CHAPTER 1: INTRODUCTION

"Man is placed in the middle between two infinities - the infinitely great and the infinitely little - both of which are incomprehensible to him." (from Pascal, in Crum 1976)

Figure 1. Bryophytes, forming their own communities on a microscale. Photo by Janice Glime.

Thinking on a New Scale

When Simon Levin (1992) presented his Robert H. MacArthur Award Lecture (presented to the Ecological Society of America August 1989), he began his abstract with the statement "It is argued that the problem of pattern and scale is the central problem in ecology, unifying population biology and ecosystems science, and marrying basic and applied ecology." He pointed out the need to interface phenomena that occur on "very different scales of space, time, and ecological organization." It is time that the scale be broadened to examine the role of bryophytes in ecosystem processes. While the scale is small, the role can at times be crucial. This treatment attempts to place bryophytes into the context of current ecological theory, to place the scale in perspective, and to raise important questions related to their behavior relative to current ecological theories.

In this treatise, we shall begin by examining the intricacies of the life styles and development of the bryophytes so that we may set forth on an informed and directed pathway toward filling our knowledge gaps.

Although bryophytes have provided a variety of uses for millennia, use in horticulture, fuels, and massive oil spill cleanups are only now beginning to threaten their existence. These ancient uses as well as new uses in medicines, pollution monitoring, and gardening place urgency on understanding their place in ecosystems – what they contribute, what they need, and how they got there.

Several factors have been important in legitimizing this new field. First, lack of taxonomic descriptions for many taxa, particularly in the new world, made ecological work all but impossible. With the publication of regional floras dealing with Europe, many parts of Asia, the Antarctic, and most of North America, those interested in bryology could begin asking more sophisticated questions. More recently, the tropical, African, and South American bryophyte floras are becoming sufficiently well known to permit study of their ecological relationships as well.

About the time our expertise in taxonomy reached an acceptable level, international attention was turning to problems of atmospheric contaminants and their effects on ecosystems of the world. Observations in Japan, Europe, and North America indicated that cryptogams (especially lichens and bryophytes) were among the most sensitive. The classical experiments with the peppered moths revealed that their color phase shift was related to the death of lichens on the trees due to industrial pollutants. Then, bryologists began documenting loss of bryophytes on the trees. Thus, bryophytes emerged as tools to indicate impending damage to ecosystems. Moss bags served as collectors of heavy metals and provided early warning systems of high accumulations. Aquatic mosses were used in transplant studies to assess river conditions. I have found more than 300 research papers dealing with aquatic bryophytes and pollution, and many more probably exist in publications not yet catalogued.

The field of bryophyte ecology has existed for as long as anyone has observed bryophytes and been curious about their requirements and growth. However, as a formal science, this is a young field. Scattered formal efforts have been made over many years, but these were mostly by taxonomists who made ecological observations as they described species, or by general plant ecologists who encountered the bryophytes in their study areas. Within the last 20-25 years, however, more papers have been published on bryophyte ecology than in all prior history. Now there are those scientists who specialize in the field of bryophyte ecology.

More recently, international interest in diminishing species diversity has resulted in "redlists" of threatened taxa. In the United States there have been many requests from the National Park Service and the U. S. Forest Service for bryological surveys, preferably with ecological studies accompanying them. As they began to understand that assemblages of species tell us more about a given site than a single species or physical measurements, foresters began to include bryophyte species in habitat classification systems and management plans. For example, at Pictured Rocks National Lakeshore, the National Park Service considered locations of unusual and endangered mosses in planning for construction of a road. These same governmental units are raising questions about dangers of moss harvesting and are seeking input on growth rates and replacement times in order to set reasonable harvest limits.

Despite all this new and exciting attention directed at mosses and liverworts, we still know very little about the role of bryophytes in the ecosystem, and we especially know very little at the species level. The information that has been published has been widely scattered in the literature and is often immersed inconspicuously in studies dealing primarily with **tracheophytes** (those plants with lignified vascular tissue). Collecting such literature is a lengthy and arduous task, although computer search engines have facilitated this job enormously. Additionally, at least three national journals regularly publish lists of current bryological literature, and these journals have also made efforts to locate older literature of significance to bryologists. Such bibliographies are making it possible to develop a picture of the role of bryophytes in the ecosystems of the world.

Adaptations to Land

Bryophytes are generally considered the first land plants, and likewise the first true plants. The algae most likely preceded them on land. (I won't try to defend the Chlorophyta as the first land plants, although some are now considered plants by some botanists.) Both of these groups exist on land as **gametophytes** (Figure 2), unlike their seed plant counterparts that exist as **sporophytes** with their gametophytes imbedded deep within **sporophyte** (Figure 3-Figure 4) tissues. The nature of these two generations, one producing gametes and existing with one set of chromosomes (**gametophytes**) and the other producing spores and existing with two sets of chromosomes (**sporophytes**) will be discussed later.

Figure 4. *Lilium* gametophytes showing developing female gametophyte inside ovule on left and developing male gametophytes (microspores) in anther on right. Photos by D. L. Nickrent, through fair use license for educational use.

The most obvious change needed in the move to land is that of obtaining and maintaining water. This is not just a need for fertilization, but also a need in surviving daily life. Proctor (2007), in discussing our intellectual impediments to the consideration of gametophytes, challenges us to think about the reasons for their success. He points out that in the course of plant evolution, two strategies developed to cope with periods of low water. **Tracheophytes** (Figure 5) developed a water-conducting system that transports water from the roots in the soil to the leaves where water is constantly lost, an **endohydric** system (Figure 6). This not only brings a continuous supply of water for most plants under most conditions, but it also brings nutrients and plant metabolites such as hormones. Gametophytes, on the other hand, lack this organized system, although bryophytes do have vascular tissue in the center of the stems of many genera, but with few exceptions this system does not connect directly with the leaves. Rather, bryophytes suspend their metabolism when water is unavailable, being controlled by movement of an external water supply (**ectohydric**), and often maintaining a water supply in capillary spaces at the bases of leaves or among spaces of a tomentum, paraphyllia, or rhizoidal covering.

Figure 5. *Geranium maculatum*, an example of the sporophyte of a tracheophyte. Photo by Janice Glime.

Figure 6. Xylem and phloem, the conducting cells of tracheophytes. The cells with red bands (stained) are **tracheids**. Photo by Spike Walker, Wellcone Images, through Creative Commons.

Proctor (2007) points out that minimizing water loss in bryophytes is regulated by boundary-layer resistances and energy budgets (see also Gates 1980; Proctor *et al.* 2007; Monteith & Unsworth 2013). For these small plants, the "intricacy of form" lies within this laminar boundary layer, a space where water vapor and CO₂ are able to move, albeit slowly, by molecular diffusion. This degree of intricacy may affect capillary storage, water movement, gas exchange, and CO₂ uptake.

Evidence in the past few decades indicates that the ancestor to the land plants, *i.e.*, to the bryophytes, was a member of the Coleochaetales, now placed in the Streptophyta, possibly *Coleochaete* (Figure 7; Graham, *et al.* 2012). This group of researchers experimented with two species of *Coleochaete*, normally an aquatic alga, to determine its ability to grow and reproduce in humid rather than aquatic environments. But to be truly terrestrial, this alga also needed to survive desiccation. And, to link it to ancestral fossils, it needed to produce degradation-resistant remains like those Cambrian fossils.

Figure 7. *Coleochaete*, a likely ancestor of bryophytes. Photo by Yuuji Tsukii, with permission.

The land form of *Coleochaete*, grown by Graham *et al.* (2012), did not look like its aquatic progenitors. Rather, it took on a form that had one-cell-thick lobes, was hairless, and formed hemispherical clusters. Furthermore, the chemically resistant cell walls did indeed resemble those of certain lower Palaeozoic microfossils that had remained a mystery. When these terrestrial forms were returned to water, they produced typical asexual zoospores and normal germlings. Even after several months of desiccation they retained their green coloration and structural integrity.

Bryo-ontogeny

An antithetic ballad, attempted free translation by Willem Meijer from the Dutch version of poet -bryologist Victor Westhoff in Buxbaumiella 40, August 1996 page 45.

As a toddler I am called protonema
A thread or thallus like structure without mom or pa
just creeping onwards without aim or thema
until I start to differentiate

and all sorts of tissues intercalate;
 to anchor me to the soil I am using rhizoids
 upwards I carry budding stems crowned with
 phylloids
 those are kind of leaflets with or without dentation
 they carry me to the realms of temptation
 they call that the arrival of puberty
 what makes me suffer during life
 now I know emotion as a plant
 because in my body swells a perianth,
 makes me aware which fate awaits me
 I can now supply some progeny
 soon an antheridium is in the make
 which makes sperm for a newborn baby embryo
 from the egg cell of an archegonium.
 Without much of a brake
 my stomach becomes gradually rounder
 and I am becoming the new founder
 of the next generation.
 A sporogonium grows in my body, a column, swank,
 poor of chlorophyll but provided with a strong will
 producing my progeny in the spore sacks,
 to follow up my hanky panky with phylogeny,
 resulting in another phase with no resemblance
 with the haploid plant.
 That makes me a good moss after all, with a life that
 raises
 me above the monotonous existence of people, pigs,
 dogs and cats
 so tame and all the same just like a lion, a cub and a
 calf.
 So our existence is always half by half.
 We always look with amazement what the purpose is
 of the seta,
 like an obelisk so full with admiration
 for the godly gift of creation
 with the change of generation.

Contributed by Wim Meijer, Bryonet 3 September 1999

Minimum Size

In our consideration of scale, let's consider the minimum size needs for bryophytes vs tracheophytes, especially seed plants. Raven (1999) suggests that a minimum size exists for a seed to succeed, and that such a minimum would be about 5 μg , the mass needed to become photosynthetically self-sufficient and to maintain its internal water content. This makes the assumption that the seedling must at the same time be able to contact the soil to obtain water and to extend into the air to obtain light. This latter need for water and light Raven suggests would require a minimum height of about 5 mm. If this is indeed true, then it is already obvious that some bryophytes, through **poikilohydry** (state of hydration controlled by external environment), have circumvented the need for 5 mm of height as there are a number of species that live with a shorter stature independently of any spore or seed.

Raven further estimated that for a seedling to succeed independently, it must attain 1.6 μg to permit it to reach this size and house the xylem tissue needed for its survival. He then stated that a spore with a radius less than 100 μm (thus a weight less than 4 μg fresh mass) will not reliably produce a gametophyte or succeed to produce a sufficiently large sporophyte to succeed. If we carry this need to plants with dominant gametophytes, *i.e.* bryophytes, then poikilohydric photosynthesis would be essential before the plant was large enough to become **homoiohydric** (state of hydration controlled by internal mechanisms). Thus, it is not just for fertilization, as we often read, but for the very survival of small plants that external water is needed, *i.e.* a poikilohydric strategy. It appears that **homosporous** (Figure 8) plants (having only one kind/size of spore) such as the bryophytes have greater desiccation tolerance in their gametophytes than do those of **heterosporous** (Figure 9) plants (bearing two genetically determined kinds of spores, generally large female and small male spores).

Figure 8. *Conocephalum conicum* spores & elaters, an example of **homospory** in liverworts. Photo by UBC Botany Website, with permission.

Figure 9. *Selaginella* strobilus showing small, male spores (left side) and large female spores (right side), a condition of **heterospory**. Photo by Ross Koning, with permission.

Proctor (2010) considers it infeasible for evolution and natural selection to produce a tracheophyte *de novo*. Rather, these must have evolved from a poikilohydric strategy. The drive toward tracheophytes could very likely have arisen from the limitations of two essential resources, water and CO₂. Whereas having air spaces within the leaves is common among tracheophytes, it is rare among bryophytes. Nevertheless, we find that a number of modern bryophytes also have such adaptations: **Marchantiales** (thallose liverworts; Figure 10), **Polytrichaceae** (haircap mosses; Figure 11), and sporophytes of **Bryophyta** (mosses; Figure 12) and **Anthocerotophyta** (hornworts; Figure 13) in particular.

Figure 10. *Marchantia polymorpha* with antheridiophores (male) and archegoniophores (female) on different plants. Note the thallus at the base. Photo by Robert Klips, with permission.

Figure 13. *Phaeoceros laevis* showing sporophytes that contain interior spaces. Photo by Bob Klips, with permission.

Although the early atmosphere most likely provided higher levels of CO₂ (~10X; Berner 1998 in Proctor 2010) than our present-day environment, an epidermis, seen in many thallose liverworts, would protect against both mechanical damage and water loss. The development of the epidermis, followed by increasing cuticle development on both epidermal and non-epidermal plants, most likely marked the beginnings for a greater need for CO₂.

The complexity required to maintain a tree simply would not work to maintain a plant that is 100 times smaller and has a volume one millionth that of a tree (Proctor 2010). This smaller size necessarily means that the bryophyte as a plant has less interaction with the atmosphere, although its surface to volume ratio is greater, creating more area for interaction per unit volume. The non-linear nature of the bryophyte surface can create eddy diffusion that permits exchange between the bryophyte and its surroundings, but this can be minimized by the tightness of the lower portions of the plant. The selection pressures of strength and movement of gases and water in a tracheophyte leaf provide no constraint on the bryophyte. Thus, slow molecular diffusion is sufficient for heat and mass transfer in bryophytes. The one-cell-thick leaves of most bryophytes present two surfaces for diffusion of CO₂ into the leaf and directly to the cells that need it. Thus, being small has its advantages, albeit requiring quite different strategies.

Do Bryophytes Lack Diversity?

Early in 2011 Bryonettors questioned why bryophytes seem to lack extensive genetic diversity despite their long evolutionary history. I question the assumption that they lack diversity and argue that they have considerable diversity. For example, *Ceratodon purpureus* has an estimated leafy plant genome size of 240-270 Mbp, whereas the mustard plant *Arabidopsis thaliana* has only 100 Mbp (Lamparter *et al.* 1998). When we read about evolution among groups of plants or animals, most of the discussions center on morphological characters. But for these early land plants, biochemical characters may have been more important. Consider their abilities to withstand cold, heat, and desiccation or to deter herbivory and disease. The rate of genetic change in bryophytes has been as rapid as in tracheophytes. Wyatt (1994) pointed out that having a dominant gametophyte suggests that genetic variation should be low. However, he notes that isozyme data refute

that assumption, indicating that bryophytes display a range of variation like that of the diploid tracheophytes. Furthermore, having only one set of chromosomes permits the organism to express every gene innovation without the overriding effect of a complementary dominant gene. Asexual reproduction permits new genes, if not lethal, to be reproduced in populations without the need for compatibility in sexual reproduction.

One restriction to morphological diversity is the limitation of size. The bryophyte sporophyte size is limited by lack of structural support due to lack of true lignin. These sporophytes furthermore rely on non-lignified gametophytes for physical support and nutrition and are no doubt confined by genes that work best for the gametophytes.

But being small can be advantageous. Miniaturization has been a strategy that has permitted lycopods and horsetails to survive as water became more and more limited. In animals, miniaturization is typically accompanied by simplification or loss of morphological structures. For example, tropical miniature frogs have lost their teeth, have fewer toes, and have a reduced laryngeal apparatus. These structures simply don't fit in the smaller organism. Lack of space may cause whole organ systems to disappear, sometimes through crowding that alters embryonic development. In beetles, flies, and wasps, miniature organisms have evolved feather wings as an apparent response to that miniaturization.

While flowering plants were responding to the evolution of insects by evolving a multitude of adaptations to insect pollination, bryophytes were evolving a multitude of secondary compounds that protected them from herbivory from the ever-increasing insect herbivores. This was a necessity due to their slow growth and small size, while at the same time costing energy that might otherwise have been diverted to growth and complexity.

Nevertheless, one must wonder why some bryophytes with horizontal growth structure, thus negating the need for support, have not developed a greater morphological diversity. Perhaps they have "limiting genes" that restrain their growth rates or freeze their diversification with age. Gerson (1972) showed that the mite *Eustigmaeus* (as *Ledermuelleria*) *frigida* was unable to reproduce when fed bryophytes, suggesting that some sort of inhibitor was present. Such an inhibitor could permit the diversion of energy to making secondary compounds for defense.

But let's consider other alternatives to this bryophyte strategy. What would be lost if they became larger or more morphologically diverse? Would they still be able to develop from fragments if they had more specialized structures? It appears not, if we consider how rarely fragmentation of leaves of most seed plants can result in a new plant. For these gametophytic plants, this could be a very limiting loss.

The "Moss"

The term "moss" has a multitude of meanings in English, and even in other languages, the term referring to this group of plants likewise has multiple meanings. In Japanese, the word is "koke" (left) and means not

only members of the Bryophyta, but also any of the small plants. Thus plants suitable for plantings under a bonsai tree are *koke*.

Beware also of Spanish moss (*Tillandsia usneoides*, a member of the pineapple family; Figure 14) and Irish moss (*Chondrus crispus*, a red marine alga; Figure 15). I was enticed to visit the Virgin Islands, where the locals insisted there were lots of mosses hanging from the trees, only to find Spanish moss.

Figure 14. *Tillandsia usneoides*, known as Spanish moss, is a moss look-alike. Photo by Alfred Osterloh, through Creative Commons.

Figure 15. *Chondrus crispus*, named Irish moss. Photo by Seaweed Collections Online, through Creative Commons.

In his *Mosses in English Literature*, Sean Edwards (1992) has this to say: "The word moss has always been used to refer to boggy ground as well as to the plants themselves, and both aspects of the word almost certainly have the same origin in northern European languages (Bradley 1908). Quotations that refer clearly to boggy ground have been excluded, but see the section *Stagnation and barrenness*. Onions (1966) says that the first "formal" reference in English to moss meaning the plant rather than boggy ground, is found in the 12th century; this may refer to the 'Durham Plant-Name Glossary' (1100-1135), but see Aelfric (993-996)."

"It is to be expected that the word moss should include all bryophytes (as it does in other European languages), although only Saint Winefride's Moss (Caxton, 1485) can be identified as a liverwort. Moss may also be used loosely to encompass algae and mould, as well as other moss-like plants such as Iceland Moss (a lichen) and Spanish Moss (a flowering plant, see Longfellow, Townsend). Grey moss probably usually refers to lichen (Clare; Longfellow; Masfield; Spenser), but generally quotations that are clearly not referring to bryophytes have been omitted."

There is no doubt that in usage by Robert Burns in Scotland and northern England the word moss refers to bogs and is based on the Danish word *mose*, meaning bog (Jim Dickson, Bryonet 4 November 2010; Simon Laegaard, Bryonet 5 November 2010). But in Danish, the word referring only to bryophytes is *mos*. In English, Moss is used in place names, such as Flanders Moss and Lenzie Moss, again meaning a boggy place (Jim Dickson, Bryonet 4 November 2010).

In German, the word for the bryophyte is *Moos*, but in Bavaria, Austria, Switzerland, and South Tyrol (Italy) the same word also means flat boggy peatland (Michael Häusler, Bryonet 4 November 2010). Such use often shows in the names of places, reminiscent of their past, but often long-gone mossy habitat.

What's in a Name?

Discussions about names, cladistics, priorities, and use of numbers to designate a taxon remind me of a conversation between Alice and a gnat in Lewis Carroll's *Through the Looking Glass*, Chapter 3:

'What sort of insects do you rejoice in, where YOU come from?' the Gnat inquired.

'I don't REJOICE in insects at all,' Alice explained, 'because I'm rather afraid of them — at least the large kinds. But I can tell you the names of some of them.'

'Of course they answer to their names?' the Gnat remarked carelessly.

'I never knew them do it.'

'What's the use of their having names' the Gnat said, 'if they won't answer to them?'

'No use to THEM,' said Alice; 'but it's useful to the people who name them, I suppose. If not, why do things have names at all?'

