation tolerance (Stark *et al.* 2013). Bryophytes also possess constitutive desiccation tolerance, a tolerance that is common among terrestrial bryophytes. For example, the desert moss *Pterygoneurum lamellatum* (**Pottiaceae**; Figure 7) exhibits both a constitutive and an inducible response. The bryophyte tolerance strategy couples **constitutive** cellular protection during dehydration with the **induction** of a recovery/repair mechanism upon rewetting (Oliver *et al.* 2005; Toldi *et al.* 2009; Stark & Brinda 2015).

More recently, Stark and Brinda (2015) have found that not only can a desert moss have both inducible and constitutive desiccation tolerance, but it can have each in different parts of the same shoot at the same time or in different stages in the life cycle. Stark and Brinda propose that as the sporophyte grows older, the presence of sugars in the sporophyte facilitates desiccation tolerance. This would help to explain the greater danger of death by desiccation in the early embryonic stage before significant sugar accumulation occurs. At the same time, the early embryo exhibits inducible desiccation tolerance (IDT) and requires slow desiccation, usually not a problem within the protection of the apical gametophyte leaves. As the embryo develops and the seta emerges from these protective leaves, the sporophyte changes from IDT to partially CDT. Stark and Brinda suggest that this evolutionary change resulted from selection pressures of intermittent drying in this exposed sporophyte. This exposed sporophyte tissue is most likely subject to faster rates of desiccation, making an inducible system inadequate to meet the time demands and selecting for the constitutive desiccation tolerance. The presence of a waxy cuticle in the capsules of *Funaria hygrometrica* (Figure 26) provide an example of this CDT (Budke *et al.* 2011, 2012, 2013).

Stark and Brinda (2015) concluded that once the seta elongation phase reaches the stage of capsule expansion, sucrose imported from the gametophyte (Renault *et al.* 1992) should be present in the sporophyte, endowing the sporophyte with the raw materials needed to tolerate rapid drying (Stark & Brinda 2015). In *Acaulon muticum* (Figure 92), small vacuoles are present in the placental region of the sporophyte-gametophyte junction (Rushing & Anderson 1996). These abundant vacuoles may be present in the embryonic sporophyte as well, where they could provide protection from water stress in the rapidly growing sporophyte.

Wolkers *et al.* (2001) had already suggested that a slower rate of drying may permit the proteins and sucrose to interact in a more protective manner. For example, in *Physcomitrella patens* (Figure 21, Figure 90) and

Syntrichia ruralis (Figure 93), a slow drying treatment induces the production of either ABA (see below) or dehydrin, or both (Werner *et al.* 1991; Hellwege *et al.* 1994; Cuming *et al.* 2007). When ABA is applied to the outside of *Exormothea holstii* (Hellwege *et al.* 1994), it elevates sucrose levels and increases protection against rapid drying (see also Pence 1998; Oldenhof *et al.* 2006). Koster *et al.* (2010) demonstrated the genetic connection between ABA and the expression of several homologs to stress proteins, including two dehydrin-like proteins. The only problem with this logic is that the natural presence of ABA is still unknown in *Physcomitrella patens* and *Syntrichia ruralis* (Stark & Brinda 2015).

Figure 90. *Physcomitrella patens* sporophyte, a species in which a slow drying treatment induces the production of either ABA or dehydrin. Photo from Ralf Reski Lab, through Wikipedia Commons.

In *Aloina ambigua* (Figure 91), Stark and Brinda (2015) considered that the seta may elongate too fast for the inducible desiccation tolerance system to respond. This exposed tissue may therefore rely on the constitutive system to provide desiccation tolerance for the developing capsules.

Hardening

Hardening is a phenomenon known for flowering plants, but the concept is usually associated with preparation for winter. Beckett *et al.* (2005) induced desiccation hardening in the moss *Atrichum androgynum* (Figure 11) by reducing the relative water content of apical portions for 1/2 to 3 days, followed by storage fully hydrated for another day. Plants were then desiccated for 16 hours over silica gel, and the recovery of PSII during rehydration was monitored. Hardening affected photosystem II (PSII) before desiccation, decreasing its efficiency, especially at saturating light intensities. Upon rehydration, however, hardened plants recovered their PSII activity more quickly and greatly increased the non-photochemical quenching in the first few hours compared to those plants not subjected to hardening. Beckett *et al.* concluded that hardening shifts the photosynthetic apparatus from a state of high efficiency to one of less efficiency but having a photoprotected state.

Hardening can confound physiological experiments when comparing desiccation tolerance. Once hardened, the plant is likely to receive the benefits in desiccation resistance for a prolonged period of time, such that a rehydration period of 24-72 hours may not remove that benefit (Bopp & Werner 1993; Stark *et al.* 2014). Instead, regenerates from fragments (regenerated more than once to eliminate prior hardening) or plants grown from spores may be necessary to create plants that have no prior desiccation experience, hence no hardening (Stark & Brinda 2015).

Desiccation-induced Changes

Iljin (1953, 1957) considered that mechanical injury to the protoplast membranes during the drying and rewetting processes is the primary cause of desiccation sensitivity. He considered the tensions that develop in cells during dehydration, pulling protoplasm inward as the vacuoles shrink and cell walls pulling membranes outward, are the primary causes of lethal injuries in drought-sensitive species. Drought-tolerant plants mitigate these tensions by

such cellular aspects as reduced cell size, small or absent vacuoles, lack of plasmodesmata, easily deformed cell walls, and reduced osmotic pressure. For example, small cytoplasmic vesicles (vacuoles) are present in such desiccation-tolerant species as *Syntrichia ruralis* (Figure 93), *Neckera crispa* (Figure 94), *Pleurozium schreberi* (Figure 64), and *Triquetrella papillata* (Figure 95) (Oliver & Bewley 1984). But this does not hold true for all species – in the desiccation-tolerant *Ceratodon purpureus* (Figure 96-Figure 98) and *Didymodon vinealis* (Figure 99), the vacuoles are quite large. And the desiccation-intolerant *Cratoneuron filicinum* (Figure 40) does not have large vacuoles. **Plasmodesmata** (microscopic channels that traverse cell walls of plant and some algal cells, enabling transport and communication between them) likewise do not seem to be related to desiccation-tolerance, but these are difficult to see and often require electron microscopy for viewing.

Henckel and Pronina (1968, 1969, 1973) suggest that those plants that are drought-tolerant are continuously prepared for desiccation, *i.e.*, have constitutive desiccation tolerance. However, this theory likewise did not fit the evidence presented by slow vs rapid drying in bryophytes. Bewley (1979) suggested that instead, three factors are critical to desiccation tolerance:

1. limiting damage during desiccation to a repairable level
2. maintaining physiological integrity in the dry state so that metabolism can be reactivated quickly upon rehydration
3. putting repair mechanisms into effect upon rehydration, in particular to retain or regain integrity of membrane and membrane-bound organelles.

As bryophytes desiccate, a series of changes occurs. In *Physcomitrella patens* (Figure 21, Figure 90), these changes include plasmolysis, chloroplast remodelling, and microtubule depolymerization, as demonstrated by desiccation for more than one month to 10% of fresh weight (Wang *et al.* 2009). Nevertheless, Wang and coworkers found that the membranes retain their integrity. These changes involved 71 responsive proteins. Most of these were involved in metabolism, cytoskeleton, defense, and signaling. But not all changes seem to be that of repair

or stability. Cytoskeletal protein degradation might cause cytoskeletal disassembly and resulting changes in cell structure. **Late embryogenesis abundant proteins (LEA proteins)** and reactive oxygen species-scavenging enzymes are among those prominently induced, possibly helping to reduce the damage caused by desiccation. Oliver *et al.* (2004) likewise found that the LEA proteins were the most abundant transcripts associated with drying tissues. They suggest that the LEA proteins might play a role in recovery from desiccation.

Oliver *et al.* (2004) took a genetic approach to understanding desiccation tolerance, using the desiccation-tolerant *Syntrichia ruralis* (Figure 93). They found that the **transcriptome** (set of all RNA molecules, including mRNA, rRNA, tRNA, and other non-coding RNA transcribed in a cell) has a diverse population of transcripts that reflects a period of metabolic upheaval in the gametophyte cells. Much of the emphasis in this transcriptome is on the protein synthesis machinery, ion and metabolite transport, and the biosynthesis and repair of membranes. When gametophytes are rehydrated, there is a large number of transcripts that code for enzymes involved in oxidative stress metabolism and phosphorylating activities.

When *Pterygoneurum lamellatum* (Figure 7) is subjected to very rapid drying, it is severely damaged throughout the entire shoot except the shoot apex (Stark *et al.* 2013). This damage results in slower growth rates, fewer regenerative shoots, and a damaged photosynthetic system as demonstrated by alterations in fluorescence.

Cell Contents

As one might expect, cell contents respond to desiccation stress. In the mosses *Bryum argenteum* (Figure 100) and *Didymodon vinealis* (Figure 101) from cryptogamic crusts, the free proline content was significantly greater than in those from a typical (wetter) grassland (Xu *et al.* 2005).

Figure 100. *Bryum argenteum* in crack in parking lot, a species that manufactures proline in dry habitats. Photo by Paul Davison, with permission.

In the moss *Plagiomnium acutum* (Figure 103), concentrations of proline, soluble sugar, and reducing sugar all increase noticeably during dehydration, reaching maximum concentration after 12 hours (Li *et al.* 2009). As the membrane permeability increases, activities of protective enzymes likewise increase, including SOD,

CAT, and POD. DNA degrades gradually, with only some of the low molecular weight fragments remaining. Upon rehydration, all of these changes reverse. *Physcomitrella patens*, like *Plagiomnium acutum*, accumulates the osmoprotectants altrose, malitol, ascorbic acid, and proline when subjected to drought stress (Erxleben *et al.* 2012).

Figure 103. *Plagiomnium acutum*, a moss that demonstrates increases in proline, soluble sugar, and reducing sugar during desiccation. Photo by Liu; permission pending.

Cruz de Carvalho *et al.* (2015) found that the low water potentials in dehydrating cells of the aquatic moss *Fontinalis antipyretica* (Figure 104) is coupled with osmoregulation due to increase of such soluble materials as soluble sugars and compatible inorganic ions. These increase turgor pressure. In addition to its role as an osmolyte, sucrose stabilizes membranes and proteins through **vitrification**, *i.e.*, by creating glasslike substances. When the moss was dehydrated slowly, the cell walls became more elastic, permitting cell shrinkage that maintained turgor and helped to preserve metabolic functions. However, in rapid drying, there was a loss of turgor and osmotic potential. Although the sucrose content increased, rehydration of the fast-dried samples resulted in 50% loss of sucrose through cell leakage as a result of cell membrane rupture. Slowly dehydrated leaves, on the other hand maintained their sucrose content upon rehydration. The thick mats of long dangling *Fontinalis antipyretica* facilitates slow drying of this species in nature.

Sucrose acts as an osmotic "spacer" in membranes (Werner *et al.* 1991; Oldenhof *et al.* 2006; Cruz de Carvalho *et al.* 2014). This is accompanied by ABA mediation of protein synthesis, strengthening the cellular glasses typical of inducible desiccation tolerance in mosses, as shown in *Physcomitrella patens* (Oldenhof *et al.* 2006).

Chloroplast Responses

Bryophyte chloroplasts undergo ultrastructural changes when undergoing desiccation. Chloroplasts become smaller and more spherical with a less-well defined internal structure (Noailles 1978). The general lamellar structure collapses, with the **thylakoids** (chlorophyll vesicles) becoming dispersed; starch granules are lost. This response is similar to that induced by ABA in experiments related to freezing tolerance (Nagao *et al.* 2005).

Bryophyte chloroplasts contain **plastoglobuli** (Tucker *et al.* 1975; Oliver & Bewley 1984) in groups within the stroma. These increase in size and number during dehydration in *Syntrichia ruralis* (Figure 93) (Tucker *et al.* 1975).

It appears that the chloroplasts may be altered by desiccation in other ways we do not fully understand. I found that I could not extract chlorophyll effectively from dry *Fontinalis* spp. (Figure 104) using acetone unless I rewet them for about 15 seconds first. Tuba (1984) reported a possible decoupling of the chlorophyll from its protein, but later (Tuba 1985) attributed that apparent phenomenon to the separation of upper and lower shoots and the extraction process. In fact, he stated that the chlorophyll *a* and *b* remained unchanged during daily desiccation and early rehydration of *Syntrichia ruralis* (Figure 93). He concluded that the **neoxanthin** (a carotenoid pigment), due to its hydrophilous nature, may be adaptive in binding the **LHCP** (light-harvesting chlorophyll protein) to the **PS II** chlorophyll core, thus stabilizing the LHCP.

One factor in the protection of chlorophyll against light damage during desiccation is that the pigment **zeaxanthin** can bind to the chlorophyll-containing thylakoid protein (Deltoro *et al.* 1998; Heber *et al.* 2001). On the other hand, loss of chlorophyll fluorescence during drying of pre-darkened mosses suggests that energy dissipation in the desiccated mosses is unrelated to zeaxanthin availability.

Figure 104. *Fontinalis antipyretica*, a moss that, when dry, has a delay before its chlorophyll dissolves in alcohol, suggesting that the chlorophyll may be complexed during dehydration. Projecto Musgo, through Creative Commons.

Even among the desiccation-tolerant bryophytes, the rate of recovery of chlorophyll fluorescence varies widely upon rehydration (Proctor 2010). For example, some species have high values of F_v/F_m in the early minutes of recovery, accompanied by low absolute values of F_m . But most recovery curves are logistic (S-shaped curve that starts slow, goes up exponentially, then approaches horizontal) for photosynthetic CO_2 fixation in the light.

Photosynthesis

Lee and Stewart (1971), using *Calliergonella cuspidata* (Figure 58), *Climacium dendroides* (Figure 105), and *Hypnum cupressiforme* (Figure 46-Figure 47), found that the degree of desiccation tolerance correlates with the degree of moisture stress experienced in the habitat. This tolerance is expressed as a rapid recovery of photosynthetic rate in taxa from habitats with severe moisture deficits, whereas those from habitats with no appreciable moisture deficits lose photosynthetic capability more quickly and are slower to recover.

Seel *et al.* (1992) made similar comparisons using *Syntrichia ruralis* (Figure 93), *Bryum pseudotriquetrum* (Figure 106), and *Dicranella palustris* (Figure 107) from a range of habitats with different water availabilities. All three species become photosynthetically inactive when dried to a water content of 100-200%. But recovery differs. The xeric *Syntrichia ruralis* from sand dunes recovers to its pre-desiccation photosynthetic rates, but its rate of recovery is affected by irradiance during its desiccation. Those mosses from hydric habitats, when rehydrated, have partial resumption of their photosynthetic electron transport if they are dried in the dark, but if they are dried in even low light they did not resume their photosynthetic activity. Their symptoms indicate a lasting photoinhibition of photosynthesis following rehydration. On the other hand, the desiccation-tolerant *Syntrichia ruralis* (Figure 93) experiences significant photoinhibition only when receiving continuous high irradiance ($1200 \mu\text{mol m}^{-2} \text{s}^{-1}$) while hydrated. But if it is dehydrated while receiving high irradiance it shows less evidence of photoinhibition after rehydrations. Desiccation at low irradiance has no effect following rehydration. Leaf curling reduces photon flux absorption by 50-60% in dry mosses compared to hydrated mosses, although it is

possible that changes in optical properties of papillae may contribute to that reduction.

Figure 106. *Bryum pseudotriquetrum*, a species that becomes photosynthetically inactive when its water content is decreased to 100-200%. Photo by Michael Lüth, with permission.

Figure 107. *Dicranella palustris*, a species that becomes photosynthetically inactive when its water content is decreased to 100-200%. Photo by Michael Lüth, with permission.

Both thylakoid lipids and chlorophyll reduction coincide with the loss of photosynthesis in dehydrating *Atrichum androgynum* (Figure 11) (Guschina *et al.* 2002).

The desert moss *Syntrichia caninervis* (Figure 12) recovers quickly when shoots are remoistened in the dark (Zhang *et al.* 2011). This is an advantage for this moss that receives much of its moisture from dew, a night-time phenomenon. Its leaf hairs are able to trap the dew (and also fog and raindrops) and direct them to the base of the leaf where it rapidly is absorbed. The chlorophyll fluorescence has a narrow optimum range. The moss seems to experience no damage to its membranes or organelles and reaches 90% of its 30-minute photosynthetic yield within the first minute of rehydration. This permits it to take rapid advantage of small amounts of moisture from fog, dew, snow, and short rainfall events.

Mitochondria

The mitochondria [cell organelle that generates most of the cell's supply of **ATP** (adenosine triphosphate), used as a source of chemical energy] become deformed as they dehydrate, becoming small and rounded (Noailles 1978). Internal cristae may be greatly reduced in size or lost completely.

Nuclei

The nuclei seem to suffer little from the effects of desiccation, retaining their normal size (Noailles 1978).

Vacuoles and Vesicles

Normal bryophyte cells have one to several large vacuoles (Noailles 1978). During dehydration, these break down to form numerous small vesicles (Oliver & Bewley 1984). It appears that ABA may be involved in this transformation, since the response is similar to that induced by ABA during freezing (Nagao *et al.* 2005). ABA-treated cells have slender chloroplasts, and the quantity of starch grains is reduced in comparison with those of non-treated cells.

Membranes

Membranes in general suffer from dehydration, including thylakoids, cristae, and cytoplasmic membranes like endoplasmic reticulum and dictyosomes, resulting in the shrinkage of organelles (Noailles 1978). The chloroplast membrane itself may exhibit clefts (Tucker *et al.* 1975). It is the ability to repair this damage that makes many bryophytes desiccation tolerant (Li *et al.* 2009).

Both desiccation-tolerant and intolerant bryophytes leak electrolytes when rehydrated (Gupta 1976, 1977, 1979), as do dry viable seeds, lichens, pollen grains, fungi, and their spores (Simon 1974, 1978). This leakage lasts only a few minutes except in cases of permanent damage (Oliver & Bewley 1984). Oliver and Bewley (1984) listed amino acids, mono-, di-, and tri-saccharides, sugar alcohols, organic acids, hormones, phenolics, phosphates, and various electrolytes as leaked substances during rehydration, although the leakage often lasts only minutes.

The desert moss *Syntrichia caninervis* (Figure 12) is the dominant species in the Gurbantunggut Desert, a cold desert in Central Asia. Wu *et al.* (2012) investigated the

membrane changes during desiccation of this species. There are no significant changes in electrical conductivity of the rehydration water during dehydration or rehydration. There also appears to be no ultrastructural damage to the membrane during dehydration or rehydration, but there are major changes in cellular ultrastructure. Wu and coworkers suggest three possible explanations for the apparent disruption of the membranes in desiccated state:

1. Adaptive morphological features of the leaf that remain intact permit the leaves to regain membrane integrity rapidly upon rehydration.
2. The moss becomes dormant rapidly, maintaining some level of membrane integrity.
3. Soluble sugars and free **proline** (constitutive substances) increase rapidly during desiccation, contributing to membrane stabilization.

Plasmolysis

One of the consequences of desiccation can be **plasmolysis** of the cells (shrinkage of protoplast away from cell wall) (Oliver & Bewley 1984). In some cases, very narrow elongate cells seem to resist plasmolysis, perhaps due to the small cell volume and strong adhesion to the cell walls. But plasmolysis can occur in bryophytes and can result in cell damage to both the plasma membrane and the cell wall.

In *Didymodon vinealis* (Figure 99) and *Triquetrella papillata* (Figure 95), the dehydrated cells contract to 50-70% of the original volume (Moore *et al.* 1982). The cell walls contract, permitting the protoplasm to fill the cell and preventing entry of air into the drying cells.

It appears that at least the liverwort *Sphaerocarpos donnellii* (Figure 108) is able to partially compensate for this plasmolysis damage (Grusak *et al.* 1980), where both normal and plasmolyzed tissues are composed primarily of hemicellulose and cellulose. But in plasmolyzed cells, labelled C¹⁴ is considerably lower than in normal cells. Rather, these cells have higher radioactivity in pectin and hemicellulose and less in cellulose, suggesting a possible mechanism for enhancing wall stability. This transformation would provide numerous sites for cross-linkage between the cellulose microfibrils as walls regenerate.

Figure 108. *Sphaerocarpos donnellii*, a species that has the ability to partially compensate for plasmolyzed cells. Photo by Belinda Lo, through Creative Commons.

Liverworts

Liverworts have received surprisingly little attention relative to their drought tolerance strategies. Granted, these plants seem to require higher moisture conditions in general, but their presence as epiphytes in many areas attests to the ability of at least some liverworts to survive long periods of drought, and certainly the thallose liverworts of flood plains and other seasonal habitats provide another set of highly desiccation tolerant or desiccation avoider species.

Pressel *et al.* (2009) found that liverworts undergo "profound" cytological changes during dehydration. As in tracheophytes and mosses, these include fragmentation of the vacuole, rounding of chloroplasts and mitochondria with thylakoids, and cristae becoming rearranged but remaining undamaged. Furthermore, chlorophyll fluorescence returns to normal within 24-48 hours during rehydration. And like the mosses, their dehydration and rehydration are associated with the depolymerization and repolymerization of the cortical microtubule cytoskeleton. But unique among the bryophytes is the presence of **oil bodies** in liverworts, membrane-bound organelles that take on many shapes among the species (Kozłowski 1921; Kis & Pócs 1997). And these cellular inclusions, long considered only for their taxonomic value, seem to have an important role in liverwort recovery from dehydration (Pressel *et al.* 2009).

Taxonomists have been aware that these oil bodies usually disappear in herbarium specimens, and that they do not reappear upon re-wetting and microscopic observation. But it appears that to see these in herbarium specimens, one must treat the liverworts as nature does – dry them slowly and give them time to recover upon rehydration. It turns out that they remain largely unchanged while they are dry (Pressel *et al.* 2009), but who observes dry specimens under the microscope? Rather, they become flattened when rehydrated and in the six liverworts tested, they require 48 hours to regain their normal shapes, long after the taxonomist has cleaned the microscope slide. Fast drying causes them to disintegrate upon redrying, along with other liverwort organelles. Pressel *et al.* interpreted this initial loss of shape upon rewetting to indicate a shift in soluble carbohydrates or other components into the cytosol, suggesting that these may be crucial energy reserves needed for recovery and desiccation tolerance.

Kronstedt (1983) found that there was seasonal variability in the oil bodies of the floating liverwort *Ricciocarpos natans* (Figure 109). But as He *et al.* (2013) made clear, the function of oil bodies in most liverworts still remains unclear.

Figure 109. *Ricciocarpos natans*, a species with seasonal variability of oil bodies. Photo by Norbert Stapper, with permission.

Habitat Relations

In their review of lichen and bryophyte desiccation and rehydration, Green *et al.* (2011) considered that the rate of recovery may relate to the length of the hydrated activity period. They reported that species that hydrate and then dry rapidly (e.g. rock surfaces) recover rapidly. By contrast, those species from habitats that remain wet for a long time recover from dryness more slowly when rehydrated.

Cruz de Carvalho *et al.* (2014) found that even the aquatic moss *Fontinalis antipyretica* (Figure 104) can survive slow dehydration, during which both dehydration and rehydration proteins are induced. These protein profiles are similar to those of the terrestrial moss *Physcomitrella patens* and *Syntrichia ruralis*. The proteins associated with photosynthesis and the cytoskeleton were reduced during dehydration. In their place, the cells accumulated proteins involved in sugar metabolism and plant defenses. Upon rehydration the protein accumulation patterns for photosynthesis and the cytoskeleton return to normal levels. However those for sugar accumulation and defense remain high. During fast dehydration, on the other hand, this moss exhibited little change in proteins. Upon rehydration, proteins were leaked. The researchers suggested that bryophytes from contrasting habitats may share common desiccation tolerance mechanisms.

Summary

Bryophytes may be **desiccation tolerant**, surviving dry tissues and beginning photosynthesis upon rehydration, or they may be **drought avoiders**, using structural adaptations and life cycle stages to escape having a dry vegetative plant. The presence of a **central strand** does not seem to correlate with the degree of internal conduction, but habitat does.

Life cycles are a major protector against dry seasons, permitting bryophytes to survive as tubers, gemmae, spores, fragments, and buds. These stages are typically timed to coincide with drought seasons. They are likely to be combined with physiological changes, including dormancy, in the plants as they respond to changes in the environment.

Xeric bryophytes are more likely to have greater internal conduction and faster external conduction than mesic and hydric taxa. It is possible that the central strand may serve as a water reservoir in some taxa. Physiologically, some bryophytes can increase the osmotic value of the cells, and they typically have a high water capacity compared to drought-tolerant seed plants. Desiccation tolerance permits some bryophytes to remain dormant in a vegetative state for as many as 23 years.

During drying, chloroplasts undergo ultrastructural changes, **mitochondria** become **deformed**, and **vacuoles break down** to form smaller vesicles. Nuclei seem to remain intact. At least some taxa apparently protect their cell membranes from oxidative destruction. **ABA** seems to induce the production of H_2O_2 in light, reduce the loss of K^+ , and may facilitate the reduction

of oxygen release from photosystem II. Despite these adaptations, plasmolysis can occur and membranes can become damaged, requiring repair upon rehydration.

Liverworts may have one more trick in their cells – **oil bodies** that disappear rapidly upon rehydration, apparently converting oils into more usable forms of stored energy that could contribute to repair.

Acknowledgments

This chapter has benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me tow the line in explaining things without leaving too much to one's imagination, but at the same time not repeating myself. I appreciate Lloyd Stark's generosity in sharing the information he found in reviewing papers and in summarizing the seeming conflicts in the literature regarding *Sphagnum*.

CHAPTER 7-6

WATER RELATIONS: REHYDRATION AND REPAIR

Uniqueness of Bryophytes

As Vitt *et al.* (2014) stated, desiccation tolerance is the ability to survive complete loss of free water, a trait found in many bryophytes. One striking difference between bryophytes and tracheophytes is that if you put a dry bryophyte into water, in most cases you will see an immediate change in turgor, and leaves will spread and take their normal hydrated position – one that presents the greatest surface area to the light and atmospheric CO₂. This is particularly striking in mosses from frequently dry habitats, such as *Hedwigia ciliata* (Figure 2) from rocks or *Syntrichia ruralis* (Figure 3, Figure 21) from open sand. In many mosses, such as *Polytrichum* s.l. (Figure 8, Figure 10) and *Syntrichia*, this ability to spread the leaves when moist and appress them to the stem when dry is the result of enlarged or hyaline leaf base cells (Figure 4) that absorb water easily and swell, forcing the leaf away from the stem.

Bryophytes can look dead, but come back to life when rehydrated. For example, Longton and Schuster (1983) noted that both *Pleurozium schreberi* (Figure 5) and *Bryum argenteum* (Figure 6) can have dark or moribund lower shoot tissues, but new shoots and protonemata can regenerate from them. Clymo and Duckett (1986) made similar observations on *Sphagnum*.

Rehydration in mosses is generally very rapid, but some taxa are rather recalcitrant about getting wet inside. *Polytrichum piliferum* (Figure 8), common on sand in dry, exposed habitats, and *Schistidium apocarpum* (Figure 9), a rock-dweller, can require two hours to become saturated, whereas *Polytrichum juniperinum* (Figure 10), a soil moss with wider ecological amplitude than *P. piliferum*, can become saturated within three minutes (Larson 1981). Larson points out that the surface area to mass ratio is very important in determining the speed of rewetting (Figure 11). The **cuticle** seems to be another contributing factor in mosses like **Polytrichaceae** and **Mniaceae**.

Duration Survival

Determining the length of time that bryophytes can survive desiccation can be tricky. Although use of herbarium specimens can provide starting dates, these are stored in the dark, which may differ considerably from survival in the light where chlorophyll can be damaged. And one can never be sure how often the moss was wet for examination, often using up resources for repair without having an opportunity to replace them before being put in the dark again and once again desiccated.

Studies to test viability directly after an assortment of desiccation times are rare, requiring careful record keeping and assurance the conditions remain relatively constant over a lengthy period of time. Specimens must then be

rehydrated at intervals, requiring multiple specimens and replication, all collected at the same time from one location.

Figure 11. Relationship between surface area and time to saturation upon rewetting of three drought-tolerant mosses. Based on Larson (1981).

Ochi (1952) reminds us that even season of collection will affect the degree to which bryophytes can survive desiccation and the length of time they can remain dry and survive, an interpretation reiterated by Kosokawa and Kubota (1957). For example, Dilks and Proctor (1976b) commented that British species of bryophytes tend to have an increased tolerance to drought in spring and summer.

Hoekstra (2005) concluded that small size was not a limiting factor in desiccation survival longevity. Factors such as membrane deterioration during desiccation affect the length of time an organism can survive the desiccation (Koster *et al.* 2010). Hoekstra (2005) likewise attributed survival to a high level of fatty acid saturation in membranes.

Longevities vary considerably among plants, ranging from a few days in some pollen to decades in some moss spores and even green moss tissue (Hoekstra 2005). In 2000, Alpert (2000) asserted that "some desiccation-tolerant species can survive without water for over ten years." Alpert cited duration periods of adult organisms as 34 years for fungi, 23 years for liverworts, 19 years for mosses, 5 years for ferns and angiosperms, and 1 year for lichens. Hornwort spores can tolerate 21 years of desiccation (Vanderpoorten & Goffinet 2009). Some bryophytes exceed these duration records (Table 1).

Even within a fen, desiccation tolerance can vary widely. When eight fen species were compared, it was the hummock moss species *Climacium dendroides* (Figure 12), *Aulacomnium palustre* (Figure 13), and *Tomentypnum nitens* (Figure 14) that had the highest desiccation survival (>10% of stems after 20 weeks of desiccation). *Hamatocaulis vernicosus* (Figure 15), *Calliergonella cuspidata* (Figure 16), and *Bryum pseudotriquetrum* (Figure 17) had moderate resilience (<10% stem survival after 12 weeks). The lowest survival rates occurred in *Campyllum stellatum* (Figure 18) and *Plagiomnium elatum* (Figure 19) (~0% survival after 6 weeks).

¹ shoots allowed to regenerate only 10–14 d² 13 species of *Sphagnum* were shown capable of hardening to DT when partially desiccated at high RHs (Hájek & Vicharová, 2014)³ in the genera *Corsinia*, *Mannia*, *Plagiochasma*, and *Riccia*⁴ based on visible presence of neutral red stain in vacuoles upon rehydration

The duration of desiccation that plants can survive is dependent on the antioxidant pool present at the time of desiccation (Kranter *et al.* 2002; Moore *et al.* 2009). This is because longer periods of desiccation result in greater oxidative damage.

Certain events must occur upon rehydration for the bryophyte to survive (Pressel & Duckett 2010). Using moss protonemata, they determined that cell death will occur if these events do not occur. Slow drying will usually prevent these cell death threats.

This raises the question of desiccation survival under desert conditions, where drying can be quite rapid. For leaves, development will be interrupted, but they seem able to resume (Stark 2005). On the other hand, when sporophyte development is interrupted frequently, the sporophyte seems to fail, with only 9 out of 248 surviving during the 4-year study period. Embryonic abortion accounted for 69% of these, whereas 30% was attributable to herbivory. In the Mojave Desert moss *Crossidium crassinerve* (Figure 20) required a rain event of at least 2 mm to fully rehydrate. In most cases, the only useful hydration periods occurred in the cooler months of October to April, with a mean hydroperiod of 3.7-4.9 days. Although most dry periods were less than 25 days, Stark recorded them as long as 191 days. In a late winter rain event, the moss patches dried slowly over a period of several days, but during a summer event, the patches were dry in as few as 3 hours.

Figure 20. *Crossidium crassinerve*, a species in the Mojave Desert where it requires at least 2 mm of rain to fully rehydrate. Photo by Jan-Peter Frahm, with permission.

Resumption of Activity

Upon rehydration, desiccation-tolerant bryophytes generally resume normal activity quickly (Csintalan *et al.* 1999), whereas the resurrection plants among the tracheophytes in the same habitat take much longer (Peterson *et al.* 1994; Marschall & Proctor 1999).

Using the moss *Anomodon viticulosus* (Figure 37) and leafy liverwort *Porella platyphylla* (Figure 23), both from habitats that dry out frequently, Hinshiri and Proctor (1971) found a consistent pattern of net assimilation upon rehydration. When desiccated up to 22 days at 50%

relative humidity in *Anomodon viticulosus* (Figure 37) and 60 days in *Porella platyphylla* (Figure 23), the plants recovered in 3-4 hours. However, after longer periods, the initial net assimilation was negative, progressively becoming positive during the next several days. After 70 days, respiration in *Anomodon viticulosus* is very high in the first 24 hours of rehydration, then drops to normal levels. However, even then recovery is not assured. This negative initial net assimilation explains why frequent desiccation with short periods in which to recover before the next one is usually lethal to the bryophytes. In *Polytrichastrum formosum* (Figure 28), full recovery requires 24 hours (Duckett *et al.* 2007).

There are two general strategies that permit drought-tolerant plants to survive periods of desiccation: cellular protection and cellular repair. Those bryophytes that are tolerant of desiccation seem to succeed primarily because of their rapid cellular repair (Oliver *et al.* 1993). According to Oliver (1991), no novel **mRNAs** (messenger RNA; molecule that carries portion of DNA code to other parts of the cell processing) are recruited or favored for translation during desiccation. Rather, in *Syntrichia ruralis* (Figure 21), there is a loss of 25 **hydration proteins** (those present in a normal hydrated state), whereas 74 **rehydration proteins** are synthesized upon rehydration. This system, rather than protecting the moss from desiccation as in most tracheophytes, prepares bryophytes for repair. This is probably essential because their one-cell-thick leaves remain at full turgor, carrying out photosynthesis, then become desiccated very rapidly before going into a state of water stress and suspended metabolism (Proctor 2000b).

Figure 21. *Syntrichia ruralis*, a moss that loses hydration proteins upon drying and synthesizes rehydration proteins upon rewetting. Photo by Michael Lüth, with permission.

Antarctic mosses can suffer severe desiccation for prolonged periods. Rod Seppelt (Bryonet 2007) relates a story of an Antarctic *Grimmia* (Figure 22). A student had made a number of attempts at sectioning the dried moss without success. Seppelt suggested wetting the moss first and was amazed to discover, upon examination, that the cells were perfectly intact. When he re-examined the mosses that had been sitting on the lab bench for 15 months, but had been rewet for the sectioning, they had sprouted new shoots!

Deltoro *et al.* (1998a) compared recovery in seven desiccation-tolerant bryophytes [Figure 23: *Hedwigia ciliata*, *Hypnum cupressiforme*, *Leucodon sciurioides*, *Orthotrichum cupulatum*, *Pleurochaete squarrosa*, *Porella platyphylla* (Figure 23), and *Syntrichia ruralis* (Figure 21)] with that of seven desiccation-intolerant bryophytes [Figure 24: *Cinclidotus aquaticus*, *Philonotis calcarea*, *Lunularia cruciata*, *Conocephalum conicum*, *Platyhypnidium riparioides*; *Barbula bolleana* (Figure 25- Figure 26), *Palustriella commutata* (Figure 1, Figure 27), J.]. All seven desiccation-tolerant bryophytes experienced full recovery, with many cellular activities back to normal rates within two hours (Deltoro *et al.* 1998a; Marschall & Proctor 1999). However, those species from the hydric and mesic habitats, the desiccation-intolerant ones, were unable to restore their photochemical activity.

Proctor *et al.* (2007) used *Polytrichastrum formosum* (Figure 28) to assess recovery from desiccation. In this endohydric moss, the relative water content (RWC) dropped to 40% before it reduced the net CO₂ uptake to zero. It took only 10-30% RWC upon rewetting for the CO₂ uptake to become positive after 9-18 days of desiccation. Net carbon balance returned after 0.3-1 hours. The F_v/F_m (= variable fluorescence / maximum fluorescence) recovery was inhibited in the light by protein-synthesis inhibitors, but had normal recovery in the dark. Without the inhibitors, the F_v/F_m reached ~80% of pre-desiccation levels within ~10 minutes of re-wetting, but it took 24 hours for full recovery.

Even aquatic bryophytes may not die following total desiccation. My experience with boiling *Fontinalis* (Figure 29) and with dead-looking mosses following snow-melt is that seemingly dead bryophytes may have living cells that initiate new growth. The desiccated tissues may not recover, but a few cells may be all that are needed to continue the population.

The seemingly drought-intolerant *Fontinalis antipyretica* (Figure 29) is actually drought tolerant, provided it is dried slowly (de Carvalho *et al.* 2011). This is consistent with its ability to survive late summer drought in the slow streams and vernal pools where it is common because the recession of water is slow and remaining water will permit the slow drying needed.

Figure 29. *Fontinalis antipyretica* in dry stream. This dead-looking moss will recover when water returns to the stream. Photo by Janice Glime.

Leakage and Membrane Repair

Dry mosses are essentially inactive. During this time, membranes often become distorted and leaky (Gupta 1977a). Viable tissues may become leaky due to the shock of sudden immersion, whereas injured or dead cells leak due to membrane disruption. Cruz de Carvalho *et al.* (2015) note that the rupture of membranes results in loss of electrolytes, and that this loss is greatest during rehydration following a rapid drying event. The ability to repair this damage may be an important factor that sets bryophytes apart from tracheophytes.

Upon rehydration, the less tolerant bryophytes initially spend time in repairing membrane damage caused by the dehydration. This is exemplified by the period of 4 to 24 hours that elapse prior to normal photosynthesis and respiration (Peterson & Mayo 1975; Dilks & Proctor 1976b; Proctor 1981). But before that repair occurs, leakage of both photosynthate and mineral ions can be severe, especially during the first two minutes following addition of water (Bewley 1974; Gupta 1977a). As in tracheophytes, the highly soluble K⁺ is readily leaked during desiccation (Minibayeva & Beckett 2001; Table 2), but in the bryophytes, much of it is retained by cation exchange sites on the cell walls (Bates 1997). Fortunately, these retained ions can be re-absorbed by the cells during early rehydration. Material leaked into a culture medium is taken back into the cell within one hour (Bewley & Krochko 1982). Furthermore, at least in some liverworts, some of the lost photosynthate is resorbed (Noailles 1978).

In *Syntrichia ruralis* (Figure 21), slowly dried plants and undried controls lose only about half as much of electrolytes as do rapidly dried plants (Bewley & Krochko 1982). However, *Cratoneuron filicinum* (Figure 30) suffers more extensive loss under both slow and fast drying regimes and the loss is not reversible. Oliver and Bewley (1984b) interpreted these studies to mean that *Syntrichia ruralis* has membranes that undergo reversible changes during desiccation, but that these changes are incomplete when they are dried quickly. Upon rehydration it requires several minutes for the membranes to revert to their normal integrity. This mechanism to regain membrane integrity apparently is not working in the desiccation-intolerant *Cratoneuron filicinum*.

Table 2. Loss of K⁺ ions during rehydration following desiccation in bryophytes. **H** = hornwort; **LL** = leafy liverwort; **M** = moss; **TL** = thallose liverwort. Data from Minibayeva and Beckett (2001).

<i>Anthoceros natalensis</i> (H)	89%
<i>Pellia epiphylla</i> (TL)	83%
<i>Hookeria lucens</i> (M)	77%
<i>Dumortiera hirsuta</i> (TL)	55%
<i>Atrichum androgynum</i> (M)	45%
<i>Sphagnum auriculatum</i> (M)	38%
<i>Plagiochila natalensis</i> (LL)	21%
<i>Rhodobryum roseum</i> (M)	0%

Figure 30. *Cratoneuron filicinum* in hydrated state. Photo by Michael Lüth, with permission.

The leakage problem causes bryophytes to be vulnerable during frequent wetting/drying events. During each rehydration event, the plant must repair its cell membranes, and that requires energy. Frequent events with insufficient recovery time will eventually exhaust the resources within the cells. Because much repair is needed upon rehydration, it is critical that dry mosses retain the ability to synthesize ATP upon rewetting (Krochko *et al.* 1979). In *Syntrichia ruralis* (Figure 21), normal levels of ATP are regained in as little as 30 minutes. On the other hand, the hydrophytic *Cratoneuron filicinum* (Figure 30) slowly loses ATP after rewetting if the moss has been dried rapidly. Such behavior would prevent this moss from living in the desert, but poses no problem in its streamside habitat. However, Dhindsa (1985) suggested that it may be NADPH that is available immediately upon rehydration, produced by transhydrogenation from NADH during dark CO₂ fixation. Thus NADPH could be the important factor in repairing cellular damage by reductive biosynthesis of membrane components and other cellular constituents.

When the membrane first begins repair, there is a period of enhanced respiration during which the cell organelles regain normal appearance (Noailles 1978). Membrane repair occurs during this period of enhanced respiration, stopping the leakage (Farrar & Smith 1976; Richardson & Nieboer 1980). This is possible because, unlike the case in tracheophytes, protein synthesis begins immediately (Dhindsa & Bewley 1978), undoubtedly because of the conservation of **polyribosomes** (cluster of ribosomes connected with messenger RNA; play a role in peptide synthesis) in desiccation-tolerant bryophytes. Nothing is known about the role of action potentials in bryophytes and their possible role in membrane repair

(Bates 2000), although Trebacz *et al.* (1994) have shown that Ca⁺² influx and Cl⁻ efflux in the thallose liverwort *Conocephalum conicum* (Figure 24) result in depolarization of the cell membranes.

Mechanical damage is probably the primary cause of desiccation damage in cells. Membranes necessarily become contorted and folded during drying and cell shrinkage. In *Syntrichia ruralis* (Figure 21) pockets or **vesicles** (membranous spheres involved in transport or storage within cell) form on the **endoplasmic reticulum** (complex system of membranous stacks involved in membrane production in cell). Oliver and Bewley (1984b) suggested that these vesicles provide membrane material to be used for immediate repair upon rehydration. Other features that can help protect a cell from mechanical damage during dehydration include small cell size, small or no vacuoles, lack of **plasmodesmata** (tiny, membrane-line channels between adjacent cells), flexible cell walls, and reduced osmotic pressure (Iljin 1953, 1957). However, there is not a strong correlation of these attributes with desiccation-tolerant bryophytes. Bryophytes do have plasmodesmata, but electron microscopy is needed to discern them and few have been thus described; thus we cannot evaluate their correlation.

In support of Iljin's (1953, 1957) suggestion, some of the largest cells among bryophytes are those of the **Hookeriaceae**, a family of desiccation-sensitive mosses. And the **Pottiaceae** (including *Syntrichia ruralis*) generally have small cells and live in dry places. But the vacuole correlation brings Iljin's suggested adaptations into question (Table 3), and even the cells of *Syntrichia ruralis* (Figure 21) shrink but are too rigid to collapse when they dry. One problem in attempting to determine just what happens as the cells dry is that in order to "fix" them for examination, we must partially rehydrate the cells (Oliver & Bewley 1984b). Until another method is forthcoming, we cannot observe what a dry cell looks like.

Table 3. Relative cell and vacuole sizes among bryophytes as listed by Oliver & Bewley (1984b).

	cell size	vacuoles
Desiccation tolerant		
<i>Ceratodon purpureus</i>	small	large
<i>Syntrichia ruralis</i>	small	small
<i>Neckera crispa</i>		small
<i>Pleurozium schreberi</i>	long & narrow	small
<i>Barbula torquata</i>	small	large
<i>Triquetrella papillata</i>	small	small
Desiccation sensitive		
<i>Cratoneuron filicinum</i>	long & narrow	small

Melick and Seppelt (1992, 1994) considered that the membrane integrity is restored rapidly and that intracellular carbohydrates likewise are replenished rapidly in the xerophytic *Syntrichia caninervis* (Figure 31). In an interesting contrast to the membrane repair scenario, Singh *et al.* (1984) concluded that membranes of *Syntrichia ruralis* (Figure 21) remain intact during desiccation, at least down to 75% relative humidity (-400 bars). The cellular membranes retain their phospholipid bilayers, and during dehydration the cytoplasmic vesicles form layers of membranes under the **plasmalemma** (cell membrane), appearing to fuse with the surface membrane. They

concluded that the cellular membranes are conserved and ready to expand upon rehydration. Wu *et al.* (2013) found a similar conservation of cell membranes in the desert moss *Syntrichia caninervis*.

Figure 31. *Syntrichia caninervis*, a desiccation-tolerant desert moss. Photo by Michael Lüth, with permission.

Based on these various responses of the cell membranes, it is not surprising that Oliver *et al.* (1993) found that electrolyte leakage alone was not a reliable measure of desiccation tolerance in *Syntrichia ruralis* (Figure 21). Instead, Stewart and Lee (1972) reported that NADP-linked glyceraldehyde phosphate dehydrogenase is affected by desiccation, and Bewley and his coworkers (Bewley 1972, 1973a, b, 1974, 1979, Bewley & Gwozdz 1975) have carefully documented the loss of polyribosomes and their effect on the ability of the cells to synthesize proteins. Oliver *et al.* (1993) found that comparison of ability to synthesize protein in hydrated and desiccated-rehydrated mosses was the best measure of the capabilities of three *Syntrichia* species to repair damage and thus to exhibit tolerance to desiccation.

Pulse release occurs in *Hylocomium splendens* (Figure 32) during rehydration, returning carbon and other nutrients, especially potassium, to the soil (Wilson & Coxson 1999). These mosses are able to concentrate carbon and nutrients from atmospheric sources and return them in concentrated form during these pulse releases caused by rainfall striking damaged membranes.

Protein Degradation and Ubiquitin

O'Mahony and Oliver (1999) compared the role of **ubiquitin** in the grass *Sporobolus stapfianus* and the desiccation-tolerant moss *Syntrichia ruralis* (Figure 21/Figure 31) as a mediator of protein degradation. They found that in *S. stapfianus* the ubiquitin exhibited greater accumulation during drying and rehydration, but that it was hardly detectable in the desiccated tissue. A depletion of ubiquitin monomer levels indicates an increase in protein degradation. In *Syntrichia ruralis*, the ubiquitin transcripts were stable in the dried tissue. The moss contrasted to the grass in that conjugated ubiquitin, indicative of proteins targeted for removal, was detectable in the moss only during slow drying, whereas it was present in all samples of the grass. O'Mahony and Oliver concluded that *S. ruralis* has stable ubiquitin transcripts that rapidly translate during rehydration to permit rapid initiation of cellular repair by degrading targeted proteins, whereas *Sporobolus stapfianus* requires several hours to replace its depleted ubiquitin supply.

Respiration

Respiration during recovery can vary considerably among species. Gupta (1977b) found that after 48 hours of desiccation at 0 and 50% relative humidity, rewetting for 32 hours varied in O₂ uptake from 2X in *Mnium hornum* (Figure 33) and *Porella platyphylla* (Figure 34) to 6X in *Scapania undulata* (Figure 35). This may in part be due to the presence of many respiring microorganisms that benefit from the leaked cellular contents (Gupta 1977a, b). Methods for measuring recovery processes need to take this microorganism respiration into account.

Reactive Oxygen Species

The greatest damage to cells is caused by reactive oxygen species (Kranter *et al.* 2002; Beckett *et al.* 2004). Among the bryophytes, Beckett *et al.* (2004) demonstrated this in desiccated thalli of the liverwort *Dumortiera hirsuta* (Figure 36). In fact, this species produces extracellular superoxide at high rates under normal conditions, but that following mild desiccation stress, it produces considerably

more during rehydration. They postulated that it might have a role in defense against pathogens.

Figure 36. *Dumortiera hirsuta*, a species that produces extracellular superoxide at a high rate, increasing production following mild desiccation stress. Photo by Paul Davison, with permission.

Even aquatic mosses like *Fontinalis antipyretica* (Figure 29) has protection from reactive oxygen species. de Carvalho *et al.* (2012) found that when this species was dried slowly and rehydrated, it had a lower production of reactive oxygen species (ROS). This reduced the cellular damage. As it rehydrated, it had an initial high oxygen consumption burst; de Carvalho and coworkers suggested that this may have been due to the burst of ROS production.

Photosynthesis

The desert moss *Syntrichia caninervis* (Figure 31) is a dominant soil crust bryophyte in deserts. As such, it has often served as a model for desiccation tolerance. Its photosynthesis recovers quickly following a dehydration-rehydration cycle (Li *et al.* 2010). The recovery occurs in two phases. The initial phase occurs in only three minutes, with a quick increase in maximal quantum efficiency of **PS II** (F_v/F_m) (photosystem II variable vs maximum fluorescence). In only 0.5 minutes from the onset of rehydration, over 50% of the PS II activities resume, including excitation energy transfer, oxygen evolution, charge separation, and electron transport. The second phase is slower and is dominated by an increase of **plastoquinone** (PQ; molecule involved in the electron transport chain in the light-dependent reactions of photosynthesis) reduction and accomplishing equilibrium of the energy transport from the inner chlorophyll antenna system to the reaction center of PS II. No *de novo* chloroplast protein synthesis is needed for this initial recovery of the PS II photochemical activity. The rapid recovery depends on chlorophyll synthesis, quick structural reorganization of PS II, and fast restoration of PS II activity without chloroplast protein synthesis.

Zhang *et al.* (2011) found that in *Syntrichia caninervis* (Figure 31), an ectohydric desert moss, minimum and maximum fluorescence and photosynthetic yield recovered quickly when the shoots were rehydrated in the dark. In fact, this species reached 90% of its 30-minute yield rate within the first minute, a phenomenon that was possible because of the lack of damage to membranes.

In *Syntrichia caninervis* (Figure 31) remoistening elicited rapid recovery of both fluorescence and photosynthetic yield (F_v/F_m) in the dark, reaching within 1 minute 90% of the value attained in 30 minutes (Zhang *et al.* 2011). The optimum moisture level falls in a narrow range, with chlorophyll fluorescence decreasing both above and below that moisture range. In its desert habitat, it is able to use dew, fog, rain, and melting snow as sources of moisture to permit photosynthesis.

At least in some species, rehydration results in an initial period of rapid respiration (Dilks & Proctor 1976b). In several temperate/boreal bryophytes, this rapid period of respiration is followed by a progressive recovery of photosynthesis generally lasting 1-6 hours. *Anomodon viticulosus* (Figure 37), a xerophytic species of well-drained, lightly shaded, base-rich or calcareous rocks and dry stone walls, reached its **compensation point** (photosynthesis = respiration) within a few minutes of hydration, whereas it required about 4 hours for *Rhytidiadelphus loreus* (Figure 38), a mesophytic forest floor species. For desiccation-tolerant bryophytes such as *Anomodon viticulosus*, *Racomitrium lanuginosum*

(Figure 39), and *Rhytidiadelphus loreus*, recovery of photosynthesis upon rehydration is rapid (Proctor & Smirnov 2000). This rapid recovery necessarily requires pre-existing proteins; *de novo* protein synthesis is generally very limited (Proctor 2001).

Dhindsa (1985) determined that desiccation-tolerant mosses such as *Syntrichia ruralis* (Figure 21) remain active and fix CO₂ (dark fixation) at an undiminished rate until tissue losses are about 60% of the initial fresh mass, whereas in the intolerant *Cratoneuron filicinum* (Figure 30) dark fixation of CO₂ slowly declines as the moss dehydrates. After that, water stress occurs, the moss rapidly proceeds to suspended metabolism, and CO₂ fixation rapidly ceases. Following rehydration, *S. ruralis* immediately begins CO₂ fixation, but *C. filicinum* does not. For tracheophytes, this recovery system has been perfected primarily in seeds that return from their suspended metabolism by metabolizing starches to sugars for the rapid supply of energy needed to grow and attain photosynthesis. Even in the desert ephemerals, the return process is slow and the frequency of wetting and drying suffered and survived by some desert bryophytes is unattainable by any tracheophyte (Proctor 2000b, 2001).

Figure 38. *Rhytidiadelphus loreus* on the forest floor, a species that is rapid to regain photosynthetic activity after rehydration, but slower than *Anomodon viticulosus*. Photo by Michael Lüth, with permission.

Figure 39. *Racomitrium lanuginosum* on rock, a species that rapidly regains photosynthetic activity after rehydration. Photo by Michael Lüth, with permission.

Guschina *et al.* (2002) related the rapid recovery to the stress hormone **ABA** in the mesophytic moss *Atrichum androgynum* (Figure 40). Changes in phosphoglyceride composition due to water stress indicate an activation of phospholipase D and of phosphatidylinositol metabolism. During rehydration, phosphoglyceride composition recovers close to the original levels. Thylakoid lipids and chlorophyll decline during dehydration, accounting for the loss of photosynthesis. Treatment with ABA reduces the overall extent of changes, probably by reducing lipid changes, thus protecting against membrane damage. But can the moss produce its own ABA? And is it inducible?

Figure 40. *Atrichum androgynum*, a moss that uses ABA to aid in rapid recovery from desiccation. Photo by Clive Shirley, Hidden Forest <www.hiddenforest.co.nz>, with permission.

Architectural Changes

We know that many bryophytes, including *Syntrichia ruralis* (Figure 21), undergo multiple architectural changes as they dry (Hamerlynck *et al.* 2000). This results in changes to the surface reflectance. Hamerlynck *et al.* found a sigmoidal (logistic) relationship between the relative humidity and the deviation of the moss mat temperature from its dew point, indicating a slow, then rapid, then slow change in the temperature of the mat, and a concomitant change in its water loss. The conditions of drying affect the ability of this species to use thermal

dissipation of excess light energy, thus affecting potential damage to the chlorophyll.

Breuil-Sée (1994) examined the cell interior upon rehydration of the thallose liverwort *Riccia macrocarpa* (Figure 41) after 25 years of dehydration in a herbarium. Whereas most bryophytes revive to normal metabolism in a few hours, this 25-year-dry bryophyte required nine days. Cytological evidence of its revival included enlargement of **nucleoli** (sites of ribosome synthesis and assembly in nucleus), evidence for protein synthesis. The dehydrated liverworts had few **mitochondria** (site in cell that generates most of the ATP) and the chloroplasts lacked starch. Its preparation for desiccation was evidenced in granular cytoplasm with many **osmiophilic globules** (lipid-containing bodies in chloroplast), especially along the cell wall. Features already known for dry spores and seeds, such as presence of **plasmodesmata** (microscopic channels which traverse cell walls of plant cells, enabling transport and communication between cells), but absence of **dictyosomes** [stacks of flat, membrane-bound cavities (cisternae) where proteins are stored and that comprise the Golgi apparatus] and **endoplasmic reticulum (ER)**; interconnected network of flattened, membrane-enclosed sacs or tubes known as cisternae; inner core of cytoplasm and membranes of ER are continuous with outer membrane of nuclear envelope), were evident. The transition of *R. macrocarpa* toward active metabolism upon rewetting was marked by 1) enlargement of nucleolus; 2) important modification of nucleus; 3) amplification of endoplasmic reticulum, Golgi, chloroplasts, mitochondria, and vacuoles; 4) disappearance of lipid reserves; 5) synthesis of starch in chloroplasts; 6) cytoplasm densification.

Figure 41. *Riccia macrocarpa*, a species that resumed normal metabolism upon rehydration after 25 years in a dry state. Photo by Michael Lüth, with permission.

The protonemata are important survival structures in some habitats and for some species. Pressel and Duckett (2010) found that in their experiments the protonemata could survive slow, but not fast drying. During dehydration, the cell experiences vacuolar fragmentation, reorganization of the endomembranes, changes in cell wall thickness, changes in the morphology of plastids and mitochondria, and a controlled dismantling of the cytoskeleton. These events cannot occur during fast drying. Externally applied abscisic acid mimicked the effects of slow drying, permitting the protonemata to survive.

Cellular Changes

Oliver *et al.* (2005) indicated that desiccated cells appear to be intact. Cellular disruption occurs upon rehydration as water is taken up rapidly. Nevertheless, the cellular integrity returns rapidly.

Desert mosses can have remarkable durability to desiccation. Moore *et al.* (1982) found that *Didymodon torquatus* (Figure 42) can survive 18 months of desiccation at a water content of only 5% or less. Nevertheless, after only 24 weeks of desiccation, the photosynthetic and respiratory rate upon rehydration were less than that of fresh (hydrated) materials. What is interesting is that in shorter time periods this species returned to control levels within one hour of rewetting. *Triquetrella papillata* (Figure 43), however, had a shorter survival time. In both species, the integrity of the organelles was maintained during short periods of desiccation, but that integrity diminished progressively with time. Net photosynthesis was delayed, apparently due to the disappearance of chloroplast and mitochondrial membranes and loss of internal structure.

Figure 42. *Didymodon torquatus* dry, a species that can survive extreme desiccation for 18 months. Photo from Canberra Nature Map, through Creative Commons.

Figure 43. *Triquetrella papillata* dry, a species that survives a short period of drought. Photo by David Tng, with permission.

Despite this degradation with time, Breuil-Sée (1994) found that the thallose liverwort *Riccia macrocarpa* revived after 23 years of drying. Upon rehydration, the endoplasmic reticulum became extended and the nucleolar volume increased, but these events were not observed until day 9.

Leptoid Recovery

Pressel (2006) pointed out the lack of study on the behavior of leptoid cells following rehydration. Using the endohydric moss *Polytrichastrum formosum*, she documented that desiccation cause dramatic changes in leptoid tissues. The endoplasmic microtubules disappear; the nucleus, mitochondria, and plastids become rounded and longitudinal alignment of the organelles disappears. Cytoplasmic polarity is at least partly retained. Instead of the prominent stacks of endoplasmic reticulum that characterize the hydrated state, the membranous tubules are arranged at right angles to the main cellular axis. The cytoplasm of the leptoids is filled with small vacuoles. The plasmalemma deposits ingrowths of cell wall material, forming labyrinthine extensions. The plasmodesmata of apical meristematic and stem parenchyma cells seem unaffected by dehydration, but in the leptoids they become plugged with electron-opaque material. Starch is depleted in the parenchyma cells adjoining the leptoids. In control plants, the cellular structure is completely re-established in 12-24 hours, but this is not the case in cells treated with oryzalin, a microtubule-disrupting drug. Pressel concluded that the microtubular cytoskeleton is key in the rapid re-establishment of the cytoplasmic architecture of leptoids during rehydration.

Chloroplast Recovery

Proctor *et al.* (2007) found that thylakoids, grana, and mitochondrial cristae of *Polytrichastrum formosum* (Figure 28) remain intact during drying and re-wetting. Nevertheless, the form of organelles changes quite noticeably. Chloroplasts lose their prominent lobes, becoming rounded when desiccated. They require ~24 hours to return to their normal shape. Photosynthesis likewise requires 24 hours for full recovery, but is independent of protein synthesis. It appears that the physical structure of the chloroplast remains the same, but that the spatial relationships among the components is altered during dehydration. Proctor *et al.* concluded that the cytoskeleton has a significant role in the bryophyte desiccation response.

Wood and coworkers may have a partial answer to the recovery of the chloroplasts following desiccation (Wood & Oliver 1999; Wood *et al.* 1999; Zeng & Wood 2000; Zeng *et al.* 2002). There is a change in gene expression during rehydration of *Syntrichia ruralis* (Figure 21), suggesting that new proteins are being made. It appears that some of these proteins may account for the rapid chlorophyll recovery. We now understand that the moss prepares for its desiccation and rehydration events by altering gene expression in response to desiccation, then altering translational controls as it rehydrates. When the drying rate has been slow, mRNPs (messenger ribonucleoprotein particles) are formed in the drying plants, and within these particles they sequester rehydrin mRNA (mRNA transcripts used during rehydration). It appears that one of these rehydrins may be responsible for the

production of antioxidants during rehydration (Oliver *et al.* 1997). It is the production of these mRNPs that makes slow dehydration so important to the recovery (Oliver 1996). If the moss is dried rapidly, it must make these when it rehydrates.

Wood and coworkers (1999) supported this discovery that *Syntrichia ruralis* (Figure 21) has an active recovery mechanism that is induced by rehydration. It makes a set of polypeptides that are not present at any time except during rehydration. These polypeptides were products of a large number of as yet unidentified plant genes and 71% of these are unknown in other plant phyla.

Among these are most likely the cDNA *Rp115* identified by Zeng and Wood in 2000 and which is conserved as mRNA in desiccated gametophytes, and two additional cDNA units (*Elipa* & *Elipb*), both of which have significant similarity to Early Light-Inducible Proteins (ELIP; Zeng *et al.* 2002). The ELIP group (coded by *ELIP* genes) includes over 100 stress-inducible proteins (Heddad & Adamska 2002). They are produced in response to light stress and accumulate in photosynthetic membranes where they have a photoprotective function. They are closely related to the light-harvesting chlorophyll *a/b*-binding antenna proteins of photosystems I and II. Because of the response of *Elipa* genes to slow desiccation, rapid desiccation/rehydration, salinity, ABA, and rehydration in high light, and the response of *Elipb* genes to ABA or rehydration in high light, Zeng *et al.* (2002) suggested that ELIPA and ELIPb provide an adaptive response to the photodamage that is likely to occur within a moss chloroplast during desiccation, most likely playing an important role in protecting and/or repairing the photosynthetic apparatus.

In support of this hypothesis, Hutin and coworkers (2003) found that when they suppressed this rapid accumulation of ELIPs during high-light stress in a mutant of the flowering plant *Arabidopsis thaliana*, the leaves became bleached and cells suffered extensive photooxidative damage, but when the plant was permitted to accumulate ELIPs before the stress, they exhibited normal phototolerance. Hence, it appears that they do indeed perform a photoprotective function, either by binding the chlorophylls that are released during turnover of the pigment-binding proteins or by stabilizing the proper assembly of those proteins when they are being subjected to high-light stress.

Lüttge *et al.* (2008) found that the three poikilohydric species *Campylopus savannarum*, *Rhacocarpus fontinaloides*, and *Ptychomitrium vaginatum* achieved photo-oxidative protection in their light-adapted state. This was accomplished by a reduction of chlorophyll fluorescence to near zero. When rewet, they have a very fast recovery in the first 5 minutes, but require more than 80 minutes to reach an equilibrium. Even though they occupy different niches on their rock outcrop habitat, they had similar recovery kinetics, with only their photosynthetic capacity differing slightly.

Photodamage

For the most desiccation-tolerant mosses, those from xeric (dry) habitats, fluorescence (emission of light of longer wavelength due to absorbance of light from outside source) levels upon rehydration indicate that the

photosynthetic apparatus is fully functional, unlike that of mosses from **hydric** (wet) and **mesic** (moderate) habitats (Deltoro *et al.* 1998a; Marschall & Proctor 1999). **Photoinhibition** (inhibition of photosynthesis by light) is a well-known consequence of desiccation because the **light quenching** is greatly diminished or absent. Only the desiccation-tolerant bryophytes exhibited photo-quenching at low water content in these experiments. Deltoro and coworkers (1998a, b) suggest that this loss of photosynthetic capability in **mesophytic** bryophytes might be not only a consequence of photoinhibition, but also a result of membrane damage, as indicated by the large K⁺ leakage. In desiccation-tolerant taxa, they suggest, the ability to enhance the dissipation of thermal energy during dehydration might permit them to take advantage of the erratic water supply in places like the desert and decrease the problems of photodamage during the dehydration stage, thus permitting them to recover quickly.

Measuring Damage

Records of survivability may sometimes be misleading. For example, Makinde and Fajuke (2009) reported survival based on microscopic views of vacuoles as soon as the cells were hydrated without any verification by regeneration, a true test for survival.

Not only do different species respond differently, but leaves and cells vary on the same plant. Streusand and Ikuma (1986) suggested a protocol that requires a large number of cells counted in a given leaf, a large number of leaves, and a large number of shoots. They considered 10 cells in 6 areas of each of 6 leaves per shoot on 10 shoots to be adequate and it provided a near perfect correlation with shoot survival in experiments with different desiccation protocols.

Factors Affecting Recovery

Temperature

In the dry state, plants are much more resilient at temperature extremes than are hydrated plants. As Alpert (2000) pointed out, some can survive as low as -272°C or as high as 100°C. He raises two questions regarding survival of desiccation: What are the mechanisms by which plants tolerate desiccation? and Why are desiccation-tolerant plants not more ecologically widespread? In general, they seem to require protection from oxidants and from loss of configuration of the macromolecules during their dehydration period.

Drying Speed

Many studies have indicated that drying speed is important to successful recovery from desiccation (Krochko *et al.* 1978; Schonbeck & Bewley 1981a; Greenwood & Stark 2014). This varies, based on **inducible** vs **constitutive** desiccation tolerance responses. Those that are harmed by rapid drying, but that recover after slow drying, are able to use an **inducible** system (one that develops in response to desiccation) to protect them against desiccation effects. The slower timing is required for that inducible system to prepare. This system is more likely to be effective in aquatic or wet-habitat species, as demonstrated by the semi-aquatic *Cratoneuron filicinum*

(Figure 30). In this species, rapid drying results in considerable disruption of the cell contents, whereas following slow drying some cells are able to maintain their cellular organization and integrity. Protein synthesis is reduced upon rehydration under both very slow and rapid drying, but these effects are reversible down to a water loss of 50% of fresh weight. Unlike the observations of Dilks and Proctor (1976b) on several terrestrial boreal/temperate bryophytes, respiration does not occur when the moss is rewet after rapid drying.

Even in such xerophytic taxa as *Syntrichia ruralis* (Figure 21), rapid drying causes visible injury, reduced total chlorophyll, reduction in chlorophyll *a:b* ratio, greatly enhanced electrolyte loss, and consequent inhibition of gross photosynthesis (Schonbeck & Bewley 1981a). Partial desiccation for 1-3 hours before rapid drying will eliminate this injury, suggesting that the moss requires time to prepare for its recovery. When *Syntrichia ruralis* and hydrophytic *Cratoneuron filicinum* (Figure 30) are dried rapidly, the chloroplasts and mitochondria swell and lose their integrity upon rewetting (Krochko *et al.* 1978, 1979), but *S. ruralis* regains normal appearance within 24 hours, whereas *C. filicinum* loses its cell contents and shows considerable cell degradation. However, if the cells are dried more slowly (*e.g.* 12 hours at 75% RH), both species recover within 24 hours. Dhindsa and Bewley (1978) attribute the ability of *Syntrichia ruralis* to survive this swelling of organelles to their ability to synthesize or retain sufficiently the enzymes needed for repair.

Hamerlynck *et al.* (2002) later found that *Syntrichia ruralis* (Figure 21) grown in high light intensity has greater desiccation tolerance than plants grown in the shade, but that those plants growing in the shade may benefit from their longer periods of metabolic activity and greater acquisition of resources, permitting them to adjust sufficiently to canopy openings and other disturbances.

Proctor (2003) subjected both desiccation-tolerant and moderately desiccation-tolerant species to drying for various periods up to 240 days. The more desiccation tolerant species (*Grimmia pulvinata*, *Syntrichia ruralis*, *Andreaea rothii*, *Racomitrium lanuginosum*, *R. aquaticum*, *Leucodon sciurioides*, *Pleurochaete squarrosa*, *Ulota crispa*) had their best long-term survival (>30-120 days) at ~100 to -200 MPa (20-45% r.h.). The moderately desiccation-tolerant *Anomodon viticulosus*, *Porrella platyphylla*, and *P. obtusata* survived best at the highest humidity used, -41 MPa (74% r.h.). The lower humidities would speed desiccation and only the most tolerant could survive.

Greenwood and Stark (2014) determined that when F_v/F_m are less than 0.1, *Physcomitrella patens* fails to regenerate. The F_v/F_m fluorescence is the standard measurement for stress in plants, testing whether or not plant stress affects photosystem II in a dark adapted state. F_v refers to fluorescence in its variable state; F_m is maximum fluorescence. They used a process of drying that permitted as long as 284 hours for drying and found a significant increase over results obtained using salt solutions to create desired moisture conditions. Survival rates and chlorophyll fluorescence both improved and tissue regeneration time was shortened, demonstrating a much greater desiccation tolerance than was previously known for this species.

Frequency of Dehydration/Rehydration

Upon rehydration, it requires time to repair membranes and regain the energy lost. Oliver and Bewley (1984a) have demonstrated that in some mosses the first 24 hours are spent in repair, and it is only after that period that there is a net photosynthetic gain. For this reason, frequent short sequences of desiccation can be devastating to many species, whereas the same moss can endure long periods of desiccation. For example, *Didymodon vinealis* (Figure 44) (Moore *et al.* 1982) recovered completely within one hour of rewetting after 18 months of desiccation at less than 5% relative water content. However, following short periods of desiccation, the integrity of the organelles was progressively lost, including membrane loss from chloroplasts and mitochondria. Repairing this damage resulted in delays in net photosynthetic gain.

Figure 44. *Didymodon vinealis*, a moss that is able to recover within one hour of hydration after 18 months of desiccation. Photo by Jan-Peter Frahm, with permission.

Dilks and Proctor (1976b) likewise promoted the understanding that frequency of desiccation can be more important than duration. Using 6 days wet – 1 day dry conditions compared to 1 day wet – 6 days dry, 1 day wet – 1 day dry, and 7 days wet – 7 days dry for a period of 18 weeks, they showed that *Hylocomium splendens* (Figure 32) grew equally well in continuous moist conditions and in 6 days wet – 1 day dry (32% relative humidity). However, there was little or no growth among the other treatments. In *Rhytidiadelphus loreus* (Figure 45), growth was best in continuously hydrated mosses, then 6 wet – 1 dry day mosses, then 7 wet – 7 dry day mosses. There was essentially no growth in the other treatments. Responses by *Syntrichia ruralis* (syn.=*Tortula ruraliformis*; Figure 21) were so variable that they could not be interpreted. However, Dilks and Proctor were able to conclude that 63 wet-dry cycles were not harmful, but that constant moist conditions were harmful in this highly desiccation-tolerant moss. *Rhytidiadelphus loreus*, unlike the other mosses, showed a **hardening** effect (process of increasing resistance to stress factor), indicating less effect from drought as more droughts occurred. *Syntrichia ruralis* is always drought-ready so hardening is not discernible.

To test the impact of intermittent desiccation on reproductive success of xerophytic mosses, Mishler and Newton (1988) measured the success of germination of both fragments and spores of four *Syntrichia* species [*S.*

ruralis (Figure 21), *S. princeps* (Figure 46), *S. norvegica* (Figure 47), *S. laevipila* (Figure 48)] in continuous versus intermittent moisture. Only *S. princeps* fragments did slightly better under the intermittent moisture conditions, as did its spore germination. In all other species, the continuous hydration seemed beneficial to the spores. Establishment success was quite different. None of the spore-derived protonemata gave rise to stems (Mishler & Newton 1988). Fragments, however, produced numerous stems both from protonemata and directly from the fragments, independent of the hydration conditions. Most likely some other physiological or environmental cue was missing for the spore-derived protonemata.

In other species, high resistance is attained after several short exposures to drought (Clausen 1952; Abel 1956; Patterson 1964; Dilks & Proctor 1976a, b). We know that *Syntrichia ruralis* (Figure 21) is capable of drought hardening (Schonbeck & Bewley 1981b). When subjected to daily episodes of desiccation and rehydration, it develops a greater desiccation tolerance. However, the wet-dry cycle may be of less importance for boreal forest mosses. Hanslin and coworkers (2001) exposed *Dicranum majus* (Figure 49) and *Rhytidiadelphus loreus* (Figure 38) to various watering regimes and found that responses, while differing greatly, lacked any consistent pattern. However, the relative growth rate increased with the length of the wet-dry cycle, provided the total number of wet and dry days remained equal, suggesting that these taxa probably would be unable to take advantage of night-time dew accompanied by day-time drought, but they are adapted to the more weekly or monthly wet-dry cycles typical of the boreal forest.

Davey (1997) showed that Antarctic hydric mosses are susceptible to damage by frequent wetting and drying, but

that was not the case for the mesic and xeric mosses, which seemingly were adapted to frequent wet/dry cycles. All the mosses suffered a greater loss of photosynthetic rate as the duration of the dehydration periods increased. Davey suggested that mosses from the drier habitats were adapted to use short periods of rehydration. This is consistent with the use of late night/early morning moisture from clouds in xeric African montane sites and other habitats where nighttime dew is the major source of water. Csintalan and coworkers (2000) supported this concept with their work on *Syntrichia ruralis* (Figure 21) in dry grasslands. They found that the moss absorbed progressive amounts of water through the night, permitting it to obtain about 1.5 hours of net photosynthetic gain immediately after dawn. Although this gain on many days may not be enough to offset the carbon loss during the remainder of the day, it does contribute to the overall carbon gain and may permit the moss to gain on a yearly scale when added to those occasions when more dew or moisture is available.

Carbon Balance

The bottom line in the dehydration/rehydration cycle over the course of the lifetime of the bryophyte is carbon gain (Alpert 2000). Short-term rehydration events can use more carbon in repair processes than can be gained from photosynthesis once everything is working properly. For those species that can regain photosynthetic activity within the first minute, an array of water sources becomes available, including dew and fog in addition to rain and snow. These may be the same species that experience rapid drying because of a desert-like habitat. For these, constitutive desiccation tolerance is important. This strategy may include structural adaptations that slow drying and cellular mechanisms that preserve the integrity of the cellular organelles. But as demonstrated in the desert moss *Pterygoneurum lamellatum* (Figure 50), tolerance to slow drying can be inducible (Stark *et al.* 2013).

Oliver *et al.* (1993) proposed a three-part strategy of tolerance that is based on carbon balance, damage limitation, and cellular repair. To support this they used protein synthesis following desiccation/rehydration in three desiccation-tolerant moss species: *Syntrichia caninervis* (Figure 31), *S. ruralis* (Figure 21), and *S. norvegica* (Figure 47). Using this as a measure of repair, they ranked the tolerance of these species as *S. caninervis* > *S. ruralis* > *S. norvegica*.

Implications

It appears that characteristics suggested for tracheophytes to permit them to survive desiccation (Iljin 1953, 1957) do not apply well to bryophytes. Rather, Oliver and Bewley (1984b) suggested that tolerant species must do three things to survive drying: (1) limit damage to a level that can be repaired; (2) maintain physiological integrity of the cell so metabolism can quickly reactivate during rehydration; (3) put repair mechanisms into effect upon rehydration, especially to regain integrity of membranes.

Many questions remain to be answered in understanding the recovery process in bryophytes. When studying the grass *Sporobolus stapfianus*, Neale *et al.* (2000) found that *Elip* genes were expressed differently in tissues that were desiccation tolerant than in those that were desiccation sensitive and suggested that there are unique gene regulatory processes occurring as desiccation ensues, permitting different drought-responsive genes to be expressed at different stages during water loss. Since these genes have been identified in bryophytes, it is likely that Zeng *et al.* (2002) are correct in their suggestion of a photoprotective role during the dehydration state of bryophytes.

As summarized by Oliver *et al.* (2005), desiccation tolerance is a primitive trait, a necessary trait for invasion of land. In bryophytes, two aspects permit their survival: constitutive cellular protection and effective recovery/repair mechanism. (To this we must add inducible tolerance in at least some bryophytes.) But upon recovery, the cells behave like any container of light-weight objects that suddenly gets an influx of water, being disrupted initially. Nevertheless, the cell soon regains its integrity. Photosynthetic activity seems little affected and recovers quickly. LEA proteins proliferate, but their role is unknown, perhaps functioning to restructure the membranes and stabilize the cell. More questions!

Summary

Desiccation tolerance most likely originated in the early land bryophytes in their colonization of land. Yet, they remain almost unique in their ability to tolerate desiccation in the vegetative state. Bryophyte gametophytes recover from desiccation by the actions of numerous **rehydration proteins**, including **rehydrins**, and **rapid membrane repair**. The rapidity is dependent upon slow dehydration that gives the bryophyte time to make mRNPs and is provided by a rehydration-inducible recovery mechanism in which new proteins are synthesized rapidly (Oliver 1996). The rapid recovery is complemented by enlargement of the nucleolus, amplification of the endoplasmic reticulum, Golgi, chloroplasts, mitochondria, and vacuoles, disappearance of lipid reserves, and synthesis of starch in chloroplasts during rewetting.

Photosynthesis resumes almost immediately, reaching normal levels within 24 hours, indicating the readiness of the chloroplasts. Because of the resources needed for recovery, short periods of rehydration between frequent drying periods deplete resources and are more harmful than long dry periods, issuing foreboding for moss gardeners.

Acknowledgments

This chapter has benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me tow the line in explaining things without leaving too much to one's imagination, but at the same time not repeating myself.

CHAPTER 7-7

WATER RELATIONS: BIOCHEMICAL ADAPTATIONS TO DRYING

Figure 1. *Grimmia affinis* drying on a rock. Photo by Michael Lüth, with permission.

The biochemistry of bryophytes is still a relatively young field. This is true of the biochemical level of response of bryophytes to desiccation stress. This chapter will attempt to portray what we know and how that biochemistry relates to the habitats of the bryophytes. But at this early stage in our studies, few species have been studied in detail, leaving much of the discussion incomplete or even somewhat ambiguous.

Membrane Chemistry

Since membrane damage is a common response to desiccation stress, Guschina *et al.* (2002) examined lipid composition of membranes in *Atrichum androgynum* (Figure 19) during desiccation in an effort to understand the role of the stress hormone ABA. Drought stress causes changes in the phosphoglyceride composition of the membranes. Reduction of thylakoid lipids, resulting in chlorophyll damage, causes a loss in photosynthesis as a result of desiccation, as already demonstrated in tracheophytes. Guschina *et al.* found that application of ABA reduced the extent of these membrane lipid changes.

Some plants may take advantage of the leakage through damaged membranes to rid cells of protectants used during dehydration. Working with canopy liverworts in the tropical rainforest of Guadeloupe, Coxson and coworkers (1992) found that for *Frullania atrata*, exposure to simulated wetting/drying resulted in production of substantial glucose, erythritol, glycerol, and sucrose. They suggest that whereas these sugars may help this liverwort survive severe desiccation, the liverwort subsequently releases them into throughfall upon rewetting.

Robinson *et al.* (2000) suggest that sugars may indeed help some mosses survive desiccation. They found stachyose, an oligosaccharide known for its role in desiccation tolerance of seeds, in *Bryum pseudotriquetrum* (Figure 2), but not in *Ceratodon purpureus* (Figure 3; most tolerant) or *Schistidium antarctici* (Figure 4; least tolerant). This is another example showing that not all bryophytes have the same adaptations to desiccation.

ABA Role

The stress hormone **ABA** (abscisic acid) is present in many groups of organisms, including animals and bacteria as well as plants (Hartung 2010; Takezawa *et al.* 2011). This ability to protect against abiotic stress may have been one of the most critical attributes permitting plants to move to land.

Using immunoassay, Hartung and coworkers (1987, 1994) demonstrated the presence of ABA in all **Bryopsida**, **Anthocerotophyta**, and **Marchantiopsida** tested. They were able to extract more ABA from the hornwort

Phaeoceros grown under slightly drier areas than from those in wetter areas. Furthermore, they have shown that the sporophyte of *Phaeoceros laevis* (Figure 5) produces ABA in response to stress and that the sporophyte guard cells close in response to ABA, much as in tracheophytes. This is in sharp contrast to the findings of Duckett and Ligrone (2004). They were unable to find any response to ABA or to moisture changes in the stomata of *Phaeoceros*.

Figure 5. *Phaeoceros laevis* sporophytes, a hornwort with stomata in the capsule. Photo by Robert Klips, with permission.

In bryophytes, this hormone occurs in *Physcomitrella patens* (Figure 6) where it has a major role in dehydration stress tolerance (Takezawa *et al.* 2011). To determine the genetic response of bryophytes to water stress, Cuming *et al.* (2007) used the lab moss *Physcomitrella patens*. These plants were subjected to ABA as well as osmotic, salt, and drought stress. The response of the protonema differed from that of the gametophore, with 130 genes in the protonema responding to dehydration. Of these, 56 were induced by ABA, but only 10 genes by osmotic stress and 8 by salt stress. Another 51 genes were induced by more than one of these treatments. Many of the ABA and drought-responsive genes were homologues of those expressed during seed development, supporting the assertions of Fisher (2008) discussed in Chapter 7-5. As seen by Wang *et al.* (2009) during dehydration, many of the ABA- and drought-responsive genes include genes for **LEA proteins**.

Figure 6. *Physcomitrella patens*, a moss in which ABA increases stress tolerance. Photo by Michael Lüth, with permission.

Werner *et al.* (1991) found that even protonemata produce ABA in response to slow drying, as shown in *Funaria hygrometrica*, and as in mature plants, it imparts drought tolerance. But it does not inhibit water loss. Rather, it appears to induce synthesis of new proteins that impart drought tolerance.

In Cyanobacteria and algae, the few studies on stress-induced ABA production indicate that the excess is released to the external medium (Hartung 2010). Taking an evolutionary approach, Hartung demonstrated that organisms that start to colonize terrestrial habitats increase their ABA production in response to even mild drought stress. Such signals seem to initiate the production of terrestrial organs, perhaps explaining the change from aquatic to terrestrial forms of *Riccia fluitans* (Figure 7; see below). In bryophytes, stomata respond to ABA. The levels of ABA in sporophytes of hornworts and mosses that have stomata is especially high, although the regulatory role of the ABA seems ambiguous. Fungi release ABA, and these hormones may interact with the bryophytes through mycorrhizal associations or just through their presence in the environment.

Figure 7. *Riccia fluitans*, exposed here to air drying. ABA can facilitate conversion to the wider terrestrial form. Photo by Jan-Peter Frahm, with permission.

One of the unusual abilities of ABA is to cause the conversion of the aquatic forms of the thallose liverworts *Riccia fluitans* (Figure 7) and *Ricciocarpos natans* (Figure 8) into their terrestrial forms (Hellwege *et al.* 1992; Hartung *et al.* 1994). This conversion results in plants with greater volume, hence a smaller surface area to volume ratio, making them somewhat less vulnerable to desiccation.

Liverworts use **lunularic acid** where other plants use ABA as a dormancy hormone and, apparently, to help prepare them for drying, as shown in *Lunularia cruciata* (Figure 9) (Schwabe 1990). When subjected to long days, their drought resistance increases (Figure 10), as does their lunularic acid content.

Figure 8. *Ricciocarpos natans*, stranded here out of water. ABA can facilitate conversion to the terrestrial form. Photo by Janice Glime.

Figure 9. *Lunularia cruciata*, a thallose liverwort that produces the ABA-like lunularic acid as a dormancy hormone. Photo by Michael Lüth, with permission.

Figure 10. Effect of long-day (continuous) light on induction of drought resistance, resulting in drought survival in the thallose liverwort *Lunularia cruciata*. Based on Schwabe (1990).

Although the presence of lunularic acid seems to be universal in liverworts, and has functions like those of

ABA, liverworts seem to be fully responsive to ABA. Pence (1998) found that ABA was necessary for the cryopreservation of some liverworts such as *Riccia fluitans* (Figure 7) and *Marchantia polymorpha* (Figure 21), preventing desiccation damage, but it had little effect on the leafy liverwort *Plagiochila* (Figure 11).

Burch and Wilkinson (2002) used ABA and sucrose to increase the success of cryopreservation of the moss *Ditrichum cornubicum* (Figure 12) protonemata. We also know that application of ABA increases the desiccation tolerance of the mesophytic moss *Atrichum undulatum* (Figure 13) (Beckett *et al.* 2000). Using *Atrichum androgynum* (Figure 19), Guschina *et al.* (2002) demonstrated phosphoglyceride composition changes during water stress. ABA treatment reduces the overall extent of these changes, possibly by reducing membrane damage by reducing the lipid changes.

Figure 11. *Plagiochila asplenioides* near a stream in Wales. Photo by Janice Glime.

Figure 12. *Ditrichum cornubicum*, a moss that survives cryopreservation with the help of ABA and sucrose. Photo by David T. Holyoak, with permission.

The Afromontane understory moss *Atrichum androgynum* (Figure 19) recovers its CO₂ fixation more slowly than recovery of photosystem II activity following 16 hours of desiccation, then rehydration (Mayaba *et al.* 2001). Pretreatment with ABA increases the recovery rate of both of these activities and doubles the non-photochemical quenching, hence reducing reactive oxygen species. Mayaba and coworkers suggest that this may partly explain the desiccation hardening process in this species. Plants pretreated with ABA, unlike untreated

plants, experience a significant increase in soluble sugars that could promote the vitrification (transformation into a glassy substance) of the cytoplasm. This could, in turn, protect the membranes during desiccation. ABA has only a slight effect on the starch concentrations during desiccation. ABA furthermore has no effect on chlorophyll breakdown.

Figure 13. *Atrichum undulatum* showing some plants drying and curling. This moss changes its phosphoglyceride composition during drought stress. Photo by Janice Glime.

But how does this relate to preventing the oxidative damage? Beckett and coworkers (2000) suggested that ABA pretreatment may act by reducing the energy transfer between light-harvesting chlorophyll II and photosystem II. This could harden the moss to desiccation stress by reducing the production of reactive oxygen at the site of photosystem II. Experiments indicated that photosystem II photosynthesis recovers faster in the pre-treated plants.

ABA may play another role as well. One of the most serious consequences of desiccation is loss of membrane integrity, causing membranes to become leaky (Bewley 1979). Beckett (1999) found that application of ABA could reduce the loss of K⁺ from *Atrichum androgynum* (Figure 19) in much the same manner as partial dehydration treatment prior to desiccation. The response is similar to that obtained by reducing the relative water content to 0.6 for three days, which reduces the K⁺ loss by 15-20%. This seems to be the ideal combination because using less humid air or more time does not decrease the K⁺ loss further. This species, and probably most, experiences **drought hardening** (process of increasing resistance to drought; see Chapter 7-5) as the dry season progresses, as indicated by the loss of 80% of its intracellular K⁺ at the beginning of the dry season, but less than 25% by the end of that season (Beckett & Hoddinott 1997).

Absciscic acid (ABA) has already been noted to have an important role in desiccation tolerance. Werner *et al.* (1991) found that slowly dried protonemata of *Funaria hygrometrica* survived desiccation, but rapidly ones did not. The slowly dried mosses experienced a six-fold increase in absciscic acid during drying. If ABA is added to the protonemata at an appropriate concentration, the ABA mediates drought tolerance, apparently by inducing the synthesis of new proteins.

Sucrose

De Cruz *et al.* (2014, 2015) found that desiccated cells of the aquatic moss *Fontinalis antipyretica* lose 50% of their sucrose through leakage when the cells are rehydrated. Fast dehydration results in higher sucrose accumulation, but it is not enough to induce desiccation tolerance. The increase in soluble sugars helps in osmoregulation during the decreasing turgor pressure of the cells. In addition to serving as an osmolyte, sucrose in bryophytes helps to stabilize membranes and proteins through **vitrification** (process of forming glasslike substances). In *Fontinalis antipyretica* desiccation tolerance requires slow dehydration, suggesting that high sucrose content does not act alone to create desiccation tolerance.

Protection from Oxidation

Just what is it that varies among the bryophytes that dry out, become metabolically inactive, and then revive? What physiological mechanism protects, or fails to protect them? How can photosynthesis achieve its maximum rate within 30 seconds upon receiving rain or dew in some desiccated species (Anderson 1980)? Proctor (1990) and Alpert (2000) suggest that in drought-hardening the cell must protect itself from oxidative damage, as well as loss of configuration of macromolecules, and this protection depends on the intensity and duration of desiccation.