'I can't say,' the Gnat replied.

We need names to communicate; without communication, there is no purpose for science. So while I might see the utility of using numbers to designate relationships among taxa, they are not a suitable way to communicate in other contexts. I think that both the lay public and the scientific community will agree with me that species names must remain with us, no matter how efficient the number system may be for phylogenetic purposes.

But the naming system is fraught with problems. As we learn more about organisms, we find they have been placed in a genus where they have no close relatives. Or their birth certificates that provide a legitimate name and

description, after being lost for a long time, resurface with an earlier name that has priority. These problems we must continue to deal with, and we have made provisions in our nomenclatural code to do so.

But in our attempts to clean up our naming, and to be consistent with conventions recently adopted by the zoologists, we have begun to erode long-standing concepts of higher taxonomic levels. I discovered to my horror that the bryophytes have been moved to the umbrella of Equisetopsida! This has stripped a very workable system in the plant kingdom of its two highest taxonomic levels for the bryophytes! I suppose it is my 50 years of understanding the Bryophyta that makes this idea so repugnant to me, but in this treatise, and elsewhere, I refuse to subscribe to that system and will continue to use Bryophyta as a phylum.

Perhaps I am as stubborn as Humpty Dumpty, again quoting from Lewis Carroll's *Through the Looking Glass*:

"When I use a word," Humpty Dumpty said in rather a scornful tone, "it means just what I choose it to mean - neither more nor less." "The question is," said Alice, "whether you can make words mean so many different things." The question is," said Humpty Dumpty, "which is to be master - that's all."

I am not so stubborn as to ignore all recent (think 50 years) name changes. I fully support breaking the traditional bryophytes into three, or perhaps four, phyla (divisions). And I fully support the standardizations of names for the higher taxonomic levels. Hence, I will not be using some of the traditional names because they have been replaced with names that follow the type concept to the very top of the classification (except perhaps kingdom). To bring you up to speed, here are the type-based names for phylum and class with their proper endings:

Phyla/Divisions

I shall use the term phylum (pl. phyla) throughout, in this case being consistent with terminology used for animals. The terms division and phylum are equally correct for plants. The division names I am using are not a new concept. Following the type concept in higher levels of classification was proposed while I was still a graduate student (see Cronquist *et al.* 1966). But it is only now reaching relatively consistent usage in bryological publications.

Marchantiophyta (Figure 8): liverworts only, previously class Hepaticae in the phylum Bryophyta; more recently also called Hepatophyta, but that name does not follow the type concept; classes include **Marchantiopsida** (Figure 8) and **Jungermanniopsida** (Figure 16).

Anthocerotophyta (Figure 13): hornworts, previously named Anthocerotae as a class of liverworts in Bryophyta; now has one class, **Anthocerotopsida**.

Bryophyta (Figure 11-Figure 12): mosses only, previously class Musci in the phylum Bryophyta; has six classes currently: **Takakiopsida** (Figure 17), **Sphagnopsida** (which may be considered a separate phylum, the **Sphagnophyta**; Figure 18), **Andreaeopsida** (Figure

19), **Andreaeobryopsida** (Figure 20), **Polytrichopsida** (Figure 11), and **Bryopsida** (comprising more than 95% of the species; Figure 12). **Sphagnophyta** (Figure 18): Considered by Crum (2001) to warrant a separate phylum, but still considered by most authors as a class of **Bryophyta** (**Sphagnopsida**) in the **Bryophyta**; two genera only - *Sphagnum* (Figure 18) and *Ambuchanania* (Figure 21).

Role of Bryology

Bryologists have a role today that far exceeds that of any prior time in history. Organizations and individuals interested in protecting the environment have realized that we know little about the contributions of the groups of small organisms, plant or animal or microscopic organism, to diversity, either in their own right or in stabilizing the diversity of larger organisms. Ecosystem biologists are realizing that bryophytes may have a major role in nutrient cycling, water retention, and water availability.

Physiologists and even medical scientists are realizing the potential of the bryophytes in understanding gene function and in producing needed proteins. Global climate modellers are realizing that massive peatlands make substantial contributions to the modification of global temperatures and water movement. And everyone involved is realizing that we know very little about this fascinating and important group of organisms. The time is now!

Summary

Scale is a major evolutionary driver for bryophytes, bringing both successes and constraints. Small size, coupled with slow growth, make them susceptible to destruction by herbivory, but their evolution of a myriad of secondary compounds have rendered them inedible or undesirable by many would-be herbivores.

Small size and lack of lignified vascular tissue have enhanced the selection for physiological means of drought survival, including metabolic shutdown and the ability to revive with a minimum or at least sustainable level of destruction.

The role of bryophytes in the ecosystem, a largely overlooked field of study, may be significant despite their small size. *Sphagnum* alone may be the genus that sequesters the most carbon of any genus on Earth. And their role in housing small organisms that ultimately increase the diversity of their predators could be vital. Ecologists are increasingly recognizing that even at their small scale they are important contributors to the ecosystem and can no longer be ignored.

Although there is ultimately a minimal size to house the essential contents of a eukaryotic cell, bryophytes seem to lack the minimal size needed to house the photosynthetic and water transport needs of a seedling. A spore less than 100 µm in diameter can provide sufficient energy for a new bryophyte to get started.

Water is clearly needed by bryophytes, but rather than maintaining hydration, they are able to become metabolically inactive, exercising an ectohydric strategy that holds water in capillary spaces while they dry slowly. Being small itself seems to be a strategy to conserve water, as seen in the miniature of lycopods and horsetails.

Bryophytes seem to lack morphological diversity, but they nevertheless exhibit as much genetic diversity as do tracheophytes, expressing it in a biochemical diversity that protects them against desiccation, heat, cold, and herbivory.

As we learn more about the evolutionary relationships of the bryophytes, we find it convenient to change the names of the groups where we place them. The group once known as the **Bryophyta** has now been accepted by most bryologists to be three phyla (divisions): **Marchantiophyta**, **Anthocerotophyta**, **Bryophyta**. But we may still see further divisions, particularly into Sphagnophyta or Takakiophyta. So despite the inconvenience of keeping track of the names and their equivalencies, the names will keep changing, keeping us on our toes as we learn by these changes.

Acknowledgments

I am grateful to Anne Stoneburner for a conversation decades ago on the diversity of bryophyte genetics. Michael Proctor, a constant source of information and guidance, has been an inspiration for this volume. And Nancy Slack has kept me encouraged through her friendship, research, collaboration, and most importantly, her invitation to the first Andrews Foray, where I learned that bryophyte identification can stump even the world-renowned experts. Thank you to John Steel for reporting several typos to me. I appreciate Jan Galkowski for numerous discussions by email and for alerting me to comprehensive references on biophysical ecology. Llo Stark reviewed the chapter and made valuable suggestions.

CHAPTER 2-1

MEET THE BRYOPHYTES

"The beauty there is in mosses must be considered from the holiest, quietest nook." Henry David Thoreau. *Natural History of Massachusetts*. 1842. Photo by Janice Glime.

Definition of Bryophyte

Before we can further consider these small organisms in any context, we all need to speak the same language. In the 1600's, Jung considered mosses to be aborted plant fetuses (Crum 2001)! Today, bryophytes occupy a position within the Plant Kingdom and may even be considered to have their own subkingdom. Recent genetic information is causing us to rethink the way we classify bryophytes, and more to the point of this book, what we consider to be a bryophyte.

The hornworts (Figure 1), sharing their small size and independent, dominant gametophyte and dependent sporophyte with the mosses and liverworts, have been considered by most systematists now to be in a separate **phylum** (*i.e.* division), the **Anthocerotophyta** (Shaw & Renzaglia 2004). Most bryologists also now agree that the liverworts should occupy a separate phylum, the **Marchantiophyta** (previously known as Hepatophyta, Hepaticophyta, and class Hepaticae; Figure 2). This leaves the mosses as the only members of **Bryophyta** (formerly known as the class Musci; Figure 3). Together, the mosses, liverworts, and hornworts are still considered by the English name of **bryophytes**, a term having no taxonomic status and to be used in its broad sense in this book. Some have suggested for them the subkingdom name **Bryobiotina**.

Nomenclature

The **type concept** of naming has dictated the current names for these phyla. It follows the premise that the first named taxon within a category becomes the type of that category. Hence, *Bryum* (Figure 3) is the type genus in the family **Bryaceae**, and as the first named genus [along with many others at the same time in Hedwig (1801)] in its order, class, and phylum/division, it is the type all the way to the top, giving us the name **Bryophyta** for the mosses. By the same premise, *Marchantia* (Figure 2) became the base name for **Marchantiophyta** and *Anthoceros* (Figure 1) for **Anthocerotophyta**.

It was necessary to define a starting date for bryophyte names to avoid finding older publications that would predate and force changes in names. Linnaeus (1753), who first organized the binomial system of names for organisms and provided the names for many common animals and plants, had little understanding of bryophytes. He put *Potamogeton* (an aquatic flowering plant; Figure 4) and *Fontinalis* (an aquatic moss; Figure 5) in the same genus. Hence, the publication by Hedwig (1801) became the starting point for moss names. Linnaeus recognized and named *Marchantia* and did not include any incorrect placements as liverworts, so his 1753 publication is recognized as the starting date for liverworts.

Figure 4. *Potamogeton turionifer*, in a genus that was originally included in the moss genus *Fontinalis*. Photo by C. B. Hellquist, through Creative Commons.

Figure 5. *Fontinalis antipyretica*, looking superficially similar to the *Potamogeton* species in the above image. Photo by Andrew Spink, with permission.

The term bryophyte was coined centuries ago when all three groups were in the same phylum, and moss, liverwort, and hornwort served to distinguish the **Musci**, **Hepaticae**, and **Anthocerotae**, respectively. Once the type concept came into use for higher categories, *Bryum* was the type for the mosses and hence the basis of the name **Bryophyta**. Thus, it kept its old phylum name and **Marchantiophyta** became the liverwort phylum based on *Marchantia* as the type (see Stotler & Crandall-Stotler 2008). So we are sort of stuck with the old meaning of bryophyte and new meaning of **Bryophyta**.

Recently the name **Sphagnophyta** has come into occasional usage, with Howard Crum (2001; S  neca & S  derstr  m 2009) as a primary proponent of its rank as a phylum/division. Although there are a number of unique characters in this group, this separation has not yet received widespread acceptance.

What Makes Bryophytes Unique?

Among the world of plants, the bryophytes are the second largest group, exceeded only by the Magnoliophyta – the flowering plants (350,000 species). Comprised of 15,000 (Gradstein *et al.* 2001) – 25,000 species (Crum 2001), they occur on every continent and in every location habitable by photosynthetic plants. Of these, there are currently 7567 accepted binomials for liverworts and hornworts (Anders Hagborg, pers. comm. 23 February

2017). And, one could argue that bryophyte gametophytes are among the most "elaborate" of any phylum of plants (Renzaglia *et al.* 2000).

Bryophytes seem all the more elaborate because of their small size. Some bryophytes are only a few millimeters tall and have but few leaves, as in the mosses *Ephemeropsis* (Figure 6) and *Viridivellus pulchellum* (Crum 2001). The more common *Buxbaumia* (Figure 7) has a large capsule on a thick stalk, but only a few special leaves protect the archegonia; the plant depends on its protonema (and later the capsule) to provide its photosynthate. The liverwort thallus of *Monocarpus* (Figure 8) is only 0.5-2 mm in diameter. At the other end of the scale, the moss *Polytrichum commune* (Figure 10) can attain more than half a meter height in the center of a hummock and *Dawsonia superba* (Figure 10) can be up to 70 cm tall with leaves of 35 mm length (Crum 2001) and be self-supporting. *Fontinalis* species (Figure 10), supported by their water habitat, can be 2 m in length.

Figure 6. *Ephemeropsis trentepohlioides*, one of the very small mosses. Photo by David Tng <www.davidtng.com>, with permission.

Figure 7. *Buxbaumia aphylla*, known as Aladdin's lamp or bug-on-a-stick moss, is a moss dependent upon its protonema for energetic support of the sporophyte, which sports a thick stalk and robust capsule. Originally, its lack of leaves caused scientists to consider it to be a fungus. Photo by Michael Lüth, with permission.

Figure 8. *Monocarpus sphaerocarpus*, a liverwort with a tiny thallus 0.5-2 mm in diameter. Photo by Helen Jolley, with permission.

Both green algae (Chlorophyta) and other members of the plant kingdom share with the bryophytes the presence of **chlorophylls a and b**, **xanthophyll** and **carotene**, storage of photosynthate as **true starch in plastids**, sperm with **whiplash flagella**, and **cellulose cell walls**. But bryophytes and other members of the plant kingdom possess **flavonoids** (a group of pigments that absorb UV light), whereas only some members of the charophytes among the algae possess these. The unique thing about the mosses and liverworts among members of the plant kingdom is that all the vegetative structures, the leaves (or thallus), stems, and **rhizoids** (filamentous structures that anchor the plant), belong to the **1n (gametophyte)** generation, having just one set of chromosomes to dictate their appearance and function. By contrast, the analogous structures are **sporophytic (2n)** in the non-bryophytic plants (**tracheophytes**), with the gametophyte becoming smaller and smaller as one progresses upward in the phylogeny of the plant kingdom. In fact, in the bryophytes, the **sporophyte is unbranched** and arises from archegonia located on the gametophyte (Figure 9)! The gametophyte **lacks secondary growth** and **meristematic tissues**, growing new tissue instead from a **single apical cell** (Crum 1991).

Figure 9. *Bryum alpinum* showing sporophyte attached to the gametophyte. Photo by Michael Lüth, with permission.

Graham and Wilcox (2000) suggest that the alternation of generations progressed from presence of egg and sperm

to retention of zygotes on the parent, resulting in embryos. The plant subkingdom **Bryobiotina** (bryophytes) is separated from the Kingdom Protista by the presence of **multicellular sexual reproductive structures** protected by a **jacket layer** (antheridia for sperm and **archegonia** for

eggs), as opposed to unicellular antheridia and oogonia in the algae, and the presence of an **embryo** (Figure 15), the forerunners of which can be found in the charophytes (Kingdom Protista; Graham *et al.* 1991; Mishler 1991).

Figure 10. Bryophytes vary in size from the large *Polytrichum commune* (upper), *Fontinalis novae-angliae* (left), and *Dawsonia superba* (middle) to the minute *Ephemerum minutissimum* (right). Photos by Janice Glime; *Ephemerum* by Michael Lüth, with permission.

Who are the Relatives?

Their nearest algal relatives appear to be members of the **Charophyta** (Figure 11). Although the charophyte reproductive structure is still only a single cell, that cell is surrounded by corticating cells (Figure 11) that give the egg and **zygote** multicellular protection. Nevertheless, the zygote fails to develop further until leaving its parent. In the green alga *Coleochaete* (Figure 12-Figure 13), however, the female reproductive organ becomes surrounded by overgrowths of cells from the thallus following fertilization, and the zygote divides (Figure 14), becoming multicellular. In bryophytes, this embryo remains attached to the gametophyte plant body and continues to develop and differentiate there (Figure 15). Recognition of these similarities to those of embryophytes has led to many studies that have revealed other similarities between charophytes and bryophytes. Less obvious among these, and perhaps of no ecological significance, is the presence of **spiral motile sperm bodies** with **anterior whiplash flagella** (Figure 16), a trait shared with nearly all tracheophyte groups and these same few charophyte algae (Duckett *et al.* 1982). In the bryophytes, these sperm are **biflagellate**, as they are in several other groups.

One advancement with implications for land colonization, visible through transmission electron microscopy, is the presence in both bryophytes and charophytes of a layer on the outside of gametophyte cells that resembles early developmental stages of the **cuticle** of tracheophytes (Cook & Graham 1998). The sporophyte was already known to possess one (Proctor 1984). Although bryophyte gametophytes were considered to lack a cuticle or possess one only as thin as that on the interior cells of tracheophyte mesophyll (Proctor 1979), Cook and Graham (1998) showed that all three relatively primitive bryophytes tested [*Monoclea gottschei* – thallose liverwort (Figure 17), *Notothylas orbicularis* – hornwort (Figure 18), and *Sphagnum fimbriatum* – peatmoss (Figure 19)] have an osmophilic layer on their outer walls. The nature of this layer in these bryophytes and in the charophyte *Nitella gracilis* suggests that some features of a plant cuticle existed when bryophytes first arose. Those taxa that are mostly **endohydric** (having most water movement occurring within the plant) were recognized earlier to have at least a thin leaf cuticle (Lorch 1931; Buch 1945), and in some species this cuticle seems to be similar to that of tracheophytes (Proctor 1979). This may account for the difficulty of getting such endohydric mosses as *Plagiommium* (Figure 20) and *Polytrichum* (Figure 21) to rehydrate. Yet the **ectohydric** taxa (those that move and gain their water across the plant surfaces above ground) seem to lack such protection from water loss (Proctor 1979), not surprisingly, since that which would keep water in would also keep water out.

Two Branches

It appears that once those algae ventured onto land to survive outside a water medium, two different journeys began, at least 450 million years ago (Stackelberg 2006). At that point, the bryophytes diverged from the **polysporangiate plants** [having multiple sporangia on a single sporophyte and including *Aglaophyton* (Figure 22), which lacks tracheids]. The polysporangiate plants soon gave rise to the **tracheophytes**. Nevertheless, approximately half the bryophyte genes are the same as those of tracheophytes. Some of these genes, however, are no longer used and remain as fossil genes, never to be turned on by modern bryophytes. Experiments now at the Missouri Botanical Garden and other places are attempting to unravel the phylogeny of bryophytes by turning on the latent genes to discover what that will do to the morphology and function (Zander 2006). Hopefully this will help us identify their closest relatives. The bryophytes (**Bryobiotina**) share with the tracheophytes the development of an **embryo** within a **multicellular reproductive organ** (Figure 23), a covering of **sporopollenin** on their spores, and the presence of **flavonoids**.

Limitations of Scale

Limited by Scale – and No Lignin

When thinking about bryophytes, one necessarily has to think on a new scale from the more familiar way of looking at **tracheophyte** (traditionally called "vascular plant") vegetation. One contribution to their small size is their lack of **lignin** (Héban 1977), limiting their size to that which their nonlignified tissues can support. Note that the presence or absence of lignin in bryophytes is still controversial. Downey and Basile (1989) found evidence for it in sporophytes of the thallose liverwort *Pellia epiphylla*, and lignin-like compounds occur in some peristomes (Crum 2001), but conclusive gametophyte evidence seems still to be lacking. Siegel (1969) reported true lignin in *Dawsonia* and *Dendroligotrichum*, which Héban (1974, 1977) questioned. Edelman *et al.* (1998) found evidence for a lignin-like substance in the cell walls of the moss *Rhacocarpus purpurascens*, but some of the specific peaks expected with lignin were absent. Erickson and Miksche (1974) likewise found phenolic cell wall contents but showed that lignin was definitely absent in six species of mosses and two liverworts. Many bryophytes possess phenolic compounds similar to lignin. The problem, at least in part, is the absence of a clear definition of lignin. In bryophytes, the "lignin-like" compounds are polyphenolics that are most likely tri-hydroxybenzene derivatives (Wilson *et al.* 1989), whereas those of tracheophytes are polymers of phenylpropanols and have different precursors. The bryophyte polyphenolics do not even seem to be ancestral precursors of the tracheophyte lignins (Savidge 1996).

In 2011, Espiñeira *et al.* suggested that the syringyl lignins, known from some liverworts, were at first "developmental enablers" and only later became

strengthening compounds in tracheids. Lewis (1980) suggested that it was the ability of boron to avoid sequestration in carbohydrate complexes that made it available to catalyze the lignin pathway and later, germination of pollen. Groundwork for this dichotomy between tracheophytes and non-tracheophytes depended on genetic selection for sucrose as a carbohydrate storage product in Chlorophyta because sucrose forms only weak bonds with borate, unlike those of other algal sugar groups.

Being without lignin imposes other limits on plants as well. It means they have no tracheids or vessels, hence lack the type of conducting system known in those plants we will call **tracheophytes**, or more traditionally, those known as vascular plants. This implies that bryophytes lack true leaves, hence making it more appropriate to call their photosynthetic extensions **phyllids** (but few bryologists do, choosing to call them leaves). The bryophytes are more appropriately termed **non-tracheophytes** (rather than non-vascular plants) because many do indeed have vascular tissue, possessing **hydroids** (Figure 24) that confer much the same function as xylem, but lack tracheids or vessels. And some, probably many more than we have detected, have **leptoids** (Figure 24), the moss version of phloem. Many moss stems possess what we often term a **central strand** (with or without hydroids, but with elongate cells) that functions in conduction, and because of its greater density of smaller cells may also provide support. But for the leafy liverworts, even these gametophytic conducting elements seem lacking.

Figure 24. Longitudinal and cross sections of a stem with hydroids and leptoids, typical of taxa such as the Polytrichaceae. Drawings by Margaret Minahan, with permission.

The lack of a sophisticated tracheid conducting system limits or slows the movement of water within the plant, and the lack of roots, substituted in most bryophytes by the non-vascular **rhizoids** (Figure 25-Figure 27), makes obtaining water from beneath difficult to impossible, although they may help in obtaining nutrients from a larger soil volume, as well as slowing the process of desiccation. With these structural limitations, many bryophytes are necessarily **desiccation tolerant** (unlike most people's perception), an advantage replaced in most tracheophytes by drought avoidance.

Limited by Scale – Forced to Be Simple

Niklas (1997) suggests that maintaining hydration necessarily imposes a small size on bryophytes. But this could be a question of the chicken or the egg. Being small

prevents bryophytes from having a complex conducting system, and lacking a complex conducting system keeps them from attaining great size. Bonner (2004) demonstrates that in general larger entities, whether they are organisms or societies, have a greater division of labor. In plants, this is manifest in a greater variety of cell types. Thus, smaller organisms are necessarily simpler.

Hedenäs (2001) studied 439 mosses to determine the types of characters that differed most. Two complex functions seem to dominate their structural differences: characters related to water conduction and retention, and characters related to spore dispersal. If we consider what might be most important when structural diversity is limited, success of these two attributes would seem to be paramount.

Figure 26. *Fontinalis* plant with rhizoids attached to paper towel. Photo by Janice Glime.

Figure 27. Microscopic view of rhizoids of the brook moss, *Fontinalis*, showing multicellular structure and diagonal crosswalls. Photo by Janice Glime.

Limited by Scale – Needing to Swim

One might suggest that getting a sperm to an egg without windborne pollen necessarily limits the size of a gametophyte on land. This suggestion certainly could be supported by the total absence of large terrestrial gametophytes in any plant group. Since the sperm must find a film of water in which to swim, and cannot swim very far, it must rely on short stature and various splashing mechanisms in order to reach the female reproductive structures, especially when they occur on another plant. Such a limit is supported by the small size of all gametophytes in the plant kingdom.

Limited by Scale – and Housing an Embryo

But does the life cycle have anything to do with size? Raven (1999) contends that it does. The algae have a minimum size determined by that which can house the genome, the smallest being about 0.65 μm in diameter, but lacking a nucleus. With the addition of both a cell membrane and nuclear membrane, a minimum size of 0.95 μm is required (Raven 1999). This lower size limit has implications for a minimum size of spores, with even larger requirements for impervious walls and extracellular decorations. But the bryophytes have added to these minimum requirements an **embryo** (Figure 28), the structure that separates them exclusively from the Kingdom Protista. To qualify as an embryo, the **zygote**, that new cell that results from sexual union of sperm and egg, must remain inside the reproductive organ of its parent and divide, developing into the initial stages of the new generation by mitotic divisions (Figure 28). Hence, this necessarily means a larger size, with at least a one-cell-thick container around the embryo. The structural organization necessary to define an embryo requires that these organisms be at least 100 μm in diameter for both life cycle generations (**1n gametophyte** and **2n sporophyte**) (Raven 1999).

On the other end of the scale, some marine algae attain the size of a giant sequoia, reaching 60 m in length and weighing more than 100 kg (Raven 1999). In their watery environment, it would seem their only constraint is the mechanical stress of such a large size being tossed about by the action of waves. But once on land, new constraints are imposed – not only is support necessary, but also plants need a means to distribute water and other substances. The bryophytes, like the algae, are predominantly **poikilohydric**. That is, their state of hydration is controlled by the environment; they cannot control it internally. It is this trait that makes it necessary for them to 1) live where they are constantly moist, 2) complete their life cycle to the production of dormant spores before the season becomes dry, or 3) be desiccation tolerant. For some "mysterious" reason, primarily poikilohydric, desiccation-tolerant embryophytes are unable to sustain a body size greater than 1 m tall (Raven 1999). Their **homoiohydric** (state of hydration controlled by internal mechanisms in plant) tracheophyte counterparts are able to maintain their homoiohydric status through such features as gas spaces, stomata, cuticle, internal water-conducting system, and water and nutrient uptake structures, structures that Raven (1999) estimates require a height of at least 5 mm.

Figure 28. Young embryo of the liverwort *Marchantia polymorpha* showing early multicellular stage enclosed within the archegonium. Photo modified from Triarch by Janice Glime.

Thus, it is with this necessary smallness in mind that we must envision the ecological role of the bryophytes. As we explore possible adaptations of bryophytes, we will see that size will indeed play a role in the structural adaptations available and that while constrained in size, physiological and biochemical adaptations abound. Even with their vascular limitations, bryophytes, and mosses in particular, can occupy large surface areas on rocks, soil, logs, and tree trunks. In boreal zones, they can virtually form the substrate around lakes. And they can spread vegetatively to occupy a large area from the minute beginnings of a single branch, a single spore, or a single fragment. If the genetics were known, perhaps it is some moss that is truly the largest "single" organism clone in the world!

Higher Classifications and New Meanings

"We need to keep firmly in mind that biological classification is a human construct, to be adopted for the uses we find most compelling in light of current understanding" (Mishler 2009). Hence, there has been a continuing battle for systematists to attain the stability needed for ease of communication and the changes needed as new knowledge shows our old concepts to be in error. Those of us who have already been through change during the early stages of our careers are reticent to re-organize our minds around a new set of names and relationships presented late in our professional lives. Nevertheless, as scientists we recognize the importance of being objective, critical thinkers, challenging and improving on existing ideas.

Chase and Reveal (2009) argued that current classification of bryophytes is not compatible with the APG III classification (Angiosperm Phylogeny Group III system) and suffers from inflated taxonomic ranks. They kindly stated that this problem was especially true for angiosperms. BUT, they further stated that if the major algal clades are considered classes, then all land plants, INCLUDING BRYOPHYTES, should be included in one class: the Equisetopsida! This system is primarily based on molecular taxonomy and does not yet seem to have entered widespread use among the bryologists. No one likes to see their group diminished, and this demotes the bryophytes from a subkingdom to three subclasses: **Anthocerotidae**, **Bryidae**, and **Marchantiidae**.

Figure 29. Schematic representation of the **Bryobiotina** phyla and classes related to other members of the Plant Kingdom (**Polysporangiophyta**), based on Shaw & Goffinet 2000.

New Meanings for the Term Bryophyte

Perhaps all this discussion of Equisetopsida vs using Bryophyta as a phylum will go away if the new PhyloCode (PhyloCode 2010) is widely adopted by the scientific community. Among the principles defined by this code, number 4 states "Although this code relies on the rank-based codes [i.e., International Code of Botanical Nomenclature (ICBN)]... to determine the acceptability of preexisting names, it governs the application of those names independently from the rank-based codes. Item 6 in the Principles states that "This code will take effect on the publication of *Phylonoms: a Companion to the PhyloCode*, and it is not retroactive. The PhyloCode is online at <http://www.ohio.edu/phylocode/>. The printed version and the Companion Volume will be published by UC Press. For a detailed example of a PhyloCode-style classification in bryology see Fisher *et al.* 2007. Here are the names that will be applied in *Phylonoms* for the clades relating to the bryophytes:

Viridiplantae

- Chlorophyta (most of the former green algae)
- Charophyta (some of the former green algae and land plants)
 - Phragmoplastophyta (Coleochaete + Chara + embryophytes)
 - Streptophyta (Chara + embryophytes)
 - Embryophyta (land plants)
 - Hepatitcae
 - Musci
 - Anthocerotae
 - Tracheophyta (etc.)

This appears to be a long step backwards, but one can argue that it lends stability in a field that is constantly changing how it views relationships. Brent Mishler reported to Bryonet, 30 January 2010, that the group of authors for these names in *Phylonoms* chose to "apply the traditional names **Hepatitcae**, **Musci**, **Anthocerotae** specifically because of their long use. And, the lack of a rank-based ending is a bonus. We did not use '**Bryophyta**' or '**Bryopsida**' anywhere, because of the ambiguity people have mentioned."

This brings us back to our earlier discussion of the term "bryophyte." Mishler states that he does agree with Jon Shaw that "bryophyte" (small "b") is a useful term for talking about plants with a somewhat similar biology, like

"prokaryote," "invertebrate," or "algae," but there is no room for it in formal cladistic classification.

But not all bryologists are enamored with cladistics. I am still wary of them because I do not think we know enough about the genetic structure to adequately interpret the data, at least in some cases. As Richard Zander put it on Bryonet (31 January 2012), there are two ways it can be wrong – bad theory and lack of adequate sampling. "Bad theory means cladistics is not the way to analyze evolution because it just clusters end members of a tree, with no discussion of what the nodes of the tree mean, i.e., totally ignoring macroevolution." Inadequate sampling has been a problem of molecular systematics, but this is being rectified by time and continuing research on more and more species, making the interpretation more reliable.

As a teacher, and for my own learning, I find grouping things to be invaluable. The molecular-based classification of genera into families (see Shaw & Goffinet 2000) has made more natural groupings and thus made it much easier to understand the relationships, permitting one to place something new into a group (genus, family) and thus more easily discover its identity. Until now, our International Code of Botanical Nomenclature has guided our naming of both species and higher categories.

These rules of nomenclature are laid out in The International Code of Botanical Nomenclature (McNeill *et al.* 2006), renamed in 2011 to the International Code of Nomenclature of Algae, Fungi, and Plants (Miller *et al.* 2011). These rules are reviewed and modified as needed every six years at the meeting of the International Botanical Congress. Of note are changes in 2011 to permit taxon descriptions in **English** or in Latin and to permit electronic publication of descriptions and names of new taxa in specified types of electronic journals and books (See Penev *et al.* 2010).

Differences within Bryobiotina

Within the **Bryobiotina**, there are distinct differences among the phyla and classes. Those morphological differences will be discussed in the next chapter, but from an evolutionary perspective, one must also consider the biochemical evidence, which will play a major role in their ecological capabilities. Those **Marchantiophyta** that possess oil bodies synthesize **mono-**, **sesqui-**, and **diterpenes** as their **terpenoids**, as do some

Anthocerotophyta, whereas Bryophyta produce **triterpenes** (Crum 2001). All of these more closely resemble the terpenoids of tracheophytes rather than those of algae. Marchantiophyta commonly have **flavonoid glycosides**, whereas only about one-fourth of the Bryophyta do. **Lunularic acid**, acting as a growth regulator and dormancy factor, occurs in all orders of Marchantiophyta, but in no Bryophyta or algae. Members of Anthocerotophyta lack lunularic acid and have a different pathway for the **degradation of D-methionine** from that of Marchantiophyta. And *Sphagnum* seems to be a non-conformist all around, with a complete acetylation of D-methionine, a process differing from that of other mosses and all liverworts, and its flavonoids also differ from those of other **Bryobiotina** and from tracheophytes as well. **Bryophyta** have **ABA**; **Marchantiophyta** do not. Even the cell wall components differ between mosses and liverworts, with mature moss (**Bryophyta**) cell walls staining with aceto-orcein, but not liverwort (**Marchantiophyta**) cell walls (Inoue & Ishida 1980).

As you will see, morphological evidence, coupled with this biochemical evidence, has led Crum (2001) to create the phylum **Sphagnophyta** (Figure 19). Nevertheless, when data from morphological, developmental, anatomical, ultrastructural, and nucleotide sequence characters have been used together, they have supported the concept of a **monophyletic** origin (single origin) for the Bryophyta, including *Sphagnum* (Rykovskii 1987; Newton *et al.* 2000).

Perhaps the bigger question that remains to be answered is whether the bryophytes are truly the first and most primitive land plants, or if they are instead derived from other land plant embryophytes by reduction. In any case, it appears that they were derived independently from the tracheophytes as we know them (Héban 1965). Their absence of lignin to protect them from UV light and other aspects of their simple structure suggests they would have been unable to survive on land until the development of larger plants to provide shade and maintain moisture. Raven (2000) suggests that such protective compounds, common throughout the rest of the plant kingdom, may have been lost by reduction. Rather, based on their CO₂ affinities through use of **RUBISCO** (enzyme that catalyzes carbon fixation in plants), it would appear that all the **embryophytes** (*i.e.* all members of plant kingdom) may have evolved under the influence of the high levels of atmospheric CO₂ present in the late Lower Palaeozoic.

Intraspecific Taxa

Bryologists recognize several types of infraspecific taxa. These include **subspecies**, **varieties**, and **forms**. Wikipedia (2016) states that in botanical nomenclature, **variety** (abbreviated var.; in Latin: *varietas*) is a taxonomic rank below that of **species** and **subspecies** but above that of **form**. In addition to these, one can find the terms race, microspecies, and cryptic species.

Darwin (1859) struggled with defining a **species**, and it hasn't gotten any easier with our much greater understanding of evolution. But these terms are useful in our understanding of ecology.

While generally a **species** is a group of potentially interbreeding organisms, isolated reproductively from other units considered to be species, that is not a practical

definition because we do not have the resources to determine it each time we find an organism. On the other hand, genetic variation and founder populations may look different from their parent populations. In attempting to indicate differences among our study locations, we are forced to apply one of the above terms to distinguish our organisms.

These differences in appearance can lead us to falsely naming different varieties as different species, while on the other hand a similar appearance may hide differences in functionality that result from physiological varieties. Both morphological and physiological differences result from genetic variations. Molecular techniques are helping us to delineate some of these microspecies or cryptic species, and some of our seemingly same species are revealing their differences through these techniques. Hence, we are left with the task of indicating these differences in our studies.

It is therefore useful to understand the current differences among these infraspecific terms. The term **subspecies** is generally used to define populations that are disconnected, *i.e.*, are **allopatric**. The assumption is that these allopatric populations have been disconnected for some time and now differ genetically. They may be unable to interbreed if they are re-connected, but they currently are unable to interbreed due to geography. A subspecies is exemplified in *Acrolejeunea securifolia* (Figure 30). This species has four allopatric subspecies, each differing from the others by 1-2 morphological characters (Gradstein 1975). Their morphs are located in eastern Malesia, Australia, New Caledonia, and French Polynesia.

Figure 30. *Acrolejeunea securifolia*, a species with several subspecies. Photo by John Braggins, with permission.

A **variety** has a genetic difference that can occur within a population or between populations. It is presumed that the varieties are able to interbreed. It differs from a **form** in that a variety has inherited traits, whereas a form is modified by its environment and its trait differences are not inherited. Generally, a variety is **sympatric**, *i.e.*, occurs within overlapping distributions.

This leaves us with **microspecies** and **cryptic species**. As the term **cryptic species** implies, the characters are hidden and cannot be identified by a field bryologist. They are species that cannot interbreed, but that cannot be recognized as morphologically different. These include genetic differences that are expressed as differences in physiology and biochemistry and can be identified as differences by using molecular techniques. Cryptic species

are exemplified in the desiccation-tolerant *Grimmia laevigata* (Figure 31) (Fernandez *et al.* 2006). This is a cosmopolitan species, occurring on every continent except Antarctica and occupying bare rock in a broad range of environments. To do this, it includes variants that survive extremes of very high temperatures, prolonged desiccation, and high UV B. These differences are the result of multiple alleles.

Figure 31. *Grimmia laevigata*, a species with cryptic species distinguished by physiological differences. Photo by Hermann Schachner, through Creative Commons.

A **microspecies** has a genotype that is perpetuated by **apomixis**, a trait exhibited by a number of bryophyte species. Hence, a microspecies is a small population with limited genetic variability. But bryophytes complicate this by having many species that rely largely on asexual reproduction, but that are also capable of sexual reproduction. *Fontinalis* (Figure 5) species are typical of this strategy, relying largely on fragmentation, but capable of having sexual reproduction. *Pohlia* is even more complex, having species with bisexual gametophytes, unisexual gametophytes with no specialized asexual propagules, and unisexual gametophytes with specialized asexual propagules. Shaw (1999) screened 50 populations representing eleven species. Using isozyme analysis, he determined that the seven propaguliferous species are less distinct from one another than are the four non-propaguliferous species.

Figure 32. *Pohlia bulbifera* with bulbils in upper leaf axils. Photo by J. C. Schou, through Creative Commons.

The use of barcoding is an attempt to remove subjectivity from identification and to provide a tool for those not trained in the taxonomic group, while exposing the crypto- and microspecies. However, identification of species by genetic markers is a young science and many caveats remain (Naciri & Linder 2015). Only when large and multiple populations have been barcoded can we reliably determine species boundaries. We must understand the range of variability within a species, and ideally understand what can breed with what. This is further complicated by the large number of species that can reproduce without having genetic mixing, *i.e.*, those reproducing asexually.

Given that differences in habitats can result in both selection pressures against certain traits, and differences in form resulting from environmentally influenced expression of physiological and morphological traits, ecologists are able to contribute to our understanding of species by their detailed observations of these expressions as they relate to habitat.

Summary

Traditional bryophytes are classified into three phyla (Marchantiophyta = liverworts, Bryophyta = mosses, and Anthocerotophyta = hornworts) and can be placed in the subkingdom Bryobiotina. The bryophytes (**Bryobiotina**) share with the tracheophytes the development of an **embryo** within a **multicellular reproductive organ**, a covering of **sporopollenin** on their spores, and the presence of **flavonoids**. Bryophytes have **chlorophylls a** and **b**, store their photosynthate as **true starch** (but may also use oils and lipids). They have spiral sperm bodies with two flagella.

Bryophytes differ from tracheophytes in having a dominant gametophyte supporting a dependent sporophyte. They **lack meristematic tissue, lignin, tracheids** (but have **hydroids** with similar function), and **sieve cells** (moss **leptoids** are similar enough to sieve cells that some biologists consider them to be such). The expected consequences of lack of lignin are not only small stature, but also lack of tracheids and vessels, hence the term **non-tracheophytes**.

Some biochemical differences support creation of the phylum **Sphagnophyta**, but others interpret total characters to support monophyletic origin of **Bryophyta**, including *Sphagnum*, but not liverworts or hornworts. Some researchers consider that **Bryobiotina** may have been derived from tracheophytes by reduction and loss of lignin.

Intraspecific taxa include subspecies (geographically separated), varieties (genetically determined morphological differences with interbreeding), **forms** (environmentally determined), **cryptic species** (non-interbreeding with no morphological differences), and **microspecies** (having genotypes perpetuated by apomixis).

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading. Heinho During read an early draft and offered numerous comments, suggestions, and encouragement. Brent Mishler offered suggestions for improvement on the section on Higher Classifications and New Meanings. Llo Stark reviewed the chapter.

CHAPTER 2-2

LIFE CYCLES: SURVIVING CHANGE

Figure 1. *Dicranum majus* showing leafy gametophyte and attached sporophyte. Photo by Michael Lüth, with permission.