Minibayeva and Beckett (2001) noted that drought-sensitive bryophytes can release an **oxidative burst** (respiratory burst; rapid release of reactive oxygen species – superoxide radical and hydrogen peroxide) in response to rehydration. These bursts developed best in the hornwort and two thalloid liverworts tested (Minibayeva & Beckett 2001). A similar oxygen burst is, however, almost absent in all the mosses tested as well as a leafy liverwort and desiccation-tolerant lichens.

Oxidative Damage

Kramer *et al.* (2002) examined the "resurrection plants" – those plants that can survive desiccation – to determine what permits them to survive. They found that in a woody plant desiccation can trigger increases in zeaxanthin and redox shifts of the antioxidants glutathione and ascorbate to their oxidized forms. New ascorbate and glutathione were produced upon rehydration and the oxidized forms from the dehydration event changed back to reduced forms. Using lichens, Kramer *et al.* (2008) further demonstrated that reactive oxygen species can damage nearly every molecule in living cells. These included nucleic acids, proteins, and lipids.

The absence of oxidative bursts in mosses lends support to the hypothesis that mosses protect themselves from the damage such highly reactive oxidative bursts can cause during rehydration. Shiono *et al.* (2000) found that in testing the liverwort *Marchantia paleacea* subsp. *diptera* (Figure 15), the moss *Barbula unguiculata* (Figure 16), and the hornwort *Anthoceros punctatus* (Figure 17), the liverwort differed from the other two in its isozyme patterns for **superoxide dismutase**. This enzyme is known for its ability to maintain safe levels of the highly reactive oxides that are produced during cell stress, including effects of desiccation.

Figure 14. *Physcomitrella patens*, a species that exhibits oxidative bursts in response to a fungal presence. Photo by Michael Lüth, with permission.

Minibayeva and Beckett (2001) conclude that patterns of oxide production are correlated with the moisture status of the habitat. Those species with high basal rates of oxide production grow in moist microhabitats, have a moderately high thallus water content, have high K^+ contents, and have well developed oxidative bursts. Species with such oxidative bursts also lose a high proportion of their intracellular K^+ (55-98% in liverworts and hornworts) upon rehydration. Mosses and the one leafy liverwort were all collected from wet habitats and all produced oxides at low rates compared to the thallose liverworts and hornworts.

Figure 15. *Marchantia paleacea* subsp. *diptera* from Japan. Photo by Janice Glime.

The aquatic moss *Fontinalis antipyretica* (Figure 18) exhibits the potential danger of high oxygen levels. De Carvalho *et al.* (2012) demonstrated that under slow dehydration, this species exhibits low production of reactive oxygen species upon rehydration, a phenomenon that reduces the cellular damage and increases cell survival. The slow drying apparently reduces the oxidative burst by limiting production of reactive oxygen species.

But some bryophytes produce high quantities of oxides even when they are not stressed, and some bryophytes produce them at extremely high rates. For example, *Anthoceros natalensis* exceeds $1000 \mu\text{mol g}^{-1} \text{ dry mass h}^{-1}$, whereas excised tracheophyte roots produce only about 1% of that amount (Minibayeva *et al.* 1998). These data do not present a consistent pattern that permits

us to interpret the role of oxidative bursts or superoxide dismutase in protecting bryophyte cells that undergo desiccation. Instead, the high oxidative responses in some species may be one to the presence of invading pathogens (see below).

Mayaba *et al.* (2002) later found that *Atrichum androgynum* (Figure 19) from the Afromontane understory displays an oxidative burst of hydrogen peroxide (H_2O_2), not superoxides, during rehydration, with maximum rates during the first 15 minutes (Figure 20). The moss even produces peroxide during times when dehydration is insufficient to cause K^+ leakage. Using polyethylene glycol to induce desiccation causes the moss to produce significant amounts of H_2O_2 . Mayaba and coworkers suggest that peroxidases might be responsible for the production of H_2O_2 . They determined that ABA and light influenced the rate of production of peroxide.

Figure 19. *Atrichum androgynum*, a moss with an oxidative burst, especially during the first 15 minutes of rehydration. Photo by Clive Shirley, Hidden Forest <www.hiddenforest.co.nz>, with permission.

Figure 20. Peroxide (H_2O_2) production during rehydration following various dehydration periods (indicated on each line) in *Atrichum androgynum* from KwaZulu-Natal Province, Republic of South Africa, during summer. Vertical bars indicate standard deviation; $n=5$. Redrawn from Mayaba *et al.* (2002).

This peroxidase system would have several advantages. Peroxidases oxidize phenolics to quinones and generate peroxide (H_2O_2). Peroxide, a well-known antibacterial agent for cleaning cuts and wounds, can itself help to kill invading organisms. Furthermore, peroxide releases free radicals that increase polymerization of phenolics into lignin-like substances. In tracheophytes,

these substances are known to reinforce the cell wall and contain the pathogens. They may have similar roles in bryophytes.

The thallose liverwort *Marchantia polymorpha* (Figure 21) contains a peroxidase that has been characterized as a glycoprotein that is different from any known tracheophyte peroxidase (Hirata *et al.* 2000). Hirata and coworkers demonstrated that this peroxidase is able to perform oxidative polymerization of **lunularin**, the liverwort counterpart of ABA.

Figure 21. *Marchantia polymorpha*, a thallose liverwort that produces a peroxidase with a glycoprotein that differs from those in tracheophytes. Photo by David T. Holyoak, with permission.

Other known constituents also influence the activity of peroxidases. Seel *et al.* (1992a) examined the effects of desiccation on **superoxide dismutase** (enzyme that destroys highly reactive superoxides by converting them into peroxide and O₂) activity in *Syntrichia ruralis* var. *arenicola* (= *Tortula ruraliformis*; Figure 22), a desiccation-tolerant moss, and *Dicranella palustris* (Figure 23), a flush moss with limited desiccation tolerance. Activity of this enzyme is known to enhance membrane integrity (Dhindsa & Matowe 1981; Dhindsa *et al.* 1981; Gong *et al.* 1997). *Syntrichia ruralis* var. *arenicola* has higher superoxide dismutase activity in both the hydrated and desiccated states than does *D. palustris* (Seel *et al.* 1992a). But effects on the activities of peroxidase or ascorbic peroxidase do not seem to be related to hydration state. Nevertheless, both species become depleted of the anti-oxidant ascorbic acid when desiccated. From these experiments, Seel and coworkers deduced that anti-oxidants may be more important than removal of chloroplastic peroxide in endowing desiccation tolerance. Using different methods, Seel and coworkers (1992b) found a greater lipid peroxidation in *D. palustris* than in *S. ruralis* var. *arenicola* following desiccation. Calcium also seems to play a role by increasing superoxide dismutase activity, thus enhancing membrane integrity (Gong *et al.* 1997).

Proctor *et al.* (2007) used the endohydric moss *Polytrichastrum formosum* (Figure 30) to try to resolve conflicting implications between physiological and cytological evidence regarding desiccation recovery in bryophytes. They found that protein synthesis inhibitors cause rapid decline of photosynthetic recovery in the light,

but not in the dark. Rapid recovery of respiration and photosynthesis indicates that systems are conserved intact during the dehydration and rehydration, an indication that is consistent with the physical evidence that thylakoids and cristae do remain intact during the dehydration-rehydration process. Microbodies that are closely associated with chloroplasts remain unchanged during the dehydration-rehydration process and play an important role in removal of the superoxide radicals (Duckett & Renzaglia 1988; Smirnov 1993; Minibayeva & Beckett 2001; Mayaba *et al.* 2002). The prominence of these microbodies in leaves of *Syntrichia ruralis* (Figure 23) (Robertson 1991) and *Polytrichastrum formosum* may be associated with the desiccation tolerance of these two species (Proctor *et al.* 2007).

Glutathione

Glutathione (GSH) is important in protecting plants from environmental stresses like oxidative stress and pathogens (Bruns *et al.* 2001; Burritt 2008). More recent studies have used glutathione to measure drought stress. Activities of the enzymes glutathione reductase, glutathione peroxidase, and glutathione S-transferase increase during slow drying and likewise during rehydration following rapid drying of the drought-tolerant moss *Syntrichia ruralis* (Figure 22) (Dhindsa 1991).

On the other hand, the activity of the enzymes malate dehydrogenase exhibit little change during either dehydration or rehydration. Treatment of the moss tissues with cycloheximide, actinomycin D, or cordycepin suppresses the increased activities of glutathione reductase and glutathione S-transferase, but has a much lower effect on glutathione peroxidase. At the same time, the percentage of total glutathione as oxidized glutathione increases. This increase is correlated positively with levels of lipid peroxidation and solute leakage, but is correlated negatively with the rate of protein synthesis. The oxidized glutathione level serves as a good indicator of oxidation stress and suggests that oxidized glutathione may mediate the drought-stress-induced inhibition of protein synthesis.

In addition to protection from oxidative damage, glutathione may help to protect the bryophyte cells from heavy metal damage following rehydration (Saxena & Saxena 2012). Although it is likely that this benefit has not had any evolutionary selection advantage for very long, current pollution conditions often deposit heavy metals that accumulate while the bryophytes are dry. These could gain entry into the cells along with the resorption of needed cell electrolytes during rehydration and before membrane repair is completed. Bruns *et al.* (2001) have demonstrated a protective detoxification role of glutathione against heavy metals in the aquatic moss *Fontinalis antipyretica* (Figure 18), Leinenweber *et al.* (2009) in the terrestrial moss *Thuidium* sp. (Figure 24), and Saxena and Saxena (2012) in the moist forest moss *Sphagnum squarrosum* (Figure 25).

Figure 24. *Thuidium tamariscinum*, a species that is able to use glutathione as protection against heavy metals. Photo by Michael Lüth, with permission.

Pathogen Danger

The damaging effects of oxides in the cells leads us to question the advantages that may have kept the oxidative burst in the bryophytes for eons. This may be explained by their role in limiting pathogen invasion and damage.

Cells with damaged membranes resulting from desiccation would be vulnerable to invasion by pathogenic microorganisms. Such oxidative bursts as seen upon rehydration can help to limit the spread of invading pathogens because of oxidation toxicity, as well as inducing expression of defense-related genes. Low and Merida (1996) considered the oxidative bursts in plants to facilitate cross-linking of cell wall proteins, induction of

defense-related genes, stimulation of **phytoalexin** (substance produced by plant tissues in response to contact with a parasite and that specifically inhibits growth of that parasite) biosynthesis, and promotion of **hypersensitive response** (HR; mechanism to prevent spread of infection by microbial pathogens, causing rapid death of cells in local region surrounding infection).

Figure 25. *Sphagnum squarrosum*, a species that is able to use glutathione as protection against heavy metals. Photo by J. C. Schou, with permission.

Gupta (1977) reported the oxidative burst in bryophytes as an "artifact." He found that *Dicranella palustris* (Figure 23; a wet-habitat moss) and *Scapania undulata* (Figure 26; an aquatic leafy liverwort) had a large number of microorganisms present following dehydration and rehydration. This is a reasonable expectation when membranes are damaged and both electrolytes and organic compounds are able to leak from the cells, especially upon rewetting. Furthermore, the respiratory oxygen uptake increased to about 6X that of controls of *S. undulata*, 2.5X for *Dicranella palustris*, and 2X for *Porella platyphylla* (Figure 27) and *Mnium hornum* (Figure 28). Little increase occurred in *Syntrichia ruralis* (Figure 22), the most desiccation-tolerant species. But it appears that the respiratory increases were due to the adhering microorganisms, not to the bryophytes. Such respiratory increase could indicate injury to the bryophytes, but it cannot be a useful tool to measure survivorship or metabolic recovery of the bryophytes. These microorganism growths indicate the potential importance of oxidative bursts that can help to protect the bryophyte cells from invasion from these potentially harmful organisms.

Beckett *et al.* (2004) demonstrated that the liverwort *Dumortiera hirsuta* (Figure 29) produced extracellular superoxide at high rates even under normal, unstressed circumstances. Nevertheless, production increased extensively during rehydration, but not during desiccation. It appears that peroxides produce the superoxide, but little H_2O_2 seems to be present in the cell. However, indications are that the concentrations of peroxides are rapidly reduced by the liverwort. Beckett and coworkers likewise suggested a role in protection against bacteria and fungi. Lehtonen *et al.* (2012) verified the importance of such

oxidative bursts in response to a fungal elicitor (chiton) in the moss *Physcomitrella patens* (Figure 14).

Figure 29. *Dumortiera hirsuta*, a thallose liverwort that produces extracellular superoxide at high rates even under normal circumstances. Photo by Michael Lüth, with permission.

White and Torres (2010) suggested that endophytes in plants may protect the plants from oxidative damage by the production of antioxidants, thus possibly protecting them against other forms of stress, including desiccation. It appears that this protective role of endophytes (fungi) has not been explored in bryophytes.

Shoot Tips – Variable Tolerance within Plants

Some moss shoot tips may have a rehydration potential not afforded the rest of the plant. In *Polytrichastrum formosum* (Figure 30), desiccation in the shoot tips induces the rapid resorption of starch grains in plastids of the meristematic cells without any major **thylakoid** disorganization (Hallet *et al.* 1987). In the adult leaves, however, the starch grains are preserved. Upon rehydration, the plastid ultrastructure of the apex is entirely restored and new starch inclusions appear in less than 4 hours. Little work has been done to relate the resistance of various parts of the bryophyte plants to differences in biochemistry.

Figure 30. *Polytrichastrum formosum*, a moss where desiccation of the apices causes rapid resorption of starch grains in plastids of the apical meristematic cells. Photo by Des Callaghan, with permission.

The Genes

While the physiologists are attempting to find substances that affect desiccation tolerance and recovery rates, the geneticists are attempting to identify genes and

the biochemical pathways they affect. Chen and coworkers (2002), working with the desiccation-tolerant model system in *Syntrichia ruralis* (Figure 22), found a new polypeptide, known as ALDH21A1, that is less than 30% identical to known ALDH proteins. Data suggest that this new aldehyde dehydrogenase plays an important role in the detoxification of aldehydes generated in response to desiccation and may represent a unique stress tolerance mechanism among eukaryotes. Could it be this aldehyde dehydrogenase, perhaps coupled with ABA, that explains why Hamerlynck and coworkers (2002) found *Syntrichia ruralis* to be **homoiochlorous** (maintaining constant chlorophyll concentration) in its response to desiccation? Growing in the sun endows these plants with a greater desiccation tolerance than that experienced by shade-grown plants of the same species.

To fit these pieces together requires a great deal of speculation because our knowledge is still too meager. However, let's look at what we know about these pieces and see if we can develop a hypothetical story (Figure 31).

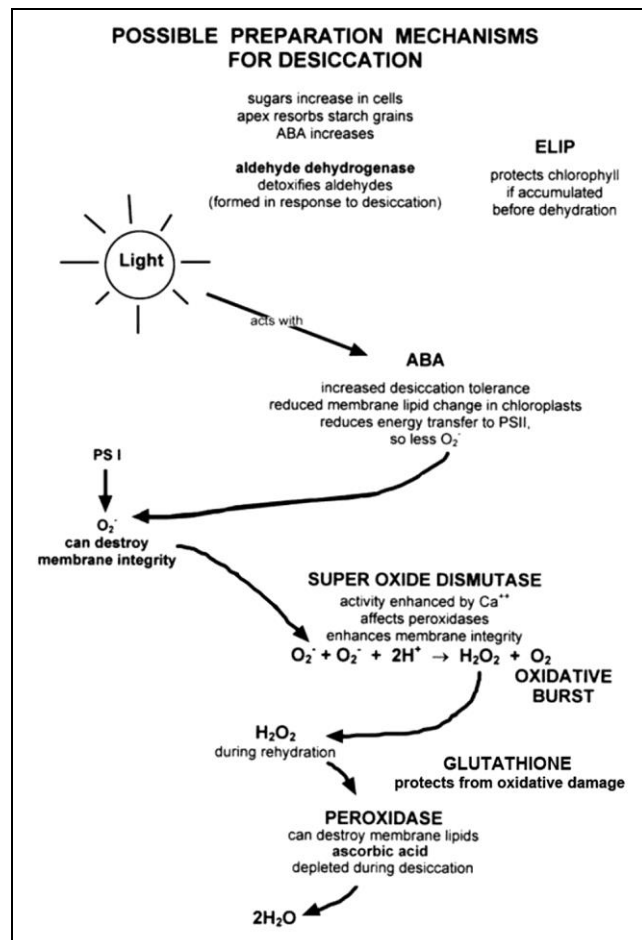

Figure 31. Speculation on possible relationships of the observations that have been made on pre-desiccation events and related rehydration events in desiccation-tolerant bryophytes.

Summary

Membranes become leaky during desiccation. Some mosses protect their membranes with sugars such as stachyose, glucose, erythritol, glycerol, and sucrose.

ABA increases the stress tolerance of bryophytes and is known to turn on the promoters of **stress tolerance genes**. Hence, it is important in controlling transcription. That is consistent with the conclusions of several authors who have determined that drought tolerance in bryophytes evokes control of gene transcription. We also know that **peroxidases** destroy H_2O_2 (**peroxide**), which is harmful to plants. We know that H_2O_2 is responsible for lipid damage of membranes and that lipid peroxidation and increased membrane permeability correlate with the decrease of **superoxide dismutase** (Dhindsa *et al.* 1981). And we know that superoxide dismutase controls **oxygen toxicity** by converting the superoxide radical to less dangerous forms (Michael Potter of Andrew McCammon's group at the University of California, San Diego). Since *Syntrichia ruralis* var. *arenicola* has a higher concentration of superoxide dismutase than the less desiccation-tolerant *Dicranella palustris*, we can then hypothesize that the superoxide dismutase is an important contributor to drought tolerance in bryophytes. Perhaps it is one of the 74 proteins produced in response to desiccation stress. Glutathione may help to protect the cells from excessive oxides, but it may have a more important role in protecting against pathogenic microorganisms while they are vulnerable with damaged membranes.

Shoot tips seem able to survive better than other parts of some mosses, but we know nothing about any differences in their biochemistry. New genetic studies are making it possible to learn more about the functions of various compounds in the cells.

Acknowledgments

This chapter, in an early version, has benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me tow the line in explaining things without leaving too much to one's imagination, but at the same time not repeating myself.

CHAPTER 7-8

WATER RELATIONS: HABITATS

Figure 1. *Bryum caespitium* at a high elevation where winds and ice crystals contribute to desiccation, but where at other times fog can maintain moisture without rain. Photo by Michael Lüth, with permission.

Habitat Relations

Proctor (2014) summarized the importance of water relations for bryophytes in their invasion of land. He pointed out that the poikilohydric strategy is optimal at smaller scales, *i.e.*, bryophytes. Microhabitat and habitat structure are important in conferring the hydration state of bryophytes, and drought sensitivity varies according to species (Irmscher 1912). Norris (1990) found that *Braunfelsia* disappeared from some areas of tropical rain forests in Papua New Guinea following disturbance to the forest because of the increased dehydration frequency and the admission of greater wind movement. In the Mediterranean area in the southern and southeastern Iberian Peninsula, Varo and coworkers (1992) found that as the climate has become drier and warmer the bryophyte taxa have changed, with leafy liverworts and pleurocarpous mosses diminishing and *Sphaerocarpos* (Figure 2) and acrocarpous mosses becoming more prominent. In central Sweden, greater numbers of bryophytes occur in spruce forests on more moist north-facing slopes, whereas

vascular plants are more abundant on the exposed south-facing slopes (Söderström 1981).

Figure 2. *Sphaerocarpos michelii*, member of a genus that becomes more prominent as the climate dries. Photo by Michael Lüth, with permission.

Bryologists learn inductively through field experience that certain bryophytes are characteristic of dry habitats and others of wet habitats. Actual studies that correlate these conditions with species are less common than descriptive observations, with a number of these being relative to water level in peatlands. Bates *et al.* (2004) used canonical correspondence analysis (CCA) to develop a more rigorous approach to these relationships by sampling epiphytes along a transect across southern Britain from southwest to northeast. With climate, presence of water courses, and forest cover contributing to the analysis, they determined that *Frullania tamarisci* (Figure 3), *Metzgeria temperata* (Figure 4), *Microlejeunea ulicina* (Figure 5), *Neckera pumila* (Figure 6), and *Hypnum andoi* (Figure 7) were restricted to habitats with high moisture availability. On the other hand, *Syntrichia ruralis* (Figure 39), *Grimmia pulvinata* (Figure 8), *Tortula muralis* (Figure 9), and *Aulacomnium androgynum* (Figure 10) only occurred as epiphytes in locations with low moisture. They did not sample these species in other habitats.

In mature black spruce forests of central Alaska, the endohydric *Polytrichum commune* (Figure 11) is able to avoid moisture stress more so than such ectohydric taxa as *Hylocomium splendens* (Figure 12; Skré *et al.* 1983). The latter species remains below its compensation point for water for nearly 50% of the July growing season.

Open expanses of urban areas are notoriously devoid of extensive bryophyte cover, even on trees where taxa are already xerophytically adapted. Hébrard and Rolando (1985) found that when comparing four holm-oak thickets in France, species composition correlated more with plot exposure than with thicket age, suggesting that desiccation, light, and temperature may be most influential. Sheard (1968) likewise found a correlation between the prevailing north wind and the pattern of moss-lichen heath on Jan Mayen Island.

Among the most significant climatic stress inducers for mosses are high temperatures, frost, and drought (Longton 1979). Dry mosses are typically much more heat resistant than wet mosses. For example, Nörr (1974) found that eight European mosses reach lethal limits at 42-51°C when turgid, but survive to 85-110°C when dry. Lange (1955) found similar dry survival of mosses from 70-110°C. Temperature relationships will be discussed more thoroughly in the chapter on temperature.

These relationships also exemplify that, although bryophytes are able to survive on rocky and shallow substrates with little water, they are unable to compete with the tracheophytes in areas where there is sufficient soil, light, and moisture for the tracheophytes to root. But at the extremes, bryophytes may have an advantage. Therefore, it is fitting to conclude our attempt to understand the water stresses of bryophytes by comparing them at the two extremes, the aquatic and the arid habitats.

Using electrolyte leakage as an indication of desiccation stress, Šinžar-Sekulić *et al.* (2005) compared the desiccation tolerance of three mosses from different moisture regimes. *Thamnobryum alopecurum* (Figure 13), a moss of open, vertical limestone cliffs, has the highest degree of desiccation tolerance among these three. *Anomodon viticulosus* (Figure 14), a moss of limestone rocks in the forest, releases electrolytes under desiccation, causing pronounced changes in the cells. The aquatic moss *Platyhypnidium riparioides* (Figure 15) suffers irreversible change following desiccation. It is likely that speed of drying plays a role for the latter species because its frequency on emergent rock habitats suggests that it should be adapted to slow drying. Nevertheless, it seems to live where it stays moist even during periods of low water levels.

Among the hornworts (**Anthocerotophyta**) little information exists on desiccation tolerance. Some are drought avoiders, producing special structures that survive periods of desiccation (Vitt *et al.* 2014). These, occurring on hornworts of seasonally dry localities, include abundant swollen, marginal or apical tubers on the thalli (*Phaeoceros* spp.; Figure 16-Figure 17) or long-stalked, subterranean ventral tubers (*Phymatoceros*; Figure 18). Both of these

special tubers form as the sporophytes mature and persist in the soil crust or soil bank after the vegetative thallus has deteriorated. Rainfall causes these tubers to germinate and form new plants (Crandall-Stotler *et al.* 2006). Hartung *et al.* (1994) found that these tubers contain large amounts of ABA, a hormone known to induce desiccation tolerance in bryophytes (Pence *et al.* 2005). These tubers can survive at least nine months of dryness and still germinate (Vitt *et al.* 2014).

Figure 18. *Phymatoceros bulbosus* ventral side with tubers. Photo by David Wagner, with permission.

Other hornworts take advantage of short life cycles. For example, rapid spore release in *Notothylas* (Figure 19), coupled with the ability to survive many years dry (Renzaglia *et al.* 2009) permit this genus to avoid drought conditions.

Figure 19. *Notothylas orbicularis* showing numerous young horizontal sporophytes. Photo by Michael Lüth, with permission.

Liverworts are known for loving damp habitats, but they contain their xerophytic members as well. Seppelt (pers. comm. 1999) relayed to me that these include species surviving in as little as 150 mm of rainfall per year [*Fossombronia* (Figure 20), *Asterella* (Figure 21), *Plagiochasma* (Figure 22)]. At somewhat higher levels (200 mm), such taxa as *Lethocolea* (Figure 23), *Cephaloziella* (Figure 24), *Riella* (Figure 66), *Enigmella*, and *Gongylanthus* (Figure 25) appear. *Enigmella* is ephemeral in its vegetative phase, but its reproductive structures are well suited to their environment. Some taxa survive drought by having a shortened life cycle, *e.g.* *Riccia cavernosa* in the Arctic (Seppelt & Laursen 1999).

Peatlands

Peatlands provide a good ecosystem for comparing adaptations for differences in moisture regimes by habitat. But the dominant moss, *Sphagnum*, has unusual structural adaptations that can complicate this analysis.

Wagner and Titus (1984) compared desiccation tolerance of the hummock species *Sphagnum nemoreum* (Figure 26) to that of the hollow species *S. fallax* (Figure 27). The hollow species is more desiccation tolerant than the hummock species. It has both a higher number of plants surviving and a better recovery of its photosynthetic rate. However, its ability to recover decreases as the desiccation periods are lengthened or the water content is decreased. Despite being close to the water, *S. fallax* apparently dries more frequently and for longer periods of time than does *S. nemoreum*. The latter species, instead, is able to remain moist in the field by holding more water when the habitat dries.

Figure 26. *Sphagnum nemoreum*, a compact hummock moss. Photo by Michael Lüth, with permission.

Figure 27. *Sphagnum fallax*, a loose moss of hollows. Photo by David Holyoak, with permission.

Schipperges and Rydin (1998) compared the responses of photosynthetic CO₂ exchange in five species of *Sphagnum* in response to tissue water content. These species ranged in microhabitat from hummock top (*S. fuscum*; Figure 28), hummock mid to top [*S. papillosum* (Figure 29) & *S. magellanicum* (Figure 30)], wet areas of ombrotrophic bogs and ditches (*S. balticum*; Figure 31), to submerged (*S. cuspidatum*; Figure 32). Laboratory experiments using infrared gas analysis (IRGA) measured recovery of net photosynthesis after several long-lasting desiccation/rehydration events. One important structural adaptation that emerged is the importance of contact between capitula and basal parts of the mosses; if the

capitula were isolated from the water table, they were unable to recover from complete desiccation (<10-20% of compensation point water content; 15°C for 2-4 days). It is interesting that they found no relationship between recovery of net photosynthesis and wetness of the natural habitat. Rather, those species that live under regularly drying conditions are able to avoid death by themselves avoiding drying out, using high capillarity or a dense growth form such as that of *S. fuscum* (Figure 28).

Hájek and Vicharová (2013) concluded that *Sphagnum* species have inducible desiccation tolerance. These species are generally desiccation intolerant, instead using mechanisms to avoid internal desiccation, as noted by Schipperges and Rydin (1998). Hájek and Vicharová tested the inducible nature of their tolerance by using various bryophyte species, including *Sphagnum*. They hardened the bryophytes by slow drying, ABA application, and chilling or frost. Both chilling and frost can create desiccating conditions by drawing water from the cells through the hygroscopic nature of ice crystals, much like the effects of freezer burn in your freezer. Presuming that the tolerance was inducible, they monitored the seasonal changes in desiccation tolerance of bog bryophytes. Among these, *Sphagnum* species in hollows and lawns developed desiccation tolerance several times during the year as a response to reduced precipitation and lowered water table. The hummock and aquatic species developed this tolerance only in the autumn, possibly responding to frost. Following initial de-hardening in the lab, untreated *Sphagnum* shoots lacked desiccation tolerance. On the other hand, all hardening treatments except chilling induced desiccation tolerance in all groups except those in section *Cuspidata* (Figure 32), a submersed species. They suggest that lack of adequate desiccation tolerance may prevent *Sphagnum* establishment in the drier habitats that are otherwise suitable. Those species that avoid desiccation typically do so by forming compact hummocks – or living submersed. Thus, hummock species invest their

resources in water retention, avoiding desiccation, but have a lower ability to develop desiccation tolerance.

Peatlands typically have moisture gradients, and Hettenbergerova *et al.* (2013) took advantage of this gradient to compare species richness relative to water availability. They were fortunate to have a system that graded from a spring fen to a semi-dry grassland in the Czech and Slovak Republics. They found that the number of species of tracheophytes tended to increase toward the lower moisture values. The species richness had a negative correlation with the N:P biomass ratio, whereas the percentage of endangered species had a positive correlation. These relationships for bryophytes differed markedly from those of the tracheophytes. Instead, bryophyte species richness decreased linearly toward the dry end of the transects, and there was no correlation with any of the nutrient measurements (N, P, K, C, Ca). Furthermore, the bryophytes exhibited a very high percentage of specialists in fen plots.

Sagot and Rochefort (1996) were concerned about the effects of desiccation on regeneration. They found that fragments of *Sphagnum fallax* (Figure 27), *S. fuscum* (Figure 28), and *S. magellanicum* (Figure 30) could survive 14 days without water when air dried at 20°C, relative humidity ~60%, but regeneration was delayed. *Sphagnum fallax* and *S. magellanicum* survived better than did *S. fuscum*.

Aquatic Habitats

The aquatic bryophytes are distributed worldwide, but they seem to be more common in temperate than in tropical areas. Aquatic species are classified as **obligate aquatics**, having little or no tolerance to drought conditions, **facultative aquatics**, having some degree of tolerance to desiccation and xerophytic conditions, and **semi-aquatic emergents** (Vitt & Glime 1984), being in locations where they are partly in the water and partly out of it, but usually moist (Figure 33).

Figure 33. *Fontinalis novae-angliae* submerged and *Plagiochila porelloides* on the rock above the water in a New Hampshire stream. The *P. porelloides* is subject to intermittent flooding but can become dry when the stream level is low in mid and late summer. Photo by Janice Glime.

Rehydration in aquatic mosses is much like that of tracheophytes. Whereas many mosses are able to protect their ribosomes during dehydration (Bewley 1974), permitting rapid recovery of protein synthesis and respiration upon rehydration, aquatic bryophytes are not. Instead, irreversible ribosome damage occurs (Krupa

1977). For example, *Cratoneuron* (Figure 34), a semi-aquatic moss, loses ATP during rapid drying, and with its damaged ribosomes it is unable to replace it upon rehydration (Bewley & Gwozdz 1975). Aquatic mosses typically suffer membrane damage during desiccation, but **xeric** (dry habitat) mosses often do not (Brown & Buck 1979). Thus, in aquatic mosses, rehydration results in loss of nutrients.

Figure 34. *Cratoneuron filicinum*, a moss known to lose ATP during rapid drying. Photo by Ivanov, with permission.

Even such obligate aquatic mosses as *Fontinalis* are subject to periods low water when they are exposed above water. Carvalho *et al.* (2011) found that the aquatic moss *Fontinalis antipyretica* (Figure 65) demonstrates desiccation tolerance. Laboratory experiments can be misleading because this species requires slow drying in order to survive, supporting the hypothesis of induced desiccation tolerance. In fact, Cruz de Carvalho *et al.* (2011) concluded that the protein profiles following rehydration were similar to those of the terrestrial mosses *Physcomitrella patens* and *Syntrichia ruralis* (Figure 39). They concluded that desiccation tolerance mechanisms were similar regardless of habitat.

Arid Habitats

Contrary to the popular concept that mosses must grow in wet places, a number of species are **xerophytic**, that is, adapted to places like the dry, hot desert. In such habitats, some mosses are able to absorb water from dew and night air, permitting brief photosynthesis during the early hours of morning. They dry again each day, cycling on a 24-hour wet-dry cycle (Kappen *et al.* 1979). Where the sun reaches the mosses directly, as on the south-facing slopes in North American deserts, the temperature can increase by as much as 20°C in the first 30 minutes of daylight, thus providing too short a period for the moss to gain photosynthetic energy before drying out (Nash *et al.* 1977). In such locations the mosses are restricted to the north-facing slopes. The biomass is quite small, less than 2 g m⁻², but at least 18 different species are able to survive, the most common being tuft-forming taxa such as *Syntrichia ruralis* (Figure 39), *Grimmia laevigata* (Figure 36), and *Bryum caespitium* (Figure 1).

One advantage of having sufficient moisture in the desert habitat is that it can provide evaporative cooling. But that does not seem to be the case in all situations. In the Mojave Desert, Nevada, USA, *Crossidium*

crossinervium (Figure 62) experienced temperatures above ambient, independent of the state of hydration (Stark 2005). During cooler months, the moss patch exhibited a temperature lower than ambient, again with state of hydration failing to play a role. The periods of hydration were essentially restricted to the cooler months of October to April with hydration lasting 3.7-4.9 days. The longest dry period was 191 days during the measurement period. In late winter, drying was slow, lasting several days, but in the summer the mosses were dry in as little as three hours.

Peatland bryophytes are not the only ones that practice avoidance and tolerance. These practices are also common among bryophytes that live in some of the most harsh moisture conditions on the planet. One mechanism is to go dormant during the dry periods, surviving as spores, gemmae, and probably in some cases protonemata (Vitt *et al.* 2014). Such an **escape strategy** is advantageous to bryophytes that lack a physiological tolerance to desiccation in the leafy gametophore (Figure 35). Liverworts have fewer genera with an escape strategy, but many thallose liverworts have tubers or other means, especially *Riccia*, to survive (see Figure 69); many leafy liverworts have gemmae.

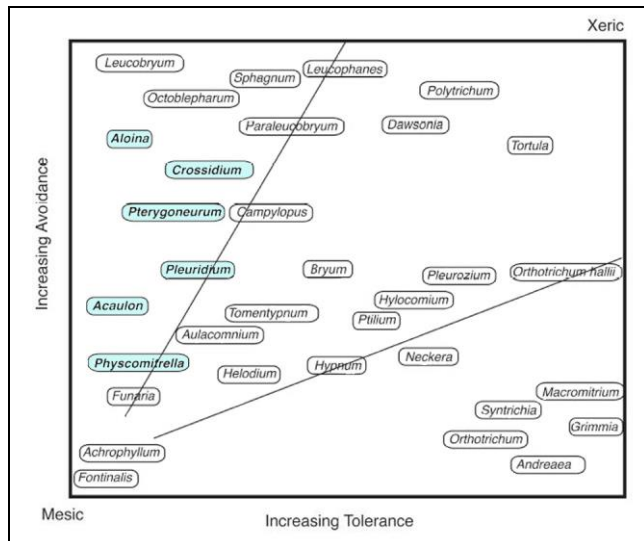

Figure 35. Comparison of representative moss genera that are able to use desiccation avoidance compared to desiccation tolerance. Those genera in blue frames are able to use escape strategies. Modified from Vitt *et al.* 2014.

Figure 36. *Grimmia laevigata*, a desert survivor. Photo by Michael Lüth, with permission.

In the Sonoran Desert of North America, Alpert (1979) found that an overnight storm provided 85% of the saturated water contents, available at 6 a.m., for *Bryum capillare* (Figure 37), *Grimmia* spp. (Figure 36), *Syntrichia* spp. (Figure 39), and *Weissia controversa* (Figure 38). By 9 a.m., eleven of the twelve species investigated had only 2 g water per g of plant dry mass, and by 3 p.m., only 0.5 g remained. By 5 p.m., less than 0.1 g per gram of plant remained, resulting in only about 9 hours of water available from that rare storm. Richardson (1981) points out that it is not damage by drought that eliminates many species from the desert, but the very short time available for photosynthesis.

Figure 37. *Bryum capillare* on a tombstone, a moss that benefits from short moisture episodes, but that holds water for only about 9 hours after a desert storm. Photo by Andrew Fogg, through Creative Commons.

Figure 38. *Weissia controversa* dry, a moss that may have only 9 hours of hydration following a desert storm. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

One adaptation that permits some mosses to tolerate frequent dehydration/rehydration cycles is that those xeric mosses with undamaged membranes are able to retain ions by binding them to the cell wall (Brown & Buck 1979). Another adaptation in the desert moss is that rapid water loss, typical of the desert, can result in a retention of 50% of the polysomes, whereas slow drying can completely deplete them. Fortunately, in drought-tolerant mosses like *Syntrichia ruralis* (Figure 39), the polysomes can be strongly rebuilt after two hours of rehydration (Oliver & Bewley 1984b), but the process continues for a longer

period of time in those that were dried rapidly. RNA synthesis likewise requires six hours after rapid drying and only two hours after slow drying to reach the level of that in non-dried control mosses (Oliver & Bewley 1984a).

Figure 39. *Syntrichia ruralis*, a drought-tolerant moss. Photo by Michael Lüth, with permission.

One unclear factor in this story is the role of nitrite. Nitrite accumulates during slow dehydration of *Syntrichia ruralis* (Figure 39), but not when desiccation is rapid (Mahan *et al.* 1998). Upon rehydration, the nitrite in the slowly-dried moss declines and reaches normal levels within one hour. Mahan and coworkers considered that the nitrite might provide a nitrogen source for the nitrogen metabolism needed during rehydration. On the other hand, Brown and Mahmood (1996) determined that nitrite apparently causes considerable membrane damage in the mesophytic *Mnium hornum* (Figure 40); thus we need further research to understand the conditions under which it is detrimental vs adaptive.

Figure 40. *Mnium hornum*, a moss in which cell membranes suffer damage from elevated nitrite concentrations during dehydration. Photo by David T. Holyoak, with permission.

Marschall (1998) examined the activity of nitrate reductase during desiccation and rehydration of nine bryophytes and concluded that there was no difference in the proportional decrease in nitrogen reductase activity between desiccation-tolerant and non-tolerant bryophyte taxa. Eight of these bryophytes did exhibit detectable nitrate reductase (NR) activity. Pretreatment with KNO_3 did affect the increase in NR activity between these two

types, with the desiccation-tolerant *Syntrichia ruralis* var. *arenicola* (Figure 39) increasing activity by a factor of 3 while the desiccation-intolerant *Dicranum majus* (Figure 41) and *Hookeria lucens* (Figure 42) had a 6-fold increase in nitrate reductase activity. Following rehydration, *Syntrichia ruralis* (Figure 39) exhibited a marked decline in NR activity during the first hour, whereas the epiphytic/saxicolous *Porella platyphylla* (Figure 43) maintained a relatively constant low level in the light but increasing NR activity in the dark. While we might assume that these physiological differences relate to survival, it is too early to explain just how this is accomplished.

Proctor (1982) considers such structures as papillae to be adaptive in ensuring that the moss does not spend a long period of time in a semi-dry state, during which it is likely to lose more carbon by respiration than it gains by photosynthesis. He notes that the papilla systems, so common on xerophytic leaves, are often separated by regions where the capillary continuity is broken at high water potentials, causing the leaf to have either an abundant water supply, or none. Such discontinuities could be amplified if the leaf rolls as it dries and bends away from the discontinuity. Vanderpoorten and Engels (2002) considered papillae so important as to be one of only four life history traits contributing to predictability of species occurrence in a particular environment on a regional scale. Nevertheless, experiments on the role of papillae in conserving water have mostly failed (Frey & Kürschner 1991).

Few bryophytes approach the succulent or sclerophyll strategies known in tracheophytes (Grime 1977), although one might argue for succulence in the Marchantiales. Plants with numerous or large papillae take on the appearance of sclerophylls, and for many years we assumed that papillae functioned to prevent the loss of water. However, as Frey and Kürschner (1991) pointed out, tests to validate that theory have failed. Nevertheless, while it appears that the papillose mosses do not slow down water loss, the papillae may have a function in water uptake (Crandall-Stotler & Bozzola 1991). As discussed earlier with leaf strategies (see Chapter 7-4a of this volume), papillae in *Andreaeobryum macrosporum* (Figure 44) are constructed in such a way that they provide a channel for the uptake of water.

Figure 44. *Andreaeobryum macrosporum*, a moss with papillae that provide a pathway for uptake of water. Botany website, University of British Columbia, Canada, with permission.

I have suggested that papillae on some mosses might also function to scatter light during dry periods, thus aiding in the protection of the chlorophyll from the UV light during the lengthy time the leaf is exposed, with no chance for repair between rainfall events.

Alpert (1979, 1982, 1985, 1988) investigated five species of **poikilohydric** mosses (those that depend on external conditions to regulate their water content): *Schistidium apocarpum* (Figure 45), *Grimmia laevigata* (Figure 36), *Hedwigia ciliata* (Figure 46), *Orthotrichum rupestre* (Figure 47), and *Syntrichia ruralis* var. *crinata* (see Figure 39). These bryophytes are characterized by short cushions of tufted growth, except for *Hedwigia ciliata*. The latter moss has a whitened appearance due to numerous papillae, and its leaves are closely appressed to the stem when dry. When wet, the leaves spread broadly, causing it to look sufficiently different from its dry state that it causes many bryologists to stop and puzzle over its identity.

Alpert (1979, 1982, 1985, 1988) found that these five mosses were able to colonize unoccupied, stressful boulder habitats, but that they were intolerant of competition or of disturbance beyond their normal desiccation regime. They grew in particular microclimatic niches on the rock substrata and were unable to occupy the most xeric conditions within the same macroclimate, although laboratory studies indicated that they can tolerate both temperatures and droughts that exceed those of the habitats they occupy. Alpert showed through transplant experiments that they could indeed occupy additional locations, suggesting that dispersal and establishment impose limits on their distribution.

The aspect and angle of slope had strong influences on the evaporation stress experienced by these mosses (Alpert 1979, 1982, 1985, 1988). Mosses growing under rock overhangs should experience the least water stress by late day, but do not regain as much moisture as those at 15° and 75° slopes (Figure 48). As expected, mosses at the tops of boulders had the greatest peaks of evaporation stress. Alpert's work illustrates the importance of 24-hour measurements in comparing potential evaporative stresses of different microsites.

Figure 48. Effects of degree of slope on potential evaporation on 21-22 February 1980 for mosses (based on uniform paper samples) on arid north sides of rocks in five slope microsites. (n=4) Modified from Alpert (1982).

Aspect separated the evaporation stresses even more clearly (Figure 49), with evaporation stress on the east side peaking at about 10:00 hours and at most other aspects peaking at about 12:00 hours (Alpert 1982). Stress on the west side peaked last, at 14:00 hours, but with a lower peak than at the other aspects. The north, as might be expected, had the least daily variation. Although daily evaporation potential was high, a brief nighttime rainfall of no more than 5 mm was sufficient to rewet the moss for several days (Figure 50, Alpert 1982).

Figure 49. Effect of aspect on potential evaporation on 7-8 March 1980 for mosses (based on uniform paper samples) on arid 45° slope in five aspect microsites. (n=4) Modified from Alpert (1982).

Figure 50. Percent hydration of natural moss cover on boulders following nighttime rainfalls of ~5 mm in spring and winter. Redrawn from Alpert (1982).

Open, exposed soils in temperate climates are arid for bryophytes because of their insignificant soil penetration by which to obtain water. In these habitats, the mosses *Barbula* (Figure 51), *Syntrichia* (Figure 39), and the thallose liverwort *Riccia* (Figure 52) are able to survive (Schofield 1985). The two mosses are both papillose and able to roll their leaves and contort them as they dry. The *Riccia* thallus usually has inrolled margins and a thick cuticle; Frey and Kürschner (1991) have demonstrated that thallus and leaf inrolling correlate with increasing aridity, suggesting a protective role. *Ceratodon* (Figure 53), *Funaria* (Figure 54), and *Cephaloziella* (Figure 55) seem to lack any structural adaptations to their sometimes dry habitats, although *Ceratodon* does have crispate leaves and rolled margins.