The General Bryobiotina Life Cycle

Perhaps one could explain most of plant and animal ecology by explaining all the factors that contribute to and control the life cycle and development of individuals of a species. These interwoven abilities and responses to signals determine who arrives, who survives, and who leaves any given community. It is in this context that plants and animals are able to contend with the changing seasons – they have programmed into their life cycle the means by which to escape when the going gets rough. Thus, it is appropriate that we continue our discussion of bryophyte ecology with a thorough understanding of the limits imposed upon a species by its developmental processes and life cycle. For bryophytes, these limits affect different stages and in different ways from those same limits on the lives of the **tracheophytes** (lignified plants).

As Niklas (1976) points out, plants "oscillate between morphological and biosynthetic adaptive impasses." For bryophytes, the limitations imposed by the lack of lignin prevented them from accomplishing significant size and

thus limited their morphological development. However, they have achieved tremendous variety in their biochemical development, often having capabilities rare or unknown in tracheophytes. This development is manifest in their biochemical protection from interactions with other organisms, including herbivores, bacteria, and fungi, as well as their ability to survive desiccation, temperature extremes, and low light levels unavailable to tracheophytes in caves and deep water. In addition, their unique biochemically driven life cycle strategies and physiological behaviors permit them to occupy a wide variety of niches – even those polluted with sulfur or heavy metals. It is indeed true that bryophytes have tremendous genetic diversity (see Krazakowa 1996), expressed in their highly variable and rich biochemistry. It appears that our definition of a species as being reproductively isolated is inadequate for representing the variety of biochemical forms that exist among bryophytes. May Father Hedwig save us from those who want to identify them by numbers!

Fortunately for the systematists, the life cycles differ among the phyla and classes in the anatomy of their specific reproductive structures and the environmental and biochemical controls that regulate them. But bryophytes have in common the characteristic of retaining the zygote within an archegonium, separating them from all algae.

Dominant Generation

One of the ways that plants manage to survive as "immobile" organisms, yet are able to survive the severe changes of seasons, is by having different life cycle stages that are adapted to different conditions. As we progress through the protist and plant kingdoms, we see that most green algae (Chlorophyta), especially in freshwater, spend most of their time in the water and most of them have only one set of chromosomes ($1n$). Although there is much disagreement about evolutionary pathways among photosynthetic organisms, all evolutionary biologists seem

to agree that this **life strategy** came first, with both invasion of land and dominant $2n$ organisms coming later. (The **dominant generation** refers to the most conspicuous and generally the most long-lived generation.) This $1n$ stage is termed the **gametophyte generation** ($1n$ or **haploid** generation that reproduces by gametes in plants) because the generation ends when it produces **gametes** (sexual reproductive structures that have one set of chromosomes and must unite with another of the same species but opposite strain to continue the life cycle) that join to form the $2n$ **zygote** ($2n$ cell resulting from fusion of male and female gametes, *i.e.* from fertilization; Figure 2). Hence, the zygote is the first structure of the $2n$ stage or **sporophyte generation** [**diploid** ($2n$) generation that reproduces by **meiospores** in plants; Figure 2]. The **meiospores** in many bryophytes are able to survive many years in a dry state, thus permitting at least some taxa to live in habitats that only occasionally get moisture.

Figure 2. Basic sexual life cycle of a bryophyte. Gemmae or other propagules, not shown here, can occur on the leafy plant or on the protonema (pl. **protonemata**: alga-like, usually filamentous, stage that develops from spores of bryophytes), giving rise to the same generation as its origin. Diagram by Janice Glime.

The Life Cycle

The dominant $1n$ condition (the **nuclear condition**, referring to having 1 **set** of chromosomes, where n represents the number of chromosomes in a complete set) begins as a **spore** (reproductive cell that develops into plant without union with another cell, usually 1-celled; Figure 3), produced by **meiosis** (reduction division; nuclear process in which each of four daughter cells has half as many chromosomes as parent cell; produces spores in bryophytes and other plants), hence a **meiospore** (Figure 3-Figure 4). Linnaeus observed these spores and considered this "fine powder" to be of the same sort as the "dust" liberated from anthers of flowers (Farley 1982). Indeed he was close, although the pollen grain (dust) is already a mature gametophyte in the flower, having divided a few times within the spore wall, whereas the spore of the moss or liverwort is the very first cell of that generation.

Figure 3. SEM of tetrad of meiospores of aquatic moss *Fontinalis squamosa*, with fourth spore hidden beneath. Photo by Janice Glime

Figure 4. *Fontinalis squamosa* spore germination. Photo by Janice Glime.

Bryophytes differ in their life cycle behavior in another way as well. They have two gametophyte phases with very different **life forms** and often very different requirements for growth. Prior to development of a leafy shoot (or thalloid plant body in many liverworts), they exist in a **protonema** stage (*proto* = first; *nema* = thread; Figure 5-Figure 10) that develops from the germinating spore (Figure 4). In most mosses, this protonema is truly the "first thread," forming a mat of green filaments (Figure 8-Figure 10), but in most liverworts (Figure 5-Figure 6) and **Sphagnopsida** (Figure 7) it becomes more thalloid after a few cell divisions.

Figure 5. Young thalloid protonema of the thallose liverwort *Cyathodium*. Photo courtesy of Noris Salazar Allen.

Figure 6. Thalloid protonema of liverwort *Sphaerocarpus texanus*. Photo from Plant Actions through Eugenia Ron and Tom Sobota, with permission.

Figure 7. *Sphagnum* protonemata on a branch of *Sphagnum*. Photo by Andras Keszei, with permission.

Figure 8. Threadlike protonema of the moss *Funaria hygrometrica*. Photo by Janice Glime.

Figure 9. Moss *Grimmia orbicularis* protonema. Photo from Plant Actions through Eugenia Ron and Tom Sobota, with permission.

Figure 10. Protonemata of the moss *Plagiomnium* sp. Photo by Janice Glime.

These protonemata produce **buds** (Figure 11-Figure 12) and grow into thalloid (thallose liverworts) or leafy plants. These plants are **haploid** (containing one set of chromosomes; $1n$); thus they are the **gametophyte generation** of the life cycle.

Figure 11. Moss *Funaria hygrometrica* protonemal bud. Photo by Janice Glime.

Figure 12. Moss protonema with bud. Photo by Janice Glime.

The mature gametophytes are the leafy plants you see (Figure 13-Figure 19). They produce **antheridia** (sing. **antheridium**; male gamete containers; sperm-containers; Figure 20-Figure 27) and **archegonia** (sing. **archegonium**; multicellular egg-containing structures that later house embryo; Figure 31-Figure 37) on the same or different plants, depending on the species. Antheridia can number

up to several hundred in *Philonotis*, but a much smaller number is typical (Watson 1964). Archegonia are generally few, but can reach as many as 20-30 in *Bryum*.

Figure 14. Leafy liverwort *Porella* antheridia in antheridial branch. Photo by Paul Davison, with permission.

Figure 15. *Porella navicularis* female with arrow indicating perianth. Photo from botany website at the University of British Columbia, with permission.

Figure 16. *Porella* archegonia in perianth. Photo by Paul Davison, with permission.

Figure 17. *Bryum capillare* males with antheridia in a splash platform. Photo by Dick Haaksma, with permission.

Figure 18. *Polytrichum juniperinum* males with antheridial splash cups. Photo by David Holyoak, with permission.

Figure 19. *Polytrichum ohioense* female showing lack of any special structures at the stem tips, but tight leaves looking somewhat budlike. Note that unopened male splash cups can be seen around the periphery of the clump at the right. Photo by Janice Glime.

The **antheridium** consists of a layer of cells, the **sterile jacket**, surrounding the **spermatogenous** cells (Figure 21), *i.e.*, those that divide to form the **spermatocytes** (sperm-containing cells). If you remember that this is the gametophyte generation and, therefore, already in the haploid state, you will realize that the **sperm** (Figure 27-Figure 30), produced in large numbers within an **antheridium** and released as a mass (Figure 28), and the **egg** (non-motile female gamete that is larger than motile sperm), produced singly within an **archegonium**, must be produced by **mitosis** (ordinary cell division).

Figure 20. *Plagiomnium insigne* antheridium and paraphyses. Photo from Botany 321 website at the University of British Columbia, with permission.

It is then the task of the sperm (Figure 29-Figure 30), with its two flagella, to find a film of water within which to swim to the awaiting egg in the archegonium (Figure 31-Figure 37). This is facilitated, most likely in all cases, by the presence of a chemical gradient produced by the archegonium and serving as an attractant (Figure 34). The archegonium is shaped like a flask with a neck (Figure 31), albeit a short one in some taxa. This neck has an outer layer of cells and a middle layer, the neck canal cells that disintegrate prior to fertilization, leaving this area as the neck canal (Figure 31). It is this disintegration that releases the chemicals that attract the sperm, and the cellular remains provide a fluid medium in which the sperm can swim. This fluid exudes from the archegonium (Figure 34) and can serve as a chemical gradient. Yet it appears that the ability of the sperm to advance any great distance by means of its flagella may be unlikely, if *Riccardia pinguis* is at all representative. Showalter (1926) found that when sperm of that species were placed at one end of a 1 x 0.5 cm pool, the majority still remained at that end of the pool an hour later, retaining motility up to 6 hours. Cronberg *et al.* (2008) showed the timescale of sperm deterioration (Figure 38).

But that does not mean that all species have such short sperm longevity. In their experiments with the **parcious** (having archegonia and antheridia on same branch) *Pohlia nutans* (Figure 39-Figure 40), a widespread moss that tolerates the high temperatures of geothermal areas and the extremes of the Antarctic, Rosenstiel and Eppley (2009) found that 20% of the sperm were still viable after 100 hours in DI or rainwater. They furthermore found that longevity was not affected by 22-60°C, but at 75°C it was significantly shortened. Dilution reduced viability. This longevity is much longer than anticipated, but it may not be representative of bryophytes with more narrow ecological distributions.

Figure 39. *Pohlia nutans* perigonia (modified leaves around antheridia in bryophytes). This species is usually **parcious**. Photo by Michael Lüth, with permission.

Figure 40. *Pohlia nutans* with capsules, a widespread moss from geothermal areas to the Arctic. Photo by Michael Lüth, with permission.

It appears to be typical for sperm to be shed within their spermatocyte cells as a mass, being squeezed out of the antheridium by the swelling tissues (Figure 41-Figure 43). Both **paraphyses** (sterile filaments among the reproductive organs; Figure 20-Figure 24) and the **antheridium** (Figure 20-Figure 27) itself, swell. Then the spermatocytes drift to the top of the splash apparatus. It seems usual that the sperm do gain distance from the antheridium when they reach the surface of the surrounding water, especially in a splash cup, and break away from their enclosing spermatocyte cell membrane (Muggoch & Walton 1942). At that point, the sperm seem to disperse readily across the surface of the water, hopefully facilitating their dispersal in splashing raindrops. Yet, this leaves them to fend for themselves once they reach the surface upon which they land, hopefully that of a female plant or near a female organ. Could it be that they are programmed to avoid wasting energy unless they are within the liquid from a female plant or near a female organ?

To put this in perspective, compare a study on corn (*Zea mays*) sperm where the researchers were attempting to improve sperm longevity (Zhang *et al.* 1992). By adjusting sucrose concentrations, using six sugars, ten buffers, five pH levels, and three membrane protective agents, they screened for the best combination. By adding 0.55 M galactose and performing other fine-tuning, they improved longevity to 72 hours with 70% viability. This was to keep a sperm alive that would normally travel in the protection of a pollen tube and female gametophyte tissue. For the bryophyte sperm, normal travel is in the harsh and unpredictable environment. In some ways, this might predict that the bryophyte sperm is tolerant of a wider range of conditions, but should we really expect it to live longer?

We know little about the ability of the archegonial fluid to attract the sperm, but it appears that **sucrose** may be one of the factors, perhaps the only one, involved (Kaiser *et al.* 1985; Ziegler *et al.* 1988). These researchers found that in the moss *Bryum capillare* (Figure 44), once the neck canal cells of the archegonium had disintegrated,

the leaves and the archegonia contained less than 20% of the sucrose found in the intact neck region. There was virtually no fructose in the intact archegonium, but the glucose concentration rose after the receptive period ended.

Figure 44. *Bryum capillare* with capsules. Photo by David Holyoak, with permission.

Once the sperm reaches the **venter** of the archegonium (the bulbous base of the flask; Figure 45), it penetrates the egg and together they form the **zygote** (Figure 46), the first $2n$ cell of the sporophyte. Unlike an alga, the bryophyte retains its zygote in the female **gametangium** (archegonium) and when conditions are right the zygote divides, forming the **embryo** (young plant still contained in archegonium). This embryo continues dividing (Figure 47) and then specializing, forming eventually a **foot**, **stalk**, and **capsule** (sporangium; spore-container of mosses and liverworts; Figure 47) with a **cuticle** (water-protective layer; Crum 2001), which together constitute the **mature sporophyte** (Figure 48-Figure 58).

Figure 45. Moss *Polytrichum* archegonia. The archegonium on the right has an egg in the bottom of the venter and a biflagellate sperm near the neck. Two more sperm are in the neck canal of the archegonium on the right. Photo from botany teaching collection, Michigan State University, with permission.

When **meiosis** occurs and spores begin development, the supply of nutrition from the gametophyte may be cut off due to material that is deposited in the spaces within the cell walls of the haustorium (Wiencke & Schulz 1978). Water, however, still moves from the gametophyte to the sporophyte.

Because the base of this sporophyte is still firmly anchored in the gametophyte tissue, the sporophyte is at least partially a parasite on the gametophyte, gaining at least some of its nutrition through a joining tissue called the **haustorium**. Being contained in the gametophyte, the zygote necessarily competes for energy, as well as space, with other zygotes or embryos, and thus it is not surprising that multiple capsules are rare. Notable exceptions occur in the mosses *Dicranum* (Figure 1), *Plagiomnium* (Figure 59), *Rhodobryum* (Figure 60), and *Mittenia plumula*, with as many as nine capsules in *Plagiomnium insigne* (Figure 59) (Crum 2001).

Consideration of the sporophyte as a parasite on the gametophyte is controversial. Some botanists find this to be an obvious interpretation, but others are adamantly opposed to such a label. Part of this reasoning against the relationship as parasitic is because most sporophytes, at least in mosses, are photosynthetic until the spores near maturity. They also argue that the fitness of the gametophyte is tied to the fitness of the sporophyte with, in at least some monoicous species, the same genome. Llo Stark (pers. comm. 25 February 2023) has also found that the strategy for desiccation tolerance can change shortly after fertilization, changing from constitutive protection to inducible protection. He suggests that this could cause the release of sugars that are moved to the sporophyte. The same dilemma of terminology applies to the human embryo, but the case against calling it a parasite in bryophytes seems stronger due to the photosynthetic ability of many sporophytes, at least in Anthocerotophyta and most Bryophyta.

Figure 55. *Bartramia pomiformis* showing leafy gametophytes and sporophyte capsules. Photo by Janice Glime.

It is this dependence on the gametophyte that makes the sporophyte unique among photosynthetic organisms. On the one hand, it differs from algae by being retained within the archegonium; on the other it differs from the remainder of the plant kingdom by being dependent on the gametophyte. Furthermore, it lies within the protection of the gametophyte tissue through a great part of its development, although less so in the **Bryophyta**. This protection shelters it from selection pressures of the environment and could therefore slow the evolution of this generation (Crum 2001). It is this greater stability of sporophyte characters that makes them seemingly more useful for deriving classification within the **Bryobiotina** (bryophytes).

The details of the foregoing structures differ among the phyla of **Bryobiotina** and in many cases form the basis for separating the phyla. These are best understood by examining each phylum and class in greater detail.

Life Cycle Controls

For life cycles to work effectively in their environments, they need controls that respond to environmental cues. Without these, they cannot respond to differences in the weather between years, to changing climate, or to dispersal to other parts of the world. Among these, response to photoperiod and temperature provide effective cues that the season is changing and it is time to initiate a life cycle stage (Newton 1972).

For example, in *Mnium hornum* (Figure 61) there is an endogenous rhythm that coincides approximately with the seasonal cycle (Newton 1972). Short days delay gametangial production, but when 7.25-hour days are maintained, neither 10 nor 20°C is capable of completely suppressing the gametangia. Newton interpreted this to mean that the short days of winter maintain coordination with the seasons. In *Plagiommium undulatum* (Figure 62), archegonial induction responds to long days (7.25-12 hours at 10°C). Males are also long-day plants, but in addition they require a diurnal temperature fluctuation.

Figure 61. *Mnium hornum* showing antheridia that cease production in response to short days. Photo by Michael Lüth, with permission.

Generation Time

The concept of generation time is well known even to the layperson. We know that in humans it means the time from birth to becoming a parent, and for the population we average the data from everybody. I like the Wikipedia definition: The average difference in age between parents and offspring when the population is at the stable age distribution. For plants, it seems the best definition is one complete life cycle. Llo Stark (Bryonet 20 February 2014) agrees with this implied spore-to-spore definition, but he suggests expanding it to include shoot fragment or fragment of a protonema as the starting point instead of a spore. For example, he and John Brinda have found that it takes only 5-6 months for a shoot fragment of *Aloina ambigua* (Figure 63) to produce viable spores. In this rapid cycle, only 40 days are required for the sporophyte to develop. On the other hand, Stenøien (Bryonet 21 February 2014) suggests that the average length of time required to replace an individual is a workable definition of generation time. But Lars Hedenäs (Bryonet 21 February 2014) cautions us that we rarely know what this means in any specific case.

Figure 63. *Aloina ambigua*, a moss with a short generation time of only 5-6 months. Photo by Hermann Schachner, through Creative Commons.

But do we have information for many, or even any, bryophytes on the amount of time required to progress from spore or fragment germination to spore production? This is easy for annual bryophytes, but for perennials, few have been grown from spore to mature capsule and field observations would be based mostly on colonists because spores are an important part of their life strategy. And some bryophytes further complicate this by rarely or never producing capsules, forcing us to guess based on gametangial maturation time. However, once fertilization occurs, sporophyte maturation can proceed rapidly as in the annuals, or take 15 months as in some *Polytrichum* (Figure 64) species.

Figure 64. *Polytrichum commune* sporophytes, in 4 cases covered by the gametophyte calyptra. Photo by Michael Lüth, with permission.

Even "annuals" might cause problems. For example, *Buxbaumia* (Figure 65-Figure 66) is usually considered an annual because the sporophyte lasts only one year and there is no leafy gametophore. But Hancock and Brassard (1974) found that despite the annual disappearance of the sporophyte, the protonema remained for several years.

Figure 65. *Buxbaumia aphylla* with mature capsules. Photo by Jan-Peter Frahm, with permission.

Figure 66. *Buxbaumia aphylla* with capsule wall peeled back and interior exposed. The greenish ground cover is caused by protonemata that will survive the winter and form new plants. Photo by Janice Glime.

Let us take an example first given by Hans Stenøien and carried further by Lars Hedenäs (Bryonet 21 February 2014). If a moose walks across a bog and kills a *Sphagnum* (Figure 67) shoot, the empty space created will most likely be filled by an expanding neighboring shoot. The probability is high that the neighbor originated by branching from the now dead shoot. This means the same individual survives despite the death of one of its shoots. Do we know anything about the frequency of this happening?

Figure 67. *Sphagnum capillifolium*, a moss that spreads by branches. Photo by David Holyoak, with permission.

To these comments, Lars Hedenäs (Bryonet 20 February 2014) adds that many bryophytes reproduce sexually numerous times during their lifetimes, perhaps for hundreds of years. Note that this can occur while the lower parts of the plants are dying so that it may be more typical for only 4-5 years of growth to remain alive. How do we treat these long-lived taxa? Do we take the average of the first to last reproduction, or do we use the first?

And how do we treat the asexual "generations?" Hedenäs points out that these clones may block the establishment of new introductions due to lack of space.

If we consider genetic change in terms of generations, the issue has even more complications. As Richard Zander (Bryonet 20 February 2014) points out, genetic change may be more the result of point mutation than of recombination. And these may be passed on through fragmentation or **ramets** (physiologically distinct organism that is part of group of genetically identical individuals derived from one progenitor; individual of clone).

By now it is clear that generation time in bryophytes cannot be defined as it is in humans (Brent Mishler, Bryonet 20 February 2014). In fact, Guy Brassard (Bryonet 20 February 2014) reminds us that it is an animal term. As Mishler concludes, "maybe there is no reasonable concept of generation time in mosses!" Rod Seppelt (Bryonet 20 February 2014) agrees: "I rather like the suggestion that 'generation time' is nonsensical in bryophytes." At the very least, we need to define the term whenever we use it in order to make clear what we mean by it. In that case, we should consider the suggestion of Hans Stenøien (Bryonet 20 February 2014): "The length of a generation could be defined as the average time it takes to replace an individual (a shoot or a ramet) in a stable population. This could be done by sexual or vegetative means, by residents or immigrants. Bog systems can be quite dynamic, and many shoots die and are replaced from time to time (because mosses do what they do, competition etc.)."

Rod Seppelt (Bryonet 2 January 2022) has suggested what might be the shortest "generation time" for a bryophyte. When in Alaska, he found a population of *Riccia cf. cavernosa* (Figure 68) on a floodplain about a week after the water receded. These were very small plants, suggesting their origin from spores rather than dormant thalli. It was late autumn, and a new submersion was imminent due to upstream rains. He collected more plants about two weeks later and found mature spores in the thalli. He estimated that these plants went from spore to producing mature sporangia in just 2-3 weeks!

Figure 68. *Riccia cavernosa*, a species that can apparently complete its life cycle in less than 3 weeks on a floodplain. Photo by Richard Orr, with permission.

Importance

So why is it important to understand generation time of a bryophyte? The question about the length of a generation was raised by Jon Shaw who wanted to know the generation time in *Sphagnum* (Figure 67). As Hans Stenøien and Richard Zander summarized on Bryonet (21 February 2014), understanding generation times (and population sizes) enables us to use population genetic models to infer the action of evolutionary processes. Likewise, phylogenetic models enable us to infer evolutionary relationships. From these, we can infer migration rates and divergence time between lineages.

Longevity and Totipotency

Bryophyte longevity can be difficult to define because unlike most other plants, they die at the bottom and continue growing at the tip. Furthermore, they may seem dead, yet still be capable of life. For example, I have boiled *Fontinalis* (Figure 69) for two weeks, replaced it in its native stream, and found a few new leaves on one stem tip a year later, whereas all the original leaves were brown or gone.

Figure 69. *Fontinalis dalecarlica*, a species that can survive two weeks of boiling because of its totipotency. Photo by J. C. Schou, through Creative Commons.

This capability of "coming back to life" is in part the result of **totipotency** – the ability of any cell of the organism to dedifferentiate and then differentiate into a new plant. We have seen this regeneration many times in the growth from fragments, to be discussed in other chapters, especially in Dispersal.

We know that *Sphagnum* (Figure 67) continues growing for hundreds of years, but only the recent few years of growth seem to be alive. But is that really true?

Recent studies in polar regions suggest that parts of some bryophytes can retain life for 1500 years under ice (LaFarge *et al.* 2013; Roads *et al.* 2014). Working in the Arctic, LaFarge *et al.* (2013) were able to grow new gametophytes from two species of buried bryophytes: *Aulacomnium turgidum* (Figure 70) ~400 years old and *Bartramia ithyphylla* (Figure 71) ~460 years old.

Figure 70. *Aulacomnium turgidum*, a species found buried in Arctic ice cores. Photo by Michael Lüth, with permission.

Figure 71. *Bartramia ithyphylla*, a moss found in ice cores from the Arctic. Photo by Michael Lüth, with permission.

Then Roads *et al.* (2014) found new growth of *Chorisodontium aciphyllum* (Figure 72-Figure 73) in Antarctic cores at 138 cm, a layer they interpreted to be ~1500 years old! They found that after 55 days the *Chorisodontium aciphyllum* grew *in situ* at the base of their ice core at 110 cm. Protonemata developed on the rhizoids at the base in 22 days. (See also Miller 2014; Zimmer 2014).

Summary

The traditional bryophytes (Subkingdom **Bryobiotina**) are classified into three phyla (**Marchantiophyta** = liverworts, **Bryophyta** = mosses, **Anthocerotophyta** = hornworts).

Bryophytes have a dominant gametophyte (1n) generation that limits their ability to store recessive alleles. The life cycle involves a **protonema** that develops from the germinating spore, becoming thalloid in most liverworts and Sphagnopsida, but becoming a branched thread in most other mosses. The protonema produces **buds** that develop into leafy gametophores. Mosses in the Bryopsida, but not liverworts or **Sphagnum**, can produce multiple **upright gametophytes** from one protonema, and therefore from one spore.

Gametophores produce **archegonia** and/or **antheridia** and the zygote divides to form an **embryo** that develops within the archegonium. Sporophytes remain attached to the gametophyte and produce spores by meiosis.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and reviewed an early draft. Peter Convey and Catherine La Farge entered an email discussion with me on their own finds and concerns about available data on the ice core finds. Thank you to Llo Stark for improving the wording in several parts of the chapter.

Distinguishing Marchantiophyta

Both the leafy and thallose liverworts are placed in the phylum **Marchantiophyta** (variously known as Hepatophyta, Jungermanniophyta, Hepaticae, and Hepaticopsida), an often inconspicuous group with about 5000 species (Gradstein *et al.* 2001), or as Crum (1991) put it, up to 10,000, "depending on who says it and when," because so many species names described from different parts of the world have proved to be synonyms.

Because of the long tradition of considering these to be bryophytes, liverworts (and hornworts) are still lumped into that group for a vernacular name instead of creating a new name that is unfamiliar to everyone. As a phylum, **Marchantiophyta** are distinguished from the phylum **Bryophyta** by their **dorsi-ventral orientation** (Figure 1, Figure 12), **unicellular rhizoids** (Figure 2), **inoperculate capsules** [*i.e.* lacking a lid (Figure 3), although there are a few exceptions], **absence of a columella** in the center of the capsule (Figure 4), and **no stomata** in the capsule. They possess a **seta** (stalk on the capsule), as do mosses, but it elongates **after** development of the capsule (Figure 11-Figure 12), whereas in mosses it elongates first, then develops the capsule. The spores, as in mosses, are all produced simultaneously by **meiosis** (Figure 5). The

capsule, unlike that of most mosses, dehisces typically by **splitting into four valves** (Figure 6), but not in the class Marchantiopsida, revealing spores mixed with **elaters** (thickened elongate cells with spiral wall thickenings that twist in response to drying; Figure 6-Figure 7).

Elaters

Elaters are notably absent in the thallose liverworts **Ricciaceae** and **Sphaerocarpaceae** (*Sphaerocarpos*, *Riella*), although sterile cells exist in the latter. Elaters respond to changing moisture conditions, most likely rather suddenly upon the first splitting of the capsule, and twist and turn among the spores as they dry. When the capsule opens, the elaters are filled with water, but as the capsule dries, so do the elaters. This causes the thin areas of the elaters to be pulled inward, distorting them. As the space between the thickenings is pulled in, the spirals tighten until the entire elater becomes a tight, twisted helix. Physical forces keep trying to untwist them, but adhesion of water inside the elater cell wall resists this extension, creating tension. When the tension of the water column finally breaks, the elater extends to its original shape so violently that it springs free of the capsule, scattering spores as it does so. The pressure in the cellular water just prior to its release can be as high as 200-300 atmospheres in *Lophozia* (Figure 8). In the tiny *Cephaloziella* (Figure 9), spores can travel up to 4-5 cm (Douin 1914 in Schuster 1966) and in *Tritomaria quinquedentata* about 2.5 cm (Meylan in Schuster 1966).

Figure 9. *Lophozia incisa* with capsules, a species whose capsules open after building up pressure of 200-300 atmospheres. Photo by Tab Tannery, through Creative Commons.

In the leafy liverwort *Frullania dilatata* (Jungermanniopsida), elaters attach to the capsule wall at both ends (Schuster 1966). When the capsule opens, the elaters are stretched, creating tension. Most likely further drying contributes to the tension until the inner ends suddenly release (see Figure 6), providing a springboard from which spores are catapulted 1-2 cm above and out of the capsule. However, Schuster felt that most of the contribution of the elaters in this case is to loosen the spore mass.

In *Marchantia* (Figure 10), elaters twist and untwist, based on moisture changes. The capsules do not open along four distinct lines of dehiscence (compare Figure 10 to Figure 14), but rather open irregularly into short lobes that bend back. Elaters twist as they dry and become entangled (Figure 10). When an elater becomes free of the others, it does so with a sudden movement that throws spores from the capsule, although the elater generally remains (Ingold 1939 in Schuster 1966). In other liverworts, such as *Pellia* (Figure 11-Figure 13), the spiral thickenings are not so thick and the movements are too

subtle to accomplish much dispersal (Schuster 1966). Rather, release of pressure at the time of dehiscence seems to be responsible for at least some dispersal. However, even the subtle movement of elaters may serve to loosen spores from each other, making dispersal easier when something disturbs the stalk and capsule (Figure 14). (See chapter on dispersal.)

Leafy or Thallose?

The Marchantiophyta can be divided into two classes (Figure 40), the **Marchantiopsida** (thallose liverworts; Figure 15 & Figure 18) and **Jungermanniopsida**, the latter with two subclasses, the **Metzgeriidae** (mostly thallose liverworts; Figure 41), and the **Jungermanniidae** (mostly leafy liverworts; Figure 47 & Figure 49). One could argue that these two classes should actually be separate phyla (Bopp & Capesius 1996), but most modern systematists disagree (Crandall-Stotler & Stotler 2000). Based on 18S rRNA genes for all bryophytes tested, the **Marchantiopsida** are clearly separated from the **Jungermanniopsida**, but the latter are in the same clade as the **Bryophyta**! Furthermore, the orders **Metzgeriales** and **Jungermanniales** are indicated on the same branch. I will

leave these arguments for the future and describe the two classes of **Marchantiopsida** and **Jungermanniopsida** as comprising the **Marchantiophyta**.

Figure 15. *Preissia quadrata* (Marchantiopsida), a thallose liverwort, showing antheridiophores. Photo by Janice Glime.

Class Marchantiopsida

Thallus Construction

The **Marchantiopsida** possess a thallus that is dichotomously forked (Figure 12) and generally has pores (Figure 16-Figure 18). The thallus is several cells thick and the upper (**dorsal**) tissue is loose, resulting from internal air spaces (Figure 18-Figure 20). The lower (**ventral**) surface usually has two kinds of **rhizoids** (Figure 19, Figure 21-Figure 22), **smooth** ones and those with "pegs" (protrusions inward from the cell wall), and usually has scales (Figure 22). The capsule dehisces irregularly (Figure 13), or less commonly by means of an operculum of thin-walled cells, as in *Cyathodium*.

Figure 16. *Marchantia chenopoda* pores. Photo by George Shepherd through Creative Commons.

Figure 17. *Marchantia chenopoda* pores. Photo by George Shepherd through Creative Commons.

The thallus in Marchantiopsida has some resemblance to the leaf of a tracheophyte. The air chambers have stacks of photosynthetic cells (Figure 18) that resemble the spongy mesophyll of a tracheophyte leaf. The pores permit gas exchange into and out of these photosynthetic cells.

Figure 18. Cross section of thallose liverwort *Marchantia polymorpha* (Marchantiopsida) showing the internal air chambers, pores, and fragments of rhizoids. Note stacks of cells in internal air chambers, somewhat resembling the spongy mesophyll of a tracheophyte leaf. Pores are surrounded with rings of cells 4-5 cells high that can, as a group, curve and close pores in a manner somewhat resembling that of guard cells in leaves. Sexual Structures

Members of the Marchantiopsida may have the archegonia imbedded in the thallus, as in *Ricciocarpos* (Figure 23), or raised on an umbrella-like archegoniophore (Figure 24-Figure 25), as in Marchantiaceae. Likewise, the antheridia may be imbedded in the thallus, as in *Ricciocarpos* (

Figure 23), or imbedded in a splash platform atop an antheridiophore (Figure 26, Figure 28-Figure 29), as in *Marchantia*. The archegoniophore and antheridiophore are made by the infolding of the thallus. The "suture" along the vertical surface, and often scales and rhizoids, can be seen along the stalk where they stick out from the stalk (Figure 25). Such elevation of antheridia within a splash platform, the antheridial head, in *Marchantia* presumably permits the sperm to be splashed away from the parent to land on the archegonial head that is just beginning to develop and is not yet elevated significantly (Figure 27-Figure 31). Once the sperm are in the vicinity of the archegonia, the archegonium attracts them with a protein (Harvey-Gibson & Miller-Brown 1927).

Figure 23. Reproductive structures of *Ricciocarpus natans* (Class **Marchantiopsida**). **Left:** Antheridium imbedded in thallus. **Middle:** Archegonium imbedded in thallus. **Right:** Spore tetrads (following meiosis) in sporophyte imbedded within the thallus and still within the archegonial wall. In *Marchantia*, this sexual expression is under the control of a small Y chromosome in the male, with no X chromosome, and a single X chromosome in the female (Lorbeer 1934). The life cycle of *Marchantia* is summarized in Figure 39.

Sperm Dispersal

But just how far can these tiny sperm travel? Showalter (1926) found that the sperm of *Riccardia pinquis* could swim at a rate up to one centimeter in one hour, but more often it was considerably slower. Furthermore, their maximum swimming endurance time was only six hours.

Duckett and Pressel (2009) found that classical knowledge of *Marchantia* fertilization did not always fit reality. Following a fire, *Marchantia polymorpha* (Figure 27) spread rapidly. Both gemmae and sexual reproduction are most likely responsible. Rather than relying entirely on splash from antheridiophores, the sperm are actively discharged from the antheridial heads to as much as 15 cm above it (Shimamura *et al* 2008). Duckett and Pressel found that every archegoniophore in this large patch had achieved fertilization, some of which were several decimeters from the nearest male. Some archegonial heads bore as many as 30-50 sporophytes with more mature ones near the ends of the arms and younger ones nearer the central stalk. Dye splashed on the antheridial heads landed up to 30 cm away, hardly explaining the distances at which some archegonia were fertilized, more than 90% of the dye solution was readily absorbed by the antheridial heads. The dye quickly moved to the ground level (within

minutes). Within an hour the dye had spread throughout the rhizoids of the entire 10 cm diameter colony. Upward movement to archegonial heads was a bit slower but nevertheless reached the heads in 30-60 minutes.

As early as 1950, Benson-Evans observed the remarkable dispersal of spermatozooids from *Conocephalum conicum* (Figure 32). She found that they are "vigorously" dispersed into the air through an ejection mechanism, but also that mites, known as dispersal vectors in other Marchantiales, were probably not involved. She found that the dry antheridia, such as those following a hot day, would eject the spermatozooids in a fine mist that occurred in regular puffs. If these plants were put into direct sunlight, the activity increased enough that the packets of sperm were visible to the unaided eye.

Shimamura *et al.* (2008) have successfully filmed <<http://www.youtube.com/watch?v=ALGDLzWcvnU>> the remarkable dispersal of **sperm** from the antheridia (Figure 32) of *Conocephalum conicum* (Figure 32). In *Conocephalum*, there is no splash platform, and instead the sperm are ejected from the antheridium in a cloud that rises into the air several centimeters (Shimamura 2008), a phenomenon originally described by Cavers (1903), and again by Muggoch & Walton (1942) and Benson-Evans (1950). In Hiroshima, Japan, these sperm are typically dispersed in April to May. Shimamura (pers. comm. 2008) relayed to me that they were able to detect many airborne sperm on a sunny day after a rain shower. After a week of dry, sunny conditions, sperm were dispersed following a rainy day, resulting in most of the mature antheridiophores being empty. In the lab, antheridia can be persuaded to release their sperm by misting them. The intense lighting for photography also seemed to help. Initially, the sperm in these droplets are non-motile. Touching the droplets causes them to swim (Masaki Shimamura, Bryonet 3 January 2008), suggesting that these might be packets that must be broken for the sperm to begin swimming (Muggoch & Walton 1942) (see Figure 80).

Figure 32. *Conocephalum conicum* males showing **antheridial heads**. The polygon shapes delineate the internal chambers and the tiny dot visible in the middle of some is the pore. Photo by John Hribljan, with permission.

At this stage, the archegoniophore has not extended and the archegonia are near the main thallus (Figure 33), making transfer of sperm easier. As in our traditional

understanding of *Marchantia*, the archegoniophore elongates following fertilization (Figure 34) and the capsules form on the underside of the archegonial head (Figure 35-Figure 37), extending from the archegonial wall. Des Callaghan has provided us with a film of liverwort sperm swimming <<http://youtu.be/Jdh8flxvZgk>>, demonstrating how they are able to reach the archegonia. Splashing can bring them close to the archegonia, but they must swim to reach the archegonial neck and enter it.

Like *Marchantia* (Figure 18, Figure 20), *Conocephalum* has a spongy photosynthetic layer in the thallus (Figure 38). The life cycle for *Marchantia* applies equally well to *Conocephalum*, except for the lack of an antheridiophore, and is illustrated in Figure 39. Sexual structures of *Cyathodium spruceanum* (Marchantiopsida) are illustrated in Figure 46. Examples of species of Marchantiopsida and Jungermanniopsida are in Figure 40.

Class Jungermanniopsida

Jungermanniopsida lack dichotomous forking, internal air spaces, dorsal pores, ventral scales, and pegged rhizoids. They may be ribbon-like, thallose, or leafy. Many have oil bodies (isoprenoid essential oils). The role of oil bodies is unclear, but they may help to prevent desiccation damage or to protect against UV light. Yet, those seem like strange functions if the oil bodies disappear

upon drying. On the other hand, species that typically live in dry habitats seem less subject to oil body disappearance. Goebel and Balfour (1905) suggested that they are the source of the unique odors found in many of the liverworts, particularly the thallose taxa. The **Jungermanniopsida** are divided into two subclasses: **Metzgeriidae** and **Jungermanniidae**.

Metzgeriidae

Plants in the subclass **Metzgeriidae** (Figure 41-Figure 45) are thalloid or ribbon-like, except that some members of *Fossombronia* (Figure 44) appear leafy, while having only one initial cell instead of 2-3 as in other members (Renzaglia 1982). But despite their thalloid nature, other features seem to place the **Metzgeriidae** within the **Jungermannniopsida**. They lack true dichotomous forking (although pseudodichotomies occur), and their tissues are solid, lacking internal air spaces. They also **lack dorsal pores** and **ventral scales**, and the **rhizoids** are all smooth, and never in clumps as in **Jungermannniidae**. Cells often have **oil bodies** (Figure 50), although these disappear upon drying.

Figure 46. *Cyathodium spruceanum* (Marchantiopsida). **Left:** male plants; R = male receptacles. **Right:** female plants; ES = sporophytes; arrows = involucres. Photos courtesy of Noris Salazar Allen.

Jungermanniidae

Members of the subclass **Jungermanniidae** are leafy and usually branching. These are the leafy liverworts. They often have reduced underleaves (Figure 47) that at least in some cases can develop into a third row of normal leaves if the plant is supplied with an ethylene inhibitor (Basile & Basile 1983). The leaves are never more than one cell thick, never have a costa or rib, and unlike the mosses, are often toothed or lobed (Figure 48-Figure 49). The leaves typically have oil bodies (Figure 50), membrane-bound, terpene-containing organelles unique to liverworts, in all their cells, although these usually disappear upon drying.