In cryptogamic crusts of arid regions, bryophytes are important in holding water, retaining several times their volume after rainfall (Mücher *et al.* 1988; Rivera-Aquilar *et al.* 2005). This leads to higher germination rates of seed plants compared to areas with no crust (Mücher *et al.* 1988; Rivera-Aquilar *et al.* 2005; Serpe *et al.* 2006)

A comparison of mosses from a variety of habitats in Israel revealed varying degrees of drought tolerance that related well to their habitats (Di Nola *et al.* 1983). The desert mosses *Tortula brevissima* (Figure 56) and *Trichostomopsis aaronis* exhibited rapid return of metabolic activity after prolonged drying and were able to resume photosynthesis without new chlorophyll synthesis. The Mediterranean moss *Barbula fallax* (Figure 57) behaved similarly to the desert mosses, but

Homalothecium aureum (Figure 58) and *Didymodon tophaceus* (Figure 59), more mesic mosses, had slow recovery after desiccation. *Mniobryum* sp. (Figure 60) had almost no drought tolerance and was killed by the prolonged drying.

Longton (1988b) pointed out the importance of dispersal among desert bryophytes, since many of them are drought avoiders. Since sexual reproduction will occur infrequently, he contends that desert mosses should be acrocarpous **perennial stayers** with long-lived, desiccation-tolerant gametophytes, small spores, and long setae. The **annual** taxa are **ephemeral** (short-lived) mosses and liverworts that can develop rapidly after a rain because their dormancy is accomplished by large spores; their capsules are often immersed, presumably shortening the time required to mature and preserving moisture. The **perennial shuttle** species are mostly thallose liverworts that have both desiccation-tolerant gametophytes and large

spores. **Fugitives** generally stay only one to two years while the habitat remains suitable at a site and produce small spores that permit them to be dispersed easily.

Figure 60. *Mniobryum wahlenbergii*, a moss that has little or no drought tolerance. Photo by Jan-Peter Frahm, with permission.

The short duration of the life cycle is one of the advantages provided to many desert bryophytes. In the southwestern desert habitat (USA), the desiccation-tolerant *Syntrichia ruralis* (Figure 39) requires a year to reach maturity, producing new innovations in midwinter and growing slowly through spring (Mishler & Oliver 1991). In late summer, it lengthens rapidly, completing its growth by midwinter. Female gametangia are initiated in midwinter and terminate the growth of these innovations. However, the female gametangia are present during the next 6 to 9 months on these innovations, ultimately disappearing some time between June and August. In the New Mexico populations observed by Mishler and Oliver, there were no male gametangia, and thus no sporophytes produced. Consequently, this plant must propagate entirely by vegetative means.

In the Negev Desert, southern Israel, the dioicous moss *Bryum dunense* takes advantage of fog and dew prior to the first winter rain to initiate its reproductive organs (Herrnstadt & Kidron 2005). The sporophytes are most common in partially shaded habitats and appear following the winter rains. This reproduction is supplemented by the typically more reliable reproduction through bulbils in the partially shaded and exposed habitats, whereas secondary protonemata are most abundant in the shaded habitats.

Alpert and Oechel (1985) hypothesized that even the xerophytic mosses cannot live in the most xeric habitats due to their inability to maintain a positive carbon balance. *Grimmia laevigata* lives under the xeric conditions of rocks and boulders. When subjected to such extreme conditions of long, severe drought and extreme temperatures, this moss supported the hypothesis.

Sporophyte Damage

The leafy gametophyte is not the only generation affected by desiccation. For desert mosses, too little rainfall in early sporophyte development can also be a problem. In the Mojave Desert, Nevada, USA, the moss *Syntrichia inermis* (Figure 61) experienced 66% abortion of sporophytes due to a reduced winter-spring rainfall

(Stark 2002). But unusually heavy rains in the summer likewise resulted in an increase in sporophyte abortion from 9 to 43%. Stark suggested that the summer abortions may have been the result of membrane damage resulting from rapid drying as well as from high temperatures while hydrated. *Crossidium crassinervium* (Figure 62) experienced similar sporophyte abortions in the same desert (Stark 2005).

Figure 61. *Syntrichia inermis* dry, a moss whose sporophytes experience considerable abortion due to desiccation. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 62. *Crossidium crassinervium* with one young sporophyte, a moss whose sporophytes experience considerable abortion due to desiccation. Photo by Michael Lüth, with permission.

Grimmia orbicularis (Figure 63) can suffer sporophyte abortion as a result of poor timing. It was summer rainstorms in the Mojave Desert that led to the demise of ~50% of the sporophytes, mostly in the seta elongation phase (Stark 2001). As in *Syntrichia inermis* (Figure 61), Stark suggests that the abortion resulted from stresses caused by wet-dry cycles during summer heat, a time when the moss would normally be dry and have arrested metabolism. This may have been complicated by the premature seta elongation that resulted in more exposure during the remainder of the summer or that set in motion the physiology for capsule maturation at a time when insufficient nutrients were available.

The arid and semi-arid lands occupy approximately 40% of the land on planet Earth (Reed *et al.* 2012). Climate change that changes annual rainfall could result in profound mortality of bryophytes growing there. An increase of rainfall frequency, resulting in only a 1.2 mm increase in summer rainfall, reduced the moss cover of

Syntrichia caninervis (Figure 64) from approximately 25% cover to less than 2% in just one growing season. The addition of small precipitation events resulted in a negative carbon balance; larger events are able to maintain carbon balance. The loss of moss cover changed the nitrogen cycling, reducing soil fertility. On the other hand, increased temperature had no effect.

Figure 63. *Grimmia orbicularis*, a moss that suffers sporophyte abortion if the wet/dry cycles have the wrong timing during sporophyte development. Photo by Michael Lüth, with permission.

Figure 64. *Syntrichia caninervis*, a desert moss. Photo by Michael Lüth, with permission.

Syntrichia caninervis has served as a model for successful desert living by bryophytes. Wu *et al.* (2015) demonstrated that when only 2 mm of precipitation wets the leaves of *Syntrichia caninervis* (Figure 64), the moss loses carbon. It requires 5 mm of precipitation for a carbon gain. Hence, short storms can be detrimental to the moss, explaining the loss of moss cover with the increase in frequency of rainfall and gain of 1.2 mm rain in the Colorado Plateau, USA (Reed *et al.* 2012).

This loss of carbon is despite the rapid recovery of *Syntrichia caninervis* (Figure 64). Within only one minute, it recovers 90% of its photosynthetic yield (Zhang *et al.* 2011). In fact, this species can use moisture from dew and fog, collected and directed into the leaf by its hair points (Tao & Zhang 2012). In addition to the collection effect of the hair tips, mosses from dry habitats have high osmotic values that enable them to absorb water vapor from the air. These attributes seem almost contradictory to the

loss of cover due to a minor increase in rainfall events in the desert, but a short daytime rainfall is quite different from the prolonged moisture available from fog or dew at night. Daytime moisture from a short rainfall lasts for a very short time, apparently insufficient to recover the lost energy before high temperatures and evaporation shut it down. Yet this leaves the question of rebuilding energy at night. It suggests that it is the cellular changes that use up one readily available form of energy but do not permit rebuilding it, whereas the hydrated cells from dew are fully functional and ready for photosynthesis with the first light of day – there should be no delay at all. At this time the moss is still cool from the night and evaporation should be slower.

Desiccation from Salt

Salt pans and regions of salt spray, when not under water, can be the most arid conditions of all. Few bryophytes are adapted to this regime, although some species of *Fontinalis* (Figure 65) can tolerate **brackish** (somewhat salty, often from a mix of fresh and salt water) waters. The liverworts *Riella helicophylla* (Figure 66), *R. numidica*, and *Carrpos* (?) are among the few (Schofield 1985).

Flood Plains

The flood plain habitat is one of extremes. For part of the year the inhabitants are under water, but once the water recedes the habitat can become extremely dry. This regime requires different adaptations from other kinds of dry habitats.

A number of thallose liverworts exhibit drought or desiccation tolerance (Figure 69) and are able to live in these alternating habitats (Bischler 1998; Wood 2007). Such genera include fairly small liverworts with thick thalli and short life cycles: *Corsinia* (Figure 67), *Cronisia*, *Exormothea* (Figure 68), *Monocarpus*, *Riccia* (Figure 52), and *Targionia* (Figure 70). But larger thalli in the *Aytoniaceae* [*Asterella* (Figure 71), *Mannia* (Figure 72), *Reboulia* (Figure 73)] also exhibit desiccation tolerance (Vitt *et al.* 2014). Much of this tolerance may be structural. For example, these genera typically roll their edges to avoid desiccation. Their pegged rhizoids serve as water conduits and help them to resist desiccation in periodically dry habitats by providing capillary spaces [e.g. *Mannia*, *Plagiochasma* (Figure 74), *Targionia*] (Duckett *et al.* 2014). On the other hand, liverworts from moist habitats tend to be drought intolerant (Figure 69). These include genera with thin thalli such as *Pellia* (Figure 75), *Fossombronia* (Figure 76), *Moerckia* (Figure 77), *Pallavicinia* (Figure 78), and *Symphyogyna* (Figure 79). Likewise, the primitive genera of *Haplomitrium* (*Haplomitriidae*; Figure 80), *Treubia* (*Treubiidae*; Figure 81), and *Apotreubia* (*Treubiidae*) all grow on constantly moist soil and are drought intolerant (Wood 2007).

Volk (1984) elucidated the behavior of the genus *Riccia* in these flood plain circumstances in Namibia. These are seasonally very dry habitats and members of the genus *Riccia* are very common. In this genus, the dorsal (upper) surface is unable to take in water. The ventral surface can absorb water through capillary action among rhizoids and scales, and in some cases hairs. During the dry period, they roll their thalli, exposing these rhizoids and scales from the ventral surface. This rolling thus facilitates the uptake of water from rainfall when it first occurs. These perennial species are very drought resistant and can survive up to seven years with no new water input. They are able to endure heat to greater than 80°C when dry, whereas temperatures above 50°C injure wet plants. They are unable to compete with other plants, but annual species survive by producing large numbers of spores. Perennial species produce fewer spores and survive primarily by going dormant.

Arctic and Antarctic

Kennedy (1993) asked "What limits the presence, distribution, and abundance of life in Antarctica?" To this question he answered that isolation restricts arrival and the paradigm has been that the extreme cold limits survival. But he challenges the latter tenet, suggesting that instead it is moisture that limits the organisms on vertical, horizontal, and temporal scales. Gradients in meltwater, seepage, and upwelling create moisture differences on a continental scale.

Antarctic communities, in particular, experience physiological extremes in water availability and bryophytes must survive both desiccation and submergence (Wasley *et al.* 2006). Growth rate is slow (mean for 17 yrs was 3.7 g dw m⁻² y⁻¹) (Kanda 1986), providing limited opportunity to compensate for losses during drying. Exposure accounts for the loss of bryophyte flora in many circumstances. This can be particularly true in Arctic climates. Flock (1978) found that acrocarpous mosses dominated in areas with only light snow cover, but in areas with deep snow the pleurocarpous mosses were more abundant. The reason for this is unclear, but one might hypothesize that pleurocarpous mosses are less likely to suffer apical damage from the heavy snow, and even if they do, they usually have numerous growing points to permit their

continuation. In this seasonally arid climate, primarily soil moisture and slope account for the distribution of moss communities (LaFarge-England 1989).

At Wilkes Land, Antarctica, colonies of *Bryum algens* with a dense tomentum of rhizoids held significantly more water than those with sparse rhizoids (Lewis Smith 1988). In *Schistidium antarcticum*, the dense shoot arrangement facilitates its high water-holding capacity in the turf form, whereas when this species has less densely packed shoots and thicker cell walls in xeric cushions it maintains a lower water content. On the other hand, the loss of water was much faster in the turf form and the tomentose form of *Bryum algens*, but this relationship was reversed when it was expressed as a percentage of the initial water content. The mosses take several times longer to reach minimal water conditions when compared to the lichens.

Some mosses form large mounds on the Antarctic terrain. Robinson *et al.* (2000) were able to demonstrate the relationship of desiccation tolerance to habitat in three of these moss species. *Schistidium antarcticum* (Figure 82), limited to relatively wet sites, had the least ability to sustain photosynthesis during desiccation. The worldwide *Ceratodon purpureus* (Figure 83) had the most and inhabited the driest sites. Intermediate in tolerance was *Bryum pseudotriquetrum* (Figure 84), which occupied intermediate habitats and exhibited the greatest plasticity of the three. These responses fit their typical habitat distribution, with *Ceratodon purpureus* being common in the driest sites and *Schistidium antarcticum* living in relatively wet sites. Following desiccation, *Bryum pseudotriquetrum* contains **stachyose**, a soluble carbohydrate known to provide desiccation tolerance to seeds.

Figure 82. *Schistidium antarcticum*, a moss limited to relatively wet sites. Photo by Rod Seppelt, with permission.

By contrast, *Ceratodon purpureus* has poor survival when it is submerged (Wasley *et al.* 2006). The wet habitat *Schistidium antarcticum*, on the other hand, has high submersion tolerance. *Bryum pseudotriquetrum* (Figure 84) is an intermediate species that is able to co-exist with both of these species and has flexible responses.

Davey (1999) summed up the Antarctic situation by stating that mosses from hydric habitats had lower carbohydrate and higher protein, nitrogen, and phosphorus content than species from drier habitats, suggesting that the

constant flushing provided nutrients. This emphasizes another aspect of the importance of both water and physical factors in the success of Antarctic mosses.

Figure 83. *Ceratodon purpureus*, the moss with the greatest ability to sustain photosynthesis during desiccation in the Antarctic study of Robinson *et al.* (2000). Photo Rod Seppelt, with permission.

Figure 84. *Bryum pseudotriquetrum*, the moss with intermediate ability to sustain photosynthesis during desiccation in the Antarctic study of Robinson *et al.* (2000). Photo by Rod Seppelt, with permission.

Are the responses of Antarctic species different from those of other habitats? Apparently not very. Davey (1997) examined effects of various desiccation regimes on photosynthesis of 14 bryophyte species. Using testing intervals of 6 months and 12 months of desiccation, Davey found that the photosynthetic rate decreased as the length of dehydration period increased in all these species. The xeric species had greater retention of photosynthetic rate than did the hydric species, but even the hydric species retained some photosynthesis. Repeated cycles of wet/dry do more harm than continuous dehydration to the hydrophytic species, but the mesophytic and xerophytic species show the opposite response, suggesting that the mesophytic and xerophytic species were able to recover better during short periods of hydration. As the season progresses from spring to autumn, the percentage loss of photosynthetic rate following dehydration/rehydration increases, and this change is most evident in the hydrophytic species. At the same time, it appears that the long winters with concomitant water stress have driven

these species to similar adaptations to those of some desert species.

Longton (1988a) concluded that phenotypic plasticity, opportunistic responses in CO₂ exchange, and a poikilohydric water strategy endowed the polar bryophytes with their considerable frost and desiccation tolerance. But he was quick to point out that this plasticity was not unique to polar bryophytes, but rather was common among bryophytes in general. To really understand polar adaptations we need to do physiological studies on the **endemic** (restricted to a certain area) species.

Bryophytes and water level are intimately related in the Arctic. Where the water table is maintained above the bryophyte surface, marshes develop. Where the water table is high above the permafrost, but remains below the bryophyte surface, fens develop. These moss tundras normally have no standing water and water courses are able to move through them from below the surface, maintaining the fen status. The standing water level is thus the primary factor determining the species alliances in that area. Some species complexes, such as that of the *Catoscopium nigratum* community (Figure 85), require a temporary period of desiccation to subsist (Vanderpuye *et al.* 2002).

Figure 85. *Catoscopium nigratum* exhibiting its fen community where temporary desiccation is required. Photo by Michael Lüth, with permission.

The role of bryophytes in mediating water in the sub-Arctic is crucial for making climate models that adequately predict the effects of climate change. Using *Sphagnum fuscum* and *Polytrichum piliferum*, Street *et al.* (2012) demonstrated that the model does not adequately predict the effect of turf water content on their primary productivity fluxes.

In subarctic mires, water balance often determines which species will dominate (Sonesson *et al.* 2002). When the codominant mosses *Sphagnum fuscum* and *Dicranum elongatum* were subjected to increased precipitation, both species increased their growth rate, up to 5 mm per day. *Sphagnum fuscum* had a 50% higher response in growth compared to *Dicranum elongatum*, a species of drier habitats than those of *S. fuscum*. In winter, the responses were affected by the neighboring plants. *Sphagnum fuscum* grew better when it was next to *Dicranum elongatum*, but *D. elongatum* also did better when next more *D. elongatum*.

In the Arctic tundra, Rixen and Mulder (2005) found that high moss species diversity increased productivity, especially in low-density plots, when the plots were

watered regularly. Furthermore, moisture retention was greater in plots with high species richness. Furthermore, plant height was greater in mixed cultures than in single-species cultures. Likewise, 10 out of 12 species grew better in mixture than in monoculture when the density was high and droughts were short. It is interesting that this is the opposite of the relationships found in temperate moss communities.

As suggested by the Antarctic species discussed above, growth form is important in these cold environments that are frequently subjected to water stress. In the subalpine habitat, Nakatsubo (1994) found that large cushions and compact mats were the most common among the xerophytic species. The mesophytic species of the coniferous forest, by contrast, were smooth mats, wefts, and tall turfs. The relation between evaporation rate per basal area of the moss and dry weight per basal area of the colony correlated closely with the growth form. Nakatsubo concluded that the difference in the evaporation rate per weight between the xerophytic and mesophytic species was largely due to the difference in dry weight per basal area of the colony, and that the growth forms of the xerophytic species were suitable for increasing dry weight per basal area of the colony without increasing surface roughness. Increasing surface roughness would lead to an increase in evaporation rate due to increased exposed surface area and increased air turbulence.

Forest Floor

The forest floor would seem to be the most straightforward and familiar habitat for most of us who have lived our lives in the temperate zone and who hunt mosses. But water relations in this habitat are not so simple. Bryophytes may actually deprive the trees of water in several ways.

In her collections of water samples under moss mats and without moss mats in a Jack pine forest (*Pinus banksiana*), Scafone (unpublished data) found that there were many occasions when 1-2 cm of water accumulated in the collectors with no moss, but the collectors under the moss mats were dry. This means the soil does not receive any of the throughfall during short or light rainfall events where there is a substantial moss mat on the surface. Such a cover is common in boreal and pine forests, depriving upper fine roots of much needed moisture.

But it appears that mosses can even derive their moisture at night from the soil. Carleton and Dunham (2003) accounted for moisture available to mosses during dry summer weather by explaining nocturnal cooling on the forest floor. Cooling of the soil surface at night was sufficient to bring the moss to dew point, reversing the daytime temperature gradient in the forest floor organic profile. By using a vapor barrier for comparison, they determined that the soil provides an upward movement of water at night that permits moss shoots to survive summer "dry-downs." This happens most noticeably in late summer when organic layers have accumulated the most warmth.

Temperate Epiphytes

Epiphytes are subjected to feast or famine for their water needs. In the growing season, they can get flooded by stem flow and may grow best on the side of the tree that

gets better stem flow. In the winter they often remain exposed, unprotected by snow, and subject to the harsh, dry winds.

Trynoski and Glime (1982) demonstrated the apparent role of winter when they mapped the locations of epiphytic bryophytes in a northern deciduous forest in the Keweenaw Peninsula of Michigan, USA. The highest cover at the base was on the north side of the tree, but contrary to popular belief, midway between the base and breast height it was greatest on the south side. They attributed this southern location to the drying winds from the north and a safe haven in the space between the tree trunk and the snow that provided a moist microcosm where sufficient sun could penetrate through the snow to permit photosynthesis in winter.

Where winters are not in a constant state of snow cover, they may afford a better growing season for epiphytes due to cooler temperatures and fewer dry days. In British woods, Pitkin (1975) found that most of the growth of the epiphytes *Hypnum cupressiforme* (Figure 86) and *Platygyrium repens* (Figure 87) occurred in autumn and winter. A similar pattern of growth was found for epiphytes at a second location, and growth periods in both locations corresponded with greater moisture. When summers were wet, the winter growth did not increase proportionally to the summer increase. In wetter climates, temperature and day length have greater importance in determining growth rates.

Figure 86. *Hypnum cupressiforme*, a species that grows mostly in winter in British woods. Photo by Michael Lüth, with permission.

Figure 87. *Platygyrium repens* with bulbils, a species that grows most in autumn and winter in British woods. Photo by Michael Lüth, with permission.

Wu *et al.* (1987) found that epiphyllous liverworts in southeast China required about two hours of direct light and ten hours of diffuse light in winter, with light, temperature, and humidity being the primary factors to control their distribution.

Tropics, Rainforests, and Cloud Forests

Cloud forest (Figure 88) and rainforest bryophytes can experience a wide range of water status in a single 24-hour period (Zotz *et al.* 1997). In a submontane tropical rain forest in Panama, both low and high water content limited carbon gain significantly on a daily basis for bryophytes exhibiting a variety of life forms. More than half of the daily carbon gain (mean 2.9 mg C per g plant) is lost through respiration at night.

Figure 88. *Macromitrium* habitat on a tree in a New Zealand cloud forest. Photo by Vita Plasek, with permission.

Although we are beginning to understand the broad aspects of tropical bryophyte ecology, understanding of their physiology has been hampered by taxonomic difficulties and remoteness of the study site from most of the research labs. Hence, only a few studies exist on their desiccation tolerance (*e.g.* Renner 1933; Biebl 1964a, b).

Johnson and Kokila (1970) reviewed desiccation responses in primitive photosynthetic organisms and surmised that in the algae, accumulation of fat in cells, thickening of the cell walls, and accumulation of mucilage can facilitate desiccation resistance. Other characters that correlate with resistance in some algae include resistance to plasmolysis in a hypertonic solution, rigid and viscous protoplasm, and more abundant granules. But in the mosses *Bryum* (Figure 1) and *Mnium* (Figure 40) the viscosity decreased during drying. Hence, Johnson and Kokila considered how applicable these attributes might be

to the desiccation tolerance of tropical bryophytes. They examined ten species that represented a wide range of habitats and exhibited a number of structural adaptations that might contribute to survival of drought.

Some species exhibit damage near the tips, with damage spreading slowly to the lower leaves, and others experience more apparent damage near the base (Johnson & Kokila 1970). The species they studied fell into two groups that mostly coincided with this pattern of damage progression:

Low resistance to desiccation:

(those with * have damage near the tips):

*Calymperes moluccense**

Fissidens crassinervis

*Leucobryum sanctum**

*Semibarbula orientalis**

*Syrrhopodon loreus**

High resistance to desiccation:

Bryum coronatum (Figure 89)

Leucophanes octoblepharioides (Figure 93)

Neckeropsis lepineana (Figure 94)

Paraleucobryum longifolium (Figure 95)

Pelekium velatum

Figure 89. *Bryum coronatum* surviving on an exposed rock. Photo by Michael Lüth, with permission.

In the tropics, epiphytes can experience long periods of drought during the dry season. Salazar Allen (1985) found that the genus *Leucophanes* (Figure 90) survives the drought by an unusual life form strategy. *Leucophanes* is an acrocarpous moss that may be branched or unbranched and that forms turfs. The unusual feature is that leaf-tip gemmae germinate on the parent plant to form a new layer of gametophores (Figure 91). In many bryophytes, there seems to be an inhibitory substance that prevents such occurrences (see interaction chapter). However, in *Leucophanes*, this seems to be an important adaptation for water retention. Lacking subterminal innovations, *Leucophanes* benefits from the thicker turf where the numerous stems can protect each other from drying out. It is my guess that if the tips were to become so dry that they would die in an unusually dry year, there would be at least some lower (older) stems with enough life remaining to re-establish the colony. If not, surely some of the gemmae would survive. In any event, this habit of germination of gemmae within the parent colony provides *Leucophanes* with a dense turf that could resist drying.

Figure 91. Protonemata forming at the tip of a gemma of *Leucophanes molleri* while the gemma is still attached to the parent leaf. Photo courtesy of Noris Salazar Allen.

Among those adapted for drying, with little damage down to 10% humidity, *Leucophanes octoblepharioides* (Figure 93) has abundant leucocysts that serve as a water reservoir (Johnson & Kokila 1970). The costa is thickened and prevents the leaf from collapsing. *Paraleucobryum longifolium* (Figure 95), a species of exposed situations in the hill forest, has a thickened costa and thick-walled lamina cells. *Pelekium velatum* (Figure 92) uses a different strategy with very small leaves pressed against the stem and with papillose cells. *Neckeropsis lepineana* (Figure 94) holds its secondary branches at an angle to the tree trunk in a way that subjects it to drying.

Those species with low desiccation resistance are damaged at humidity of 63% and are likely to die at 10% (71-94% of cells damaged) (Johnson & Kokila 1970). These species live in habitats that have near saturation humidity levels. Three of these species live on the ground where the humidity is constantly and exceedingly high. Two are **corticolous** (growing on bark) species [*Calymperes moluccense* (Figure 96) and *Syrrhopodon loreus*) that live on the wettest side of the tree in areas that are constantly wet due to runoff.

Pardow and Lakatos (2013) explored the desiccation tolerance of epiphytic bryophytes from contrasting microsites in tropical lowland forests of French Guiana. Canopy species are well adapted, as indicated by the recovery of chlorophyll fluorescence, with 13 of the 18 species maintaining more than 75% of their photosynthetic capacity after 9 days at 43% relative humidity. On the other hand, understory species were sensitive to desiccation and were only able to withstand a reduction to 75% relative humidity. The bryophytes were able to reactivate by reaching equilibration with water vapor as their only moisture source.

Pardow *et al.* (2012) noted the importance of lowland cloud forests in the Guianas as a site for high epiphytic bryophyte diversity. This area is subject to frequent early morning fog events that provide moisture for the bryophytes. The growth forms were those that could take greatest advantage of this cloud moisture: tail, weft, and pendent (Figure 97).

Figure 97. *Papillaria*, a pendent moss in the cloud forest at Mt. Budawang, Australia. Photo by Peter Woodard, through Public Domain

Romanski *et al.* (2011) likewise studied epiphytes, in this case in the lower montane (2400 m) rainforest of Peru. A single tree of *Weinmannia* supported 110 bryophyte species (77 hepatics, 1 hornwort, 32 mosses). They divided the tree into **Johansson zones** (lower trunk, upper trunk, mid-crown, mid-outer crown, outer crown) and found the greatest species richness and abundance on the upper trunk and large branches of the mid-crown. Exposure to light and desiccation appeared to account for the bryophyte distribution, but more research is necessary to tease out these relationships.

Atala *et al.* (2013) expressed concern that dendroid mosses with conducting tissues likewise lacked study. They examined desiccation tolerance in the *Dendroligotrichum dendroides* (Figure 98) from Chile, where it grows in the understory of temperate forests. They tested plants from two contrasting moisture conditions and found that both populations exhibited desiccation tolerance. But the responses were not equal. Those from the northern population lost water more slowly and recovered the PSII Fv/Fm to higher values when compared to the southern population. They suggested that exposure to summer droughts in the northern population could contribute to differences in their response.

Epiphytes

Epiphytes in most habitats have sharply contrasting moisture conditions. When it rains, they can be in a river of water rolling down the tree trunks. But when the rain stops, they are elevated where there is more access to wind and drying can be rapid.

These conditions are not so severe in a cloud forest due to the moisture in the clouds. Bryophytes are able to use such moisture and some are even adapted to collect it by providing fine wirelike structures, expressed as such structures as thin awns or pendent growth forms.

In two Venezuelan cloud forests, León-Vargas *et al.* (2006) the rainfall averages only 20 mm or less in January and February, 200 mm or more in August to October, and variable year-round. Continuous 100% relative humidity occurred 8.5% to 52.2% of the time. Humidity increased at night. Although these cloud forests are among the most ideal for epiphytic bryophytes, even they can have short periods droughts at any time of year. They noted that the pendent life form was probably important in harvesting the moisture from the air in these forests. All of the six pendent bryophyte species survived at least a few days of desiccation.

Pendent Mosses

Pendent mosses (those that hang down; Figure 99-Figure 100) often suffer desiccation, with little surrounding them to help hold in the water. *Floribundaria floribunda* (Figure 99) and *Pilotrichella ampullacea* (Figure 100) from Uganda humid tropical forests survive partly by avoidance, holding large quantities of external capillary water, with *Pilotrichella ampullacea* holding approximately twice as much as *Floribundaria floribunda* (Proctor 2002). Both species were able to recover from 11 months of dry storage at 5°C, although they required several days to recover, with *F. floribunda* recovering more slowly and less completely. Following 20 hours of air drying, *P. ampullacea* achieved a positive carbon balance within 30-60 minutes after rewetting.

Figure 99. *Floribundaria floribunda*, a species from humid forests in Uganda that survives partly by avoidance, holding large quantities of external capillary water. Photo by Jan-Peter Frahm, with permission.

León-Vargas *et al.* (2006) studied the epiphytes in the Venezuelan cloud forests. The rainfall there drops to an average of 20 mm or less in January and February and increases to 200 mm or more from August to October. Nevertheless, the longest recorded dry period was only 143 hours. Nighttime humidities of 90% relative humidity were common, with 100% for significant periods, creating cloud water deposition in about 50% of the nights. Although these cloud forests are among the most ideal for epiphytic bryophytes, even they can have short periods droughts at any time of year. They noted that the pendent life form was probably important in harvesting the moisture from the air in these forests. All six species of pendent bryophytes survived for at least a few days of desiccation; these recovered better from high than from low humidities.

Altitude Differences in the Tropics

In the tropics, altitude can have a strong effect on both biomass and diversity among bryophytes (Bader *et al.* 2013). The lowlands are characterized by low abundance and low species richness. These could be a consequence of short daily periods of suitable light, temperature, and moisture and nighttime high respiration due to high temperatures. Moisture regimes are quite different, with lowland forests having more concentrated but less frequent precipitation than montane cloud forests. They furthermore have sunny mornings that cause rapid drying. The high levels of moisture in high altitude cloud forests is manifest in a high diversity and cover by bryophytes (Figure 101). But both lowland and montane species are able to survive more than 80 days of dry periods, far exceeding the duration of lowland tropical dry periods.

Summary

Because of their small size, bryophytes are able to occupy microsites in otherwise unfavorable habitats. Their ability to recover from dehydration typically correlates with habitat, with aquatic bryophytes having little ability to tolerate dehydration and resume photosynthesis, whereas dry habitat bryophytes can withstand extended periods of desiccation. In aquatic bryophytes, ribosomes can be damaged irreversibly and membranes are more likely to be damaged than in dry habitat taxa. On the other hand, there is no difference in nitrogen reductase activity between dry and wet habitat bryophytes.

Peatland bryophytes (*Sphagnum*) of lawns and hollows are typically desiccation tolerant, benefitting from inducible tolerance. Those of hummocks generally are intolerant but are desiccation resistant. Submersed species rely on the water of their habitat and have little tolerance for desiccation.

Aquatic bryophytes have poor desiccation tolerance, especially with rapid drying, but usually benefit from slow drying and sometimes can survive considerable dry periods.

A number of bryophytes are xerophytic. Their life cycle is typically short and the strategy is adapted to the short periods of rainfall. But in some arid habitats, nighttime dew is the only source of water for bryophytes. Hair points gather the dew and facilitate its uptake. In others, cooling of soil can bring bryophytes to dew point and draw water upward from the soil. The real limiting factor is carbon balance. If the bryophyte loses too much carbon by respiration and experiences a hydrated state for which the duration is too short to recover it, the bryophyte will perish. Rapid repair and recovery of photosynthesis permit these bryophytes to take advantage of short periods of hydration. The rapid daytime drying makes constitutive desiccation tolerance essential for survival where short daytime storms are common. But at least some of these bryophytes also have inducible desiccation tolerance. Some use an **escape strategy** of desiccation-tolerant gemmae, spores, and protonemata that help these bryophytes succeed in habitats with extensive dry periods. Nitrite and nitrate reductase both seem to be involved in

recovery, but more research is needed to determine the mechanisms involved. Leaf rolling and papillae seem to provide a protective role, perhaps by reducing light damage of dry cells and facilitating water uptake, but their role in water retention remains to be demonstrated. Compact growth form is also important.

Flood plains have extremes of habitat and require special strategies to weather these. Many of the bryophytes adapted to these extremes are species of the thallose liverwort *Riccia*. This genus is able to go dormant when it is dry with a variety of strategies, including rolling the thallus, surviving as tubers, having hairs on the surface. Some have small thalli with short life cycles; others have thick thalli that survive the desiccation.

In the Arctic and Antarctic, frost can be a desiccant. Water height above permafrost determines existence of fens, where bryophytes are emergent, and marshes exist where the water table is high above the bryophyte surface. Arctic bryophytes suffer from exposure that creates desiccating conditions. Aspect and angle of slope play important roles in speed and frequency of drying. Acrocarpous mosses do better in areas of light snow cover, whereas pleurocarpous mosses suffer less apical damage from heavy snow. In the Antarctic, the longer the dry period, the lower the subsequent photosynthetic rate, especially among hydrophytic species.

On the forest floor, bryophytes may sequester all the water from a brief rainfall (1-2 cm). In the dry summer, bryophytes may derive moisture from the soil during the cooling temperatures.

Temperate epiphytes may take advantage of cooler temperatures of winter for maximum growth.

In the tropics, carbon balance can, as in the desert, be a problem. When the mosses are hydrated at higher temperatures, respiration loss exceeds photosynthetic gain. This is generally not a problem at higher altitudes in the cloud forests; bryophytes are abundant on nearly every substrate there. Physiology is poorly known for tropical bryophytes, but it appears that they have similar adaptations to those of other locales with similar moisture conditions such as thick costa and thick cell walls. Some (*Leucophanes*) have leaf-tip gemmae that germinate and layer the colony, making a thick turf.

Acknowledgments

This chapter benefitted from Beth Scafone and Medora Burke-Scoll, who offered helpful comments on the text. Jean Faubert provided helpful comments and suggestions.

CHAPTER 7-9

WATER RELATIONS: WINTER PHYSIOLOGY

Figure 1. *Racomitrium heterostichum* encased in ice. Photo by Michael Lüth, with permission.

Freezing tolerance must necessarily be coupled with drought tolerance and therefore this chapter would be incomplete without a discussion of winter effects. While other plants are dormant and have either lost their leaves, died back to ground level, or adapted in other ways to prevent damage from heavy snow and loss of water due to ice crystals, many bryophytes remain exposed, ready to have photosynthesis whenever light, water, and temperatures permit (Figure 1). Here we will examine the conditions related to their winter water relations. Temperature relations will be covered in a different chapter.

Problems in Winter

Bryophytes do have problems to deal with in winter. These include damage to their DNA and photosynthetic tissue (chlorophyll) from the UV light, temperature stress, cellular freezing and structural damage, and desiccation damage due to ice crystals. Alberdi *et al.* (2002) consider

that adaptations to cold include high resistance to light stress, high freezing resistance, and high photosynthetic capacity at low temperatures. To this list I must add the ability to regain hydration quickly upon thawing. Most of these topics will be discussed elsewhere in chapters that deal with that particular physiological parameter. This chapter will examine the winter water relations.

The all-important water, whether as fog or rain or dew, is suddenly no longer liquid, but solid. Not only does this present problems for obtaining water, but it also means that hygroscopic ice crystals can draw water from the bryophyte cells.

But not all bryophytes suffer from the problem of ice damage. The thallose liverwort *Ricciocarpus natans* (Figure 2-Figure 4) can spend the winter encased in ice and can tolerate temperatures to -30°C (Frahm 2006). Frahm suggested that it was able to survive this frozen condition because it has no water vacuoles, thus providing no free internal water to form crystals that could destroy its

membranes. Rod Seppelt (Bryonet discussion 14 November 1997) also noted an absence of vacuoles in Antarctic mosses. Both *Ricciocarpos natans* and *Riccia fluitans* (Figure 5-Figure 6) are common in Arctic streams, so we might expect them to have this absence of vacuoles. I find it interesting that no one seems to have reported either presence or absence of vacuoles in *R. natans* (based on literature search and question posed on Bryonet in April 2015). Rather, lipids and starch bodies may help in their winter tolerance (Rod Seppelt, Bryonet discussion 14 November 1997).

Frost Damage

Those venues of green in the spring attest to the survival of bryophytes through the winter, subjected to frost before snow cover arrives and subsisting at near 0°C under the snow. But few studies give us specifics on what species survive and which ones are damaged.

Fletcher (1982) had the opportunity to document the frost responses of a number of species in cultivation. Among the winter survivors, reaching temperatures as low as -3°C, are species from New Zealand [*Papillaria crocea* (Figure 7), *Hypopterygium* spp. (Figure 8), *Rhizogonium bifarium* (see Figure 9), *Cyathophorum bulbosum* (Figure 10), *Eriopus brownii*], South Africa [*Hypopterygium* sp.], Australia [*Gigaspermum repens* (Figure 11), *Goniomitrium acuminatum* subsp. *enerve* (= *Goniobryum enerve*; Figure 12)], and Florida, USA [*Rhizogonium spiniforme* (Figure 13)]. Even the delicate-looking *Takakia lepidozoides* (Figure 14-Figure 15) remains healthy. As we might expect, the widespread mosses *Sphagnum* spp. (Figure 16) and *Mnium* spp. [probably *Plagiomnium* since no *Mnium* species are present in New Zealand (NZOR 2015); Figure 17] survive the frost. On the other hand, *Haplomitrium hookeri* (Figure 18) from New Zealand and *H. mnioides* (Figure 19) from Japan had no healthy plants remaining after an exposure to -3°C, despite their ability to survive and grow in the winters in their native habitats.

Figure 19. *Haplomitrium mnioides*, a liverwort that is sensitive to freezing in the lab but survives it in the field. Photo by Li Zhang, with permission.

Experiences with freezing in *Plagiomnium undulatum* (Figure 20) may help us to understand some of these differential responses (Hudson & Brustkern 1965). If this moss is cooled slowly, it experiences extracellular freezing;

this prevents the intracellular freezing that could be fatal. Following that experience, the leaves can be cooled down to -30°C without injury. The slow freezing prevents the formation of extensive extracellular ice. Young shoots, however, cannot withstand temperatures below -12°C .

Figure 20. *Plagiomnium undulatum*, a moss that uses extracellular freezing to prevent intracellular crystal formation. Photo by Michael Lüth, with permission.

Among the thallose liverworts, *Lunularia* (Figure 21), *Pellia* (Figure 22), *Preissia* (Figure 23-Figure 24), *Riccardia* (Figure 25), *Riccia* (Figure 26), and *Marchantia polymorpha* (Figure 27), all survive frost (Fletcher 1982) and remain healthy. On the other hand, the thallose liverworts *Moerckia blyttii* (Figure 28-Figure 29), *Symphogyna* sp. (Figure 30), *Corsinia coreandra* (Figure 31-Figure 32), and *Asterella* (Figure 33) all can become severely bleached when subjected to frost. *Dumortiera hirsuta* (Figure 34-Figure 35) doesn't die, but it becomes blackened. Similarly, *Fossombronia* (Figure 36) and *Anthocerotophyta* experience decay, but for them the decay is a normal winter occurrence; growth resumes in the spring. In the greenhouse, which reaches -5.5°C , *Asterella* and *Monoclea forsteri* (Figure 37) are blackened by frost, whereas *Marchantia* spp, *Dumortiera hirsuta*, *Anthoceros punctatus* (Figure 38), and *Phaeoceros laevis* (Figure 39) remain healthy in the same greenhouse.

Figure 39. *Phaeoceros laevis* with capsules, a species that remains healthy to -5.5°C . Photo by Michael Lüth, with permission.

Corsinia coreandra (Figure 31-Figure 32) is a puzzle. It is a xerophyte, but in cultivation frost causes it to become bleached (Fletcher 1982). At the same time in the same garden as the cultivation containers, it remains healthy on an exposed wall top and likewise remains healthy in the greenhouse that goes down to -5.5°C .

Much of what we know about cold tolerance has come from Antarctic studies. The Antarctic continent has only

2% of its land free from ice (Seppelt & Ochrya 2008). These areas are dominated by bryophytes (24 species of mosses; 1 liverwort), lichens, and algae.

We have learned that macromolecular substances (ice-active substances or IASs) can modify the shape of the growing ice crystals (Raymond & Fritsen 2001). These semipurified substances from *Bryum* sp. (Figure 40) from the Antarctic contain both protein and carbohydrate. The substances lose most of their recrystallization ability by heat treatment. Raymond and Fritsen suggest that these substances might increase freezing tolerance by preventing ice recrystallization.

Figure 40. *Bryum pseudotriquetrum* in Antarctica, a species in which protein and carbohydrate might increase freezing tolerance by preventing ice recrystallization. Photo by Catherine Beard, with permission.

Some bryophytes thrive in habitats where they regularly get exposed to sub-zero temperatures. *Bryoxiphium norvegicum* (Figure 41) is such a species (Shirasaki 1984). In Japan, *B. norvegicum* subsp. *japonicum* lives in an altitudinal range of 80-2350 m, being most abundant in districts where deep snow covers the ground for a long period. But it does not grow where the snow is, but rather grows on the vertical sides of overhanging rocks in ravines. Hence, it survives winter without the protection of snow, but it is sheltered by the rocks from the cold, desiccating winds.

Figure 41. *Bryoxiphium norvegicum*, a species that grows on vertical surfaces where it is exposed to sub-zero temperatures without snow cover in winter. Photo by Bob Klips, with permission.

Ice Crystals

Ice crystals can cause plant tissues to dry out. Ice crystals are very hygroscopic and thus their presence can result in water being drawn out of tissues. But they also gather water from the atmosphere. Moffett *et al.* (2009) suggest that these ice crystals can sequester water that becomes available when they melt. Because bryophytes are able to absorb water through their leaves, this water can be immediately available and provide rapid rehydration.

Rod Seppelt (pers. comm. 7 April 2015) does not consider it to be unusual that *Ricciocarpos natans* (Figure 2-Figure 4) and *Riccia fluitans* (Figure 5) can be encased in ice or survive under a layer of snow. As he points out, temperatures within the ice are not typically very cold. As an example, he cites putting a pot of water 80 cm under the Alaskan snow overnight. The air temperature that night dipped to -22°C, but the pot of water remained unfrozen.

Of course dehydration caused by freezing can have other consequences. Dependence on the symbiont *Nostoc* is interrupted and nitrogen fixation is significantly reduced in winter due to dehydration resulting from freezing in the epiphytic leafy liverwort *Porella* (Figure 42-Figure 43) in Oregon, USA (De Gezelle 2003).

Figure 42. *Porella cordeana* in one of its vertical habitats where the symbiotic Cyanobacterium *Nostoc* provides it with needed nitrogen. Photo by Michael Lüth, with permission.

Figure 43. *Porella cordeana* on a vertical substrate, a species that suffers in winter from diminished nitrogen fixation by its symbiont. Photo by Michael Lüth, with permission.

Desiccating Conditions

If you have ever gone out in early spring in areas where there is snow cover all winter, bryophytes provide a refreshing green cover on the newly emergent ground. This fresh green color requires the presence of water to rehydrate the tissues. But where does it come from?

In many temperate regions, spring brings rain, hence making rehydration an easy task. But in some regions, my own home in the Keweenaw Peninsula of Michigan included, snowmelt is followed by drought, and this is exacerbated along roads by the sand and salt that was used to provide traction for vehicles during winter ice and snow.

Nevertheless, in northern habitats, snowmelt can provide water for a considerable time. In the Cairngorm Mountains, Scotland, *Kiaeria starkei* (Figure 44) is immediately ready for photosynthetic activity when its own snow cover disappears (Woolgrove & Woodin 1996). It has just spent its winter at temperatures of 0°C to slightly above, but with no light penetration while the snow depth is greater than 50 cm. When the snow disappears from it, its tissue chlorophyll recovers rapidly to 250% of its winter low and within two weeks its carbohydrate concentrations increase by 60%. This moss has nitrate reductase activity and is able to take advantage of pollutant nitrate, accumulated by the snow, that becomes available as the snow melts.

Figure 44. *Kiaeria starkei*, a species that is ready to photosynthesize as it emerges from the snow. Photo by Michael Lüth, with permission.

One advantage for bryophytes is that they have a low temperature compensation point. Hence, snowbed bryophytes such as *Anthelia juratzkana* (Figure 45-Figure 47) and *Polytrichastrum sexangulare* (Figure 48-Figure 49) can maintain photosynthesis at low temperatures with a lower temperature compensation point of about -4 to -5°C. Furthermore, *A. juratzkana* can survive in the dark under cold, wet conditions for nine months with no effect on its photosynthetic capability. This makes *A. juratzkana* well adapted to grow in the border zone along permanent snow patches. However, the net photosynthesis is reduced due to an increase in respiration rate. *Polytrichastrum sexangulare*, on the other hand, does not tolerate this border regime as well as does *A. juratzkana*.

In tracheophytes, freezing can cause ice to form within cells, potentially causing membrane damage and subsequent loss of cell constituents. Lenne *et al.* (2010) write "A dehydrating moss gathers no ice." Using the widespread moss *Ceratodon purpureus* (Figure 50-Figure 51), they demonstrated that no ice accumulates in the cells during freezing. But external ice does induce desiccation. The effects of this desiccation depend on the cell type. Water-filled hydroid cells **cavitate** like tracheophyte xylem cells, becoming **embolized** (blocked, in this case by ice) at -4°C . Parenchyma cells of the inner cortex of the stem exhibit **cytorrhysis** (complete and irreversible collapse of a plant cell wall due to loss of water through osmosis), losing 20% of their original volume at -20°C **nadir temperature** (lowest temperature of a cycle). It is puzzling that chlorophyll fluorescence shows no evidence of damage after thawing from a -20°C event, especially since the sugar concentrations are insufficient to confer freeze tolerance in these conditions (see below). Furthermore, ice nucleation occurs in hydrated tissues at $\sim -12^{\circ}\text{C}$. The answer to this puzzle seems to lie in the desiccation itself. No damage occurs to those desiccated mosses at -20°C . The very desiccating nature of ice crystals appears to be the

mechanism that prepares the moss for the low temperatures.

Figure 50. *Ceratodon purpureus* in Antarctica, a species with small leaf cells that do not accumulate ice crystals in winter. Photo courtesy of Rod Seppelt.

Figure 51. *Ceratodon purpureus* with capsules, a species that gathers no internal ice. Photo by Ivanov, with permission.

This desiccation relationship is supported in the Antarctic moss *Polytrichum juniperinum* (Figure 52) wherein repeated freeze-thaw cycles cause a greater reduction in photosynthesis than constant freezing for the same time period (Kennedy 1993). This is much like the effect of repeated dehydration/rehydration that causes a net carbon loss. This is supported by the observation that freeze-thaw cycles every 12 hours cause more damage than those every 24 or 48 hours. Most of the damage occurs during the first cycle with little occurring during subsequent cycles. Kennedy found that at 10°C the gross CO_2 flux is directly proportional to moss water content between 0.3 and 3.5 g g^{-1} dry mass. Mosses with a low water content withstand freeze-thaw cycles to sub-zero temperatures better than do samples with a high water content. Kennedy suggests that on Signy Island in the Antarctic the populations of *Polytrichum juniperinum* may be limited in distribution by sub-zero temperatures and freeze-thaw cycles at times when snow cover is insufficient to provide insulation.

Figure 52. *Polytrichum juniperinum*, a moss that is damaged by freeze-thaw cycles when snow cover does not provide insulation. Photo by Jan-Peter Frahm, with permission.

Davey (1997) examined Antarctic bryophytes and demonstrated the importance of water. The photosynthetic rate decreased as the length of the dehydration period increased in all bryophytes examined. The photosynthetic capacity is affected by stress, and Davey found that both desiccation and winter freezing caused a loss of photosynthetic capacity. But the base level of photosynthetic capacity is able to survive both. Furthermore, frequent dehydration and rehydration cycles cause a loss of photosynthetic rate that is greater than that in continuous dehydration. Davey hypothesized that water availability is an important contributor to the distribution of bryophytes in the Antarctic, where winter-like weather can occur on almost any day of the year.

Barker *et al.* (2005) found bleaching in *Syntrichia caninervis* (Figure 53) during winter in the Mojave Desert, USA. They attributed this loss of green color to frequent rain events during warmer months that year, citing appearance of chlorosis just after that. This is consistent with the effects of frequent dehydration-rehydration events seen by Davey (1997). Under this regime, particularly for short, light rainfall events, the plants do not have enough time to repair membranes before they become dehydrated again, thus losing energy with each mild rainfall event. This leaves them with diminished color for the winter, a condition hopefully to be repaired in the spring.

Figure 53. *Syntrichia caninervis*, a desert species that suffers from too much rain in winter by losing its green color. Photo by Michael Lüth, with permission.

Crossidium crassinervium (Figure 54), from the Mojave Desert, benefits from late winter rain because it permits the moss to dry slowly (several days), whereas in summer the moss dries in as little as 3 hours (Stark 2005). The winter months of October to April constitute the hydrated period for this species, with hydration periods lasting 3.7-4.9 days.

Figure 54. *Crossidium crassinervium*, a moss that benefits from late winter rains in the desert. Photo by Michael Lüth, with permission.

Desiccation Tolerance

Desiccation tolerance is seasonal, probably in most bryophytes. Only the moss *Andreaea rothii* (Figure 55-Figure 56) failed to show seasonal variation in net assimilation following 24 hours of remoistening, compared to clear seasonal differences in the leafy liverwort *Plagiochila spinulosa* (Figure 57-Figure 58) and mosses *Hylocomium splendens* (Figure 59), *Scorpiurium circinatum* (Figure 60), *Syntrichia ruralis* (Figure 61-Figure 62), and *Racomitrium aquaticum* (Figure 63-Figure 64) (Dilks & Proctor 1976). Those with seasonal variation usually had low desiccation tolerance in autumn and winter and greater tolerance in spring and summer. *Hylocomium splendens* differed in having relatively high tolerance in January (winter), with little change from then until July.

Burch (2003) noted that some mosses are able to survive **cryopreservation** (preservation at low temperatures) with no prior treatment. She suggested that

their natural desiccation tolerance already gave them adequate protection during cryopreservation. What is it about freezing that actually kills or damages the bryophytes? Crystals can damage the membranes, but isn't the real damage ultimately desiccation damage? For example, 90-100% of the protonemata of the desiccation-tolerant *Bryum rubens* (Figure 65) survived freezing, whereas only 30% of those encapsulated and 20% non-encapsulated *Ditrichum cornubicum* (Figure 66) protonemata, with limited desiccation tolerance, survived freezing. These two species each had slightly better survival numbers after 18 days of desiccation with no freezing. *Cyclodictyon laete-virens* (Figure 67), a desiccation-intolerant species, did not survive desiccation or freezing. In *D. cornubicum*, pretreatment with sucrose or ABA in the medium caused a reduction in growth rate of the protonemata, but these compounds resulted in a high level of protection against tissue damage in both dehydration and freezing – 100% regeneration of pretreated plants after thawing compared to 53% of controls (Burch & Wilkinson 2002). Sucrose plus ABA gave the best results.

Syntrichia ruralis (Figure 62) is one of the model organisms for studying desiccation tolerance. When subject to slow freezing at 3°C decrease in temperature per hour to -30°C, hydrated *Syntrichia ruralis* suffers only temporary metabolic changes, and these are reversible (Malek & Bewley 1978). Malek and Bewley attributed the changes to desiccation tolerance resulting from extracellular ice formation. When this same moss is subject to rapid freezing in liquid nitrogen and rapid thawing in 20°C water, all aspects of its metabolism deteriorate. Ribosomes, proteins, and ATP levels decrease and protein synthesis activity is rapidly lost. Malek and Bewley suggest that these problems are the result of intracellular ice crystals. Changing the freezing rate to 60°C per hour – a slower rate than in liquid N, but still a rapid rate – only reduces the levels of ATP and protein synthesis. The **polyribosomes** (protein-synthesizing apparatus) remain intact and active 24 hours after the freeze-thaw cycle. Segreto *et al.* (2010) reported that all species cryopreserved *in situ* regenerated mostly through budding; the number of regenerating samples correlates positively to desiccation tolerance and show higher frost tolerance than previously thought. Herbarium samples up to 7 years old of the most desiccation-tolerant species regenerate by protonemata; shoot tips regenerate better than small plant fragments.

Desiccation tolerance can be an **antagonistic** (one species benefits at the expense of another) interaction. *Sphagnum fuscum* (Figure 68) and *Dicranum elongatum* (Figure 69) dominate a subarctic mire (Sonesson *et al.* 2002). In winter, *Sphagnum fuscum* growth increased when *Dicranum elongatum* was its immediate neighbor, but *D. elongatum* grew better when it grew with other members of its own species. Neither increased temperature nor UV-B radiation affected these relationships, implying that moisture relations were probably important.

Ice-nucleating Proteins

Ice-nucleating proteins can help to create desiccating conditions and prevent cell freezing. These proteins are small structures that become surrounded by ice, but the water does not crystallize. The principle has been used by orange growers to prevent desiccation of the fruits during winter freezing events. Small nucleating bacteria are able

to accomplish desiccation protection by out-competing the larger nucleating bacteria. These small species are sprayed on oranges to protect them. Such proteins or bacteria form centers for ice formation on the outsides of cells, providing a protective covering (Zachariassen & Kristiansen 2000).

Clouds use nucleation centers to create their precipitation (Ahern *et al.* 2007). Bacteria have been known from clouds for a long time. Clouds may be an ideal habitat for these bacteria to live and thrive. Ahern and coworkers found 100 OTUs (operational taxonomic units – used when species cannot be named) among 256 clones from clouds. Half of these were identified as bacteria from **psychrophilic** terrestrial habitats (habitats where low-temperature-tolerant organisms can live). Among these bacteria, a mix of fluorescent *Pseudomonas* species dominate and some are known ice nucleators. But none of the cultures demonstrated the ice-nucleation gene. Rather, 55% of the isolates from cloud and rain samples had significant biosurfactant activity. **Surfactants** influence droplet size and are important in lowering the critical supersaturations necessary for activating aerosols into cloud condensation nuclei. Such bacteria facilitate water scavenging and counteract desiccation. Could they perform such functions in some bryophytes?

In *Sphagnum capillifolium* (Figure 70-Figure 71) the **chlorophyllous** (containing chlorophyll) cells exhibit extended freezing **cytorrhysis** immediately after ice nucleation at -1.1°C in water (Buchner & Neuner 2010). This cytorrhysis is exhibited as cell shrinkage that appears within only 2 seconds. And the shrinkage is significant – 82%, with chloroplast diameter reduction from 8.9 to 3.8 μm . This is accompanied by a sudden rise in chlorophyll fluorescence. On the other hand, frost damage occurs at a much lower temperature (LT50 at -16.1°C) (LT50 = median time until death after exposure of organism to toxic substance or stressful condition). The ice-nucleation temperature of -1.1°C is likewise the temperature threshold of PS II. Surprisingly, the LT50 for freezing in *S. capillifolium* is higher than that in most tracheophytes in the European Alps in the summer.

Atmospheric Source

One big question in this story is the source of the nucleating proteins. Until recently, bacteria seemed to be the only organic source of nucleating proteins (Möhler *et al.* 2008). But only a few bacteria, the pseudomonads, seem capable of this role (Lindow 1983; Ahern *et al.* 2007). This notion has been challenged by the research of Kieft and coworkers (Kieft 1988; Kieft & Ahmadian 1989; Kieft & Ruscetti 1990) and more recently by Moffett *et al.* (2009).

Bauer *et al.* (2002) supported their challenge and reported that both bacteria and fungal spores contribute to the organic content of cloud water. In fact, the fungal spores in clouds of the Austrian Alps contribute 1.5% of the organic content, whereas the bacteria contribute only 0.01%. Although Pouleur and coworkers did not discuss the roles of these groups in nucleation, their study (Pouleur *et al.* 1992) suggests that slime molds might also provide nucleating proteins.

Hyphomycetous fungi (*Fusarium* spp.; Figure 72) were also added to the list of organisms providing nucleating proteins to clouds (Pouleur *et al.* 1992). We also know that the fungal partner of at least some lichens contribute nucleating proteins (Kieft 1988; Kieft & Ahmadian 1989; Kieft & Ruscetti 1990) and that the *Fusarium* proteins are more similar to those of lichens than to those of bacteria (Pouleur *et al.* 1992).

Figure 72. *Fusarium* with macroconidia, a filamentous fungal genus that serves as an ice-nucleating center. Photo by Ninjatacoshell, through Creative Commons.

Despres *et al.* (2007) determined aerosol particles in the air by using DNA sequencing. They found that most of the bacteria were **Proteobacteria**, with some **Actinobacteria** and **Firmicutes**. Fungal DNA came from **Ascomycota** and **Basidiomycota**, most likely from spores. Two different DNA sequences came from moss spores.

Christner *et al.* (2008) reported that ice nucleators are widespread in snowfall and the most active ones are biological. Most of these are bacteria. Many of these nucleators, therefore, are likely to be added to the mosses during snowfall and may contribute their survival of low temperatures and winter desiccation.

Fukuta (1966) found that more than 20 organic compounds out of 329 were able to nucleate ice at temperatures $>-5^{\circ}\text{C}$. Hence, it is possible that even pollutants may contribute to nucleation of water on bryophytes.

Nucleating Proteins in Lichens

Our knowledge of lichens may help us to understand the nucleation relationship in bryophytes. Like bryophytes, lichens are able to survive year round and renew their photosynthetic activity when suitable temperatures and hydration resume. Perhaps the response of lichens can give us some insight into moss behavior relative to nucleation. Most of the **epilithic** (rock-dwelling) lichens (*Rhizoplaca*, *Xanthoparmelia*, and *Xanthoria*) tested by Kieft (1988) had ice nucleation at temperatures above -8°C , whereas their substrates showed negligible nucleation above that temperature. The nucleation activity in the lichen appears to be non-biological. No nucleation-active bacteria could be isolated, and the activity did not cease when the lichen was heated to 70°C or subjected to sonication. An axenic culture of the fungal part of the lichen *Rhizoplaca chryssoleuca* showed nucleation activity at -1.9°C . Kieft hypothesized that these frost-tolerant lichens benefit from increased moisture deposition that results from ice nucleation.

Henderson-Begg *et al.* (2009) remind us that for water to freeze above -36.5°C requires the activity of an ice nucleator. Bacteria are the best known of these, inducing freezing at temperatures up to -1.8°C , but seem to be of little importance in the lichens. The nucleators are common in lichens and can become airborne. Many of these are non-bacterial, but are biological, probably fungal and lichen.

There are several studies that support the presence of lichen fragments in the atmosphere (Tormo *et al.* 2001; Ahern *et al.* 2007). Marshall (1996) demonstrated that lichen **soredia** (asexual reproductive structures) were the most abundant of the airborne propagules of lichens, with peaks occurring after the winter snowmelt while subzero temperatures continued.

Kieft and Ahmadjian (1989) found that of 14 species of **mycobionts** (fungal partners) in lichens, five have nuclei active at -5°C . However none of the 13 photobionts (algae & Cyanobacteria) have ice-nucleating activity at -5°C or warmer. Hence, the ice-nucleating nuclei are produced by the fungal partner of the lichen. Kieft and Ahmadjian suggested that these ice-nucleating proteins are involved in moisture uptake and frost protection.

Kieft and Ruscelli (1990) found that biological ice nuclei in the lichen *Rhizoplaca chryssoleuca* were active at $\sim 4^{\circ}\text{C}$. Their sensitivity to various substances indicated that they were proteinaceous, and they were relatively heat stable and active without lipids, demonstrating that they were significantly different from bacterial ice nuclei.

Nucleating Proteins as a Source of Water

Lindow (1983) found that ice-nucleation activity occurs primarily in the outer membrane of the cells of *Pseudomonas syringae* and *Escherichia coli* into which it has been inserted.. It does not occur in soluble components of these cells. The ability of the ice-nucleating bacteria to operate depends on incubation temperature, growth medium composition, culture age, and genotype (Lindow *et al.* 1982). Their optimum conditions for nucleation in culture occur on nutrient agar containing glycerol at $20-24^{\circ}\text{C}$. Their ability to mitigate ice injury on corn seedlings depends on the bacterial population size and the number of ice nuclei active at that temperature.

Compounds for Winter?

Bryophytes produce record numbers of secondary compounds. These are best known for their antibiotic effects, but they can also play a role in both drought tolerance and freezing survival (Xie & Lou 2009). Among these, **bibenzyls** and **bis(bibenzyls)** have desiccation tolerance activity; **phenylpropanoids** have freeze tolerance activity. But the nature of these activities is unknown.

We know from several studies that the proportions of various fatty acids change with temperature (Saruwatari *et al.* 1999). Among these, linolenic acid and eicosapentaenoic acid might increase freezing-tolerance, as suggested by *Marchantia polymorpha* (Figure 27). Xie and Lou (2009) likewise reported the freeze tolerance activity of fatty acid derivatives in bryophytes.

Sugars

Sugar concentrations have a role in frost tolerance. **Sucrose** can increase the ability of bryophytes to tolerate rapid drying (Stark & Brinda 2015). Among the bryophytes tested by Rütten and Santarius (1992), only *Mnium hornum* (Figure 73-Figure 74) among seven **Bryidae** and one of **Marchantiidae** lack an increase in sucrose concentration concomitant with an increase in frost hardiness. Insignificant changes in **glucose** and **fructose** contents accompany these frost hardiness events.

Figure 73. *Mnium hornum* forest floor habitat. Photo by Michael Lüth, with permission.

Brachythecium rutabulum (Figure 75-Figure 76) and *Hypnum cupressiforme* (Figure 77-Figure 78) have high sucrose concentrations in summer, similar to those of other species in winter, and thus are frost tolerant even in summer (Stark & Brinda 2015). Those mosses that are highly frost-resistant have a total sugar concentration of $\sim 90-140$ mM. Of this sugar, 80-90% is sucrose. Artificial degradation of the sucrose during higher temperatures causes a decline in cold hardiness, supporting the hypothesis that it is important in frost hardiness in these species.

Figure 78. *Hypnum cupressiforme*, a species with high sucrose content and high frost tolerance, even in summer. Photo by Michael Lüth, with permission.

Some species [*Polytrichastrum formosum* (Figure 79-Figure 81), *Atrichum undulatum* (Figure 82), *Plagiomnium affine* (Figure 83-Figure 84), *Mnium hornum* (Figure 73-Figure 74), *Pellia epiphylla* (Figure 85-Figure 86)] exhibit a distinct increase in cold tolerance from summer to winter (Rütten & Santarius 1992). Mosses have significant differences in frost resistance between summer and winter (15->25°C), but the thallose liverwort *Pellia epiphylla* experiences relatively little winter hardening capacity.

Melick and Seppelt (1994) suggest that the lack of significant changes in soluble carbohydrates in Antarctic bryophytes may result from the extreme climate and the rapid temperature fluctuations during the growing season. On the other hand, maximum water content is present in the summer. Chlorophyll levels decrease in winter in both total chlorophyll and the chlorophyll *a:b* ratio, as do the total carotenoids. This decrease may be a response to low light levels that are insufficient for making more pigment.

Using the *Physcomitrella patens* (Figure 87) protonema as a model organism, Nagao *et al.* (2003, 2005) concluded that ABA-induced soluble sugars play a role in freezing tolerance. The accumulation of the sugars, at the expense of starches, is associated with morphological changes in the organelles and reduce freezing-induced structural damage to the plasma membrane, while the freezing tolerance of the protonemal cells increases. Nagao *et al.* (2006) identified the sugar as **theandrose**, a sucrose that occurs in close association with ABA treatment that enhances freezing tolerance. **Cycloheximide** inhibits the accumulation of theandrose, resulting in a marked decrease in freezing tolerance. The accumulation of theandrose is promoted during cold acclimation and treatment with hyperosmotic solutes, both of which increase cellular freezing tolerance.

Figure 87. *Physcomitrella patens*, a moss that stores the sugar **theandrose** in preparation for winter. Photo by Michael Lüth, with permission.

Using the bryological lab rat *Physcomitrella patens* (Figure 87), Oldenhof *et al.* (2006) demonstrated that sucrose helps to protect cells during freezing and drying, but accumulation of sucrose alone is not sufficient for survival. ABA serves to cause this sucrose accumulation, up to 22% of dry weight, but only 3.7% occurs in non-ABA-treated tissues. A combination of ABA treatment and the cryoprotectant DMSO permit the tissues to survive a freeze-thaw cycle down to -80°C . DMSO-mediated changes involved in the membranes are important and may be relevant to the essential desiccation tolerance.

Polyols may contribute to cold hardiness as well. Tearle (1987) found that Antarctic lichens contained up to three times the amount of polyols when compared to temperate lichens, endowing them with extra freezing protection. The soluble sugars and polyols from mosses and lichens leach into the fellfield soils in the spring.

ABA

ABA is the stress hormone, and it plays a role in freezing tolerance of plants as well (Minami *et al.* 2003; Takezawa *et al.* 2011). Nevertheless, slow freezing of the protonemata of *Physcomitrella patens* to -4°C under normal growth conditions kills more than 90% of the cells. Application of ABA for 24 hours causes a marked increase in the freezing tolerance (see also Nagao *et al.* 2001, 2005, 2006). Cold treatment only slightly increases the freezing tolerance within the same period. Treatment with ABA causes a marked increase in expression of all the PPAR genes within 24 hours. Several of these genes also respond to cold, but much more slowly than they respond to ABA. Treatment with hyper-osmotic concentrations of NaCl and mannitol also increases the expression levels of eleven PPAR genes and the freezing tolerance of the protonemata. Minami and coworkers (2003) suggest that these relationships indicate that stresses increase the expression of genes that result in protection of the protonemata, but the nature of that relationship is unclear.

Nevertheless, in *Physcomitrella patens* (Figure 87) protonemata, as in tracheophytes, freezing tolerance increases following incubation at low temperatures in the range of $0-10^{\circ}\text{C}$, indicating the importance of acclimation (Minami *et al.* 2005). This tolerance is accompanied by an accumulation of several transcripts for **late-embryogenesis-abundant (LEA)** proteins and boiling-soluble proteins. De-acclimation causes reduction in expression of these proteins and loss of freezing tolerance. But surprisingly, unlike events in tracheophytes, in *P. patens* low-temperature-induced freezing tolerance does not coincide with an increase in endogenous ABA, despite increases in expression of stress-related genes. In short, the acclimation is somewhat different from that of tracheophytes.

These observations are further confounded by the experiments of Minami *et al.* (2003) on *Physcomitrella patens* (Figure 87). They found that treatment with ABA for 24 hours greatly increases the freezing tolerance of the protonemata; cold treatment alone has only a slight effect on freezing tolerance. Even slow freezing to -4°C kills more than 90% of the cells. On the other hand, hyperosmotic concentrations of NaCl and mannitol increase freezing tolerance of protonemata.

At the same time, research by Takezawa and Minami (2004) identified genes coding for membrane transporter-like proteins. These newly identified proteins increase considerably following treatment with low temperatures, hyperosmotic solutes, or ABA. These genes are regulated by calmodulin.

Arachidonic Acid

Prins (1982) suggested that one reason small mammals eat mosses in winter is the content of **arachidonic acids**. These fatty acids make membranes more pliable and may make it easier for these rodents to run around on frozen ground and snow. But what do these do for bryophytes in winter? Does this extra flexibility also make it easier for them to survive? One protection against freezing is the ability to lose water, avoiding crystal formation that could damage membranes and organelles. With flexible membranes and withdrawal of water, the cells could shrink within the walls during the cold (and dry) period.

In *Physcomitrella patens* (Figure 87), production of arachidonic acid increases with higher concentrations of sugar (Chodok *et al.* 2010). Al-Hasan (1989) found that in *Bryum bicolor* (Figure 88) more arachidonic acid is produced at 5°C than at 25°C. Both of these studies support the production of arachidonic acid as winter approaches.

Figure 88. *Bryum bicolor*, a species that produces more arachidonic acid at low temperatures than in warm ones. Photo by Michael Lüth, with permission.

Polyribosomes

Polyribosomes (cluster of ribosomes connected by a strand of messenger RNA and active in protein synthesis) respond to cooling temperatures. In the xerophytic moss *Syntrichia ruralis* (Figure 61-Figure 62), when temperatures descend to 2°C an accumulation of polyribosomes occurs while the single ribosomes decrease (Malek & Bewley 1978). This change in numbers reflects rearrangement, but does not involve a change in the number of ribosomal units. Slowly dried *S. ruralis* does not contain any polyribosomes when rehydrated, but these reform at 2, 8, and 20°C. Leucine rapidly incorporates into the protein when the plants are rehydrated at 20°C, but its incorporation is less dramatic at 2°C. Cold-hardened *S. ruralis* has no changes in the rate of protein synthesis at

low temperatures (2°C). In fact, even in summer this species can carry out protein synthesis at low temperatures.

Summary

One of the dangers of frost damage is desiccation. Ice crystals on the inside of cells damage membranes and those on the outside pull water from the cells. Some bryophytes are protected by being encased in ice, preventing the formation of crystals and insulating against severe cold. Absence of vacuoles or having only small vacuoles can help to protect the interior of cells.

Many species survive winter and are ready for photosynthesis when the snow disappears, using the snowmelt water to rehydrate their tissues. Slow cooling, like slow drying may be important in survival. Extracellular freezing can protect against intracellular freezing. Some macromolecular substances can modify the shape of ice crystals in ways that do not damage the cells. Some ice-nucleating structures, made by the plants or available from the atmosphere, including proteins, create a small crystalline structure likewise protecting against damage from larger crystals. On the other hand, some ice crystals on the outsides of the cells can sequester water that is available at suitable temperatures. Desiccation can protect the cells by preventing crystal formation. Cell shrinkage helps to prevent crystal formation. Frequent freeze-thaw cycles, like dehydration-rehydration cycles, can damage the cells if the hydration and photosynthetic period is insufficient to repair membranes and accomplish a carbon gain.

Polyribosomes are active immediately following the freeze-thaw cycle. Lipids, starch bodies, sucrose, ABA, bibenzyls, bis(bibenzyls), and phenylpropanoids help to increase freezing and desiccation tolerance. Arachidonic acid helps to make membranes more pliable. These compounds permit some bryophytes to have seasonal tolerance. In desert habitats winter is often the best growing season because mosses remain hydrated for several days following rainfall events.

Some species become bleached from frost damage, but shoot tips and other parts may remain healthy and provide new growth in spring.

Acknowledgments

Thank you to Niels Klazenga, Marshall Crosby, and Pina Milne for helping me track down the current nomenclature for *Goniobryum enerve*. And of course a big thank you to all who have given me permission to use their images.

CHAPTER 7-10

WATER RELATIONS: SNOW ECOLOGY

Figure 1. Late snowbeds in an alpine habitat in the Khibiny Mountains, Russia. *Bucklandiella microcarpum* is in the foreground. Photo by Michael Lüth, with permission.

Snow Effects

Snow can contribute in multiple ways to enhance the productivity. We know little about productivity of bryophytes under snow. What we do know is that light can penetrate snow, but that the light quality is altered. We know that snowmelt provides moisture, and that this melt can occur while the snow pack is still present, even in the middle of winter. We know that the snow can buffer the temperature, maintaining it close to 0°C. Dorrepall *et al.* (2004) demonstrated that *Sphagnum fuscum* (Figure 2) experienced an enhancement of 33% in productivity as a result of winter snow addition, while, nevertheless, not increasing growth in length.

Even in areas with considerable snow, bare areas exist, often as a result of winds that clear the snow. Some of these surfaces are rock surfaces that protrude, making them vulnerable to those wind movements of the snow (John 1990). One moss species capable of living in such exposed areas is *Grimmia longirostris* (Figure 3) in the Canadian Rocky Mountains.

Figure 2. *Sphagnum fuscum*, a moss that experiences greater productivity as a result of winter snow. Photo by Julita Kluša <daba.dziedava.lv>, with online permission.

Figure 3. *Grimmia longirostris*, a species of exposed areas. Photo by Michael Lüth, with permission.

I have long suspected that at least some bryophytes are able to carry out photosynthesis under snow as long as it is not too deep for sufficient light penetration. Pannowitz *et al.* (2003) demonstrate that photosynthesis under the snow occurs in lichens. The snow cover provides effective insulation against the bitter cold of the Antarctic atmosphere, protecting both the mosses and the lichens. But in spring, this insulation proves to be detrimental. It retains the severe cold of winter and prevents the bryophytes from benefitting from the early warming of the air. This delay can last 10-14 days. Furthermore, the hydration provided to the lichens by the snow lasts only briefly once the snow disappears, providing only a brief period for photosynthetic activity. Is this same shortening of the photosynthetic period in effect for bryophytes, or are they able to retain the water longer?

In our study of the bryophytes on trees in the Keweenaw Peninsula of Michigan, USA, we found that those about 1 m above the ground were most common on the south sides of the trees (Trynoski & Glime 1982). We attributed this to a combination of winds from the north and sufficient light and moisture for these bryophytes to have photosynthesis in winter. Trees always have a narrow funnel of space between them and the snow (Figure 4). In this area where snow on the ground reaches a meter or more depth, the snow is an insulator. Dark-colored bark is able to absorb heat and the funnel remains somewhat humid. Light is able to penetrate. I have no measurements of growth or photosynthetic activity for these epiphytes – that needs to be done.

Figure 4. Snow-covered forest showing space between snow and tree trunk. Photo by Janice Glime.

Snow can affect the distribution of species. For example, in Japan *Bazzania trilobata* (Figure 5-Figure 7) grows on ground that is well drained all year and is typically sunny (Shirasaki 1987). *Bazzania yoshinagana* (Figure 8), on the other hand, grows on the forest floor in densely shaded coniferous forests. It spends its winter covered with deep snow that insulates it from freezing and provides it with moisture.

Snowbed Communities

"Areas which experience prolonged snowlie and possess a distinctive bryophyte-dominated vegetation are termed snowbeds" (Woolgrave & Woodin 1996). Snowbeds (Figure 9) create their own unique characters. They shorten the growing season but can extend the period of hydration. Some bryophytes are dependent on these sources of hydration. On the Antarctic peninsulas the snow cover and site exposure seem to define the plant distribution (Melick *et al.* 1994).

Figure 9. Late snowbed at Bjoerndalen, Spitzbergen. Photo by Michael Lüth, with permission.

Snowbeds form in crevices and depressions in alpine regions (Figure 9). These are among the last areas to lose their snow, often near the end of the growing season. Nevertheless, some species grow only in these areas (Björk & Molau 2007). One such species that indicates a location with late snowbeds is the liverwort *Anthelia* (Figure 10), a genus whose fossils also indicate areas of late-lying snow in the late-Pleistocene landscape (Miller 1989). These snowbeds provide both a steady water supply and a steady nutrient supply to the adjacent plant communities. Because of this dependence, these communities are particularly vulnerable to climate warming.

Figure 10. *Anthelia juratzkana*, an indicator of late snowbeds. Photo by Hermann Schachner, through Creative Commons.

Many of the alpine bryophytes display adaptations that make their snowbed habitats tenable. *Andreaea nivalis* (Figure 11-Figure 12) is a reddish moss that hangs where snow water glides over the rocks and cliffs (Bailey 1933). Even its name (*nivalis*) means snow-covered. *Brachymenium erectum* (Figure 13) grows in snow water in alpine areas and disintegrates so rapidly after maturity that it is easy to miss it altogether. *Pohlia ludwigii* (Figure 14-Figure 15) lives in or near snow water. *Pohlia filum* (Figure 16) grows in snow water on the south side of Mount Rainier, Washington, USA, and produces brood bodies (Figure 17) in the snow water. *Polytrichastrum sexangulare* (Figure 18-Figure 20) likewise lives near the snow. Its setae begin to elongate before the snow is completely gone and as a result they become trailing and twisted (Figure 20). *Bryum muehlenbeckii* (Figure 21) has deep red leaves and stems, probably protecting it from UV radiation, and possibly increasing its temperature in its cold habitat near the snowbeds. *Pohlia wahlenbergii* var. *glacialis* (Figure 22-Figure 23), by contrast, has whitish leaves. On Mt. Rainier it covers large expanses that are wet with snow water. *Meiotrichum lyallii* (Figure 24) becomes visible at high elevations as soon as the snow disappears and is common on the higher slopes of Mt. Rainier. All of these bryophytes are acrocarpous mosses. Only *Isopterygiopsis pulchella* (Figure 25) is a pleurocarpous snow lover associated with these snowbeds. In all cases, it is likely that these bryophytes are non-competitors with tracheophytes and that take advantage of their C_3 photosynthesis to grow in the cold temperatures when adequate moisture is available.

In Scotland, some of these same species are dependent on the snowbeds (Rothero 2007). These include *Andreaea nivalis* (Figure 11-Figure 12), *Polytrichum sexangulare* (Figure 18-Figure 20), *Kiaeria falcata* (Figure 26-Figure 27), *Anthelia juratzkana* (Figure 10), and *Pohlia ludwigii* (Figure 14-Figure 15). Additionally, snowbeds in the UK are habitats for *Racomitrium heterostichum* (Figure 28), *Marsupella brevissima* (Figure 29-Figure 30), *Kiaeria starkei* (Figure 31), *Moerckia blyttii* (Figure 32), *Pleurocladula albescens* (Figure 33-Figure 34), *Marsupella arctica*, and *Marsupella condensata* (Figure 35). The flushes and mires resulting from melting snowbeds also support growths of *Pohlia wahlenbergii* var. *glacialis* (Figure 22-Figure 23), *Scapania paludosa* (Figure 36), and occasionally *Sphagnum riparium* (Figure 37) and *S. lindbergii* (Figure 38-Figure 39).

In snowbeds, more than 40% of the cover is often comprised of bryophytes (Jägerbrand 2011). This may be as little as 3% of the exposed area during early melt to 80% in the late-melting areas. Björk (2007) found 26 species that grow mostly in snowbeds, 13 of which are found only in those areas. In a late snowbed in western Newfoundland, Canada, Belland (1983) found some of the same species associations as named above for the UK. In particular, *Andreaea nivalis* (Figure 11-Figure 12) was common in late snowbeds. Belland found 49 bryophyte species in the eight late snowbeds he investigated. Other dominant species included *Kiaeria falcata* (Figure 26-Figure 27), *Moerckia blyttii* (Figure 32), and a species of *Trematodon* (Figure 40). The uniqueness of this habitat is demonstrated by the disjunct distribution for 13 of these species between western and eastern North America. Eleven of the species are characteristic of snowbed habitats throughout most of the world.

Figure 40. *Trematodon longicollis*, in a genus represented in snowbeds in Newfoundland, Canada. Photo by Michael Lüth, with permission.

The unique combination of temperature regime and moisture support some of the rare species of the world. On Mt. Washington, New Hampshire, USA, Slack *et al.* (2013) found *Haplomitrium hookeri* (Figure 41), *Aulacomnium turgidum* (Figure 42-Figure 44), *Dicranum elongatum* (Figure 43), and *Pseudocalliergon trifarium* (Figure 45) – all rare species in the northeastern USA.

Growth Form Variability

Snowbeds can create unusual growth forms. For example, in the high Arctic of Spitsbergen, the fellfield type of *Sanionia uncinata* (Figure 46-Figure 48) had few branchless shoots and formed dense colonies, leading to better desiccation avoidance (Ueno *et al.* 2001). The snowbed type had many branchless shoots and more sparse colonies. Furthermore, there were fewer branches in the upper part of the shoot than in the lower part in the snowbeds. Was this a response to the snow, possibly damaging branch buds, or was the more dense branching in the fellfield an adaptation selected to permit survival in the drier climate there?

Figure 48. *Sanionia uncinata* with capsules and showing pinnate growth form. Photo by Michael Lüth, with permission.

The multiple growth forms of some species in the Antarctic seem to be a response to submersion (Seppelt & Selkirk 1984). For example, *Bryum pseudotriquetrum* (Figure 49-Figure 50) was originally named as *Bryum algens* there due to its different growth form. *Calliergon sarmentosum* (Figure 51-Figure 52) assumes a different morphology when shoots develop under water or in damp conditions (Priddle 1979). *Bryum argenteum* (Figure 53-Figure 54) in the Antarctic assumes longer and narrower leaves with increased cell size in etiolated shoots (Longton 1981; Seppelt & Selkirk 1984), perhaps due to submersion,

or possibly due to growth in the reduced light under snow. *Ceratodon purpureus* (Figure 55-Figure 60) lives in shallow lakes in the Antarctic and was originally known as *Ceratodon minutifolius* there, differing in leaf shape and leaf apex (Horikawa & Ando 1963; Seppelt & Selkirk 1984).

Duration of Snowbeds

The duration of the snowbeds separates communities in Scotland (Woolgrove & Woodin 1994). Prolonged

snowlie has negative effects on the *Marsupella-Anthelia* community (Figure 29-Figure 30, Figure 35; Figure 10). On the other hand, the *Polytrichum-Kiaeria* (Figure 18-Figure 20; Figure 26-Figure 27) community is positively affected by its prolongation. *Pohlia* (Figure 14-Figure 16, Figure 22-Figure 23) seems less affected by the duration, but the substrate moisture content is important for it.

Snowmelt

Kaiser (1921) describes his "journey into mossland" during a February thaw in Pennsylvania, USA. So many mosses appeared, bright green, and ready to grow. These winter survivors, especially along streambanks, included *Plagiomnium cuspidatum* (Figure 61-Figure 62), *Leucobryum glaucum* (Figure 63-Figure 67), *Bryoandersonia illecebra* (Figure 68-Figure 69), *Dicranum scoparium* (Figure 70-Figure 71), *Plagiomnium ciliare* (Figure 72), *Rhizomnium punctatum* (Figure 73), *Conocephalum conicum* (Figure 74), *Marchantia polymorpha* (Figure 75), *Pellia epiphylla* (Figure 76), *Atrichum* (Figure 77), *Dicranella* (Figure 78), *Pohlia nutans* (Figure 79-Figure 80), and *Bartramia pomiformis* (Figure 81-Figure 82), among others, all benefitting from the snowmelt moisture.

Gaberščik and Martinčič (1987) demonstrated seasonal changes in growth of *Sphagnum papillosum* (Figure 83-Figure 85) in a raised bog in Slovenia, Yugoslavia. They found the greatest growth at the beginning of the growing season, a time when water is usually plentiful. During winter months, the photosynthetic activity declines and ceases completely in February.

One restoration technique in peat-mined bogs in Canada has been an attempt to enhance the moisture content (Rocheffort *et al.* 2002). To do this, *Sphagnum* (Figure 83-Figure 85) is reintroduced in the restoration areas and may be covered by extended periods of flooding, especially following snowmelt or heavy rainfall. These flooding events can cause production of **innovations** in which the buds and shoots grow. Some species grow **capitula** (compact apical branches of *Sphagnum*) from fragments under a variety of conditions. The most species in their study grew from whole plants under long-term conditions of shallow flooding. However, many of the species under long-term flooding suffered from **etiolation** (condition of plants grown in partial or complete absence of light, characterized by long, weak stems and smaller, sparser leaves).

In the Niigata Prefecture of Japan, the floating liverwort *Ricciocarpos natans* (Figure 86) is common in cultivated rice fields (Shirasaki 1996). It grows best where there are warmer temperatures and a snow depth of 0.5-3.0 m.

Figure 86. *Ricciocarpus natans* with duckweed. Photo by Martin Hutten, with permission.

In western Norway, *Andreaea rupestris* (Figure 87-Figure 89) occurs along the flushing gradients created by snowmelt or is associated with snow cover (Hedger 2001). Species in the alpine areas of Norway are sensitive to the timing of snowmelt. In 43 sampled transects, 22 of the 41 taxa show a significant relationship to the time of snowmelt as the altitude increases. But these relationships are not necessarily direct responses to the temperature or water. Rather, at least some of them avoid locations of earlier snowmelt because of competition from other plants, especially tracheophytes.

Snowbed bryophytes must utilize low light and short growing seasons with low temperatures to attain sufficient photosynthesis for carbon gain. *Anthelia* (Figure 10) does especially well in the border zone of snowbeds because of its resistance to long-lasting cold, wet, and dark conditions (Lösch *et al.* 1983). *Polytrichastrum sexangulare* (Figure 18-Figure 20), on the other hand, is more productive and is therefore able to compete with the tracheophytes at less extreme sites.

Mechanical Effects

Snow has its down side for plants. The sheer weight can crush or break the plants. So how do tiny plants like bryophytes fare under this weight? Kennedy (1993) commented on how few studies have included the biomechanics of bryophytes, reminding us of their need for snow cover resistance.

Among the mosses receiving the greatest mechanical stress due to height is *Dendroligotrichum dendroides* s.l. This moss stands alone, supporting a height up to 40 cm where it lives in the forests of Chile and New Zealand. For this species, the dense hypodermal sterome provides considerable stiffness comparable to that of woody stems of tracheophytes. But for many smaller mosses, such support is usually not needed. Rather, the mosses of various habitats have a wide range of mechanical conformations. By contrast, size, development, and phylogenetic position seem to be less important than the habitat in determining growth form and mechanical adaptations.

Freeze-thaw Cycles

Free-thaw cycles can have some of the same damaging effects as dehydration-rehydration. And like many other epiphytes that tolerate the wet-dry cycles, the rock face and tree-trunk-dwelling *Leucodon sciurioides* (Figure 90) in the Mediterranean tolerates freezing and thawing with its photosynthetic apparatus fully operational after freezing (Deltoro *et al.* 1999). Both CO₂ fixation and chlorophyll fluorescence return to pre-freezing values during thawing. And like many desert mosses, it recovers its photosynthesis rapidly during thawing. Deltoro and coworkers suggest that this rapid recovery is possible through dissipative pathways that absorb excess light energy in frozen plants.

Figure 90. *Leucodon sciurioides* on tree bark, a species that tolerates freezing and is ready for photosynthesis as soon as it thaws. Photo by Michael Lüth, with permission.

Melick and Seppelt (1992) experimented with up to 16 freeze-thaw cycles in Antarctic bryophytes. After 16 days of immersion in water, there is a relatively low loss of glucose and fructose [10-29% of the total sugar pool in healthy mosses, but 69% from the dead *Schistidium chrysoneurum* (= *Grimmia antarctici*; Figure 91-Figure 92)]. Freeze-thaw cycles increase this leakage up to 2-3 times except in the dead mosses. *Bryum pseudotriquetrum* (Figure 49-Figure 50) lost 65% of its total sugar when subjected to 16 freeze-thaw cycles. The other species [*Ceratodon purpureus* (Figure 55-Figure 60, Figure 92), *Schistidium chrysoneurum*, *Cephaloziella exiliflora* (Figure 93)] lost less than 28%. This loss does not seem to be related to the freezing temperature.