Note the oil bodies resembling bunches of grapes and the numerous small chloroplasts clumped around the periphery of cells. Cell walls also have **trigones** (swellings in the walls). Photo by Zen Iwatsuki, with permission.

In the leafy liverworts, the leaf may be folded to create a pocket or pouch (**lobule**; Figure 51), usually on the lower side, but the smaller lobe may occur on the upper side in such genera as *Scapania* (Figure 52). Rhizoids, unlike those in the **Metzgeriidae**, usually occur in clumps at bases of underleaves (Figure 53).

Figure 51. *Frullania dilatata* (Class **Jungermanniopsida**), a leafy liverwort showing the ventral (under) side of the stem with hood-shaped lobules under each leaf and underleaves on the stem. Photo by Michael Lüth, with permission.

Figure 53. *Chiloscyphus polyanthus* with a clump of rhizoids at the base of the underleaf. Photo by Paul Davison, with permission.

In all the bryophyte phyla, the spore is a **meiospore** (produced by meiosis and therefore $1n$; Figure 54-Figure 56). These structures can be variously decorated and their size and decorations can contribute to their dispersal ability. Germination (Figure 56) in liverworts is apparently inhibited inside the capsule, thus occurring only after capsule **dehiscence** (splitting apart) and spore dispersal (Figure 57-Figure 59).

Figure 58. *Lophocolea* capsule dehiscing. Photo by George Shepherd, through Creative Commons.

Figure 59. *Lophocolea* capsule fully open into four valves. Photo by George Shepherd, through Creative Commons.

The spore, once finding a suitable condition of moisture and lighting, germinates (Figure 56-Figure 61). Here, the liverwort **sporeling** differs from that of most mosses. In liverworts the protonema is variable, even within orders, with the protonema ranging from **filamentous** to **thalloid**, but mostly forming only a few cells (Figure 64-Figure 61).

In the leafy liverworts *Frullania moniliata* and *Drepanolejeunea*, as in all **Porellales**, the protonema is formed within the spore (**endosporic**); in *Cephalozia otaruensis* it is an **ectosporic** filamentous protonema; in most of the liverworts it is **ectosporic** (developing outside the spore) and thalloid (Figure 61-Figure 65) (Nehira 1966).

Liverworts differ markedly from mosses not only in most species having a thalloid rather than filamentous protonema (exceptions in some Cephaloziaceae), but in producing only one upright plant per protonema. Furthermore, unlike many mosses, they never produce protonemal **gemmae** or other protonemal **propagules** (Schofield 1985) and rarely reproduce by fragments (Crum 2001). [See Glime (1970) for a new plant produced by a fragment in *Scapania undulata* (Figure 66)]. Nevertheless, in all bryophytes the sporeling is quite different in structure and appearance from the mature gametophyte that will develop from it.

But what links the thallose liverworts to the leafy ones? Steenbock *et al.* (2011) reported an interesting find from Vancouver Island, British Columbia, Canada. In the Eocene flora, they found a liverwort unlike any currently known, either as fossils or extant. This liverwort had three-ranked leaves arranged in a spiral, with the underleaves **larger** than the lateral leaves. The rhizoids were in fascicles associated with all three ranks of leaves. These and other characters caused them to name a new family, the Appianaceae, based on the name of the type locality at the

Appian Way. This arrangement of leaves is reminiscent of the leaf arrangement in *Haplomitrium* (Figure 67-Figure 68). The genus *Treubia* (Figure 69) is yet another unusual liverwort (Anonymous 2010) and appears to be one of the basal groups among liverworts. This liverwort might be described as a thallus with leaves. It is intermediate between thallose and leafy liverworts and is most closely related to *Haplomitrium*.

Figure 67. *Haplomitrium gibbsiae* plants demonstrating the three-ranked leaves in this family. Photo by Jan-Peter Frahm, with permission.

Figure 69. *Treubia lacunosa*. Photo by Jan-Peter FFrahm, with permission.

Within the Jungermanniopsida, the **gametophore**, or mature gametophyte, can be either of two forms, depending on the family. The thalloid form has a blade-like appearance and usually produces its antheridia and

archegonia within the thallus. The leafy liverworts produce their antheridia (Figure 70-Figure 73) and archegonia (Figure 74-Figure 79) along branches.

Mucilage filaments usually occur among the gametangia (Schofield 1985), presumably helping them to retain water and to help squeeze the antheridia when it is time for sperm to emerge.

Once reaching a female plant, the biflagellate sperm presumably swim, in all cases, to the archegonium. In some genera, for example the thallose *Aneura* (**Marchantiopsida**), it may take several hours for the sperm to travel a mere 10 mm (Showalter 1925 in Walton 1943). In fact, in many taxa, it is the **spermatocytes** (cells that become converted into sperm), prior to sperm release, that travel across the thallus by means of surface tension over the free water surface (Figure 80). This is at a much faster rate of 20 mm per minute (Muggoch & Walton 1942).

Figure 80. *Porella navicularis* (**Jungermanniopsida**) antheridium expelling sperm. Photo by Jonathan Choi, through Botany 321 University of British Columbia website, with permission.

By contrast to these earlier observations of Muggoch and Walton (1942), in *Pellia*, the emerging **spermatocytes**, in this case housing the sperm within a membrane, emerge from the dehiscing antheridium in grey masses. These masses spread rapidly across the wet surface, breaking apart as they reach the surface, with sperm emerging in about 15 seconds. It takes only 15 seconds for these spermatocytes to reach the archegonial **involucre** (protective sheath of tissue of thallus origin surrounding single antheridium, archegonium, or sporophyte; Figure 81). Another 15 minutes is required for the free sperm to emerge from the spermatocyte. Thus, the sperm disperse and are ready to enter the archegonia in little more than 15

minutes from the time of antheridial dehiscence. Such rapid movement could not be achieved by the slow-swimming sperm, which would require hours to achieve the same distance, often failing to reach their destination before the necessary water was gone.

Figure 81. *Pallavicinia lyellii* (**Metzgeriidae**) showing filamentous fringe of the involucre where archegonia are located on the thallus. **F** denotes female gametophyte; **M** denotes male gametophyte. Photo by Noris Salazar Allen, with permission.

Following fertilization, the stalk supporting the archegonial head elongates and elevates the archegonial head several cm above the thallus where the capsule enlarges. This is of little advantage, it would seem, until the sporophytes are mature and the spores ready for dispersal. When the spores are mature, the capsules (sporangia) split (with very few exceptions having a lid), revealing the spores and **elaters** (in **Marchantiophyta**, elongate one-celled structures with two spiral thickenings and associated with spores).

In **Jungermanniidae**, the antheridia are not imbedded, but occur at the bases of leaves, whereas the archegonia are at the ends of stems or branches, surrounded by a **perianth** (Figure 82), and that is again surrounded by an **involucre** of two **bracts** and often a **bracteole**, all of which are often joined. The capsule develops inside the **perichaetium** (modified leaves that surround the archegonia), but ultimately sits atop an elongate, **hyaline** (colorless), delicate **seta** (stalk; Figure 83-Figure 85) that soon withers away. The capsule itself opens by four valves and usually contains **elaters**.

Figure 82. *Frullania* sp. perianth. Photo by George Shepherd, through Creative Commons.

Figure 83. *Porella navicularis* with young sporophyte emerging, through Botany 321 University of British Columbia website, with permission.

Figure 84. *Lophocolea cuspidata* perianth and developing sporophyte. Photo through Botany 321 University of British Columbia website, with permission.

By contrast to the mosses, liverworts lack a split-off **calyptra** (covering of capsule formed from upper part of torn archegonial wall) and the capsule matures while it is still immersed among the protecting leaves. As the capsule (sporangium) expands, the archegonial wall is ruptured and remains at the base of the sporangial stalk. In contrast to the **Marchantiopsida** taxa that may have thalloid stalks supporting the archegonia and ultimately the capsules (*e.g.* *Marchantia*), and the sporophyte stalk remains small and is typically not visible among elevated scales and thallus, in the **Jungermanniopsida** the sporophyte stalk is conspicuous. In leafy taxa (**Jungermanniidae**) and other thalloid taxa this sporangial stalk elongates only after the capsule matures. The stalk elongates (in leafy liverworts) by rapid (3-4 days) elongation of the watery stalk (**seta**) cells (Bold *et al.* 1987) and extends the capsule away from the plant (Figure 85), using turgor pressure within the delicate cells to maintain this position. This **seta** supports and extends the capsule of most mosses and liverworts.

Figure 85. *Lophocolea heterophylla* with mature sporophytes. Photo by David Holyoak, with permission.

The spores are all of equal maturity and all ready for dispersal at the same time (Schofield 1985). Once the spores are shed, the deliquescent stalk soon collapses and the capsule disintegrates.

Liverworts frequently produce **gemmae** that occur on leaves of leafy liverworts (Figure 86-Figure 91) or on the thallus of thallose taxa (Figure 92). These permit the plants to reproduce asexually in places where sexual reproduction is unsuccessful. As will be discussed in a later chapter, this is especially important when the sexes are on separate plants. These gemmae are often useful for taxonomic purposes because they have a variety of shapes and colors.

Summary

Marchantiophyta are distinguished from the phylum Bryophyta by their **dorsi-ventral orientation**, **unicellular rhizoids**, **inoperculate capsules**, **absence of a columella**, and **no stomata** in the capsule. Marchantiophyta are generally considered to have two classes: **Marchantiopsida** (thallose liverworts) and **Jungermanniopsida**, including **Metzgeriidae** (thallose liverworts) and **Jungermanniidae** (leafy liverworts).

Marchantiophyta have a dominant gametophyte generation with a dependent, short-lived sporophyte. The life cycle involves a **protonema** that develops from the germinating spore, becoming thalloid or globose in most liverworts. The protonema produces a **bud** that develops into a **leafy** or **thallose plant**.

Gametophytes produce **archegonia** and/or **antheridia** and the **embryo** develops within the archegonium.

Sporophytes remain attached to the gametophyte and produce **spores** by **meiosis**. Marchantiophyta produce spores from the sporophyte only once, *i.e.* simultaneously. These spores are dispersed, in most genera, by **elaters** that are produced among the spores and that have spiral thickenings, causing them to twist as moisture changes.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading. Rob Gradstein suggested clarifications and Christine Cargill provided important information and references. Eugenia Ron Alvarez and Tomas Sobota secured permission for me to use images from the PlantActions website and to obtain the original images. Norbert Stapper helped me get an email address needed to obtain permission to use an image. George Shepherd has made many wonderful images available through Creative Commons. As in most of these chapters, images from Michael Lüth and Des Callaghan have been invaluable. Noris Salazar Allen has provided me with several morphological images. Wilf Schofield helped me to obtain permission to use images from the Botany Website at the University of British Columbia. Heino Lepp of the Australian National Herbarium shared his preliminary website information on elaters with me, helping me to find original sources on their mechanisms of dispersal. Thank you to Llo Stark for alerting me to errors and formatting problems in this chapter.

BRYOPHYTA – TAKAKIOPSIDA

Figure 1. Mt. Daisetsu from Kogan Spa, Hokkaido, Japan. The foggy peak of Mt. Daisetsu is the home of *Takakia lepidozioides*. Photo by Janice Glime.

Figure 2. Hunting for *Takakia* in its typical damp, high elevation or foggy habitat. Photo with permission from <<http://www.botany.ubc.ca/bryophyte/LAB8.htm>>.

Phylum Bryophyta

Bryophyta, *sensu stricto* (in their narrowest sense), are the mosses. These comprise, roughly, 13,000 species worldwide (Crum 2001), but with many tropical taxa likely to be as yet undiscovered, the number could be much higher. Three classes have been recognized traditionally,

the **Bryopsida**, **Andreaeopsida**, and **Sphagnopsida** (Crum 1991). However, as more evidence from genetic and biochemical relationships have become available, and the interesting genus *Takakia* has produced sporophytes in our presence, further division seems justified. Buck and Goffinet (2000) define six classes: **Takakiopsida**, **Sphagnopsida**, **Andreaeopsida**, **Andreaebryopsida**, **Polytrichopsida**, and **Bryopsida**. Recent cladistic analyses using morphological, developmental, anatomical, ultrastructural, and nucleotide sequencing data supports placement of these classes into a single phylum (Newton *et al.* 2000).

Class Takakiopsida

Takakia seems to be among the most primitive of mosses, possessing many characters similar to those of the liverworts, and is the only known genus of its class, having two species [*T. ceratophylla* (Figure 6-Figure 23), *T. lepidozioides* (Figure 24-Figure 35)]. Its leaves in groups of fours, often fused at the base (Figure 5, left), made it immediately stand out as unique. *Takakia* was actually discovered in the Himalayas in 1861 by Mitten (Renzaglia *et al.* 1997), but it was described as a species of liverwort in the genus *Lepidozia*, *L. ceratophylla*. Then it was forgotten for nearly a century. When it was again discovered high in the mountains of Japan, Sinske Hattori sent it to specialists around the world. The phycologists looked and decided it was not one of theirs, and eventually it produced multicellular archegonia, supporting their claim. The pteridologists concluded it was not a reduced fern, nor a lycopod or other tracheophyte cryptogam. It seemed the more likely choices were mosses and

liverworts. Although its 3-dimensional structure seemed a bit out of place, it seemed most like a liverwort, and there it stayed for several decades (Hattori & Inoue 1998; Hattori & Mizutani 1958). But eventually, its **slime papillae** (Figure 4), its **leaves in 3 rows** (Figure 5), its **simple oil bodies** – not granular as in liverworts, its **archegonia** (Figure 3) sometimes on a **pedestal**, and its archegonial **neck cells in 6 vertical rows** began to raise questions. Its chromosome number was 4 or 5, unlike the typical 10 in liverworts and even higher numbers in most mosses.

Figure 3. Archegonium of *Takakia lepidozoides*. Photo with permission from <www.botany.ubc.ca/bryophyte/LAB8.htm>.

Then, at one of its former collection sites, it produced capsules (Smith 1990; Smith & Davison 1993)! And there

was the proof. Although not too distant from a liverwort capsule, it **dehiscid spirally** in a single valve (Figure 5, right), and **no elaters** emerged. Indeed, aside from its **filamentous, divided leaves**, it had much in common with *Andreaea*, a moss. The spiral line of dehiscence splits and twists, creating a more efficient spore dispersal (Renzaglia *et al.* 1997; Higuchi & Zhang 1998).

Figure 4. Slime papilla of *Takakia lepidozoides*. Photo with permission from <<http://www.botany.ubc.ca/bryophyte/LAB8.htm>>.

In trying to resolve the phylogenetic position of *Takakia*, Schuster (1997) referred to it as "one of a handful of isolated and unique plants." It is like the Monocleales of the liverworts in its longitudinal suture of the capsule and its "feeble conducting strand" of the sporophyte. Its lobed leaves are like those in the Jungermanniales of the liverworts. The leafless horizontal stolons, slime papillae, massive secretions of mucilage, orange antheridia nestled among leaves of all three rows (Figure 5, middle), and absence of rhizoids are characters like those of the Calobryales among the liverworts. Its capsule with 3-4-5 layers and thickened epidermal cells with thin inner cells and its absence of stomata and air spaces resemble *Symphogyna* in the Metzgeriales, also a liverwort.

Figure 5. *Takakia*. **Left:** vegetative plant of *Takakia lepidozoides* showing filamentous leaves. **Middle:** leafy plant of *Takakia ceratophyllum* with young capsule. **Right:** dehiscing capsule of *Takakia ceratophyllum* showing spiral split and exposed spores. Note single suture that splits, hence a single valve. Photo permissions on left from www.botany.ubc.ca/bryophyte/LAB8.htm; photo in middle from website of the Hattori Botanical Laboratory; photo on right from Ken McFarland, Mosses website, through fair use.

Some of its characters are unlike those of either mosses or liverworts. The antheridia of *Takakia* lack perigonia or any structure to surround them, and likewise the archegonia lack perichaetial leaves or any modified surrounding structures.

But it clearly has moss characters as well. The calyptra ruptures distally and is carried by the sporophyte on an elevated capsule. The capsule differentiates and sporogenesis occurs after the seta elongates. The sporophyte is persistent, and the capsule lacks elaters and operculum, but it has a "feeble" **columella** (mass of sterile tissue in center of capsule). Hence, as is often the case in the bryophytes, the gametophyte and the sporophyte tell different stories. In this case, the gametophyte is most like the Marchantiophyta, but the sporophyte is clearly more like members of the Bryophyta. Looking so much like a liverwort, yet also much like a moss, this apparently primitive plant seems an appropriate link between these two major groups.

The genus is distributed in western North America (Queen Charlotte Islands) and central and eastern Asia (Himalayas and mountains of China and northern Japan). The known locations all have cool climates where fog is often present to keep this strange moss moist.

Summary

Bryophyta can be considered to have six classes: **Takakiopsida**, **Sphagnopsida**, **Andreaeopsida**, **Andreaobryopsida**, **Polytrichopsida**, and **Bryopsida**. **Gametophores** of Bryophyta, including Takakiopsida, produce **archegonia** and/or **antheridia** and the **embryo** develops within the archegonium.

In **Takakiopsida**, as in all Bryophyta, **sporophytes** remain **attached** to the gametophyte and produce **spores** by **meiosis**. Bryophyta, hence **Takakiopsida**, produce spores from the sporophyte only once. Takakiopsida have **capsules** that split spirally into valves.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading of an early version. Karen Renzaglia and Hironori Deguchi kindly gave me permission to use their many web images. Llo Stark helped me improve the clarity.

CHAPTER 2-5

BRYOPHYTA - SPHAGNOPSIDA

Figure 1. *Sphagnum papillosum* with capsules. Photo by Janice Glime.

Class Sphagnopsida – the peat mosses

The class **Sphagnopsida** is very different from other members of **Bryophyta** (*sensu stricto*). It certainly is worthy of its own class, and some agree with Crum (2004) that it is likewise worthy of its own phylum, the **Sphagnophyta**. Certainly its morphological differences play a major role in its unusual ecology. Until recently it was composed of only one genus (*Sphagnum*; Figure 1), but now the family **Ambuchananiaceae** (one genus, *Ambuchanania*) has been described from Tasmania, and possesses rhizoids. The only other member of **Sphagnopsida** with rhizoids is *Sphagnum* (= *Flatbergium*) *novo-caledoniae* (Figure 2-Figure 4), an **epiphyte** (Iwatsuki 1986; plants that grow on another plant without deriving nutrients from it) that grows in or near rivers (IUCN 2013).

Figure 2. *Sphagnum* (= *Flatbergium*) *novo-caledoniae*. This species is an endemic to New Caledonia and is the only *Sphagnum* species known to produce rhizoids. Photo by Louis Thouvenot, with permission.

Figure 3. *Sphagnum novo-caledoniae* showing its habitat that is often on riverbanks. Photo by Juan Larrain, with permission.

Figure 4. *Sphagnum novo-caledoniae* rhizoids. Photo by Louis Thouvenot, with permission.

Sphagnaceae

Of all the Bryobiotina, *Sphagnum* is best known to the layperson because of its formation of peat and use in horticulture. The class Sphagnopsida is distinguished by **leaves** that are **one cell thick** and mostly possessing two types of cells – **photosynthetic cells** that possess chloroplasts and that form a network arrangement, and **hyaline** (colorless) **cells** that are dead at maturity, have one or more **pores** (giving access to the environment), and hold water (Figure 44). These hyaline cells form transparent patches among the network formed by the photosynthetic cells and may be equal in height to those cells or may surround them on the top (inner leaf surface) or on both surfaces. This arrangement seems to correlate well with the ability to avoid desiccation because the hyaline cells provide a reservoir of water to the photosynthetic cells. Those species typically occupying drier habitats generally have more of the hyaline cell surrounding the photosynthetic cell. These hyaline cells are usually strengthened by bar-like thickenings (**fibrillae**, Figure 44) in the cell walls, making them look superficially like many cells instead of the single long cell that they are. These leaves never possess a **costa** (moss version of a midrib).