Figure 93. *Cephaloziella* sp. *Cephaloziella exiliflora* loses some of its stored sugar during freeze-thaw cycles. Photo by Kristian Peters, with permission.

Schlensog *et al.* (2004) compared the recovery of lichens and mosses after winter in the continental Antarctic. Whereas the lichens recover **photosystem II** (PS II, first protein complex in light-dependent reactions of oxygenic photosynthesis; it captures photons of light to energize electrons) almost fully within a few minutes of hydration, the mosses take much longer to recover. The moss *Bryum subrotundifolium* (Figure 94-Figure 96) maintains highly elevated respiration rates for several days following activation. Like the response to desiccation, it appears that this moss must repair damages before it can make a positive photosynthetic gain.

Figure 94. Bed of *Bryum subrotundifolium* in meltwater on Antarctica. Photo by Rod Seppelt, with permission.

Figure 96. *Bryum subrotundifolium* in the Antarctic infected with a fungus that is taking advantage of suitable moisture conditions. Photo by Catherine Beard, with permission.

Freeze-thaw protection can be conferred on bryophytes by various compounds present prior to freezing (Rütten & Santarius 1993). In *Plagiomnium affine* (Figure 97) the uptake and release of sucrose does little to change the permeability of the leaf cell plasma membranes to sugars, **proline** (amino acid), or polyethylene glycols. However, pretreatment with these compounds sufficient to induce plasmolysis does protect the moss cell membranes from freeze-thaw damage. On the other hand, pretreatment with **glycerol** (compound that is soluble in water and is hygroscopic) causes **plasmolysis** (shrinking of cell membrane away from cell wall) without endowing the cells with protection against freeze-thaw damage.

Figure 97. *Plagiomnium affine*, a moss protected from freeze-thaw damage by various compounds and plasmolysis. Photo by Michael Lüth, with permission.

Winter Short-term Warming Events

Noting that climate change in northern high latitudes is likely to be greater in winter than in summer, Bjerke *et al.* (2011) examined the potential effects of more frequent short-term warming events. Whereas these warming event effects are known to be damaging to tracheophytes, their effect on bryophytes could be quite different. And the bryophytes and lichens are of major importance in these

high-latitude ecosystems. By simulating winter warming events with infrared lamps and soil warming cables in a sub-Arctic heath, Bjerke *et al.* were able to monitor the responses of the feather moss *Hylocomium splendens* (Figure 142). In the three winters of simulated warming events, this moss experienced significant reductions in net photosynthetic rates and growth rates (of up to 48% and 52%, respectively), starting in the first summer after these events began. In this species, growth begins early in the spring season, exposing young, vulnerable shoots to the effects of cold. The researchers suggest that the damage under winter warming events may be due to breaking dormancy and experiencing premature growth during the winter warming events that causes damage to those sensitive young shoot tissues. Subsequent drying following these events may cause desiccation damage to the tender shoots.

These winter warming events could change the distribution of acrocarpous vs pleurocarpous mosses in areas with winter snow cover. In the Front Range of the Rocky Mountains, USA, Flock (1978) found that acrocarpous mosses are more abundant in areas that are dry and maintain light snow cover. Pleurocarpous mosses, on the other hand, are more abundant in wet sites with deep snow cover.

As Longton (1988) has pointed out, bryophytes in general have phenotypic plasticity, opportunistic responses in CO₂ exchange, and a poikilohydrous water relationship that endows them with considerable tolerance for desiccation and frost. These make it possible for them to occupy snowbeds where few tracheophytes can succeed.

Protection from Light Damage

A potentially serious problem for desiccated mosses at low temperatures is that they are still able to absorb light energy. This can be a special problem for forest epiphyte species that experience more light exposure in winter, compared to summer, when the tree canopy has lost its leaves. Particularly on those cold days that lack snow cover, over excitation of chlorophyll electrons can be damaging. However, Heber *et al.* (2006) report that some mosses have seasonal differences in their ability to dissipate that excess light energy into heat.

Freezing and thawing can result in photoinhibition, as demonstrated by the endemic moss *Schistidium chrysoneurum* (Figure 91) from the Antarctic (Lovelock *et al.* 1995a). Jägerbrand (2011) considered the time immediately following snowmelt to be the most dangerous time for UV damage to bryophytes. Rehydration, lingering low temperatures, and rising UV levels coincide with a time when bryophytes must repair the damage due to absence of light and desiccation from winter. This is especially problematic in the Antarctic where the ozone layer is thinning. Fortunately, this highly variable photoinhibition is reversible during periods of warmer temperatures (Lovelock *et al.* 1995a). The inhibition that occurs between freezing and thawing events recovers best under low light conditions. After four cycles, recovery of hydrated mosses occurred within 12 hours of transfer to 5°C at 15 μmol quanta m⁻² s⁻¹.

During the dry summers, some desiccation-tolerant mosses are more protected against photo-oxidative damage when they are dry than they are in the humid winters (Heber *et al.* 2006). In mosses such as the **poikilohydric** *Rhytidiadelphus squarrosus* (Figure 98), desiccation reduction of chlorophyll fluorescence does not occur under even strong illumination in the desiccated state once the moss has achieved phototolerance. One protectant is **zeaxanthin** (one of the most common carotenoid alcohols and a powerful antioxidant), which requires drying in light. If the water is lost slowly, fluorescence is quenched. Quenchers accumulate during desiccation and remain stable until hydration occurs. Hydration results in their reversion to non-quenching molecules.

Figure 98. *Rhytidiadelphus squarrosus*, a moss that requires drying to induce protection (zeaxanthin) against photoquenching. Photo by Michael Lüth, with permission.

Lovelock and Robinson (2002) found that surface reflective properties of leaves also plays a role in dissipating the light, hence protecting the plants from light damage. They suggested that the water content, but not pigments, of the mosses are important in altering the red-edge and photochemical reflectance index. The water content may account for the differences in reflectance among the species. All the mosses maintain high levels of xanthophyll pigments that serve as photoprotectants. Interestingly, their abilities to reflect UV light differs little. *Bryum pseudotriquetrum* (Figure 49-Figure 50) has greater reflective values than the other mosses studied and also has higher levels of UV-absorbing pigments, but its carotenoid levels are lower than the other species tested. *Ceratodon purpureus* (Figure 55-Figure 60) has higher levels of anthocyanins but lower total chlorophyll concentrations. *Bryum pseudotriquetrum* has higher levels of the specific UV-screening pigments; *Ceratodon purpureus* and *Schistidium chrysoneurum* (Figure 91) have higher levels of pigments that protect against excess visible light.

For *Schistidium chrysoneurum* (Figure 91), freezing in darkness reduced the F_v/F_m ratio (ratio of variable:maximum fluorescence) and the initial fluorescence (Lovelock *et al.* 1995b). These were reversible when the mosses thawed. The reduction of

F_v/F_m may be the result of conformational changes in the pigment-protein complexes due to the desiccation that occurs during freezing. The photoinhibition during freezing is reversible and indicates that processes that protect the moss from photoinhibitory damage during freezing temperatures occur in consort with high solar radiation levels. These protections therefore limit the repair needed when favorable temperatures return.

Winter Growth

Proctor (2000) points out that bryophytes have a desiccation tolerance strategy that differs from that of tracheophytes. Bryophytes are able to survive because they can photosynthesize and grow when water is freely available, then suspend their metabolism when it is not. By being **ectohydric** (conducting water externally), many species can have wide variability in their external capillary water without affecting the water content of the cells. This external source permits the cells to function most of the time with full turgor. When they do desiccate, the period of water stress is brief. They have a carbohydrate content that is similar to that of the maturing embryos of desiccation-tolerant seeds. It is likely that these carbohydrates contribute to their rapid recovery upon rehydration. In short, they mimic temperate winter annuals or mesic desert ephemerals. For example, in the maritime climate of Britain, the wall top moss *Grimmia pulvinata* (Figure 99) takes advantage of the mild climate of autumn and early winter for most of its growth (Proctor 2004). During that period the moss is able to maintain hydration for long periods of time to carry out photosynthesis. Like many mosses, it is adapted to frequent and often short wet-dry cycles.

Figure 99. *Grimmia pulvinata* on rock where it grows mostly in autumn and early winter when it is well hydrated frequently. Photo by Michael Lüth, with permission.

Even growth rates seem to adjust to differences in temperature, perhaps because of differences in available moisture, perhaps just to acclimation (see Fornwall & Glime 1982). For example, *Brachythecium rutabulum* (Figure 100) has superior growth in winter compared to summer when grown at temperatures below 18°C (Furness & Grime 1982). Most species of temperate regions seem to have their optimum growth temperature at 15-25°C, but growth can be extensive at temperatures even below 10°C. Gaberšček and Martinčič (1987) demonstrated seasonal changes in growth of *Sphagnum papillosum* (Figure 83-Figure 85) in a raised bog in Slovenia, Yugoslavia. They found the greatest growth at the beginning of the growing

season, a time when water is usually plentiful. During winter months, the photosynthetic activity declined and ceased completely in February.

Asada *et al.* (2003) found that winter growth of a number of bryophyte species [*Racomitrium lanuginosum* (Figure 101-Figure 103), *Pleurozium schreberi* (Figure 104), *Sphagnum austinii* (Figure 105-Figure 106), *S. fuscum* (Figure 2), *S. rubellum* (Figure 107-Figure 108), *S. papillosum* (Figure 83-Figure 85), *S. lindbergii* (Figure 38-Figure 39), *S. tenellum* (Figure 109-Figure 110), *S. pacificum* (Figure 111)] in a coastal peatland in British Columbia, Canada, is an important contribution to the productivity of the system. But for this productivity to occur, water must be available during those times when the temperature permits photosynthesis to occur. Asada further supported the importance of water by demonstrating that productivity in these species correlated more strongly with precipitation than with temperature.

Growth can actually occur at sub-zero temperatures. *Brachythecium geheebii* (Figure 112) and *Homalothecium philippeanum* (Figure 113-Figure 114) in Romania montane areas are able to assimilate CO₂ down to -9°C (Atanasiu 1971). *Isoetecium alopecuroides* (Figure 115-Figure 116) had net gain down to about -8°C. Both of these temperatures are lower than those for evergreen trees tested in winter. But not all bryophytes are created equal. Davey and Rothery (1996) found that in *Brachythecium austrosalebrosum* from the Antarctic, respiration rates were highest in summer and lowest in winter regardless of temperature within the natural range, but that in *Chorisodontium aciphyllum* (Figure 117-Figure 118) and *Andreaea depressinervis* (Figure 119), there was little change with season.

A recent addition to the known flora of the British Isles, the thallose liverwort *Athalamia hyalina* (Figure 120) is a Northern Hemisphere montane species (Long *et al.* 2003). In Scotland it has its active growth in the winter and produces its spores in spring. This permits it to live on the thin soil of eroding limestone ledges where it can take advantage of the moisture in fog of winter and intermittent thaws.

Figure 120. *Athalamia hyalina*, a liverwort that grows in winter in Scotland. Photo by Michael Lüth, with permission.

Winter warming (and possibly summer drought?) in the UK seems to account for the increases in *Campyliadelphus chrysophyllus* (Figure 121) and *Fissidens dubius* (Figure 122) in a limestone grassland, as demonstrated with experiments in winter warming and increased supplemental rainfall in summer (Bates 2006). Spread of the epiphytes *Cololejeunea minutissima* (Figure 123) and *Colura calyptrifolia* (Figure 124) seems likewise to be the result of rising temperatures in winter, and possibly a change in the summer moisture. On the other hand, winter warming coincides with decreases in *Rhytidiadelphus squarrosus* (Figure 98) and *Lophocolea bidentata* (Figure 125).

Winter and Reproduction

Since winter is often the season with moisture in some habitats like deserts, we can expect this to be the season of gamete transfer and fertilization. In the Negev Desert of southern Israel, Herrnstadt and Kidron (2005) found that *Bryum dunense* initiates its reproductive organs prior to the first winter rain, using atmospheric humidity from dew and fog as the source of water. The most sporophytes form in the partially shaded microhabitats following winter rains, interestingly exceeding those in the shaded microhabitats. When the first rain arrives, *B. dunense* is ready to disperse its bulbils and to complete fertilization. The shrubs seem to be essential to provide the partial shade in which this species is most successful at reproducing.

Too little rainfall in winter can be detrimental to desert mosses. *Syntrichia inermis* (Figure 126) in the Mojave Desert, Nevada, USA, failed to initiate sporophytes in 1996 and 1997 when the winter-spring rainfall was reduced (Stark 2001). In *Crossidium crassinerve* (Figure 127), the appropriate hydration periods occurred in the cooler months of October to April (Stark 2005). Hydration in the summer was detrimental because the patches dried too quickly (as few as 3 hours) following the rainfall, prohibiting sufficient repair and carbon gain. During the

four years of the study, the five patches monitored initiated 248 sporophytes; only 9 survived. Embryonic abortion (69%) and capsule herbivory (30%) accounted for most of the deaths.

Acaulon triquetrum (Figure 128) in southwest Germany initiates most of its gametangia in October to December (Ahrens 2003). These develop rapidly, permitting fertilization to occur during the same time period. Sporophytes grow in October-November to January-February, with dispersal in April or May. The **chloronemal** (branches of protonemata that give rise to gametophore buds) filaments are persistent through summer but die off during winter (December – February). The rhizoid system, however, persists throughout the winter, once again giving rise to new chloronemata and gametophores in the spring. Having rhizoids that persist through the winter permits this moss to rapidly occupy bare surfaces, especially the loess created by small, burrowing mammals.

Laaka-Lindberg and Heino (2001) found that the leafy liverwort *Lophozia ventricosa* (var. *silvicola*; Figure 129) in southern Finland has two types of gemmae. One of these becomes dormant and the other is non-dormant. Only the dormant gemmae are able to survive the winter. She provided the evolutionary argument that if the winter mortality (of non-dormant gemmae) increases compared to the mortality during the growing season, then evolution would favor an increase in the percentage of dormant gemmae, especially among those produced at the end of the growing season.

Figure 129. *Lophozia ventricosa* with gemmae. This species produces two types of gemmae, one of which survives winter. Photo by Jan-Peter Frahm, with permission.

Spore dormancy is also subject to temperature. Spores require water to germinate, but dormancy loss also occurs in response to temperature. For *Sphaerocarpos texanus* (Figure 130) at 35/20°C, loss of spore dormancy increases faster than that in even modestly lower temperatures of 30/15°C or 25/15°C (McLetchie 1999). The best spore germination occurs at 16/10°C and spores fail to germinate at 35/20 or 30/15°C. But low temperatures induce the spores to return to dormancy. McLetchie considered this behavior to be similar to that of seeds of obligate winter annuals.

Figure 130. *Sphaerocarpos texanus*, a species that loses its spore dormancy at higher temperatures. Photo by Martin Hutten, with permission.

Longton and Greene (1969) demonstrated that in Britain the boreal forest moss *Pleurozium schreberi* (Figure 104) sustains survival of its antheridia through winter. The antheridia begin development in August but remain immature through winter. The archegonia likewise overwinter in an immature stage. When spring arrives, both undergo rapid development, preparing them for fertilization in April and May. The sporophyte matures in autumn and spores are dispersed between January and April.

It is likely that the moss *Dichelyma japonicum* is excluded from high altitudes and latitudes because its sporophytes have a late sporophyte maturation (Shirasaki 1997). This species grows on the woody plants beside ponds and streams and is covered by deep snow in winter. In the aquatic family **Fontinalaceae**, this species requires deep snow in winter and high precipitation in summer.

Riccia cavernosa (Figure 131) avoids most of the problems of cold, dark, dry winters by having an extremely short life cycle on the banks and sandy flats of the Kobuk River in Alaska (Seppelt & Laursen 1999). Its spore to spore cycle is only three to four weeks of late summer and autumn! Hence, it is able to overwinter as spores and avoid all the problems. On the other hand, this same species (perhaps a different race?) has a life cycle of two - three months of winter and early spring in Australia.

Asexual Survival

We have learned much about preparation for winter conditions through studies in cryopreservation. The pioneer moss *Ditrichum plumbicola* (Figure 133) survives winters and desiccation in the field, but has poor survival of cryopreservation, even with pretreatment (Rowntree *et al.* 2007). Using a series of treatments and observations, Rowntree and co-workers attempted to determine the effects of ABA, sucrose, and desiccation on various stages of the protonemata. What they found was that most of the protonemal cells pretreated with ABA and sucrose died, but the ones that survived had thick cell walls with deep pigmentation, numerous small vacuoles, and cytoplasmic lipid droplets. Those with only desiccation and cryopreservation exhibited little cytological change. Removal of the ABA-sucrose pretreatment permitted normal development and activity of the protonemata, whereas the pretreatment induced propagules from the protonemata, and these propagules were highly desiccation tolerant and easily survived the cryopreservation. In nature, this species forms highly desiccation-tolerant rhizoids that serve the same perennating function.

Figure 133. *Ditrichum plumbicola*, a species that survives winter and desiccation in the field, but it has little ability to survive cryopreservation except as propagules. Photo by Des Callaghan, with permission.

Sympatric Differences

Seasonal differences in reproduction often separate **sympatric** (existing in same or overlapping geographic area) species and keep them separated reproductively. Such is the case for three species of *Dicranoloma* in Australia (Milne 2001). In *D. menziesii* (Figure 134) and *D. platycaulon* (Figure 135), the antheridia are initiated during winter and archegonia in the following spring, whereas in *D. billardiarei* (Figure 136) the antheridia initiate during late spring to summer whereas archegonia originate in autumn. Differences in development time place the times of fertilization in three different time periods, late summer for *D. menziesii*, mid autumn for *D. platycaulon*, and early winter for *D. billardiarei*. For all three species, the winter season is an important period for this process, providing sufficient moisture and avoiding these activities during the high summer temperatures that can cause excessive respiration.

In Japan, *Trachycystis flagellaris* (Figure 137) has developing sporophytes that do well in the lower temperatures and deep snow at higher altitudes (Shirasaki 1998). *Trachycystis microphylla* (Figure 138), on the other hand, has its sporophyte maturation in early spring; it seems to be restricted to coastal areas with only thin snow cover in winter.

Effects of Bryophytes on their Communities in Winter

We cannot ignore the importance of the perennial nature of most bryophytes. Many remain active in winter, but even more importantly they are present and active within hours of snowmelt on their leaves.

The ability of the mosses to remain green and moist throughout winter in some areas is important for their invertebrate inhabitants. For example, in the Black Forest of Germany, *Rhytidiadelphus squarrosus* (Figure 98) is home to several species of tardigrades (water bears) (Schuster & Greven 2007). These tiny animals are well attuned to the seasonal changes in moss habitats. Their diversity is greatest in winter, although numbers decline then. (See Volume 2, Chapter 5).

Mosses are able to modify the effects of frost on the soil community. In a feather moss community in northwestern Alberta, Canada, dominated by *Pleurozium schreberi* (Figure 104), removal of the moss layer increased soil temperatures in summer and lengthened the frost-free period (Startsev *et al.* 2007). But rather than causing the soil to be warmer, the bare soil had temperatures as low as -13°C during the frost-free times.

In China, mosses are a critical part of the gall nut industry, a valuable source of medicines and chemicals. The gall aphid, *Kaburagia rhusicola* spends its winters on mosses, including *Brachythecium* spp., *Entodon*, and *Oxyrrhynchium* (Lai & Zhang 1994). The mosses are able to provide both cover and a moist location. The gall aphid *Kaburagia ovogallis* uses eight species of the *Brachytheciaceae* for its winter hosts (Li 1990). In fact, as of 1990, 24 species of mosses were identified as winter hosts of various species of gall aphids. By providing more of these mosses, those in the gall nut industry were able to sustain higher yields.

Lichens (especially reindeer "moss") are well known as food for caribou and other large herbivores in winter. But bryophytes are less well known for this role. Oloffson *et al.* (2002) demonstrated the importance of bryophytes and other food sources by using exclosures around parts of snowbeds in Arctic-alpine tundra communities. Following eleven years of exclosure, the snowbed developed significant increase in both tracheophytes and bryophytes. The same response did not occur in the tall herb meadow. The primary herbivores in the study were rodents – grey-sided voles (*Clethrionomys rufocanus*), red voles (*C. rutilus*), field voles (*Microtus agrestis*), root voles (*M. oeconomus*), and lemmings (*Lemmus lemmus*). Bryophytes accounted for most of the cryptogamic changes in biomass. Predominant among those increasing in biomass were *Sanionia uncinata* (Figure 46-Figure 48) (584% increase) and *Polytrichum juniperinum* (Figure 139) (113,584% increase). *Pleurozium schreberi* (Figure 104) was absent in the controls and increased by 2.7g m^{-2} in the exclosures. The researchers concluded that the low competition of the unproductive snowbeds was caused by these mammalian herbivores that depressed the plant biomass. The presence of food under the snow, including the bryophytes, permits these animals to remain hidden from aerial predators.

Figure 140. *Polytrichum juniperinum*, a species that increases in biomass following grazing by rodents in the Arctic. Photo by Michael Lüth, with permission.

Prins (1982) asked why mosses are eaten in cold climates only. Could it be that they like the sweet taste of sucrose that is stored in some species in preparation for winter?

Winter Dispersal

Winter can be a time for dispersal. Dry, brittle mosses easily break, presenting fragments that can travel long distances across the smooth snow or caught up in winds unimpeded by canopy leaves. McDaniel and Miller (2000) demonstrated this by collecting bryophyte fragments from late-spring snowbeds in the Adirondack Mountains, New York, USA. The diversity of fragments from the higher elevations of alpine and krummholz vegetation was much greater than that in the forested site. (The diversity also surpassed that of the tracheophytes.)

Miller and Howe Ambrose (1976) were able to collect bryophyte fragments from late snowbeds on Bathurst Island in the Canadian high Arctic. These collections contained large numbers of both mosses and liverworts. Most of the species represented those on the nearby ridges and slopes and Miller and Howe Ambrose presumed that these had been dispersed during the previous winter, resulting from surface winds. In lab cultures, 12% of these fragments exhibited viability, producing protonemata, new shoots, rhizoids, or renewed growth. But parts were not equally viable. Detached moss leaves did not grow and only one leafy liverwort fragment was viable. Rather, the leafy gametophore tips were the most successful. Nevertheless, the researchers estimated that a cubic meter of granular snow contained more than 4000 viable propagules!

Pollution Effects – Vital Water or Deadly Poisons?

Kennedy (1993) reminded us that traditional wisdom tells us that life in the Antarctic is restricted by the arrival of new species and the extreme cold. But recently biogeographical evidence indicates that water may be the primary limiting factor. But it can also bring danger.

Winter can be a particularly dangerous time for bryophytes that are subject to air pollution. The snow collects the pollutants over the extended period of snow cover (Thomas 1981). When melting occurs, the bryophytes are subjected to that long-term collection of

pollutants, *i.e.*, concentrated pollutants, in what is known as **acid flush** (Woolgrove & Woodin 1996). Woolgrove and Woodin documented that these concentrated pollutants in the snowbed moss *Kiaeria starkei* are causing damage to the underlying bryophytes. This damage is greatest when the snow cover is gone and meltwater is delivered to the active plants. This exposure can last for a sufficient period of time that no recovery is measured after 4 weeks. This, combined with the short growing season of these mosses in snowbeds, can have serious impacts on their survival.

Markert and Weckert (1993) found that plants of *Polytrichastrum formosum* (Figure 141) had the maximum concentrations of pollutants in winter and the lowest in summer, attributing this to the higher biomass productivity of this species in the spring. But I suspect that part of this effect was due to the accumulation effect by the snow. Hynninen (1986) attributed the greater winter accumulation of heavy metals by *Sphagnum* (Figure 83-Figure 85) in moss bags in Finland to the summer holiday breaks. Could these winter highs be due to the absence of rain to wash the pollutants away and the long time for continuous collection?

In the boreal forest *Hylocomium splendens* (Figure 142) uses both organic and inorganic nitrogen deposited in the snow (Forsum *et al.* 2008). Snowmelt N is dominated by nitrates (86%), followed by ammonia (11%) and amino acids (3%). The *H. splendens* is able to take up 24% of the nitrogen from the snow nitrogen. On the other hand, Björk (2007) showed that 1.0 g m⁻² yr⁻¹ N added to the snow water had little effect on the bryophyte community over a three-year period. Other nutrients become available in the snowmelt water as well (Björk & Molau 2007; Jägerbrand 2011).

Figure 141. *Polytrichastrum formosum* with capsules, a species that accumulates the most pollutants in winter. Photo by David T. Holyoak, with permission.

Like growth, uptake of pollutants depends on the availability of water, and it may or may not be significantly affected by temperature. As concluded by Hébrard *et al.* (1974) for *Grimmia orbicularis* (Figure 143), the activities of ⁹⁰Sr transfer to the mosses coincide with those times of maximum rainfall in autumn, winter, and spring. The accumulations of the pollutant in dust on the moss is unavailable to the moss until water enters the cells.

Summary

Late snowbeds provide a refuge for bryophytes where there is sufficient water in "spring" and reduced competition from tracheophytes. Species living there have life cycles that take advantage of snowmelt water and that have life cycle stages that can live through winter. The growth forms may be altered and duration of the snow is a determining factor in species composition. Prominent among the snowbed bryophytes are species of *Anthelia* and *Kiaeria*. Snowmelt waters create flushes that have their own species, including several *Sphagnum* species.

Freeze-thaw cycles can be beneficial to some and detrimental to other bryophytes. Short thaw periods may be insufficient to repair damage from desiccation and freezing. These can become lethal for some bryophytes that are unable to realize any carbon gain. In some locations, especially the Antarctic, exposure in winter subjects the bryophytes to higher UV light intensities, coupled with low temperatures. Some live in exposed sites where wind clears the snow or on vertical surfaces that do not hold the snow, exposing the bryophytes to drying, intense light, and extreme low temperatures.

On the other hand, some bryophytes grow best in winter when more moisture is available. Others survive winter through asexual propagules. The life cycle adaptations to winter microclimate are effective means for maintaining species differences among sympatric members of the same genus.

Bryophytes occupy habitats where tracheophytes cannot complete their life cycles in the short growing seasons. These bryophytes provide a refuge and food for invertebrates, rodents, and even some large free-range mammals. They modulate the ground temperature, preventing extremes, hold water longer than bare ground, and prevent destructive runoff during spring flushes.

The dry air of winter facilitates breakage of bryophyte fragments. These easily blow across the snow, taking advantage of the absence of leaves on the trees in deciduous forests, making winter dispersal significant.

Pollutants accumulate in the snow and rapid melt may expose the bryophytes to heavy concentrations in a short time frame. In some cases, the bryophytes gain important nutrients from the collected pollutants, but some are detrimental.

Acknowledgments

Thank you to all the photographers who kindly gave permission for use of their photos. Omar Pokorni was kind enough to tell me the link to this chapter was not working.

CHAPTER 8-1

NUTRIENT RELATIONS: REQUIREMENTS

Figure 1. Mosses growing on an old iron stove, demonstrating their rather low nutrient requirements. Photo by Janice Glime.

What Do Bryophytes Require?

Bowen (1933) claimed that bryophytes are necessarily limited in nutrient supply by their **poikilohydric** (state of hydration controlled by environment) method of water regulation. Their method of receipt of water – predominantly from rainfall and, for most bryophytes, almost nothing from ground water – relegates them to receive nutrients that are dissolved in rainwater or that accumulate as dust. After the first few minutes of rainfall, those nutrient concentrations are extremely small compared to soil nutrients and are biased in their relative concentrations in very different ways. Therefore, it is not surprising that culture conditions designed for tracheophytes are often unsuitable for bryophytes. But is this what the bryophytes "prefer"? Or are these conditions they tolerate and that provide them relatively less competition from tracheophytes? And do they gain any nutrients from the soil?

Nutrient Requirements

Even in the slow-growing bryophytes, nutrients can be a major determinant of both species composition and diversity (Raabe *et al.* 2010; Stevens *et al.* 2010; Schrijver *et al.* 2011). For tracheophytes, we know that the **trace**

elements (micronutrients) (Fe, Zn, Mn, Cu, Ni, B, Mo, and Cl) are essential (Welch 1995). These seem to be important for bryophytes as well, but in lower concentrations. Nevertheless, the levels of requirements and tolerance can vary widely not only among species, but also within species (Shaw 1988).

Most knowledge about nutrient requirements of bryophytes comes from culturing them (Voth 1943; Brown 1982), although more recently we have learned much through the effects of atmospheric pollution. We soon learned that concentrations that favored the growth of tracheophytes in the laboratory were too strong for the poikilohydric bryophytes, and dilutions of 10:1 seemed more satisfactory.

Hoffman (1966) performed a complex set of experiments on the moss *Funaria hygrometrica* (Figure 2) in which he determined anion (N:P:S) and cation (K:Ca:Mg) combination effects. In his anion experiments, the absence of any of the three nutrients caused poor protonemal growth and no gametophores. On the other hand, the protonemata responded quite differently from the responses of the gametophores to the various cation combinations. This suggests that our usual descriptions of

conditions based on leafy plants may not provide us with any useful information on requirements needed for establishment. Even spores and gemmae may have different requirements (Brown 1982).

Figure 2. *Funaria hygrometrica*, a species of disturbed habitats that requires N, P, and S among its nutrients. Photo by Michael Lüth, with permission.

Bryophytes seem to require the same nutrients, mostly for the same purposes, as do the tracheophytes. An easy way to remember the **macronutrients** (those needed in large quantities) is with the acronym **CHOPKNS Mg CaFe**, read as See Hopkin's mighty good cafe. These essential metabolic nutrients are maintained **within** the cell in relatively consistent high concentrations. The inconsistencies often found in measurements generally result when the bound portion on the cell surface is included. Table 1 lists the concentrations of macro- and micronutrients typical of various tracheophyte groups.

One factor that plays a major role in bryophyte nutrient needs and toxicity is the osmotic effect. Lacking an epidermis (except some thallose taxa) and having little wax

on their surfaces, most bryophytes are especially susceptible to osmotic shock. Voth (1943) used *Marchantia polymorpha* (Figure 3) to show that a concentrated nutrient solution could kill the tips and wings of a growing thallus while reducing dry biomass and production of gemmae cups. At intermediate concentrations that retained the same nutrient ratio, the liverwort increased in size, produced a darker color, had more ascending tips, and developed more rhizoids, especially at the lower end of that concentration range. At the lowest set of concentrations, the rhizoids, scales, and lower epidermis had a more intense red-purple color, rhizoids were quite numerous, and gemmae cups diminished in number. Cell walls were especially thin in the strongest solutions and many cells collapsed, whereas in the most dilute solutions the cell walls were thickest.

Figure 3. *Marchantia polymorpha*, a species that is sensitive to high nutrient concentrations. Photo by David T. Holyoak, with permission.

Table 1. Average mineral element content among plants of several habits. (All data are in parts per thousand). Based on published compilations included in Larcher 1983 and Epstein 1965 for agricultural plants.

Element	Land Plants (g·kg ⁻¹ dry matter)		Stored in Soil (g·kg ⁻¹ DM) Mean	Marine Organisms (g·kg ⁻¹ DM) Mean	Sea Water (g·L ⁻¹)	Agricultural Plants (g·kg ⁻¹ DM)
	Range	Mean				
N	10-50	20	1	50	0.0003	15
P	1-8	2	0.7	6	0.00003	2
S	0.5-8	1	0.7	10	0.9	1
K	5-50	10	14	10	0.4	10
Ca	5-50	10	14	5	0.4	5
Mg	1-10	2	5	4	1.3	2
Fe	0.05-1	0.1	38	0.4	0.00005	0.1
Mn	0.02-0.3	0.05	0.9	0.02	0.000005	0.05
Zn	0.01-0.1	0.02	0.05	0.2	0.000005	0.02
Cu	0.002-0.02	0.006	0.02	0.05	0.00001	0.006
Mo	0.0001-0.001	0.0002	0.002			0.0001
B	0.005-0.1	0.02	0.01	0.02	0.005	0.02
Cl	0.2-10	0.1	0.1	40	19.3	0.1

Considering these osmotic responses, it is not surprising to find that the same species of bryophytes from different habitats can respond quite differently to various concentrations of nutrients and heavy metals (Brown & Beckett 1985). If a plant has grown from spores at a certain nutrient/ion level, then its osmotic potential is more likely to be adjusted to that of its environment. The same is likely to be true for plants grown from fragments and other propagules. Moving a plant to another location can strongly affect that balance. Hence, monitoring studies that move bryophytes from one location to another need to account for normal ambient ion differences. Taxonomists likewise need to account for ionic differences in the environment because these can alter the morphology of the plants (Brown & Beckett 1985; Glime unpub. data).

The needs of young shoots are typically greater than those of older shoots; thus N, P, and K are found in young shoots in their highest concentrations (Tamm 1953). Nitrogen and phosphorus are essential in making proteins and DNA, and phosphorus is needed in ATP to maintain energy. A relatively high content of potassium is believed to be needed for the normal folding of cytoplasmic enzymes (Bates 2000). Magnesium is needed in chlorophyll and as an activator of several enzymes. Calcium acts as a messenger and is rarely present in the cytoplasm; it is, however, needed to maintain integrity of the plant by being part of the "glue" that cements the cell walls together. Calcium is not easily translocated and accumulates in older segments. However, its increasing concentration in older tissues is partly due to the recalcitrance of the cell wall, where Ca is concentrated, and the loss of dry biomass from older cells, increasing the ratio of Ca to leaf biomass (Bates 1979).

Macronutrients

Some macronutrients often are bound in rocks, unavailable to most plants. Nevertheless, bryophytes and lichens can affect biogeochemical cycles by surface weathering (Porada *et al.* 2014). Porada and coworkers calculated the degree of obtaining N and P from the rock substrate by quantifying the amounts needed by the organisms to account for their biomass increase. Using this indirect method, they estimated that these cryptogams contributed to chemical weathering of 0.058 to 1.1 Km³ yr⁻¹ of rock.

Nitrogen

Nitrogen (N) relationships for bryophytes are complex. For that reason, most of the discussion of this important nutrient are treated in a separate subchapter on nitrogen.

Nitrogen is essential for amino acids, proteins, DNA, and RNA. For bryophytes, slow growth means that requirements are low. Bryophytes are able to use both nitrate and ammonium, with differences among species. Nevertheless, some can use both (Schuler *et al.* 1955; Burkholder 1959). Others may have abnormalities in development in media with ammonium (Killian 1923; Southorn 1977).

On the other hand, the aquatic moss *Fontinalis antipyretica* preferentially assimilates ammonium ions (Schwoerbel & Tillmanns 1974). Others have shown that nitrate reductase only forms in the light (Fries 1945; Schwoerbel & Tillmanns 1974). This might explain why nitrate is the best source of N for *Funaria* and *Weissia*

controversa protonemata in the light (Dietert 1979). Nevertheless, growth on a nitrate medium requires the bryophytes to convert it to ammonium ions before they can assimilate it (Brown 1982). In some habitats, at least some species are able to use amino acids for their N source (Simola 1975). (See Chapter on nitrogen in this volume.)

When bryophytes are co-existing with tracheophytes, the tracheophytes can benefit from added nitrogen, growing faster and out-competing the bryophytes (Berendse *et al.* 2001; Malmer & Wallén 2005). On the other hand, high levels of N in the environment can cause the decrease of both tracheophytes and bryophytes (Dupré *et al.* 2010). In this case, low soil pH seems to contribute to the loss of species, but high N levels seem to be more important in the decline of diversity. These results are similar to those of Ferris *et al.* (2000) in coniferous plantations in Britain. In their study, both bryophyte and tracheophyte diversity decreased as available nitrogen increased, but in this case, the pH, calcium, and nitrate increased, whereas ammonia decreased.

Schrijver *et al.* (2011) stated that "elevated inputs of biologically reactive nitrogen (N) are considered to be one of the most substantial threats to biodiversity in terrestrial ecosystems." We know that high N levels can be detrimental to bryophytes. This has been demonstrated for *Leucobryum juniperoideum* (Figure 4) (Wang *et al.* 2014) and *Sphagnum* spp. (Figure 10, Figure 24-Figure 25) (Bragazza *et al.* 2004). Arróniz-Crespo *et al.* (2008) reported decline in bryophyte biomass production and cover in grasslands. Armitage *et al.* (2010) likewise noted that alpine bryophytes have reduced biomass production and reduced cover under high N concentrations. Using transplants of *Racomitrium lanuginosum* (Figure 5) they determined that at least this moss has the ability to recover when the high loading of N is gone.

Figure 4. *Leucobryum juniperoideum*, a species sensitive to high N levels. Photo by Michael Lüth, with permission.

In the Arctic, Gordon *et al.* (2001) found that added nitrogen caused a decrease in lichen cover but did not affect other functional types of plants. Rather, 10 kg ha⁻¹ yr⁻¹ increased the proportion of active bryophyte shoots while decreasing their nitrate assimilation capacity, suggesting that the critical load is less than 10 kg ha⁻¹ yr⁻¹. It is important to note that not all species responded the same way.

Figure 5. *Racomitrium lanuginosum*, a species that is able to recover from high N loadings. Photo by Michael Lüth, with permission.

To complicate our understanding of suitable levels of N, we find that when N is no longer limiting, P and K can become limiting, as shown for *Sphagnum* (Figure 10, Figure 24-Figure 25) (Bragazza *et al.* 2004). Furthermore, the increased atmospheric N deposition can cause a reduction in the retention of Ca and Mg, a condition that was accompanied by a decrease in stem volumetric density in *Sphagnum* hummocks. Weber and Wiersma (1998) found that in two forested watersheds, the leafy liverwort *Bazzania trilobata* (Figure 6) and moss *Dicranum fulvum* (Figure 7) had elevated N concentrations in the watershed treated with $(\text{NH}_4)_2\text{SO}_4$ while simultaneously expressing a depression of other nutrients (Al, B, Ca, Cu, Fe, K, Mg, Mn, N, P, Zn).

Figure 6. *Bazzania trilobata*, a species that is able to accumulate elevated N. Photo by Robert Klips, with permission.

Figure 7. *Dicranum fulvum*, a rock-dwelling species that is able to accumulate elevated N. Photo by Michael Lüth, with permission.

Phosphorus

Like nitrogen, phosphorus (P) is essential for amino acids, proteins, DNA, and RNA. As in the algae, luxury uptake of P occurs, at least in some mosses, *e.g.* *Pseudoscleropodium purum* (Figure 8) (Bates 1987), but in these experiments there was significant **luxury uptake**, followed by storage, in excess of that is needed) only when plots were fertilized to 50% above the control.

We have seen that P can interact with nitrogen. Ellwood and Whitton (2007) found that the aquatic moss *Warnstorfia fluitans* (Figure 9) uses only organic phosphate, including P from DNA. Cellular P content is important in influencing phosphatase activities.

Figure 8. *Pseudoscleropodium purum* with capsules, a species that is able to take in luxury P when it is increased by at least 50%. Photo by Des Callaghan, with permission.

Figure 9. *Warnstorfia fluitans*, a species that is able to take in luxury P. Photo by Misha Ignatov, with permission.

Gordon *et al.* (2001) found that not only N, but also P changed both the composition and cover of individual species of bryophytes in a high Arctic heath. They pointed out that the species differed in their response to fertilization, warning that the bryophytes should not be

considered as a single functional group, a concept likewise warned by Turetsky (2003) in her review of the role of bryophytes in carbon and nitrogen cycling.

Benner and Vitousek (2007) found that increasing P on the epiphytic community had a strong effect on N-fixing lichens in Hawaii, but mosses and non-N-fixing lichens also increased somewhat in both abundance and diversity. Increased N, however, had no effect on the epiphytic communities.

N:P Ratios

One of the interesting aspects of nitrogen deficiency is that it can be offset by phosphorus (Gordon *et al.* 2001). That is, these two nutrients are **colimiting**, so the critical load of nitrogen is lower when available phosphorus is greater. On the other hand, Riis *et al.* (2010) found that the growth rate of *Warnstorfia fluitans* (Figure 9) increased when the moss had increased P content, but did not with increased N content.

Jirousek *et al.* (2011) used a nitrogen deposition gradient in *Sphagnum* (Figure 10, Figure 24-Figure 25) in a highly polluted region of Central-East Europe to assess the N:P ratio. A higher P concentration in the capitula resulted in a lower N:P ratio for these mosses in most of the bogs, despite their N saturation, causing N to still be limiting. Conversely where there was higher atmospheric N deposition, the N:P ratio increased significantly. Species in the *Cuspidata* section (Figure 10) of *Sphagnum* demonstrated significantly lower N:P ratios in locations with low N deposition.

Figure 10. *Sphagnum cuspidatum*, a species with low N:P ratios when N deposition is low. Photo by Michael Lüth, with permission.

Arróniz-Crespo *et al.* (2008) assessed the effects of enhanced N deposition on *Pseudoscleropodium purum* (Figure 8) and *Rhytidiadelphus squarrosus* (Figure 11) in an acidic grassland. The enhanced N deposition caused up to 90% loss of bryophyte cover, with no recovery after 22 months of no further deposition. The N:P ratios increased up to 3X under the enhanced N loading. Activity of the enzyme phosphomonoesterase showed good recovery, especially in *P. purum*. P limitation appears to be the key factor in bryophyte loss in these grasslands.

Calcium and Magnesium

Calcium (Ca) is an essential nutrient for plants and is used in various structural and regulatory roles in cell walls and membranes (White & Broadley 2003). In this role, it is important in maintaining membrane integrity and cellular adhesion (Brown 1982). In *Leucolejeunea* (Figure 12), when Ca was omitted in the growth medium, cells in new growth were not glued together (Fulford *et al.* 1947). There are implications that Ca may be associated with nutrient absorption (Odu 1978), especially at the rhizoid base where it accumulates in *Marchantia* (Figure 3). In *Funaria* (Figure 2), rhizoids developed at the point of maximum Ca entry on the protonema. Iwasa (1965) presented data that implicated its role in promoting bud formation in *Funaria*. This is consistent with its role as a regulator of growth and development in tracheophytes (White & Broadley 2003; Hepler 2005).

Figure 11. *Rhytidiadelphus squarrosus*, a species that is sensitive to excess N deposition. Photo by Michael Lüth, with permission.

Figure 12. *Leucolejeunea*, a leafy liverwort that requires Ca to glue its cells together. Photo by Paul G. Davison, with permission.

Uptake of Ca in plants is passive, requiring no energy. Since Ca is insoluble, once it resides in a cell it will normally stay there and not move to other parts of the plant. In tracheophytes, it is carried to its destination by the xylem. In bryophytes, it is probably carried primarily externally and may accumulate at the tips of stems and branches where it occupies all available exchange sites and makes a visible crunchy, off-white deposit (pers. obs.).

Calcium can be effective in keeping other ions off the exchange sites. In this role, it can cause nutrient deficiencies. This is particularly noticeable in many species of *Sphagnum* (Figure 10, Figure 24-Figure 26).

Magnesium (Mg) is essential as the center of the chlorophyll molecule as well as other plant processes. Sources for this nutrient include bedrock and soil, with alkaline and humus-rich soils containing more than acidic soils. Its dynamics are often intertwined with those of calcium. Because both are cations, they compete for binding sites in cation exchange (CEC). In other cases (Canadian mires), however, they may be taken up in proportion to their concentrations in the environment (Malmer *et al.* 1992). In rich fens, both of these nutrients are supplemented from ions dissolved in surface water. Based on their field data, Malmer and coworkers suggested that Ca could give the brown mosses, typical of rich fens, a competitive advantage over *Sphagnum* (Figure 10, Figure 24-Figure 26).

Iron

Iron (Fe) can be a micronutrient, but in other species it is a macronutrient. It seems premature to make any generalizations about this in bryophytes.

Iron is important in plants in many enzymes and in the production of chlorophyll. Bryophytes can collect iron in dustfall (Gorham & Tilton 1978), but may also obtain it in water that carries it to and around the plant. It is likely that some can also obtain it from rock substrata.

In low oxygen of deep water, iron forms soluble ferric compounds that can be absorbed by bryophytes. In oxygenated streams, this form quickly oxidizes. Instead of being absorbed, it forms plates on the plants, soon covering them sufficiently to block photosynthesis (pers. obs.).

Micronutrients

Tracheophytes require significant quantities of macronutrients and considerably less of those called **micronutrients** (Mn, Cu, Zn, Mo, Ni, Cl, B). Although comprehensive studies of nutrient deficiency for bryophytes are lacking, we have no reason to believe they would have different requirements than these, but nutrients may be required in different proportions, and certainly in different concentrations.

Most micronutrients will not be limiting in most habitats in nature, but must be included for long-term growth in artificial media. For short periods, bryophytes can generally call upon their stored nutrients and those in surface dust until returned to a natural medium.

Rühling and Tyler (1970) found the sorption and retention relationship of the moss *Hylocomium splendens* (Figure 41) to be Cu, Pb>Ni>Co>Zn, Mn. This series has likewise been observed in other bryophyte studies (Brown 1982).

There are many questions about micronutrients for which we have no answers, or have them for very few

species. Can they substitute one micronutrient for another? What processes and structures use these micronutrients? Can the presence, absence, or deficiency of a nutrient change the form of the bryophyte? Can such differences make them look like different species in different habitats? What are their deficiency symptoms?

Boron

Boron (B) is used in plant cell walls and affects nucleic acid and carbohydrate metabolism (Pilbeam & Kirby 1983). Boron is important in maintaining membrane structural integrity. As in monocots, bryophytes do not have a strong requirement for boron. Known symptoms of boron deficiency are usually secondary effects of changes in permeability of the membranes.

Boron is essential in the plant process of making lignin, which is, in turn, essential for tracheophyte vascular tissue (Lewis 1980). Thus, before tracheophytes could evolve, a means for uptake and incorporation of boron was necessary. But we know that uptake of boron is present in bryophytes. Sameka-Cymerman *et al.* (1991) found that boron, among other minerals, was taken up from the water by *Scapania uliginosa* (Figure 13). On the other hand, the amount incorporated into bryophyte cell walls is considerably less than that in tracheophytes (Matsunaga *et al.* 2004). To date, it is not clear that bryophytes actually require boron.

Figure 13. *Scapania uliginosa*, a species that extracts minerals from the water, including boron. Photo by Michael Lüth, with permission.

As for iron, bryophytes can collect boron from dustfall (Sabovljević *et al.* 2005). However, at least some, including *Sphagnum* (Figure 10, Figure 24-Figure 25) species, may not accumulate it to the same degree as do trees (Gorham & Tilton 1978). Obviously, trees have a much greater need for boron because they must make lignin, and they do not generally rely on dust for their nutrients.

Copper

Copper (Cu), like iron, is important in enzymes in plants. As such, it facilitates many plant processes (Yruea 2005). But copper is needed only in small quantities and becomes toxic in larger quantities. This heavy metal is available in soil and can be carried with water that moves up the bryophyte.

Copper can be limiting in some aquatic habitats, and probably some terrestrial ones as well. In their studies on *Fontinalis dalecarlica* (Figure 14), Glime and Keen (1984) found that natural Lake Superior water had less than ideal copper concentrations for maximum chlorophyll concentration, with 0.01 mg per liter providing the best chlorophyll (Figure 15). At higher concentrations, chloroplasts lost their green color and at 10 mg / L the cells became brown (Figure 16). With increasing concentrations, the tips of *F. antipyretica* became yellow (Figure 19).

Claveri and Mouvet (1995) found that the aquatic moss *Platyhypnidium riparioides* (Figure 17) suffered from denaturation of chlorophyll pigments after spending 12 days in a copper concentration of 80 µg L⁻¹. They found that uptake of copper was not related to photosynthesis, permitting it to continue uptake even when the chlorophyll was damaged. Furthermore, its uptake does not appear to be influenced by temperature, whereas its damage to chlorophyll increases with temperature. Similar damage to chlorophyll occurs in the aquatic moss *Fontinalis* (Figure 50) (Glime & Keen 1984). But this is not just an aquatic phenomenon. It is known also in *Thuidium* spp. (Figure 18) (Shakya *et al.* 2008) and is likely to be the case in all except perhaps the copper mosses.

Heavy Metals

It is perhaps more likely that micronutrients, particularly the heavy metals, will be toxic at greater than trace amounts. Many bryophytes have means of sequestering these in ways that are not toxic. The moss that seems to have the greatest tolerance in many polluted and otherwise heavy metal situations is *Pohlia nutans* (Figure 20-Figure 21), a species with known tolerance to copper, zinc, and nickel (Shaw 1989).

Figure 20. *Pohlia nutans* below old mine. Photo by Michael Lüth, with permission.

Figure 21. *Pohlia nutans*, a heavy metal tolerator. Photo by J. C. Schou, with permission.

Some heavy metals in the environment have no known use by plants, including bryophytes. One such heavy metal is **cadmium**, a toxic by-product of mining and smelting, among other things. In our experiments with *Fontinalis duriaei*, cells became plasmolyzed at 100 μg Cd per liter (Figure 22) (Glime & Keen 1984). At 1000 μg , the cells deplasmolyzed in a way that suggested membranes were damaged.

Figure 22. Effects of cadmium on cell contents in *Fontinalis duriae*. At 100 µg per liter, cells become plasmolyzed. At 1000 µg per liter, the cells deplasmolyze, demonstrating membrane damage. Photos by Janice Glime, based on Glime & Keen 1984.

Nutrient Content

What is normal nutrient content for bryophytes? Or is there one? In the scattered literature that addresses nutrients outside the laboratory, we find that content can depend on habitat, season, uptake ability, and source. But our understanding of bryophyte mechanisms for regulating their nutrient content is meager at best.

Habitat Differences

Habitats can range widely in nutrient availability. These differences can serve as limiting factors for bryophytes, but for most species we do not understand these limitations. In his discussion of *Sphagnum* (Figure 10, Figure 24-Figure 25), Malmer (1988) considered that the concentration differences among the species are mainly caused by differences in growth pattern and site conditions. The concentrations in the living moss and those in the underlying dead peat are not related.

Streams

In streams, phosphorus is typically a limiting nutrient, not to mention CO₂ limitations. On the other hand, pollution, including phosphate from such sources as agricultural fertilizers, can often cause bryophytes to disappear or begin to look unhealthy. One problem for stream bryophytes in high nutrient conditions, whether natural or from pollution, is that the high nutrient level may promote the growth of the periphyton living on their surfaces (Glime, unpublished), causing them to suffer from CO₂ and light competition.

Phosphorus often occurs as agricultural pollution or sewage waste. Frequently it arrives in streams, changing the N:P ratio of those streams. Steinman (1994) examined the effect of phosphorus enrichment on the leafy liverwort *Porella pinnata* (Figure 23) in two woodland streams of eastern Tennessee, USA. Not surprisingly, the N:P ratio decreased significantly, and the P:C ratio increased significantly in the liverworts. In this case, the expected epiphyte structure and abundance in the liverworts were not significantly affected, perhaps due to greater grazing by snails.

Figure 23. *Porella pinnata*, a species that can incorporate added phosphate into its cells. Photo by Des Callaghan, with permission.

Christmas and Whitton (1998) compared the phosphorus content of the stream mosses *Fontinalis antipyretica* (Figure 50) and *Platyhypnidium riparioides* (Figure 17) to that in the River Swale-Ouse in NE England. They found that both P and N concentrations increased with downstream distance. The mosses likewise showed their lowest concentrations at the headwater site, with increasing levels of both elements with distance downstream. More interesting was the change in N:P ratio with distance downstream, decreasing from 14.9:1 to 6.8:1 in *F. antipyretica* and from 12.5:1 to 5.5:1 for *P. riparioides*, suggesting luxury uptake of P. The PMEase (phosphomonoesterase) was greatest at the lower pH (5.5) compared to the higher pH values. The enzyme decreased at all three pH values with distance downstream. Nevertheless, mean primary production increased by only 15% following enrichment, a difference that was not statistically significant.

Bogs and Fens

We know that by definition, **bogs** and **poor fens** have low nutrient content, **intermediate fens** are characterized by intermediate nutrient levels, and **rich fens** have the highest nutrient levels among these habitats. The bogs and poor fens have similar nutrient concentrations and similar bryophyte species, but differ in their nutrient sources, whereas the species of bryophytes in the intermediate and rich fens differ from each other and from those of the bogs and poor fens. Wojtuń (1994) found that N, P, K, Ca, Mg, and Na were in significantly higher concentrations in *Sphagnum* (Figure 10, Figure 24-Figure 25) from the **minerotrophic** (nutrient-rich) fens than from the **ombrotrophic** (low-nutrient) bogs and fens, with K and P

having the greatest differences. As already noted, in the aquatic moss *Warnstorfia fluitans* (Figure 9) from an Arctic lake, increased P content caused increased growth, but increased N content did not (Riis *et al.* 2010). Hence we can conclude that at least some nutrients do make a difference to the bryophyte species. This indicates differences in physiology for which we have only minimal understanding.

For *Sphagnum* (Figure 10, Figure 24-Figure 25) species, cation exchange (see Chapter 8-4, Uptake) plays a major role in the ability to take up nutrients in low-nutrient situations, but can make a species intolerant of divalent cations such as Ca^{++} . Cation exchange causes calcium to adhere to cells, replacing H^+ ions along the cell walls. Since the Ca^{++} ion has two positive charges, it occupies two exchange sites. In this way it competes preferentially with other needed nutrients with only one positive charge, especially potassium (Koedam & Büscher 1982).

Hájek and Adamec (2009) found that nutrient content of *Sphagnum* (Figure 10, Figure 24-Figure 25) species varied between contrasting microhabitats. The greatest difference was shown between *S. angustifolium* (Figure 24) and *S. magellanicum* (Figure 25), with the latter having a 40% lower intracellular N content, even when it grew alone. This lower uptake ability by *S. magellanicum* can permit *S. angustifolium* to outcompete *S. magellanicum* when the two are mixed.

Figure 25. *Sphagnum magellanicum*, a species that is a poor competitor for N. Photo by Michael Lüth, with permission.

In *Sphagnum fallax* (Figure 26) from a fen woodland, its annual accumulation of N, P, and K differed little between a dry and a wet year (Brock & Bregman 1989). How can we account for this ability to maintain the same level of these three essential and often limiting nutrients, despite different opportunities for uptake in different precipitation regimes? On the other hand, Lembrecht and Vanderborcht (1985) examined the mineral content (Na, K, Ca, Mg, Al, Fe, P, Cu, Mn, Pb, Zn) of nine species of *Sphagnum* (Figure 10, Figure 24-Figure 25) in Belgian bogs and found that the concentrations of all elements except Ca, Zn, and Mn were related to the moisture of the habitat. The concentrations of Ca and Cu were lower in one site due to trophic status and air pollution, respectively.

Figure 26. *Sphagnum fallax*, a fen species for which N, P, and K accumulation differences between years seems not to be affected by annual precipitation differences. Photo by Michael Lüth, with permission.

The pH plays an important role in determining how Ca affects bryophytes, best known in bog and fen systems. Clymo (1973) found that most *Sphagnum* (Figure 10, Figure 24-Figure 25) plants grew well in low Ca^{++} at a low pH, at high pH, or at high Ca^{++} , but not when both pH and Ca^{++} concentration were high.

Turetsky *et al.* (2008) found that *Sphagnum* species exhibit resource partitioning, with a tradeoff between metabolic and structural carbohydrates. The way that bryophytes use their nutrients has interesting implications for their decomposition and their roles as ecosystem engineers through sequestration of certain nutrients. And these differences must be examined at the species level, not at the bryophyte level, due to species differences.

Forests

In forests, a primary source of nutrients derives from decomposition of leaf litter. But in industrialized areas, air pollution becomes a major source of N, as well as a number of trace elements. P is often limiting. Species diversity is fostered by habitat diversity that provides nutrient levels differing from those of the forest floor. We can observe considerable species differences on soil, rocks, trees trunks and leaves, and logs, which we usually attribute to differences in moisture, but we lack an understanding of the role that nutrients may play in these species differences.

Substrate can make a difference in nutrients available. As already noted, the moss *Leucobryum juniperoides* (Figure 4) is sensitive to high concentrations of nitrogen,

preferring the lower N levels on rocks and logs in some locations with high N in the soil, whereas in others the soil has a low enough concentration to be suitable (Wang *et al.* 2014).

In the highly polluted region of Central-East Europe, Jirousek *et al.* (2011) found that local forestry practice affected the N-limitation experienced in areas with high P and N saturation.

Arctic and Alpine

Bryophytes can be very important in sequestering P in Arctic soils. Chapin *et al.* (1987) found that 75% of the above ground annual P accumulation was in the mosses of an Alaskan black spruce (*Picea mariana*; Figure 27) forest. The mosses *Sphagnum subsecundum* (Figure 28), *Hylocomium splendens* (Figure 41), and *Pleurozium schreberi* (Figure 31) have higher absorption capacity for phosphate than do the fine roots of the spruce. The uptake comparison demonstrated that absorption capacity increases with age in green tissues while decreasing with age in brown tissues in three of the four studied mosses. In the fourth moss species, the endohydric *Polytrichum commune* (Figure 44), phosphate is absorbed most rapidly from stems in mineral soil. When mycorrhizal fungi were killed in the plots, phosphate retention by mosses increased and transfer out of the plots decreased, suggesting that P is transferred from the moss carpet to the tree roots by fungi.

Species Differences

Nutrient content, as we might expect, can differ widely among species. For example, copper mosses such as *Scopelophila cataractae* (Figure 29) can be expected to have high concentrations of copper, although in some cases it is iron rather than copper that is accumulated (Shaw 1987b).

Figure 29. *Scopelophila cataractae*, a moss with high tolerance of, and possibly dependence on, copper. Photo by David T. Holyoak, with permission.

We have already noted the importance of cation exchange sites in determining the habitat of *Sphagnum* (Figure 10, Figure 24-Figure 25) species. Malmer (1988) found that in three hummock *Sphagnum* species the cation concentrations of Na, Mg, and Ca depended on the exchange capacity of the species. The sum of the divalent ions Ca^{++} and Mg^{++} was the same throughout the plant. Hájek and Adamec (2009) compared locations of various ions in six species of *Sphagnum*, demonstrating differences in locations and concentrations (Figure 30).

To understand the ability of mosses to sequester nutrients differentially, Berg and Steinnes (1997) compared wet deposition data to the concentrations of 48 elements in the feather mosses *Hylocomium splendens* (Figure 41) and *Pleurozium schreberi* (Figure 31). Their results suggest that for some elements, moss content reflects environmental content. This was true for V, Fe, Co, As, Y, Mo, Cd, Sb, Ce, Sm, Er, Tl, and Pb in *Hylocomium splendens*, and for Mg, V, Fe, Co, As, Se, Y, Mo, Cd, Sb, Tl, and Pb in *Pleurozium schreberi*. Among these results, I find the difference in Mg as the most interesting. Mg is the element in the center of a chlorophyll molecule and thus is essential for all photosynthetic plants and algae. *Hylocomium splendens* had the highest concentrations of Cr, Fe, Co, Ni, Cu, Ga, Nb, Mo, Sb, Eu, Gd, Tb, Dy, Er, Tm, Lu, W, Tl, Pb, and Th, whereas V, Mn, Rb and Cd were highest in *Pleurozium schreberi*. These differences are interesting because these two species frequently occur in the same habitats, especially in boreal forests.

Figure 30. Exchangeable cation fraction from the total cation pool in apical (uppermost) and dead shoot segments of six *Sphagnum* species. Symbols below the columns are p values of the t-test for dependent samples testing the differences between shoot segments: # $p < 0.001$; + $0.01 < p < 0.001$; * $0.05 < p < 0.01$; n $p > 0.05$. Redrawn from Hájek & Adamec 2009.

Figure 31. *Pleurozium schreberi*, a species for which cell contents reflect the Mg levels in the environment. Photo by Janice Glime.

Williams *et al.* (1999) found differences in labelled N in waters from two species of *Sphagnum* in a bog in northeast Scotland. In the hummock species *Sphagnum capillifolium* (Figure 32), labelled dissolved organic nitrogen in moss water was proportional to that added as inorganic N, but in the hollow species *S. recurvum* (Figure 33), it was not.

Figure 32. *Sphagnum capillifolium*, a hummock species in which N content is proportional to that added. Photo by J. C. Schou, with permission.

Adaptability and Acclimation

One question that has received little attention is the ability of bryophytes to acclimate or adapt to high concentrations of any given nutrient or pollutant. With the wide range of minerals and other nutrients in the environment, how does an **ectohydric** (moving water on the outside of plant) bryophyte respond to these differences? There is some evidence that they do change

their tolerance. Shaw (1987a) showed that protonemata responded to pretreatment with copper and zinc more than did the stems of *Funaria hygrometrica* (Figure 2). But overall, genetic differences had a greater role than acclimation through pretreatment, with some individuals showing a significant response and others showing little or none.

Figure 33. *Sphagnum recurvum*, a hollow species in which N concentrations do not reflect those of the atmosphere. Photo by Malcolm Storey, <www.discoverlife.com>, through Creative Commons.

In culture conditions, Shaw (1988) demonstrated that populations exhibited a wide range of tolerances in the protonemal and stem stages. To confound the story, Shaw found that in experiments with copper and zinc the populations of *Funaria hygrometrica* expressed a greater similarity among environmental correlations than among genotypic correlations, suggesting some sort of acclimation.

A genetic ability to survive and even require some heavy metals such as copper is exhibited by *Scopelophila cataractae* (Figure 29) (Shaw 1987b). Out of six populations in eastern USA, five were associated with high copper concentrations. The sixth was associated with high iron concentrations. When cultivated, these populations grew best on soil contaminated with copper, lead, and zinc. It is interesting that this species lacks sexual reproduction in North America. Could that be related?

Plant Nutrient Locations

Nutrients not only have different purposes, but also are located in different positions within the plant and within the cells they occupy. Some are needed structurally and some are used **constitutively** (always present, such as defense compounds). For example, potassium, a highly soluble and mobile nutrient, is present in *Grimmia donniana* (Figure 34) and *Calliergonella cuspidata* (Figure 35) in a soluble form within the cell, whereas the calcium is primarily in extracellular locations in exchangeable form (Brown & Buck 1985; see also Brehm 1968; Bates 1992; Bates & Brown 1974; Brown & Buck 1979, 1985). Magnesium and zinc, on the other hand, were intermediate, with their locations depending on the species and concentrations. Turetsky *et al.* (2008) demonstrated that a tradeoff between structural and constitutive use of nutrients, especially C and

N, in *Sphagnum* species gave hummock species the ability to maintain their hummocks by putting more nutrients in recalcitrant structural forms that did not decompose easily.

Figure 34. *Grimmia donniana*, a species with soluble K in its cells. Photo by Henk Greven, with permission.

Figure 35. *Calliergonella cuspidata* growing among sedges. Photos by Michael Lüth, with permission.

Wojtuń (1994) determined that N, P, and K accumulate in the upper parts of *Sphagnum* (Figure 10, Figure 24-Figure 25) through active uptake; all three are typically found within the cell, being used in cell metabolism rather than cell wall metabolism (Brown & Wells 1990b). On the other hand, Ca, Mg, and Na are obtained through passive cation exchange. These and other elements acquired through cation exchange tend to accumulate in the lower parts of the plants. The concentration of iron either does not correlate or correlates negatively with the other

elements (Wojtuń 1994). Contents of N, P, K, Ca, Mg, and Na were significantly higher in mosses from **minerotrophic** (high nutrient) habitats than in those from **ombrotrophic** (low nutrient) habitats. The greatest difference among species were for K and P.

Brown and Wells (1990a) showed that heavy metals could alter ion locations, for example by causing potassium leakage due to membrane damage. It is interesting that in the liverwort *Dumortiera hirsuta* (Figure 36), pretreatment with 80 mM KNO₃ actually stimulated cadmium uptake, presumably because the potassium removed potentially competing cations from the exchange sites, thus permitting more Cd to bind and be taken up by the cells (Mautsoe & Beckett 1996). This suggests that potassium ions are able to occupy environmentally exposed exchange sites as well as their interior sites. Such locations could make these ions readily available when needed by the cells.

Figure 36. *Dumortiera hirsuta*, a species in which K⁺ removes competing cations from exchange sites, permitting Cd⁺⁺ to bind and then enter cells. Photo by Michael Lüth, with permission.

Ron *et al.* (1999) used *Hookeria lucens* (Figure 37) to observe the cause of reddish-brown deposits of minerals in the cells. They identified the minerals bohemite, calcite, diaspore, feldspar, ferrihydrite, gibbsite, jarosite, lepidocrocite, opal, pirolusite, and quartz inside the **hydrom** (unit of water-conducting cells), cortex, and leaf cells. Since not all of these minerals were present in the soil substrate, they hypothesized that the additional ones were derived from a biomineralization process inside the moss cells from such elements as Mn and S, and from those in the soil on which the mosses were growing.

Bates (1987) found that in *Pseudoscleropodium purum* (Figure 8) fertilization caused a small net increase in Mg, but shoot N had no significant change in the plant. Ions held on exchange sites did not increase much with fertilizer addition in the field, but in the laboratory, a 30-minute exposure to these caused Ca⁺⁺ and Mg⁺⁺ concentrations to rise notably, whereas exchangeable K⁺ fell. But the disappearance of these exchange site nutrients when the mosses were returned to the field caused Bates to question the utility of the exchange sites. Could they serve to keep a ready supply while at the same time preventing excess within the cells? Weekly watering with fertilizer caused maximum net uptake of P, Mg, and Ca. Pulse watering with more concentrated solutions at greater intervals had the least uptake.

Figure 37. *Hookeria lucens*, a species that can be discolored by minerals in the hydrom, cortex, and leaf cells. Photo by Michael Lüth, with permission.

Determination of the interior location of plant elements has been complicated by damage to the cell membranes during the measurement technique (Brown & Wells 1990b). When this damage happens, ions are released and may become bound to newly exposed cell walls on the insides of the cells.

Cell Wall Sites

The cell walls of tracheophyte roots have exchange sites that permit binding of nutrient ions and facilitate uptake. Similar, and very active, exchange sites are well known on *Sphagnum* (Figure 10, Figure 24-Figure 25) leaves (Clymo 1963; Spearing 1972; Schwarzmaier & Brehm 1975). But other bryophytes can have exchange sites as well (Brown & Buck 1979; Glime *et al.* 1982). Unfortunately, this capacity has scarcely been examined for non-*Sphagnum* bryophytes. Nevertheless, as described above, it appears that such sites exist to varying degrees among the bryophytes in general.

Brown and Buck (1979) reported that in bryophytes Ca⁺⁺ is bound to exchange sites in the cell wall and is insoluble within the cell. The quantity of an element bound to such sites depends on the concentration of that element. The ability of a **cation** (positive ion) to reach a stable equilibrium is relatively rapid, whereas its departure rate when the external supply is removed and replaced with a solution free of the element is often slower, the former taking only about 4.5 minutes to reach half maximum extracellular uptake for 100 µM L⁻¹ Cd in *Rhytidiadelphus squarrosus* (Figure 11) (Brown & Beckett 1985), but taking days at lower concentrations of <0.13 µM L⁻¹ Cd in some aquatic species (Mouvet 1987).

Vázquez Castro *et al.* (1999) examined the location of heavy metals in three aquatic mosses. They found that most of the metal uptake was to the extracellular compartment compared to the intracellular fraction. *Scapania undulata* (Figure 48) in particular has a high exchange site affinity for the heavy metals, whereas *Fissidens polyphyllus* (Figure 38) has a relatively low attraction. On the other hand, *F. polyphyllus* has the highest intracellular contents.

Figure 38. *Fissidens polyphyllus* in limestone cave, a species with low affinity for heavy metals. Photo by Janice Glime.

The mechanism of cation exchange is discussed in the subchapter on Uptake (Chapter 8-4 of this volume). Binding preferences vary with concentrations and can be determined based on availability of the ions, previous filling of the exchange sites, type of ligand in the exchange site, and type of ions (Brown & Wells 1990b). For example, potassium, calcium, and magnesium prefer oxygen-rich **ligands** (ion or molecule that binds to a central metal atom to form a complex) such as carboxylic groups (Nieboer & Richardson 1980). Others such as mercury, lead, and gold prefer sulfur- and nitrogen-rich ligands. Some are borderline and have intermediate preferences with heavier elements tending to prefer the sulfur- and nitrogen-rich ligands.

Intracellular Sites

Brown and Wells (1990b) reminded us of the need to separate the locations of the elements within the cells. They furthermore pointed out that many of the elements became bound into compounds, onto membranes, or onto the interior of the cell walls. Others could be stored in vacuoles. Not only potassium, aluminium, and nitrogen occurred inside cells of *Sphagnum* (Figure 10, Figure 24-Figure 25), but also magnesium and sodium (Hájek & Adamec 2009). Magnesium is stored in the chlorophyll molecule, where it is essential for that molecule to function in photosynthesis (Brown and Wells 1990b). Sodium has no known use in bryophytes.

Brown and Buck (1979) found that potassium is mainly dissolved within the bryophyte cells. Magnesium is found not only in the cells but also adhering to exchange sites and cell membranes. Hájek and Adamec (2009) looked at nutrient locations in *Sphagnum* (Figure 10, Figure 24-Figure 25) and reported that K, Mg, N, Al, and Na occurred within cells, although Mg and Na also could be found on exchange sites. (Note, Al and Na are generally not considered to be plant nutrients.)

Microhabitats and species differences seem to account for nutrient content in *Sphagnum* (Figure 10, Figure 24-Figure 25) (Hájek & Adamec 2009). For example, *Sphagnum magellanicum* (Figure 25), a hummock species, had an intracellular nitrogen content that was about 40% lower than that in associated species. Such unequal

competition for N, even when compared to *S. magellanicum* grown alone, suggests its inability to compete for N in mixed patches.

Vertical Distribution

The base of the plant has different concentrations of most elements compared to the apex (Brown & Wells 1990b; Hájek & Adamec 2009). For example, potassium, a soluble and translocatable nutrient, is most concentrated in the actively growing apex of the plant and is intracellular (Figure 39) (Brown & Wells 1990b). Other cellular metabolic components such as nitrogen and phosphorus are likewise concentrated in the growing apex (Brown & Wells 1990b; Hájek & Adamec 2009 – see Figure 30).

Figure 39. Location of four elements in 2-cm sections from new apical segment to base along the stems of laboratory-grown *Rhytidadelphus squarrosus* (Figure 11). Redrawn from Brown & Wells 1990b.

As in tracheophytes, bryophytes are able to move at least some of their nutrients to actively growing tissue. In *Hylocomium splendens* (Figure 41) less new growth occurred when branches of mature segments were removed (Brümelis & Brown 1997). The metals K, Mg, Ca, and Zn in new growth correlated with the initial contents in the juvenile plus mature segments but not with the levels in the pre-experimental segments, suggesting the importance of moving nutrients to growing tissues.

Those elements that are predominantly bound to extracellular sites tend to accumulate in the basal regions of the plant (Brown & Wells 1990b). These include the heavy metals. Their accumulation at the base may be the result of cell death in that region, exposing exchange sites on the cell interiors. Those elements such as manganese that are poorly bound to exchange sites may move upward through evaporative water movement and accumulate at the apex (Lötschert & Wandtner 1982; Malmer 1988), a phenomenon sometimes referred to as transpiration transport.

Malmer (1988) divided three hummock *Sphagnum* (Figure 24-Figure 25) species into four segments for nutrient and growth analysis. As one might expect, weight increases mostly in the capitulum, but length increases further down. To facilitate this growth, N, P, and K accumulate in the upper parts of the mosses. The trace elements Al, Fe, Zn, Cd, and Pb increase with the age of the plants. Both Ca^{++} and Mg^{++} are at first bound to exchange sites on the outside the plant and the sum of these two minerals is consistent throughout the *Sphagnum* plant.

Nutrient Sources

Mineral nutrients result from weathering and atmospheric deposition (Bates & Farmer 1992). Bryophytes can use five major sources of nutrients: soil, stream water, atmospheric dust, precipitation (including throughfall), and litter (Babb & Whitefield 1977; Parker 1983; Frego & Carleton 1995). For **saxicolous** (rock-dwelling) bryophytes, the only feasible sources are dust and precipitation (Rieley *et al.* 1979), especially for potassium (Bates 1976), although Hébrard *et al.* (1974) demonstrated the ability of *Grimmia orbicularis* (Figure 40) to obtain radiolabelled ^{90}Sr from an artificial rock. For pleurocarpous taxa and taxa living in the forest, the atmosphere (dust and precipitation) is generally considered to be the major nutrient source (Brown 1982), but as we shall see, this may not be the whole story. More to the point, what can we expect in uptake of the macronutrients such as phosphorus, nitrogen, and potassium, and are these values controlled, or are they determined by the concentrations in the ecosystem?

Figure 40. *Grimmia orbicularis*, a species with the ability to take up minerals from its rock substrate. Michael Lüth, with permission.

In a study of bog mosses, Malmer (1988) found that variations in S, Cu, Zn, Cd, and Pb are the results of varying man-made emissions. Na and Mg variations can be traced to oceanic influence. P, Na, Mg, and Ca also seem to vary with moss productivity. Al and Fe are greatest near agricultural and industrialized regions. Unlike the other elements, Mn concentrations are related primarily to the soil and bedrock.

Precipitation

Clearly rainwater has a very different chemical makeup than soil. Some elements are more abundant, whereas others, like Mg, are virtually absent in the open. Hence, mosses that grow in the open and do not get any leachates from canopy trees are likely to be very deficient in some elements. Could the lack of Mg in *Funaria hygrometrica* (Figure 2), a species of open sites, explain why it is so short, or might being short be an adaptation to living there?

Larsen (1980) describes the mosses in the boreal forest as growing vigorously, using nutrients that they receive in throughfall, and Weetman (1968) likewise found that feather mosses in a black spruce (*Picea mariana*; Figure 27) forest relied on dust and precipitation for both nutrients and moisture. Tamm (1953, 1964) found that rainwater was sufficient to account for all the nutrients needed by the

feather moss *Hylocomium splendens* (Figure 41). Weetman and Timmer (1967) concluded the same thing for *Pleurozium schreberi* (Figure 31) in the black spruce forest, where N, K, Ca, and Mg were leached from the canopy. This canopy throughfall source annually supplied 9 kg of N per hectare to the moss. In fact, the spruce trees are known to be N-deficient and root prolifically at the base of the green layer of mosses. Since feather mosses such as *Pleurozium schreberi* and *Hylocomium splendens* are known to mineralize nitrogen, they interpreted this to mean that the moss layer provided the major source of nitrogen for the trees. It is likely that mosses also held a portion of rainfall N in interstitial spaces among leaves in this layer, retaining it where tree roots could absorb it during the time that there was sufficient moisture for them to grow. It is also likely that in late summer when nutrients in the soil are depleted, rehydrating mosses could release nutrients collected as dust, but also from cells with membranes damaged by the drought (Leary & Glime 2005).

Figure 41. *Hylocomium splendens* gametophytes. Photo by Janice Glime.

Nutrient availability from precipitation can vary widely, depending on the canopy, with the lowest nutrient concentrations occurring in the open. Tamm (1953) showed that *Hylocomium splendens* (Figure 41) grew more under the canopy than in the open, and that its annual dry biomass increments under the canopy increased with distance from the tree trunk. He attributed these differences to light intensity increases outward from the trunk, whereas in the open he considered there to be insufficient nutrients due to lack of canopy trapping and leaching. However, despite the differences in precipitation nutrient concentrations, tissues of those *Hylocomium splendens* plants located in the open had the same nutrient concentrations as did the ones under the canopy, suggesting that they must have obtained their nutrients from something other than rainfall (Brown 1982), but also grew more slowly, thus requiring lower concentrations from the environment.

Forsum *et al.* (2006) not only compared the forms of nitrogen use by *Hylocomium splendens* (Figure 41), but also analyzed the nitrogen components of rain. Typically, amino acids in the rainfall are ignored, but Forsum and coworkers found that rain in their boreal forest study site had 78% of its nitrogen in ammonia (NH_4^+), 17% in amino acids, and 5% in nitrates (NO_3^-). Furthermore, they found

that *H. splendens* absorbed more N from ammonia than from nitrate or the amino acid glycine when they were applied in solutions similar to those of the local rainfall. See the subchapter on Nitrogen in this volume for a further discussion of amino acids as a nitrogen source.

But certainly the water regime is different in the open as well (Tamm 1953). Trees in the forest redirect the rainfall, with much of it flowing down the trunk, or never reaching the forest floor at all. Trees can have either **centripetal water movement** (toward the bole, *i.e.* main trunk), for example *Acer*, *Fagus*, and *Fraxinus*, or **centrifugal** (toward the outer branch tips), for example *Betula*, *Picea*, and *Tilia*, depending on tree morphology. These patterns affect the source of nutrients and degree to which they reach the ground.

Tamm (1953) and Abolin (1974) both found that water volumes increased at the canopy margin. Barkman (1958) found that the percentage of rainfall reaching the tree bole of spruce (*Picea*) was only 1%. Nihlgård (1970) found that beech retained 19% of the rainfall, permitting 70% to go through the canopy as throughfall and 11% as stemflow. For spruce it was 39%, 58%, and 3%, respectively. In the open, all rainfall will reach the mosses. In her study of nutrient cycling through *Sphagnum russowii* (Figure 42) in a Jack pine (*Pinus banksiana*) forest and an open mat, Scafione (unpublished data) often found that moss throughfall collectors in the open had abundant water when those under the canopy were empty. Therefore, since more water reaches the mosses in the open, the total nutrients reaching those mosses could be relatively greater than that estimated by concentration levels, because more water reaches them.

On the other hand, forest trees serve as collectors of minerals in dust, releasing these as they are washed off by rainfall. In the forest, short rainfall events, which are likely to contain high nutrient levels, may not reach the mosses at all, whereas in the open field, they will. Both field and forest mosses will receive nutrients as dustfall, but open field mosses could receive more because there will be no trees to serve as filters or to block the wind.

Figure 42. *Sphagnum russowii*, a species that grows in both the sun and forest where nutrient inputs are very different. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Bates (1992) suggests that growth rate plays a role in the source of nutrients used by the forest bryophytes. The slow-growing moss *Pseudoscleropodium purum* (Figure 8)

obtains its minerals largely from "wet deposition," but phosphate is in low concentration in precipitation. Instead, it typically gets this mineral from the substrate.

Bogs

Bogs are defined by their source of nutrients. These come entirely from precipitation (Malmer *et al.* 1992); ground water does not move through the mat. This may be a bit too exclusive for a definition because dust from the atmosphere will also collect on the mosses, and when rainfall occurs the collected dust can go into solution and subsequently into the mosses. This is in contrast to nutrients in fens, particularly rich fens where Ca and Mg are available in surface water.

Atmospheric Dust

In some habitats, atmospheric dust can provide most or all of the mineral nutrients. In many *Sphagnum* (Figure 10, Figure 24-Figure 25) bog species, the mosses seem to depend exclusively on aerial deposition for their mineral nutrients (Hájek & Adamec 2009).

The composition of rainfall changes during a single rainfall event as it cleanses the atmosphere of its load of dust. Early rainfall in polluted areas is more acidic than later in the storm because it is washing the pollutants such as sulfates and nitrates out of the atmosphere. This lower pH causes more nutrients from the collected dust to go into solution. In the forest, this early rainfall will most likely not reach the mosses on the forest floor, being trapped by the canopy leaves. Meanwhile, the low pH of initial rainfall can leach nutrients from the canopy leaves, making them available in the throughfall that later reaches the mosses on the forest floor and on the tree bole. In the field, this low pH can be an effective way to dissolve the nutrients in the collected dust on the moss surfaces. A heavy rainfall might wash away a considerable portion, but a light rainfall may simply serve as a solvent while being insufficient to drip through the moss to carry the nutrients away.

By these mechanisms, throughfall alters the composition of rainfall considerably. The canopy enriches the rainfall by collecting dust that subsequently releases nutrients into solution in the rainfall. Schlesinger and Reiners (1974) demonstrated, by using artificial, plastic conifer needles, that the particulate matter of throughfall could increase by 4.5X. But living tree leaves can remove nutrients as well, and may hold more than artificial leaves due to hairs, snail trails, glands, and other features that trap dust particles. N can be removed almost completely from the rainfall by the canopy leaves, whereas K and P are typically enriched by the canopy (Brown 1982). Caterpillars in the canopy can contribute substantial amounts of both N and P through their excreta and feces (Szabó & Csontos 1975), presumably recycling that which is stored in leaves and thus including nutrients that originated in the soil. Mn is rich in litter, but apparently not in the soil, and may also possibly be leached from the canopy (Brown 1982).

In a lab study of *Mnium hornum* (Figure 43), Thomas (1970) found that the moss could obtain an adequate supply of Ca and Mg from the substrate below, but that K and P concentrations were less than those found in the soil, suggesting that these nutrients required additional input from precipitation, dustfall, or throughfall. Longton and

Greene (1979) showed similar relationships with *Pleurozium schreberi* (Figure 31). The plants had nutrient deficiency symptoms unless additional nutrients were supplied to the leaves. Precipitation and litterfall in the boreal forest were unable to supply sufficient Ca, Mg, and K for *P. schreberi* (Brown 1982) so we must consider that precipitation, dustfall, and substrate are all needed to meet the nutrient demands of at least some bryophytes.

Figure 43. *Mnium hornum* with capsules, a species that obtains Ca and Mg from the substrate below, but requires additional sources for K and P. Photo by Michael Lüth, with permission.

For the **endohydric** (moving water internally) *Polytrichum* (Figure 44) species, inorganic bulk precipitation of N and dust does not account for the entire N input (Bowden 1991). Even when biological nitrogen fixation by associated organisms is included, 35% of the N that has been accumulated by the plant is unaccounted for. Bowden attributed these missing sources to bulk precipitation of organic nitrogen, dry deposition, and dew. Most likely some soil input was also involved, whether directly through rhizoids or by upward movement through external capillary action. Furthermore, we cannot ignore the possibility of transfer from litter and other sources through **mycorrhizae** ("root"-fungal associations), as we will discuss later in this subchapter. Nevertheless, at least 58% of the N in the plant came from bulk precipitation.

Figure 44. *Polytrichum commune*, an endohydric moss that obtains its N from multiple sources. Photo by Michael Lüth, with permission.

Soil

Several studies cited above have shown that nutrients in rainfall are insufficient to account for the concentrations found in the mosses. Binkley and Graham (1981) found that precipitation could account for only 75% of the nitrogen in *Eurhynchium oregonum* (Figure 45) and *Hylocomium splendens* (Figure 41) in an old-growth Douglas fir (*Pseudotsuga menziesii*; Figure 46) forest, and they suggested these mosses might obtain some of their N from the underlying soil. Tamm (1953, 1964) felt that *Hylocomium splendens* was most likely to obtain its nutrients from accumulations on overlying shoots rather than from the soil by capillary action. But in the tundra *Hylocomium splendens*, *Aulacomnium palustre* (Figure 47), and *Sphagnum* (Figure 10, Figure 24-Figure 25) can obtain nitrogen (as ammonium, nitrate, and the amino acid glycine) from 3-8 cm soil depths (McKane *et al.* 1993). Perhaps the translocation of water upward by capillary action brings the nutrients up from lower soil depths. Or is there a fungal connection? In any event, soil seems to contribute to the moss nutrient supply. This concept of soil contributions is further supported by a study on *Pleurozium schreberi* (Figure 31), another pleurocarpous feather moss with a growth form similar to that of *Hylocomium splendens*, that can obtain calcium from CaCO_3 in soil as well as from dilute solutions on its leaves (Bates & Farmer 1990).

Figure 47. *Aulacomnium palustre* gametophytes. Photo by Janice Glime.

Van Tooren *et al.* (1990) further supported the concept that *Hylocomium splendens* (Figure 41) as well as *Pleurozium schreberi* (Figure 31) can obtain micronutrients from the soil. They observed that mosses often have bits of soil and detrital matter nestled among the leaf bases. They tested the hypothesis that these could be derived from the soil substrate and found that indeed nutrients did arrive on the plants from the soil. De Caritat *et al.* (2001) found that geological aspects, sea spray, and human activity all influence the nutrients stored in *Hylocomium splendens* and *Pleurozium schreberi* in northern Europe. These two moss species had considerable composition of the elements of the underlying bedrock, including B, Ca, K, Mg, Mn, and P. Part of this substrate input is due to redistribution of the soil as dust from open areas. It is in this arena that human activity is most likely to be a contributor by making open, disturbed areas through mining, construction, agriculture, lumbering, and other surface disturbances.

Bryophytes of many habitats seem to have the ability to obtain nutrients both from the soil and from rainwater. Van Tooren and coworkers (1990) explored the relative importance of soil vs precipitation as a source of nutrients for pleurocarpous *Calliergonella cuspidata* (Figure 35) on sand and chalk grassland soil. They found that the concentrations of N, P, and K in the plants were higher on chalk soil than on sand, and that these were enhanced by fertilization. However, the plants on the chalk soil did not increase growth when fertilized, whereas those on sand did. They concluded that the soil was providing sufficient nutrients on the chalk grasslands and that some other factor must be limiting their growth.

Our first clue that bryophytes are affected by soil nutrients should have come to us with the realization that some prefer acidic soils and some prefer calcareous soils (Nagano 1972; Bates 1978; Büscher & Koedam 1979; Nakanishi & Hiraoka 1981). *Grimmia orbicularis* (Figure 40) demonstrated the ability to absorb ^{54}Mn and ^{90}Sr from the soil (Hébrard *et al.* 1972). Even more impressive, however, is the ability, already noted, of this species to obtain labelled ^{90}Sr from an artificial rock substrate (Hébrard *et al.* 1974). We need to stop thinking of bryophytes as passive collectors and recognize their ability to move substances from one place to another both internally and externally.

Micronutrients

Bryophytes are known for their ability to take up nutrients and accumulate them. This ability has made them useful in geological prospecting and in measuring accumulation of pollutants. Samecka-Cymerman and Kempers (1993) used aquatic bryophytes [*Scapania undulata* (Figure 48), *Pellia epiphylla* (Figure 49), *Fontinalis antipyretica* (Figure 50), *Platyhypnidium riparioides* (Figure 17)] to indicate mineralization in Poland, confirming the presence of geologically documented polymetallic deposits and indicating their presence in areas that had not yet been explored. The interesting story here is that bryophytes are sometimes able to meet these very minor amounts needed by getting them from the rock substrate.

Litter and the Role of Trees

Parker (1983) suggested that atmospheric nutrients include both dry and wet deposition that not only can provide nutrients to the mosses directly but that also can enrich the litter (and leaves on the trees), permitting the leaves to provide nutrients to the mosses secondarily (see Table 2). *Brachythecium rutabulum* (Figure 51) achieved its greatest biomass gain when it was in contact with the stem litter of *Urtica dioica*, apparently intercepting the nutrients in decay products. In a different study, Bates (1992) has related nutrient source to growth rate, concluding that in the rapid-growing species *Brachythecium rutabulum*, mineral inputs from seasonally deposited tracheophyte litter are especially important.