The branches in Sphagnopsida occur in **fascicles** (bunches) along the stem, usually with some descending branches close to the stem (helping in capillary movement

of water) and some extending outward. The stems have a wood-like cylinder that may be brittle or soft. The most readily distinctive feature is the arrangement of young branches in a tight **capitulum** (Figure 45), the result of branch production and elongation without the elongation of the stem. As older portions of the stem elongate, new branches form and the capitulum is maintained. This gametophyte can reproduce by fragmentation, often bifurcating at the apex to produce two capitula.

This large genus can be divided into two groups based on the large, succulent-looking leaves vs the small leaves on more narrow branches. But this grouping did not work well phylogenetically, so instead nine sections were recognized. These were recently reorganized into subgenera based on 11,704 nucleotide sequences from the nuclear, plastid, and mitochondrial genomes (Shaw *et al.* 2010):

Subgenus *Sphagnum* is characterized by tightly or loosely imbricate, hood-shaped (**cucullate**) branch leaves and large, tongue-shaped (**lingulate**) or fan-shaped stem leaves (> 1 mm long) (Figure 5-Figure 12).

Subgenus *Rigida* is the other group with cucullate branch leaves but is separated by small (< 1 mm long), triangular stem leaves and somewhat (or not) **squarrose** (spreading at right angles) branch leaves (Figure 13-Figure 14).

Subgenus *Cuspidata* has a pronounced difference between hanging branches and spreading branches, usually with hanging branches longer and more slender than spreading branches; stem leaves are much smaller than branch leaves and usually hang downward on the stem; colors vary but are never red; they are typical in wet mineral-rich depressions, submerged or near the water level (Figure 15-Figure 24).

Subgenus *Subsecunda* has flexuose hanging and spreading branches that are very similar, about the same length, or with few or no branches; stem leaves are much smaller than branch leaves and usually hang downward on stems; plants are various colors but never red (branches and stems sometimes pinkish) (Figure 25-Figure 29).

Subgenus *Squarrosa* has distinctly squarrose branch leaves and large (1-1.5 mm long) lingulate stem leaves (Figure 30-Figure 31).

Subgenus *Acutifolia*

Section *Acutifolia*, like Subgenus *Cuspidata*, has a pronounced difference between hanging branches and spreading branches, usually with hanging branches longer and more slender than spreading branches; they differ from *Cuspidata* in having stem leaves nearly the same size as branch leaves or larger and usually upright on stems; plants are various shades of green, brown, or red (Figure 32-Figure 41).

Section *Polyclada* is monotypic and lacks the cucullate leaf structure, being distinguished by having six or more branches per fascicle and a dense, rounded capitulum (Figure 42).

Section *Insulosa* has toothed branch leaves and pores in hyaline cell ends (Figure 43).

Photos by Janice Glime, except as noted.

Figure 45. *Sphagnum fimbriatum* showing capitulum where archegonia will arise. Photo by Janice Glime.

The **antheridia** are nearly globose (Figure 46) and are nestled among the leaves near the tips of the capitulum branches, usually endowing those tips with a reddish color (Figure 47). The **archegonia** are terminal on short branches near the center of the capitulum.

Figure 46. Globose *Sphagnum* antheridia nestled among the leaves of a capitulum branch. Photos by Janice Glime (**top**) and Yenhung Li (**bottom**), with permission.

Jennings (1915) and Bryan (1915 in Jennings 1915) recognized the unique character of *Sphagnum*. They described a globose antheridial head that began development in August, before the September initiation of the archegonia. They discovered that some of the oldest archegonia matured by 25 October, whereas others did not mature until spring. But the uniqueness was the structures. The archegonia have a stalk, thick venter, and a narrow, twisted neck, all characteristic of mosses. But their inactive cover cell, intercalary growth of the archegonia, and the small number of canal cells (8-9) are characteristic of liverworts.

Figure 47. Antheridial branches in the capitulum of *Sphagnum*. Red coloration is from the antheridia. Photo by Janice Glime.

Sphagnum capsules (Figure 48), or sporangia, are rarely seen in many of the species, but some fruit abundantly. Nevertheless, one must be lucky to see them because they, like the liverwort sporophytes, are **short-lived**. They develop from fertilized eggs (**zygotes**) in the capitulum (Figure 45). As these develop embryos, they likewise form a **foot**, **stalk**, and **capsule** (Figure 48), but the stalk does not elongate. Instead, it remains with its foot, embedded in gametophyte tissue. *Sphagnum* is much like the liverworts in that its stalk matures after the capsule is mature, but in *Sphagnum*, this watery stalk (**pseudopodium**, pl. **pseudopodia**) is part of the gametophyte generation, not the sporophyte (Figure 48). It soon disintegrates, as do the liverwort stalks.

The capsule does not split as in liverworts and the **Takakiopsida**, **Andreaeopsida**, and **Andreaebryopsida** in the **Bryophyta**, but instead possesses an **operculum** (lid; top part of capsule of mosses that comes off for spore dispersal) that is shed prior to spore dispersal (Figure 48), as in the **Bryophyta** classes **Bryopsida** and **Polytrichopsida**. However, unlike most members of the latter two classes, it lacks a **peristome** (set of teeth-like appendages around the opening of capsule; Figure 48). The **columella** (Figure 48), that central mass of sterile tissue that is like a column in **Bryopsida** and **Polytrichopsida**, is globose in *Sphagnum*, protruding like a knob into the center of the capsule without reaching its top. **Elaters are lacking**, a characteristic shared with all other **Bryophyta** (*sensu stricto*).

Within the capsule, meiosis occurs, producing the spores. When the spores are mature, the **operculum** (Figure 48) is shed explosively when the capsule shrinks and compresses the gases, dispersing nearly all the spores in one blast of 4-6 atmospheres of pressure (Crum 2004; see Chapter 4-9). In fact, bryological folklore claims that one can hear the explosions when the sun and moisture are just right to cause the capsules to explode. No extant sphagnologist seems to have actually heard this, but following a *Sphagnum* field trip at an international meeting in Great Britain, one of the bryologists was startled

to hear ping...ping-ping...ping-ping-ping while he was sitting in bed reading. He had put his *Sphagnum* with capsules under the bed lamp to dry, and so it had, with capsules shrinking and exploding. The pings were opercula hitting the metal shade on the lamp!

It appears that *Sphagnum* is prolific in its spore production, with mean number per capsule ranging from 18,500 in *Sphagnum tenellum* to 243,000 in *S. squarrosum* (Sundberg & Rydin 1998) and **source strength** (estimated original number of spores in capsules that dehiscid during experiment) ranging 8-90 million spores (Sundberg 2005). And these spores seem to disperse quite well, with only 2-14% of those dispersed remaining within the parent colony. Being large helps. The

larger capsules dispersed a greater percentage of spores, had a smaller percentage trapped within the parent colony, and thus dispersed more spores to greater distances.

In the presence of moisture and light, and at least some nutrients, particularly phosphates (see Sundberg & Rydin 2002; Claeys 2017), the spores germinate to form a short thread. This thread soon, however, divides in more than one direction to form a **thalloid protonema** (Figure 48), as in most liverworts. A similar thalloid protonema is present also in other bryophytes such as *Andreaea* (Bryophyta class Andreaeopsida) and would be more appropriately called a **sporeling**. Like the liverworts, and unlike the other mosses, each protonema produces **only one bud**, thus only one mature gametophyte.

Figure 48. *Sphagnum* life cycle stages. Upper left photo by Zen Iwatsuki; others by Janice Glime. Protonema drawing by Margaret Minahan and Noris Salazar Allen, with permission.

Flatbergiaceae (= Sphagnaceae?)

Shaw (in Shaw *et al.* 2010) separated this family morphologically from **Sphagnaceae** by its e fibrillose leaves. It is currently monotypic, with only the species ***Flatbergium sericeum***. Currently, however, both Tropicos and The Plant List (Kew) consider this genus to belong in the **Sphagnaceae**. A second species is implicated for the family (Devos *et al.* 2016), based on molecular data. This would transfer ***Sphagnum novo-caledoniae*** to ***Flatbergium novo-caledoniae*** (Figure 49).

Figure 49. *Flatbergium novo-caledoniae*. Photo courtesy of Kjell Flatberg.

Ambuchananiaceae

Not many of us get to describe a new order. And certainly no one was expecting one in the **Sphagnopsida**! (Shaw 2000; Buchanan 2008). But this organism, this moss, was certainly something new! – ***Ambuchanania leucobryoides*** (Figure 50).

Figure 50. *Ambuchanania leucobryoides* showing similarity to some species of ***Sphagnum***. Photo by Lynette Cave, with permission.

Excerpts from correspondence with Rod Seppelt

"We knew it from two localities in south western Tasmania. Alex Buchanan found it in acid gravelly sand outwash near the coast. Heathy vegetation, very low nutrient status soils. The plants were mostly buried in the sand, only the top few mm showing."

"When I first saw the material I kept trying to put it in **Leucobryaceae**. Same habit, hence the epithet. Initially I thought I saw a peristome. The leaves did not

fit anything in **Leucobryaceae**. Then the penny dropped – it had no peristome. The position of the archegonia also started to ring bells."...

"So, no protonema is, as yet, known. We have a second locality, inland, from acid, low nutrient, peat amongst button grass moorland (*Gymnoschoenus*, which is a tussock sedge, not a grass). Alex spotted it amongst the base of some *Isolepis* material (pressed) that had been brought into the Tasmanian Herbarium for incorporation."

"Leaf morphology. Yes, it does have chlorophyllose cells and hyaline cells. The thickenings on the walls of the hyaline cells are a bit weird... Norton Miller first asked me if I thought of describing it as a second genus in Sphagnaceae."

"Ultimately, Howard Crum wrote to say that he was so convinced that it was so different from ***Sphagnum***, but within the **Sphagnales**, that it required a separate genus ***Ambuchanania***, new family **Ambuchananiaceae**. Incidentally, Jon Shaw has managed to get some DNA sequencing (incomplete) but he concurs that it is not ***Sphagnum***, although (I believe) happy to see it remain in the Sphagnales."

An endemic of Tasmania, ***Ambuchanania leucobryoides*** occurs in sandy washes known as "daisy pans" derived from Precambrian quartzite (Johnson *et al.* 2008). ***Ambuchanania*** has been collected at two relatively inaccessible, high elevation localities in western Tasmania (Yamaguchi *et al.* 1990).

Now, this strange, yet somewhat familiar genus resides not just in a new family, but a new order, the **Ambuchananiales** (Shaw 2000; Shaw *et al.* 2003). It differs from ***Sphagnum*** in **lacking fascicles**, being **sparsely branched**, and **lacking the "wood" cylinder of the stem**. Its **leaves are partially bistratose** but have those telltale **hyaline** and **photosynthetic cells** (Figure 51-Figure 52). It is anchored by **rhizoids**, a character found in ***Sphagnum*** only in one epiphytic species. Its **archegonia** are located **terminally** on stems and its **capsules** are **cylindrical**, and likewise perched on an elevated **pseudopodium**.

Figure 52. *Ambuchanania leucobryoides* leaf cross section showing hyaline and photosynthetic cells. Photo by Lynette Cave, with permission.

In addition, the genus *Eosphagnum* has been added to the **Ambucananiaceae**, an older species that has been reclassified (Shaw *et al.* 2010). This genus has the single species *E. rigescens* (an older name for *E. inretortum*; Figure 53) (Shaw *et al.* 2016).

Summary

The **Sphagnopsida** are in the **Bryophyta**, although some researchers put them in a separate phylum, the **Sphagnophyta**. Only four genera are known, a large genus – *Sphagnum*, *Ambuchanania* and *Eosphagnum* – monotypic genera in a separate order, and *Flatbergium*.

Sphagnopsida have a **dominant gametophyte** generation with leaves that have a network of **hyaline** and **photosynthetic cells**. Gametophores produce **archegonia** and/or **antheridia** in the **capitulum** and the **embryo** develops within the archegonium.

Sporophytes remain attached to the gametophyte and produce **spores** by **meiosis**. The stalk supporting

the *Sphagnum* sporophyte is a deliquescent extension of the gametophyte (**pseudopodium**) and it develops after the **capsule** is mature. **Sphagnopsida** lack teeth in the capsule but have an **operculum**, which the capsule sheds explosively.

The life cycle involves a **protonema** that develops from the germinating spore, becoming **thalloid** in *Sphagnum*, whereas it becomes a branched thread in true mosses. The protonema produces one **bud** that develops into a leafy **gametophore**.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading. I appreciate Rod Seppelt's correspondence that added human interest to this story. Louis Thouvenot took pictures of *Flatbergium* (= *Sphagnum*) *novo-caledoniae* for me so I could illustrate rhizoids. Lynette Cave answered my call for pictures of *Ambuchanania* and notified me of an error in the text. Jon Shaw helped me update the nomenclature and classification for the **Sphagnopsida**. Blanka Aguero provided me with images of *Eosphagnum*. Llo Stark provided a valuable review of the chapter.

CHAPTER 2-6

BRYOPHYTA - ANDREAEOPSIDA, ANDREAEOBRYOPSIDA, POLYTRICHOPSIDA

Figure 1. *Andreaea rupestris* with open capsules. Photo by Michael Lüth, with permission.

Andreaeopsida – The Granite Mosses

This is a small, cool-climate class of **siliceous**-rock-dwelling mosses (Schofield 1985), again with only one genus, but with approximately 100 species. They are typically **blackish** or **reddish**, **brittle**, and **short** (Figure 1). One can recognize them by rubbing one's hand across them and discovering small fragments stuck to the hand. This no doubt has dispersal potential.

The leaves are but **one cell thick** (Figure 2), but some species have a multiple cell thickness in the center, forming a **costa** (Figure 3). The arrangement of leaves is multi-ranked and the stem typically has colored cell walls (Figure 4). Unlike most mosses, they have a **thalloid protonema**.

Of ecological significance, *Andreaea* is **autoicous** (having male and female reproductive organs in separate clusters on the same plant; Figure 5-Figure 7). This ensures there will be others around to accomplish fertilization.

Figure 2. *Andreaea mutabilis* leaves with no costa. Photo by Tom Thekathyl, with permission.

Figure 3. *Andreaea subulata* leaf showing costa. Photo by Tom Thekathyil, with permission.

Figure 7. *Andreaea nivalis* antheridium. Photo from website of Botany department, University of British Columbia, with permission.

The capsule is reminiscent of liverworts, opening in **four valves**, but having the tips remaining **attached** to each other, making it look like those paper lanterns we made as children for Halloween (Figure 8). Unlike the liverworts, it **lacks elaters**. And unlike most liverworts and Bryopsida, it **lacks a seta** and has a gametophyte **pseudopodium**, a character in common with **Sphagnopsida**, a stalk produced at capsule maturity from the gametophyte tissue.

Figure 8. *Andreaea rupestris*, Class **Andreaeopsida**, gametophyte with sporophyte showing four valves of capsule and pseudopodium of gametophyte. Photo by Janice Glime.

Andreaebryopsida

This class likewise is comprised of a single genus, *Andreaebryum* (Figure 9), which has been considered by most to belong to the Andreaeopsida, but recently separated in the treatment by Buck and Goffinet (2000). It differs in being **dioicous** (having male and female reproductive organs on separate plants) and possessing a **seta**. Its **calyptra** is larger, **covering the capsule**, and the capsule is **valvate**, but unlike the Andreaeopsida, the apex erodes, so the **valves are free**, not joined at the apex. The distribution is narrow, restricted to the northwestern part of Canada and adjacent Alaska, where it grows on calcareous rocks, contrasting with the acidic granite preference of *Andreaea* (**Andreaeopsida**).

Figure 9. *Andreaebryum macrosporum* with valvate capsules. Photo from Biology 321 Course Website, UBC, with permission.

Polytrichopsida

With bryophytes, the determination of primitive or advanced often depends on the generation being examined. The gametophyte may have changed considerably while some set of characters of the sporophyte remained constant. And of course, the reverse can be true. The **dioicous** condition (male and female reproductive organs on separate plants) that characterizes **Polytrichopsida** is considered to be primitive (Longton & Schuster 1983), with the

monoicous condition (male and female reproductive organs on the same plant) that is so frequent in **Bryopsida** typically being derived by doubling of the chromosome number. Likewise, **nematodontous peristome teeth** (having evenly thickened walls and whole dead cells lacking eroded walls; Figure 10) of **Polytrichopsida** would seem to be an earlier development than the **arthrodontous** (having 1-2 rings of separated teeth with differentially thickened walls; Figure 11) condition of **Bryopsida**.

Figure 10. **Nematodontous** peristome teeth of *Tetraxis pellucida* (**Polytrichopsida**). Note the separation at the tips and absence of thickenings. Photo from Biology 321 Course Website, UBC, with permission.

Figure 11. Capsule with **arthrodontous** teeth. Note the projections along the edges. Photo by Laurie Knight, with permission.

All members of the class **Polytrichopsida** possess an elongate sporophyte **seta** (Figure 12), supporting an **operculate peristomate** capsule (Figure 13), and a **columnar columella**, characters that are more advanced than in **Sphagnopsida** but typical in **Polytrichopsida**. Spores are produced by meiosis in a single event in **sporogenous** tissue that surrounds the columella (Figure 14-Figure 15).

Figure 12. *Polytrichum juniperinum* with capsules and seta. Photo by Ralph Foster, through Creative Commons.

Figure 13. *Polytrichum commune* capsules with some showing reddish operculum. Photo by Kristian Peters, through Creative Commons.

Figure 14. Cross section of immature *Polytrichum* capsule showing sporogenous tissue. Photo by Janice Glime.

Figure 15. Longitudinal section of *Polytrichum* capsule. Photo by Janice Glime.

The moss gametophyte is often very specialized, being characterized by stems with a **central strand**, reaching its peak in **Polytrichaceae** (Figure 18), with the presence of **hydroids** (water-conducting cells) and **leptoids** (sugar-conducting cells). The leaves of the class are **all costate** (having a midrib-like structure; Figure 16-Figure 17).

Figure 16. *Atrichum undulatum* leaves showing costa. Photo by Bernd Bäuml, through Creative Commons.

Figure 17. *Atrichum undulatum* excised leaves showing costa. Photo by Hermann Schachner, through Creative Commons.

Polytrichaceae

In many ways, this family looks like a tracheophyte wanna-be. It attains a greater height than the typical moss and can even stand alone to nearly half a meter in the case of *Dawsonia longifolia* (Figure 19). *Polytrichum commune* (Figure 20) likewise attains similar heights, but only with the support of other individuals, forming a hummock. Even in the cold climate of Macquarie Island, *P. juniperinum* reaches hummock heights of 30 cm (Rod Seppelt, pers. comm. 16 March 2007).

Figure 18. Cross section of a *Polytrichum* stem showing green **hydroids** in center and larger **leptoids** surrounding them. Photo by Izawa Kawai, with permission.

Figure 19. *Dawsonia longifolia* from New South Wales, Australia. Photo by Janice Glime.