Figure 51. *Brachythecium rutabulum*, a species that obtains nutrients from tracheophyte litter. Photo by Michael Lüth, with permission.

Table 2. Nutrient inputs and moss accumulation in an oakwood in Wales. Based on Rieley *et al.* (1979).

	$\text{mg m}^{-2} \text{yr}^{-1}$			
	K	Ca	Mg	Na
throughfall	1900	1000	1390	10380
litterfall	1920	2100	420	310
bryophyte accumulation	1430	410	390	160

Dicranum polysetum (Figure 52), *Ptilidium ciliare* (Figure 53), and *Ptilium crista-castrensis* (Figure 54) intermixed in a mat of *Pleurozium schreberi* (Figure 31) all experienced enhanced growth from an application of thick needle litter (Frego & Carleton 1995). But we must again question if fungi have a role here, taking from the litter and supplying to the moss. Nevertheless, litter seems to play an important role in providing a nutrient supply.

Figure 52. *Dicranum polysetum* with capsules and litter that serves as a source of its nutrients. Photo by Janice Glime.

Figure 54. *Ptilium crista-castrensis*, a species that benefits from nutrients in conifer needles. Photo by Adolf Ceska, with permission.

Although epiphytic bryophytes (those living on other plants) do not penetrate their substrate to obtain nutrients, they can benefit from nutrients flowing down the bole (main trunk) of a tree, some of which are derived from internal metabolites of that tree. Hoffman (1972) found that bryophytes and lichens at the bases of *Liriodendron tulipifera* (tulip tree) recovered 9% of labelled cesium that had been injected into the tree trunk. This illustrates the cycling of nutrients from the tree, probably through **leachates** (solution that percolates through canopy), to the bryophyte layer. The tree base likewise is the recipient of considerable stemflow that carries with it nutrients washed off the leaves and branches. Hence, the bryophytes at the tree base benefit from both leachates from the leaves and from accumulated dust that may contain important nutrients (Figure 55). Fluctuations in K, Ca, and Mg in nature suggested that appreciable quantities are absorbed by bryophytes during autumn from leaf leachates (Bates 1989). Of course, this also makes epiphytes vulnerable to concentrated pollutants in areas where the tree leaves are able to collect these.

Figure 55. *Dicranum scoparium* growing at tree base where it collects stemflow nutrients and escapes burial by leaf litter. Photo by Janice Glime.

Even in bogs, the critical nutrient potassium, as well as manganese, becomes available to *Sphagnum* (Figure 10, Figure 24-Figure 25) in ombrotrophic bogs through litter decomposition (Malmer 1988).

The more we learn about bryophyte nutrient relationships, the more we realize that they are no simpler than are those of the tracheophytes. Each nutrient and each species must be examined for its own uniqueness, and thus far, we lack sufficient evidence to correlate **functional groupings** (those having similar roles in the ecosystem) with taxonomic or morphological groupings.

Decomposition

The phenomenon that keeps the Earth from running out of nutrients is decomposition. Through a series of breakdowns, organisms return their nutrients to the soil or other substrate. Even bryophytes participate in this process, albeit usually slowly. Rather than losing leaves annually like trees, or dying back and regrowing from underground parts, most bryophytes die from the base while still growing at the tips.

In the taiga, bryophytes form the dominant cover and provide considerable primary productivity in the scheme of things (Oechel & Van Cleve 1986). With this dominance in the ground cover, they play a major role in rapid nutrient absorption, thereby having a large role in controlling ecosystem function. They are able to collect nutrients from dust, incorporate it, and release it slowly. In this way, bryophytes act as **nutrient sinks**.

In a study to understand the effect of climate change on Arctic ecosystems, Lang *et al.* (2009) measured decomposition rates of bryophytes, lichens, and tracheophytes over a 2-year period. Mass loss (decomposition) in tracheophytes was 56%, lichens 44%, and bryophytes a paltry 11%. Nevertheless, percentage loss in **cryptogams** (bryophytes and lichens) varied considerably among species. In particular, *Sphagnum* (Figure 10, Figure 24-Figure 25) loss was much slower than that of other mosses and liverworts. Mass loss of non-*Sphagnum* mosses correlated with the initial N in the plants, a phenomenon that may relate to their nutritive value to the decomposers.

Brock and Bregman (1989) likewise found that organic weight loss during decomposition of the fen moss *Sphagnum fallax* (Figure 26) was low. However, the release of N, P, and K (especially) was in greater proportion than that of organic matter loss. These soluble nutrients could easily leak out from damaged membranes of dead or desiccated cells. But despite this, N and P remained as a large proportion of remaining tissues even 12 months after decay initiated. Instead, they found that after a year of death, the cells demonstrated little damage and were poorly colonized by microorganisms.

The same sequestration seen in the Arctic is also present in the tropics. Tropical epiphytic bryophytes are known to sequester N collected from dust and the atmosphere, putting it into recalcitrant forms that remain in the canopy (Clark *et al.* 1998a, b).

What seems to be a common theme in bryophyte decomposition is that it is slow: Russell 1990 – tundra; Verhoeven & Toth 1995 – *Sphagnum* (Figure 10, Figure 24-Figure 25); Hobbie 1996 – tundra; Sand-Jensen *et al.* 1999 – Arctic lakes; Liu *et al.* 2000 – montane moist evergreen broad-leaved forest; Moore *et al.* 2007 – temperate peatlands; Turetsky *et al.* 2008 – *Sphagnum* in boreal peatlands; Lang *et al.* 2009 – subArctic. This makes the bryophytes a nutrient sink compared to other plant species in most ecosystems. This implies that they get most of their decomposition nutrients from litter decomposition of tracheophytes, not from recycled nutrients from their own tissues.

Snow

We know that snow forms around dust particles in the atmosphere and thus brings nutrients to the soil, efficiently removing them from the atmosphere (Woolgrove & Woodin 1996). As snow partially melts throughout the winter, melt water supplies nutrients to the soil below. When the weather warms in the spring and the snow melts quickly, it typically melts in a flush.

But what role does it have in supplying nutrients to the bryophytes? Are they able to take up nutrients at these near-freezing temperatures? Can they store nutrients to prepare for their spring flush of growth? And what role

does spring melt play in providing a flush of nutrients to be grabbed by mosses before they can reach the soil? Do mosses then serve as sinks, releasing nutrients later as the summer warms and the mosses become desiccated and leak their precious nutrient supply? Or are the mosses damaged and leaking themselves, unable to take advantage of this flush until they have accomplished their own new growth?

If the mosses are able to trap cations on exchange sites, even though they cannot yet absorb and use them, this could later provide a nutrient supply to the roots of tracheophytes at a time when their resources are dwindling, but when they are still actively growing and needing them. Or, bryophytes could deprive them of these atmospheric nutrients by trapping and holding them for an extended period of time – or indefinitely. And how are the important anions held, like NO_3^- and PO_4^{3-} ? Certainly nitrogen compounds arrive in this way, suggesting that mosses may take them in immediately if they are removing them from the system.

Woolgrove and Woodin (1996) examined the effect of snowmelt and nitrate uptake in the moss *Kiaeria starkei* (Figure 56) at a snowbed in the Cairngorm Mountains of Scotland. They found that although the conditions under the snow are unsuitable for photosynthetic activity due to the low light intensity, this moss is capable of photosynthesis as soon as the snow cover is removed. Tissue chlorophyll increases by 250% and carbohydrate concentrations increase 60% within only two weeks. This moss is also capable of nitrate reductase activity at temperatures as low as 2°C and is thus able to assimilate more than 90% of the high levels of pollutant nitrate released during the melting season.

Figure 56. *Kiaeria starkei*, a moss capable of nitrate reductase activity at 2°C. Photo by Michael Lüth, with permission.

On the other hand, in my moss garden in Houghton, Michigan, USA, in an area characterized by northern deciduous forest, the mosses and even the liverwort *Marchantia polymorpha* (Figure 3) are brown and appear dead when the snow recedes. Obviously there are still living tissues there because the mosses and the liverwort both produce new growth within a few weeks, dependent on adequate rainfall and temperature. But under these conditions, it would appear that the mosses should be more

poised to lose nutrients from these brown tissues than to gain them. Certainly more research is needed on the role of individual bryophyte species in sequestering and later releasing nutrients collected during a season of heavy snow. And what effect does a loading of heavy metals, sulfates, and nitrates have on the survival of the bryophyte layer following a sudden snowmelt release?

A further problem occurs once the snow melts in my moss garden. The snow melt water can be gone in a week, and instead of spring rains, this is typically followed by an extended dry period. In some years, it appears that this wet period is insufficient for them to recover before the drought and they can remain largely brown the entire growing season.

The Salmon Story and Other Animals

The salmon (*Oncorhynchus* spp.) are fish, so when I read the title of an article on uptake of salmon-derived nitrogen by mosses and liverworts, I was expecting a story about aquatic mosses (Wilkinson *et al.* 2005). However, instead I was soon reminded of the massive midge outbreaks in Iceland that bring the rich geothermal nutrient source of Icelandic lakes to the terrestrial scene, because these salmon are brought to land by their predators and the remains of the carcasses provide a nitrogen source. In both cases, an aquatic nutrient source is brought to land.

It appears that in at least one forested watershed in coastal British Columbia, Canada, the percent N in moss tissues, especially the common moss *Rhytidiadelphus loreus* (Figure 57), is higher in forest mosses below the falls where the salmon are than above the falls, where they are not. N content was higher in mosses near bony remains from previous years and near wildlife trails (Wilkinson *et al.* 2005). Seven of the eight bryophyte species examined exhibited decreasing N uptake with distance from the spawning region; the exception was *Rhizomnium glabrescens* (Figure 58), an epiphytic species that showed no relationship. Below the falls, the thallose liverworts *Conocephalum conicum* (Figure 59) and *Pellia neesiana* (Figure 60), both indicators of soil rich in nitrogen and calcium, had the greatest cover. Even species richness was higher in forest areas near the salmon stream than elsewhere.

Hilderbrand *et al.* (1999) determined that adult female brown bears (Figure 61) excrete as urine 97% of the N consumed from salmon. This most likely is distributed primarily along the wildlife trails. Thus, wolves, bears, and river otters contribute to the success of the bryophytes by bringing their dinner into the forest and leaving the scraps, but also as they venture through the forest by distributing the N as urine and possibly feces.

Fungal Partners

A long-neglected aspect of bryophyte nutrient uptake is that of **mycorrhizal** (fungal-"root" symbiosis) associations. This has gotten somewhat recent attention and needs to be considered in understanding bryophyte nutrient relations. Details of studies will be covered in Volume 2 on Interactions – Fungi.

We know that conifers and orchids depend on fungal partners to obtain nutrients, and indeed it may be the case for all forest trees. Now we know that it is a part of some bryophyte relationships, but we lack sufficient data to determine how widespread it is.

In the boreal forest, mycorrhizae are therefore of critical importance. And that forest floor is dominated by feather mosses. Mosses can release significant quantities of N and P from their shoots, especially after drying (Carleton & Read 1991). More of this is released from dead and **senescent** (growing old) parts than from the green parts. Leakage of the sugars glucose, fructose, and sucrose from dry moss shoots is sufficient to support growth of three mycorrhizal fungi in pure culture, so we might hypothesize that the bryophytes at least are capable of enhancing the growth of the tree mycorrhizal fungi. When moss shoots were added to the cultures, the fungi readily colonized them, especially in the senescent regions. Labelled phosphate and carbon previously "fed" to the moss shoots were absorbed by the mycorrhizae and transferred across centimeters to roots infected with these fungi. The extent to which the bryophytes are important in this relationship remains to be investigated.

This raises the question of the value of mycorrhizae to bryophytes. The **achlorophyllous** (lacking chlorophyll) liverwort *Cryptothallus mirabilis* (Figure 62) is unable to fix its own carbon through photosynthesis. Both this species and its photosynthetic sister species *Aneura pinguis* (Figure 63) interact with **endophytic** (living within a plant) **Basidiomycetes** – the group of fungi responsible for producing all the mushrooms (Ligrone *et al.* 1993). In *Cryptothallus*, the young fungal hyphae contain abundant **glycogen** (carbohydrate – polysaccharide that forms glucose on hydrolysis) and sometimes **amyloid** (starch-like protein) deposits within the *Cryptothallus*. The fungi associated with both genera very closely match those of orchids – a group with obligate mycorrhizal associates.

pH Relationships

It is not unusual to find bryophytes in habitats with low pH. Merunkova and Chytrý (2012) reported that bryophytes in upland grasslands of the southern Czech Republic were mostly on the low-pH soils that were low in Ca and P, as well as on organic soils. Underwater bryophytes are relatively rare in limestone streams where the carbon is present as carbonate and not as free CO₂ (pers. obs.). This is discussed further in the subchapter on CO₂ in this volume.

The pH not only affects the nutrient uptake ability of the bryophytes, but also can affect the toxicity of such minerals as aluminium (Al) (Bates 1992). Low pH makes many minerals, including Al, more soluble. In most cases, this increases the ability of the minerals to enter the bryophyte along with water. Bates found that in woodland soil and on rock substrates, the bryophyte cation exchange capacity (CEC) decreased with decreased Ca and the pH in the substrate.

On the margins of forested stream channels, Hylander and Dynesius (2006) found that mosses were more influenced by the pH than were liverworts. They furthermore found that having pockets with higher pH increased the bryophyte richness. Corrales *et al.* (2010)

found that pH was one of three factors in determining bryophyte distribution in secondary and planted montane forests in the Central Cordillera of Colombia. Low pH is a major factor in making nutrients available.

Protective Devices

As already seen, not all minerals are good minerals. At low pH levels, aluminium becomes soluble – and toxic. For some heavy metals the cation exchange sites serve as protection, binding the metals and thus immobilizing them.

The toxic heavy metal lead is accumulated in large quantities in cell walls, but also can occur in the cytoplasm (Basile *et al.* 1994). In bryophytes it accumulates preferentially in gametophyte **hydroids** (water-conducting cells in mosses), sporophyte hydroids at the foot, and transfer cells adjoining the sporophyte. It also occurs in the cytoplasm, chloroplasts, mitochondria, vacuoles, and cytoplasmic reticulum. In *Funaria hygrometrica* (Figure 2), the lead is sequestered in tissues, preventing it from reaching the seta and capsules where it could damage developing spores. The **placenta** that joins the gametophyte and sporophyte blocks the transfer of lead to the sporophyte.

Seasonal Nutrient Behavior

Seasonal differences in available nutrients result from litter fall, snow melt, flooding, runoff, available moisture, and seasonal deposition from some kinds of pollution. Nutrient availability may be further mediated by changes in biological needs during the changing life cycle stages of the bryophytes and the tracheophytes that surround them.

Bryophytes, like tracheophytes, have different needs for nutrients in different seasons, and their uptake and movement of those nutrients likewise differs with the seasons. For example, in the boreal feather moss *Hylocomium splendens* (Figure 41), airborne nutrients dominate uptake to the growing tissues during winter in a pine forest in Latvia; Ca and Mg are held in green tissues (Brümelis *et al.* 2000). During the relatively dry autumn, Mg is transferred from older brown and decaying tissues upward to the young tissues, but Ca is not.

Snow concentrates nutrients and releases them in a spring pulse (Brümelis *et al.* 2000). Yet, despite the fluctuations of availability of nutrients in the surrounding environment, there is no evidence that bryophytes suffer leaching as a means of maintaining chemical equilibrium with their environment. The cell membranes must therefore control the entry and exit of ions.

The forest floor moss *Brachythecium rutabulum* (Figure 51) exploits seasonally deposited vascular plant litter (Bates 1992). *Pseudoscleropodium purum* (Figure 8) seems to depend largely on wet deposition for minerals, making its greatest nutrient availability during the season(s) with the most rainfall. But in their study of *Hylocomium splendens* (Figure 41) and *Pleurozium schreberi* (Figure 31), Berg and Steinnes (1997) found no variations in the element concentrations on different dates in the sampling season. This again raises the question of whether bryophytes are able to regulate their nutrient concentrations, and if so, how?

Markert and Weckert (1989) examined minor elements in *Polytrichastrum formosum* (Figure 64), a weedy species in Europe but somewhat rare in North America. They

found considerable variation between stands as well as between seasons. K had little seasonal variation; Al, Fe, Cr, Mg, Pb, and Ti had roughly 80% variation, with their highest concentrations in winter and lowest in summer.

Figure 64. *Polytrichastrum formosum* with capsules, a species that has considerable variation in nutrient content among locations. Photo by David T. Holyoak, with permission.

Because of their ability to take up large quantities of heavy metals, bryophytes have been used for monitoring heavy metal pollution, as has been discussed already in several books. These bryophytes often exhibit symptoms of excess, including **chlorosis** (loss of chlorophyll), brown tips (Figure 19), and **plasmolysis** (shrinkage of protoplast of plant cell resulting from loss of water from cell; results in space between cell membrane and cell wall) (Figure 22). In other cases, the damage is so great that membrane integrity is lost and the cells exhibit **deplasmolysis** (swelling of the cytoplasm of a previously plasmolyzed cell; reversal of plasmolysis) (Figure 22).

Richardson (1981) suggested that there are greater seasonal fluctuations in ectohydric mosses like *Aulacomnium* sp. (Figure 47) than in endohydric ones like *Polytrichum* (Figure 44) due to the ability of ectohydric mosses to absorb nutrients throughout the plant. In the black spruce forests (Figure 27) of Alaska, *Polytrichum* (*Polytrichastrum*?) had its highest phosphate uptake rates in below-ground portions. But we must also consider that this moss has ectohydric movement of water that carries water and nutrients to the apex where they are absorbed. The leaves rehydrate slowly, suggesting that they are more water repellant than absorptive.

Williams *et al.* (1999) compared the seasonal nitrogen dynamics in two *Sphagnum* species: *S. capillifolium* (Figure 32) occupying hummocks and *S. recurvum* (Figure 33) in hollows. Rather than rely on natural sources, the researchers added labelled NH_4NO_3 at the levels in the ecosystem where the mosses lived. The proportion of labelled N in the mosses ranged from 11 to 100% during the 14-month study. The lowest measurements occurred in October when the water table reached the surface of the mosses. This was particularly true for *S. recurvum*. A very small amount of the labelled N was detected as dissolved organic nitrogen in the moss water. There were also times when they could not account for a large proportion of the added N.

In *Sphagnum* (Figure 10, Figure 24-Figure 25) in the southern Alps, Na, Mg, and to a lesser extent Ca, became progressively more concentrated in the tissues as the growing season progressed; N, and to a lesser extent, P, were enriched in the photosynthetic cells during this period of intense growth, but were leaked from the cells when the growth rate slowed (Gerdol 1990). Likewise, during cold months, Na, Mg, and Ca were leached from the cell walls.

Bryophyte growth periodicity can differ between years, being influenced by precipitation (Brock & Bregman 1989). And surprisingly, capsules of *Sphagnum fallax* (Figure 26) in a fen woodland were formed only during the dry year, somewhat reminiscent of flowering plants that bloom in response to drying conditions or algae that reproduce sexually when nutrients begin to diminish in the water.

Streams have seasonal pulses in nutrients, with the largest usually corresponding to snowmelt and spring runoff. In an acidic stream in Northeast England, Ellwood and Whitton (2007) found that organic phosphate, the form used by those bryophytes, reaches a high peak in late spring. In the moss *Warnstorffia fluitans* (Figure 9) this peak coincided with higher concentrations of organic P.

On the other hand, in their study of the aquatic mosses *Fontinalis antipyretica* (Figure 50) and *F. squamosa* (Figure 65) in a mountain stream in Spain, Martínez Abaigar and coworkers (2002) found that concentrations of K, Fe, P, and N increased in every portion of the plant through summer and autumn and decreased through winter and spring. Since these concentrations did not track the concentrations of the stream water, they presumed that the concentrations of the mobile elements depended on the growth cycle. Na increased in the plants in winter, presumably as a result of winter deicing salts. Ca and Mg seemed to fluctuate randomly throughout the plant.

Figure 65. *Fontinalis squamosa*, a species that increases its concentrations of K, Fe, P, and N throughout the plant in summer and autumn. Photo by Janice Glime.

It is hard to generalize from the few studies presented here (see Table 3), but it appears that minor elements may be high in the plants in winter when they are not being used and that the three major elements (N, P, K) are relatively conserved throughout the year. Translocation can provide mobile nutrients from older parts to younger parts prior to and during early stages of growth, thus maintaining sufficient nutrient supply to support the relatively slow growth rate of a bryophyte.

Table 3. Seasons of uptake and loss of nutrients in bryophytes from different habitats. + indicates uptake for that group; - indicates loss for group; no symbol indicates season of highest concentration. These positions should not be interpreted as representative as so few bryophytes have been evaluated seasonally.

Species	Spring	Summer	Autumn	Winter	Reference
<i>Hylocomium splendens</i>				+Ca,Mg	Brümelis <i>et al.</i> 2000
<i>Fontinalis antipyretica</i>	+K,Fe,P,N	+K,Fe,P,N	+K,Fe,P,N	Na	Mártínez Abaigar <i>et al.</i> 2002
<i>Sphagnum</i>		+N,Na,Mg,Ca	+P,Na,Mg,Ca	-N,P,Ca,Mg,Na	Gerdol 1990
<i>Polytrichastrum formosum</i>		K		Ba,Ca,Cd,Cu,Sr,Mg,Zn Al,Fe,Cr,Mg,Pb,Ti,	Markert & Weckert 1989

Effects on Species Composition

When nutrients increase, it is not unusual for bryophyte cover to decline and even disappear (Arróniz-Crespo *et al.* 2008). In an acidic grassland, Arróniz-Crespo and coworkers found that up to 90% of the bryophyte cover was lost due to enhanced nitrogen deposition. The tissue N:P ratio increased up to three times the original levels. They concluded that it was the limitation by phosphorus that caused damage to photosystem II and consequently caused loss of bryophyte biomass. Pigment concentrations and chlorophyll fluorescence were also affected.

We have seen that bryophytes often do not benefit from added N. Armitage *et al.* (2010) found that high N concentrations in alpine mosses can lead to a decline in production of biomass, reducing the cover of bryophytes. In *Sphagnum* (Figure 10, Figure 24-Figure 25) bogs, higher N can increase productivity of tracheophytes and consequently reduce the competitiveness of the bryophytes (Berendse *et al.* 2001). On the other hand, *Sphagnum* is a major sink for the sequestration of carbon in the Northern Hemisphere. Elevated CO₂ has little effect on *Sphagnum* biomass and N depresses it due to increased competitive growth of tracheophytes and the moss *Polytrichum strictum* (Figure 66). Loss of *Sphagnum* can reduce the sequestration of carbon.

Figure 66. *Polytrichum strictum*, a species that can outcompete *Sphagnum* when given an enhanced N source. Photo by Michael Lüth, with permission.

When Armitage *et al.* (2010) did transplant experiments with alpine *Racomitrium lanuginosum*

(Figure 5), they found that after 2 years, tissue N in transplants from high N sites to a lower site only partially equilibrated to its new N availability. On the other hand, reciprocal transplants to the higher N regions almost matched the N concentrations of the native plants. The surprise was that mosses experienced greater shoot growth when stimulated by higher N deposition. In the lower N site, moss depth and biomass increased in transplants, apparently due to a lower C:N ratio that slowed decomposition.

Summary

Although there seems to be little in the way of a comprehensive summary of bryophyte nutrient processes in nature, there are many pieces from which a somewhat clear picture emerges. First off, bryophytes can receive their nutrients from the substrate as well as from precipitation and dust. Those forming thick but horizontal mats are more likely to depend predominantly on precipitation, whereas acrocarpous mosses may receive considerable input from the substrate through upward movement externally and subsequent internal movement.

Bryophytes can suffer osmotic shock when transferred to substrates with high nutrients and most lack sufficient wax in the cuticle to help slow the process. They require the same nutrients as tracheophytes (CHOPKNS Mg CaFe), but in lower concentrations. Needs of young shoots are greater than those of older shoots and nutrients may be moved from old to young tissues. Bryophytes trap nutrients leached from the canopy and may provide it to roots of trees, especially spruce trees, possibly through *mycorrhizae*. Ca and Mg can be obtained from the soil, but K and P require additional sources. Litter of herbaceous and woody plants may supply some of the needed nutrients, provided they don't bury the plants or damage them with tannic acid. Snow collects dust particles and these go into solution as the snow melts, dripping down on the bryophytes. Fungal partners may transfer nutrients into the bryophytes or from the bryophyte mat to tree roots. Even salmon, dragged ashore by bears and other predators, contribute to bryophyte nutrients.

Nutrients tend to increase in bryophyte tissues in late summer and fall, then decrease in winter and spring

when the plants are growing, but this varies with the species, the nutrient, and of course with geographic region. The three major elements (N, P, K) are relatively constant throughout the year. pH affects solubility and toxicity of nutrients and heavy metals.

Protective devices include sequestration of heavy metals on cation exchange sites and blocking transport from gametophyte to sporophyte in the placenta.

Elevated nutrients, especially N, can favor tracheophytes, at the expense of bryophytes, through competition. They can also alter the bryophyte species composition.

Acknowledgments

I appreciate the contributions of undergraduate Phil Gaudette and M. S. student Jennifer Jermalowicz Jones for their critical reading of the manuscript from the perspectives of students interested in nutrient relationships of bryophytes. Dana Richter made many helpful suggestions on the fungal section. Jean Faubert reported several errors to me.

CHAPTER 8-2

NUTRIENT RELATIONS: CO₂

Figure 1. Peat moss, *Sphagnum fimbriatum*, covering the largest area of carbon sink in the world. Photo by Michael Lüth, with permission.

CO₂ Sources and Limitations

Early Carbon Relations

Colonization of life on the land of Earth began billions of years ago (Graham *et al.* 2014). Evidence suggests that bacteria, then **eukaryotic** (having a nucleus) algae, then bryophytes ventured to endure those early conditions. These early forms made possible the development of the first organic soils. To understand this progression and continuation of life, it is prudent to understand carbon cycling. For most terrestrial plants and algae, the source of this carbon is carbon dioxide (CO₂). Both green algae and bryophytes produce a degradation-resistant form of carbon from that CO₂ that is consequently sequestered. This, in turn, reduces the CO₂ in the atmosphere, having an important impact on the Earth's carbon cycle for 40-100 million years.

This early atmosphere was high in CO₂ compared to levels today (Raven & Edwards 2014). Isotope comparisons using liverwort fossils indicate that in the mid-Cretaceous in the Antarctic, CO₂ concentrations ranged 1000-1400 ppm, agreeing generally with

independent proxy data and long-term carbon cycle models (Fletcher *et al.* 2005). Furthermore, the concentration gradient from the atmosphere to the carboxylase in the plant would further drive CO₂ into the plant (Raven & Edwards 2014). This additional CO₂ would permit higher photosynthetic rates per surface area of plant. Later adaptations included increasing the surface area of photosynthetic tissue through development of complex structures and air spaces to permit greater harvesting of light.

Proctor (2010) suggested that in the early atmosphere of plant evolution in the mid-Palaeozoic, the atmosphere had 10X its present concentration of CO₂. It is thus unlikely that these early plants were CO₂ limited. Rather they may have increased their cuticularization, then increased their air spaces to permit them to take up more CO₂ and compensate for the blockage by the cuticle.

Rod Seppelt (Bryonet 27 June 2022) described the interior of the cushions. Due to their tightly packed shoots, they maintain humidity better than do the tracheophytes. This added humidity promotes a high CO₂ concentration

(ca. 2000 ppm compared to 350-400 ppm ambient), largely due to the microbial associates.

Relationships Today

In 1958, the CO₂ in the atmosphere had a concentration of 315 ppm (Scripps CO₂ Program 2016). In December 2016 it had grown to 404 ppm. Elbert *et al.* (2012) estimated that cryptogams (including Cyanobacteria, algae, fungi, lichens, and bryophytes) extract ~3.9 Pg carbon per year, or around 7% of the net production of terrestrial vegetation. Thus, the CO₂ uptake by bryophytes is an important component of global carbon cycling and a necessary contributor to climate modelling.

Normally we don't think of carbon as a limiting resource, although experiments on higher plants have shown that increased carbon dioxide usually increases productivity. Mosses are typically **C₃ plants** with high **CO₂ compensation points** (CO₂ concentration at which net CO₂ fixation is zero) (Raven *et al.* 1998). In other words, they require high levels of CO₂ to balance the CO₂ lost to respiration. **C₃ plants** are those plants that have no special mechanism for storing carbon from CO₂ temporarily in a compound such as **malate** or **oxalate**. Instead, they put all their CO₂ directly into the photosynthetic pathway in a 3-carbon compound, hence the term C₃. This pathway is less efficient because the enzyme **Rubisco** (Ribulose biphosphate carboxylase/oxidase) is much less effective at binding the atmospheric CO₂ into a 3-C compound within the cell than is **PEP carboxylase**, the enzyme used in the C₄ and CAM pathways to put the carbon in temporary storage C₄ compounds for later use in photosynthesis. However, mosses are not limited by guard cell closure in obtaining CO₂ and thus should be able to obtain CO₂ any time of the day.

In examining 32 terrestrial C₃ plants, Bauer and Martha (1981) found an average CO₂ compensation point of 36.2 µl L⁻¹ (=71 mg m⁻³). However, among these, two mosses showed a somewhat higher CO₂ compensation point of ~43 µl L⁻¹. The compensation point for tracheophytes ranged 31-40 µl L⁻¹. Bain and Proctor (1980) found that the CO₂ compensation point of the aquatic bryophytes they studied were over 100 times higher than those of the C₃ aquatic tracheophyte *Elodea* (Figure 2) and the alga *Chara* (Figure 3). They were likewise somewhat higher than those of terrestrial bryophytes reported by Dilks (1976).

Figure 2. *Elodea canadensis*, an aquatic plant with a very low CO₂ compensation point compared to that of mosses. Photo by Sean Blaney, through Creative Commons.

Figure 3. *Chara* in Keweenaw Peninsula, Michigan, USA, an aquatic alga with very low CO₂ compensation point compared to that of mosses. Photo by Jason Oyadomari, with permission.

Among tracheophytes, CAM plants, convert CO₂ to malate at night and store it to be used in the daytime, permitting the plants to conserve water by keeping stomata closed in the daytime. In C₄ plants a bundle sheath permits plants to convert CO₂ to a 4-carbon compound for use later. This likewise permits the plants to conserve water by closing stomata when the air is dry but to continue using CO₂ derived from the stored 4-C compounds for photosynthesis.

Bryophytes must live in a delicate balance between sufficient moisture and sufficient CO₂. When leaves are wet on the outside, that water offers significant resistance to CO₂ diffusion. Surprisingly, a thin cuticle permits greater diffusion than even a thin film of water, so mosses living in very wet habitats often are protected from waterlogging by well-developed waxes or other cuticular material (Proctor 1984). *Polytrichum commune* (Figure 4) and *P. strictum* (Figure 5) are good examples of this, but less obvious examples are *P. wahlenbergii* (Figure 6), *Pohlia cruda* (Figure 7), *Philonotis* (Figure 8), *Schistostega pennata* (Figure 9), *Saelania glaucescens* (Figure 10), and *Bartramia pomiformis* (Figure 11), all with a whitish appearance to the naked eye (Proctor 1984).

Sphagnum (Figure 1) partially solves this balance by having water-holding cells (**hyaline cells**) that bathe the photosynthetic cells (Figure 12), while exposing at least one surface (in most) of the photosynthetic cell to the atmosphere. Furthermore, air bubbles become trapped among the leaves and between the leaves and the stem, thus providing an additional source of CO₂. Robinson (1985) considered that no CO₂ was obtained from the **hyaline** (water-holding) cells because all the chloroplasts of the cells were positioned along the wall most exposed to light. On the other hand, members of *Leucobryum* (Figure 13- Figure 16) do indeed trap air bubbles in their colorless cells (Robinson 1985), providing an internal source of CO₂ for the chlorophyllous cells residing there and causing these plants to somewhat mimic the internal structure of a seed plant. This same character seems to be present throughout the **Leucobryaceae** family, permitting their multi-layered leaves to function photosynthetically.

Shinde *et al.* (2015) determined that the moss *Physcomitrella patens* (Figure 17) has 814 genes that are affected by elevated CO₂ (1500 ppmV). These affect transcriptional reprogramming, photosynthetic regulation, carbon metabolism, and stress responses. CO₂ relationships are not simple!

Structural Adaptations

Proctor (2010) explains that the maximum rate of CO₂ diffusion is limited by the difference between the external CO₂ concentration and the CO₂ **compensation point** (level of O₂ at which respiration = photosynthesis), as well as the resistance of the moist external bryophyte cell wall to the liquid-phase diffusion of the CO₂. This is limited by the thickness of the external cell walls. Structural differences can increase the plant uptake. A large, simple thallose liverwort provides a single flat photosynthetic surface. This is improved in an epiphyte such as *Metzgeria* (Figure 18) that exposes both surfaces. *Marchantia* (Figure 19) further increases the uptake surface by its system of internal chambers with photosynthetic cells arranged like tissues of a sponge (Figure 20).

Perhaps the most obvious adaptation of plants to intake of CO₂ is having stomata in leaves. This apparatus permits tracheophyte leaves to regulate moisture concentration in the leaves. However, when they are closed to conserve water, they are also closed to atmospheric CO₂ that is vitally needed for photosynthesis. Mosses and leafy liverworts lack stomata in their leaves, but generally have leaves that are only one cell thick, thus exposing two sides of the cell for absorption of CO₂. Some thallose liverworts, on the other hand, have a plant body that consists of multiple layers. These typically have a chambered interior with sponge-like tissues that provide lots of surface area. For these to obtain atmospheric CO₂, the chambers connect to the exterior atmosphere through pores that permit its diffusion into the chamber. Raven (2002) suggested that "stomata evolved from pores in the epidermis of plant organs which were at least three cell layers thick and had intercellular gas spaces and a cuticle."

But does this sponge-like interior make a difference? Meyer *et al.* (2008) demonstrated that both external and internal conductances, as well as water use efficiency, were higher in the ventilated (spongy) liverworts and hornworts. Within these two taxonomic groups, however, the values were similar, suggesting that various factors must serve to optimize the involved species for that life form.

Soil CO₂

Šimůnek and Suarez (1993) modelled the CO₂ transport and production in soil. CO₂ can be transported in the unsaturated zone in both the liquid and gas form. Both root and microbial respiration contribute to soil CO₂. The rate of this respiration is affected by water content, temperature, growth, salinity, and plant and soil characteristics.

In a temperate rainforest of New Zealand, bryophytes form a nearly continuous cover (62%) on the forest floor, with a depth less than 30 mm (DeLucia *et al.* 2003). The CO₂ was elevated relative to the atmosphere, presumably due to bacterial and fungal respiration. The net CO₂ exchange was very dependent on water content. Although the CO₂ uptake was quite variable, the annual net carbon uptake by the forest floor bryophytes was 103 g m⁻², compared to annual loss of carbon from the forest floor (bryophyte and soil respiration) of -1010 g m⁻². This accounted for a reclamation of ~10% of the forest floor CO₂ emitted by respiration.

Tarnawski *et al.* (1994) measured 24-hour changes in atmospheric CO₂ concentrations within and above cryptogam stands in a New Zealand temperate rainforest. They found that CO₂ levels within the forest exceeded those in the open by 30 ppm and had a more variable **diel** (denoting a period of 24 hours) pattern (up to 70 ppm). The mean CO₂ level at a depth of 25 mm in the moss layer was 50% higher than those in the clearing and were higher than in the air of the rainforest.

In the Arctic tundra, there are definite differences in soil respiration rates related to microscale topography, mainly due to differences of soil water table and soil temperatures (Sommerkorn *et al.* 1999). The moss layer serves as a high impact modifier of the CO₂ emission, assimilating 51% to 98% of the daily amount CO₂ released from wet tundra soils.

For most forest floor mosses, the CO₂ should be ample to supply the slow-growing mosses due to production of CO₂ from litter decay. In the tropics, the CO₂ concentrations on the forest floor are greater than those above the canopy (Holtum & Winter 2001), but that enriched supply is still limiting. At 10 cm above the soil the CO₂ level is somewhat higher.

Because CO₂ is often limiting, even in the terrestrial system, increasing levels of CO₂ on the Earth could positively affect the bryophytes. Strain and Cure (1985) reported that the rate of photosynthesis in tracheophytes increases with a rise of atmospheric CO₂. Because bryophytes are C₃ plants, they are able to take advantage of high CO₂ levels. The increased temperatures that accompany the higher CO₂ through the greenhouse effect will cause greater below ground respiratory processes of roots, bacteria, and other organisms (Heal 1979; Silvola 1985). Bryophytes on the soil surface are the first photosynthetic organisms to have an opportunity to use this increased CO₂. Csintalan *et al.* (1997) found a small, but significant increase in CO₂ uptake in the drought-tolerant moss *Syntrichia ruralis* (Figure 21) when grown in a concentration of 700 ppm compared to that at the ambient level at that time of 350 ppm.

Figure 21. *Syntrichia ruralis* hydrated, a species that benefits from higher levels of CO₂. Photo by Misha Ignatov, with permission.

Sonesson *et al.* (1992) were able to show that the boreal forest moss *Hylocomium splendens* (Figure 22-Figure 23) can adapt to higher ambient CO₂ concentrations and utilize higher CO₂. Increasing CO₂ levels to 600 ppm (compared to 350 ppm), resulted in a significant increase in its photosynthesis and growth (Sonesson *et al.* 1996). Botting and Fredeen (2006) similarly showed that CO₂ (430 ppm) was limiting to moss productivity on the sub-boreal forest floor in central British Columbia, Canada.

Role of Water in CO₂ Uptake

Both high and low water content are limiting to carbon uptake (Titus *et al.* 1983; Silvola 1991; Zotz *et al.* 1997; Schipperges & Rydin 1998; Jauhiainen & Silvola 1999; Turetsky 2003). This appears to be due to the inability of the bryophytes to use the CO₂ under these conditions. Insufficient water inhibits the enzymes in photosynthesis. When the plants are water saturated, CO₂ diffusion is slowed (Williams & Flanagan 1996; Tuittila 2000). This limitation works differently in *Sphagnum* from its behavior in tracheophytes (Rice 2000). In tracheophytes, water limitation lowers chloroplastic demand and increases the resistance to carbon uptake. By contrast, in *Sphagnum* water limitation actually decreases the resistance to carbon uptake.

CO₂-Concentrating Mechanisms

CO₂-concentrating mechanisms are familiar in tracheophytes. In tracheophytes, allowing CO₂ into the leaf through stomata means allowing water vapor out (Hanson *et al.* 2014). Even chloroplasts leak water as they allow CO₂ in because both require the same pore size.

Bryophytes have neither of these carbon-storing mechanisms and it seems that all bryophytes are C₃ plants. But it appears that at least some do have a means to concentrate CO₂ (Meyer *et al.* 2008). Like members of the green algae, many hornworts (**Anthocerotophyta**; Figure 24-Figure 25) have **pyrenoids** (protein bodies in chloroplasts of some algae and hornworts; Figure 25) associated with the chloroplasts (Hanson *et al.* 2002, 2014). These pyrenoids are able to maintain a pool of dissolved inorganic carbon (DIC) of 19-108 nmol mg⁻¹ chlorophyll (Hanson *et al.* 2002).

Villareal and Renner (2012) remind us of the important role of enzyme Rubisco (Ribulose-1,5-Biphosphate-carboxylase-oxygenase) in carbon fixation. But Rubisco is slow compared to PEP carboxylase, which they lack. These researchers noted that many scientists have hypothesized that carbon-concentration mechanisms evolved during periods of low CO₂ to concentrate CO₂ around the enzyme. But the cladistic analyses of Villareal and Renner do not support this hypothesis; pyrenoids have come and gone in the **Anthocerotophyta** (Figure 24-Figure 25) clades multiple times and do not always coincide with low CO₂.

Raven and coworkers (1998) have suggested that some aquatic mosses might have a "CO₂ concentrating mechanism" that differs from a typical C₃ pathway. The

Anthocerotophyta use pyrenoids to accomplish CO₂ concentration, with the exception of *Megaceros* (Figure 26), in which there is no pyrenoid, but the mechanism in aquatic mosses is unknown. In evaluating a number of taxa, Raven's group found no evidence of C₄ or CAM pathways in bryophytes, but Salvucci and Bowes (1981) found that two aquatic taxa, *Fontinalis antipyretica* (Figure 27) and *Fissidens cf. mahatonensis*, seem to be able to concentrate CO₂. What is even more interesting, it appears that it might be facultative. When they measured the CO₂ compensation point of *F. cf. mahatonensis* in the cool Florida winter (12°C, 10 h day length), the compensation point was consistent with that expected for a C₃ pathway. However, when they measured it for the hot Florida summer (30°C, 14 h day length), the CO₂ compensation point was much lower, although not as low as in a C₄ pathway. They found similar summer/winter CO₂ compensation point relationships in all the aquatic bryophytes tested from Florida. This would be a very beneficial adaptive feature since the CO₂ is easily lost from water at high temperatures. The Section below on Aquatic CO₂ will detail what we know about obtaining CO₂ in water.

Bryophytes may be able to use fixed carbon compounds that are different from those used by

tracheophytes. Simola (1969) experimented with *Sphagnum nemoreum* (syn of *S. capillifolium*; Figure 28) in sterile culture and found that whereas **mannose** [hexose monosaccharide (6-carbon sugar) with a structure very similar to glucose] and its 6-carbon derivative, **rhamnose**, are toxic to many flowering plants, mannose promotes the growth of *Sphagnum nemoreum*. On the other hand, other common sugars such as **arabinose**, **galactose**, **ribose**, and **xylose** are toxic to *Sphagnum*. While the literature is not as complete as that on tracheophytes, we know that at least *Funaria hygrometrica* (Figure 29) can use the sugars fructose, glucose, maltose, and sucrose as internal carbon compounds (Simola 1969).

Further evidence of differences in carbon usage by *Sphagnum* come from studies on carbon isotope discrimination. In three species that occupy hollows (*S. recurvum* – Figure 30), carpets (*S. palustre* – Figure 31), and hummocks (*S. tenerum* – Figure 32), the delta ¹³C values (indicating their ability to discriminate CO₂ on the basis of the ¹²C or ¹³C isotope) ranged from 19.0 to 27.1, but were unrelated to species (Rice 2000). Rather, they differed significantly ($p < 0.001$) with season. In the spring, discrimination was lower (mean 22.5), with the highest

discrimination in winter (24.7). This difference was mainly due to low photosynthetic rates in winter that reduce the effects of diffusional resistance on carbon isotope discrimination. Microhabitat differences that were present in the field disappeared in the common garden and eliminated any doubt about species differences in ability to discriminate. The observed seasonal differences in carbon isotope discrimination appear to be different from those of tracheophytes, where water limitation lowers chloroplastic demand and increases resistance to C uptake. In *Sphagnum*, water limitation lowers the chloroplastic demand but also decreases the resistance to C uptake, suggesting that the moss continues to incorporate carbon as it dries.

Carbon isotope ratios have been used for dating all sorts of biological materials, including the age of peatlands. Using carbon isotope technology, MacDonald *et al.* (1987) found that peatland mosses consistently registered carbon ages that were considerably older than those of the macrofossils of the same layer. They found ages that ranged 1400 to 6400 years older than that of their contemporary tracheophytes, and even the live *Drepanocladus longifolius* (Figure 33) had a ¹⁴C content that was only 85% that of other present-day taxa. They

explained this moss phenomenon as an isotope exchange with older sediments, the formation of CO₂ from bicarbonate by chemical processes, and the metabolic production of CO₂, presumably including bacterial decomposition, especially by mycobacteria.