The genus *Dawsonia* has many unresolved species, some of which have been moved to a different genus. Even the well known *D. superba* (Figure 19) has been merged into *D. longifolia*. *Dawsonia longifolia* s.l. is a native of New Zealand, Australia, and Papua New Guinea and breaks the height record for upright mosses. It grows up to 48 mm in a year and in this study ranged 6-38 cm tall (Green & Clayton-Greene 1981). This compares well with known growth rates of *Polytrichum commune* of 3-5 cm in one growing season (Figure 21) (Sarafis 1971). It occurs in a temperate climate and its growth tracks available moisture and temperature. Its sperm dispersal is aided by an antheridial splash cup, with sperm known to reach females 1.5-2 m from the males in the field, but experimental tests showed they could splash to heights up to 3.3 m in the lab (Clayton-Greene *et al.* 1977)! Ligrone *et al.* (2002) showed that *Dawsonia* responded differently to antibodies used to label the arabinogalactan proteins in the water conducting cells (WCC), suggesting that their chemical structure differed from that of other mosses tested. On the other hand, *Dendroligotrichum* (Figure 22) and *Polytrichum* demonstrated a strong reaction in the leptoids (Figure 18; Figure 23) of the stem. These three genera differed in other marker reactions as well, supporting the uniqueness of the **Polytrichopsida**.

Antibodies against varied carbohydrate epitopes of arabinogalactan proteins gave different results. The 'arabinogalactan proteins (AGP)' antibody labelled the WCCs in all mosses, except *Dawsonia*, whilst no labelling was observed in hepatics.

The **Polytrichaceae** lead the way to complexity with their unusual leaf structure, possessing vertical **lamellae** (vertical tiers of cells like the pages of an open book; Figure 24-Figure 26) that provide an interior somewhat resembling that of a maple leaf. In fact, in the genus *Polytrichum*, some members have the outer portion of the blade folded over the lamellae (Figure 27-Figure 28), creating an internal chamber resembling palisade mesophyll surrounded with epidermis. The **cuticle** (in this

case, a waxy, water-repellant covering on the outer surface of the leaf; Proctor 1979) of *Polytrichum* is more developed than in most other bryophytes, and *Polytrichum* seems to repel water from its leaves rather than to absorb it (Figure 27), a phenomenon that may prevent the spaces among the lamellae from flooding that would block access of CO₂ to the chloroplasts within. Its rhizoids function not only for anchorage, but also seem to facilitate external water movement.

Figure 30. *Polytrichum* antheridial head showing paraphyses and antheridia. Note space where mucilage collects between the dark sperm tissue and the sterile jackets of the antheridia. Photo by Janice Glime.

In some mosses, like *Polytrichum*, the antheridia are in splash **cups** or **platforms** (rosette of leaves from which reproductive units such as sperm, gemmae, or spores can be splashed by raindrops; Figure 29), and when the **sperm** (male reproductive cells; male gametes) are mature, the antheridium (Figure 30) swells and bursts during a rainy period. The bases of the antheridia, in taxa such as *Polytrichum* and *Atrichum* (Figure 37), collect fluid between the sperm tissue and the antheridial jacket (Figure 30) (Bold *et al.* 1987). When the cells at the tip of the sterile jacket open, the antheridial jacket contracts. At this time, the fluid at the bottom acts as a hydraulic ram and forces the sperm out of the antheridium. Once in the open water of the splash cup, the sperm are splashed from the cup. Hopefully, some of these sperm will splash near the tip of a female plant (Figure 31) and will begin swimming toward the archegonium (Figure 32).

Figure 31. Female plants of *Polytrichum ohioense* showing the tight leaves at the apex where archegonia are housed. To the right of the female plants, the yellow swollen tips are male plants with unopened antheridial splash cups. Photo by Janice Glime.

Figure 32. Archegonia nestled among terminal leaves of *Polytrichum*. Photo from Michigan State University botany collection, with permission.

But it appears that the sperm of *Polytrichum commune*, and perhaps others, may have some help in this process from another source (Harvey-Gibson & Miller Brown 1927). A variety of invertebrates visit the male splash cups once they are fertile and get the mucilage with sperm stuck on their bodies. While visiting the plants, the insects lap up the mucilage and lick the saline crystals that form on the margins of the perichaetial leaves. The same insects, bodies and limbs smeared with mucilage in which sperms were abundant and motile, likewise appear on female plants. Now, can someone show whether the red color of splash cups (Figure 29) in several members of this family have the ability to attract any dispersal agents?

After fertilization, the zygote divides to form an **embryo** within the **archegonium**. Eventually this sporophyte embryo tissue forms a **foot**, **seta**, and **capsule**. The capsule develops within the **calyptra** (Figure 33-Figure 35), which is the expanded archegonium. The calyptra is essential for normal development in most mosses, and a split on one side can cause asymmetrical development. In the case of *Polytrichum*, the calyptra is very hairy (Figure 35), earning the moss the name of haircap moss or goldilocks moss. If it is removed early in development, the capsule will not develop properly.

Eventually the **calyptra** (Figure 35) is shed, exposing the capsule. Then the **operculum** (lid) must come off to permit spore dispersal. In this family the capsule has 64 short teeth joined by a membrane (**epiphragm**) that covers

the capsule like skin on a drum (Figure 36). These small spaces permit spores to escape the capsule a few at a time, providing maximum chances for some escaping under the right conditions for dispersal and establishment.

Tetraphidaceae

Tetraphis (Figure 38), also in the **Polytrichopsida**, looks more like a typical moss than do other **Polytrichopsida**, with thin, 1-cell-thick leaves and a costa (Figure 38-Figure 39). *Tetraphis* is unique among mosses in having **gemmae** (Figure 40-Figure 42) arranged in splash cups at the tips of the stems when sexual reproduction is not in season, arguably a primitive remnant. These gemmae are asexual bits of plant material that can grow into a new plant. Its most unusual character is that its protonemata are not threads, but rather flaps (Figure 43). Antheridia are borne terminally on the leafy plants (Figure 44), as are the archegonia. The capsule (Figure 45) has only four long, unjoined, nematodontous teeth (Figure 10, Figure 46).

Buxbaumiaceae – Bug on a Stick

Buxbaumia (Figure 47-Figure 51) is one of the strangest of all mosses. It lacks any leafy stem at all (Figure 47). Its archegonia and antheridia arise directly from the protonema. Hence, its capsules (Figure 49) arise directly from this persistent protonema (Figure 47). They all tend to orient in the same direction (Taylor 1972), most likely in response to the predominant direction of light. Its capsules, although possessing teeth (Figure 50), more typically split across their broad, flattened surface, hence exposing the spores (Figure 51) (Koch *et al.* 2009). Koch and coworkers demonstrated that in *Buxbaumia viridis* (Figure 47) this capsule surface is covered with "massive" wax layers that have embedded and superimposed platelets and granules on them. When these waxy layers peel back, the epidermis peels with them.

Figure 47. *Buxbaumia viridis* sporophyte and protonema. Photo by Bernd Haynold, through Wikimedia Commons.

The *Buxbaumia* capsule interior is chambered and spongy, somewhat like a spongy mesophyll of Magnoliophyta. It typically occurs with tiny, black leafy liverworts such as *Cephalozia* (Figure 52). Campbell (1918) had considered this moss to be saprophytic, exhibiting almost no chlorophyll, but Mueller (1975) demonstrated dense chlorophyll in the protonema and considered that to be the primary photosynthetic organ, one that persists throughout the life of the moss. The protonema is not a good competitor, so you can find it after forest fires, on soil banks, on roadsides, and other places that are not very hospitable to plants that could easily overgrow the photosynthetic protonemata. The capsule (Figure 47-Figure 49) is rather unusual, with its broad, flattened side and a rounded side. This strange shape has earned it a number of common names, including humpbacked elves, elf-cap moss, Aladdin's lamp, and bug on a stick.

Figure 48. *Buxbaumia aphylla* on a soil bank with all capsules pointing the same direction. It has been suggested that common habit is advantageous to maximize light absorption by the photosynthetic capsule. Photo by Janice Glime.

Figure 52. *Cephalozia bicuspidata*, member of a genus of tiny liverworts that often occur with *Buxbaumia aphylla*. Photo by Kristian Peters, through Wikimedia Commons.

In *Buxbaumia aphylla*, Hancock and Brassard (1974a) found that almost all elements that occurred in the protonema also occurred in the sporophyte, suggesting they were transported internally. Hancock (1973) also suggested that its protonemata were perennial. In northern climates, this is advantageous because the capsules are very susceptible to mortality from sudden early frosts. Normally, the capsules form in fall and overwinter as green capsules (Hancock & Brassard 1974b). They complete development and disperse their spores early in spring, then disappear.

Diphysciaceae

Diphyscium (Figure 53-Figure 60) is distributed mostly in the northern hemisphere (Milne & Klazenga 2012). Its three genera have been reduced to one (Magombo 2002; Goffinet 2012), which has an asymmetrical capsule (Figure 57-Figure 60) of similar shape to that of *Buxbaumia* and lacks a leafy female stem except for perichaetial leaves (Figure 60), but the male plant of this genus has large, strap-shaped leaves and leads an independent and separate existence (Figure 53-Figure 56). The capsule opening is quite small and the teeth extrude like a wisp of hairs (Figure 60). The perichaetial leaves are unusual, having a long, excurrent costa and often being fimbriate on the margins (Figure 59-Figure 60). As in *Buxbaumia*, the capsule shape is responsible for several common names – nut moss, powder gun moss, grain of wheat moss. It shares the phototropic behavior of *Buxbaumia* by having its capsules all oriented in one direction with their flat sides facing the direction of the light (Figure 57-Figure 59).

Summary

Bryophyta can be considered to have six classes: Takakiopsida, Sphagnopsida, Andreaeopsida, Andreaobryopsida, Polytrichopsida, and Bryopsida, differing most consistently in capsule structure. Gametophores of **Andreaeopsida**, **Andreaobryopsida**, and **Polytrichopsida** produce **archegonia** and/or **antheridia** at the apex and the **embryo** develops within the archegonium.

Sporophytes remain attached to the **gametophyte** and produce **spores** by **meiosis**. These classes, and all Bryophyta, produce spores from the sporophyte only once.

Takakiopsida, **Andreaeopsida**, and **Andreaobryopsida** have capsules that **split** into valves, but lack elaters. **Sphagnopsida** lacks valves and has an **operculum** that is shed at dispersal time, but lacks peristome teeth. In capsules of **Polytrichopsida** and **Bryopsida**, an **operculum** usually covers **peristome** teeth that often aid dispersal, contrasting with liverworts wherein the capsule splits into four valves with elaters that possibly facilitate spore movement. **Polytrichopsida** have **nematodontous** peristome teeth; **Bryopsida** have **arthrodontous** peristome teeth. All other classes of Bryobiotina lack peristomes. **Andreaobryopsida** is **dioicous** (two sexes on separate plants) and possesses a **seta** (stalk of capsule), whereas **Andreaeopsida** is **monoicous** (both sexes on same plant) and lacks a seta.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading. Heino Lepp alerted me to the invertebrate dispersal of sperm by his 3 September 2006 contribution to Bryonet. Llo Stark provided valuable suggestions on the chapter.

CHAPTER 2-7

BRYOPHYTA – BRYOPSIDA

Figure 1. *Aulacomnium androgynum* with asexual gemmae on a modified stem tip. Photo by Michael Lüth, with permission.

Bryopsida Definition

By far the largest class of Bryophyta (*sensu stricto*) (84% of families) (Goffinet *et al.* 2001) and ~98% of the species, the class **Bryopsida** (formerly Musci) (Figure 1) is unquestionably the most diverse. Their evolution by both advancement and reduction makes circumscription difficult, with nearly every character having exceptions. It appears that the only unique and consistent character among the Bryopsida is its peculiar peristome of **arthrodontous teeth** (the lateral walls of the peristome teeth are eroded and have uneven thickenings; Figure 2).

This arrangement of teeth has implications for dispersal – the teeth form compartments in which spores are trapped. The outer surface is **hydrophilic** (water loving, hence attracting moisture) whereas the inner layer has little or no affinity for water (Crum 2001), causing the teeth to bend and twist as moisture conditions change. Whether this aids or hinders dispersal, and under what conditions, is an untested question. Yet even this character does not hold for some taxa; some taxa lack a peristome. And all other characters, it would seem, require the adjectives of most or usually.

Figure 2. Electron micrograph of the arthrodontous peristome teeth of the moss *Eurhynchium praelongum*. Photo from Biology 321 Course Website, UBC, with permission.

Chromosome Numbers

Known chromosome numbers in bryophytes range widely. The assumption is that the basic number is 9 and that all other numbers are derived from that basis by loss of chromosomes, chromosome fusion, chromosome breakage, addition of chromosomes through fertilization, polyploidy, and complications during meiosis. The lowest number is 3, ranging from 4 to 10 in the **Anthocerotophyta**, where 5 is the most common (Przywara & Kuta 1995). In the **Marchantiophyta**, the number ranges (3)4 to 48 with most species having $n=8$ or 9. In the **Bryophyta**, the number ranges 4 to 72(96) with chromosome numbers of $n=10$ and 11 being most common. In 1983, the highest reported number in pleurocarpous mosses was that of *Stereophyllum tavoyense* – 44 (Verma & Kumar 1983).

Przywara and Kuta concluded that polyploid numbers are $n>10$ in **Anthocerotophyta** and **Marchantiophyta** and $n>9$ in **Bryophyta**, although they consider the basic numbers in those groups to be 5, 9, and 7 respectively. They report 0% polyploids among the **Anthocerotophyta**.

There have been suggestions that polyploidy permits some polar tracheophytes to survive the extreme conditions, so it would be interesting to examine that correlation in bryophytes. One must also ask if the severe climate causes greater ploidy, or if having greater ploidy makes those species more fit to succeed. But in her study on bryophytes of Signey Island in the Antarctic, Newton (1980) found that there was no increase with latitude in polyploidy number among the 13 moss and 6 liverwort species there. However, she did conclude that it warranted further investigation, particularly in *Bartramia patens*, *Brachythecium austrosalebrosum*, *Pohlia nutans*, *Tortula robusta*, and *Riccardia georgiensis*.

The interest in chromosome number has been superseded by an interest in mapping chromosomes and identifying the functions of genes. Information on nuclear, chloroplast, and other cellular DNA is helping us to understand relationships among the bryophytes. Chromosome numbers, however, still give us useful information on ways that new species have been created (see, for example, Ramsay 1982; Newton 1989).

Spore Production and Protonemata

As in all bryophytes, the spores are produced within the capsule by meiosis. In the **Bryopsida**, once germinated (Figure 3), they produce a **filamentous protonema** (first thread) that does not develop into a thalloid body. This germination process (Figure 4) can be rapid (1-3 days in *Funaria hygrometrica*) or lengthy, involving a long dormancy period.

Figure 3. Germinating spore of *Fontinalis squamosa*. Photo by Janice Glime.

Figure 4. Protonemata among leafy plants of *Plagiomnium*. Photo by Janice Glime.

Many mosses differentiate their protonemata into **chloronema** and **caulonema** (Figure 5-Figure 6). The **chloronema**, meaning light green thread or chlorophyll thread, is the first part of the protonema to form when the spore germinates. The **caulonema**, meaning stem thread, is the portion that develops later, but not in all mosses, and that gives rise to the upright **gametophores**, or leafy plants. The caulonema differs from the younger parts of the protonema, the chloronema, in having longer cells with slanting cross walls, usually brownish cell walls, and fewer, less evenly distributed, smaller spindle-shaped chloroplasts. The chloronema exhibits irregular branching, whereas the caulonema exhibits regular branching.

Figure 5. Protonema of moss such as *Funaria hygrometrica* with differentiated caulonema and chloronema. Drawing by Noris Salazar Allen, with permission.

Figure 6. Protonema of *Funaria hygrometrica* showing chloronema (short cells with perpendicular walls and dense chloroplasts) and caulonema (long cells with diagonal cross walls and more dispersed chloroplasts). Photo by Janice Glime.

Gametophore Bud

As the protonema continues to develop and produce buds (Figure 7-Figure 9), the mosses and liverworts again differ. In liverworts, the bud is produced by the apical cell, hence ending further growth of the protonema and accounting for its single gametophore. In mosses, on the other hand, the bud originates from a cell behind the apical cell, hence permitting the apical cell to continue to divide and the protonema to continue to grow. The result is that moss protonemata produce many buds and upright plants (Figure 10). This provides the possibility for somatic mutations to arise, affording genetic variation among the leafy plants.

Figure 7. Moss protonema with young bud. Photo by Chris Lobban, with permission.

Figure 8. Protonema (caulonema) and young developing bud of the moss *Funaria hygrometrica*. Photo by Martin Bopp, with permission.

As the bud develops, **rhizoids** (Figure 9, Figure 102) form, functioning largely in anchorage, but at least in some mosses, also functioning in moving water and nutrients from substrate to moss. This may be especially important as the atmosphere dries and the rhizoids help to maintain a humid substrate.

Figure 9. Moss protonema with developed bud. Brown threads are rhizoids. Photo by Janice Glime.

Figure 10. Leafy buds on the protonemata of *Funaria hygrometrica* forming a doughnut shape. Each of these circles of buds is the result of one spore. The hole in the middle is the area where the protonemata is in the chloronema stage and does not produce buds. Photo by Janice Glime.

Gametophores

The bud develops into the upright (or horizontal) **gametophore**. These plants are leafy **haploid** ($1n$) plants; thus, they are the **dominant gametophyte generation** of the life cycle. The stem may have a **central strand** (Figure 11), or lack it (Figure 12); this strand may or may not have **hydroids**.

Figure 11. Stem cross section of *Rhizogonium* illustrating central strand of hydroids. Photo by Isawa Kawai, with permission.

Figure 12. Cross section of stem of the brook moss *Fontinalis dalecarlica* showing absence of central strand and conducting tissues. Photo by Janice Glime.

Their leaves, more accurately known as **phyllids** (but rarely called that), are usually in **more than three rows** (Figure 13), but there are exceptions with two (Figure 14) or three rows (Figure 15). Typically they are one cell thick, but there are modifications on this scheme that are expressed in some mosses by leaves folded over on themselves, creating a pocket in the genus *Fissidens* (Figure 14), or alternating **hyaline** (colorless) and photosynthetic layers as in *Leucobryum* (Figure 16-Figure 18), or just multiple layers of tissue, sometimes in patches.

Figure 13. *Brachymerium* from the Neotropics, illustrating that leaves arise in more than three rows. Photo by Michael Lüth, with permission.

Figure 14. Pockets in leaf of *Fissidens arnoldii*. Note the leaves in two rows. Photo by Michael Lüth, with permission.

Figure 18. *Leucobryum glaucum* leaf cells. Photo by Ralf Wagner <www.drralf-wagner.de>, with permission.

Some leaves may have borders (Figure 19-Figure 20) which likewise can be one or more layers thick. These leaves often have a multi-layered **costa** (Figure 19, Figure 21) in the center, or double (Figure 22), or even triple costa. The **costa** itself (Figure 23) consists of long, narrow cells that offer support and seem to function in moving water more quickly than their wider and often shorter neighboring cells.

Location of Sex Organs

Based on the branching patterns and location of sexual organs, the Bryopsida have traditionally been divided into two major groups, although there are good arguments for additional groupings. The **acrocarpous** mosses (Figure 24) are generally those upright mosses with terminal sporangia. They usually are unbranched or sparsely branched. **Pleurocarpous** mosses (Figure 25), by contrast, produce their sporangia on short, specialized lateral branches or buds and typically are prostrate, forming freely branched mats. The truly pleurocarpous mosses appear to represent a single monophyletic clade (Buck & Goffinet 2000; Buck *et al.* 2000a, b; Cox *et al.* 2000) and may be an adaptation to forming mats of continuous growth in mesic conditions (Vitt 1984). Those mosses that bear sporophytes terminally on short, lateral branches form a special category of pleurocarpous mosses termed **cladocarpous**. The branching patterns and positions of sporangia determine not only the **growth form**, but also influence success of fertilization, availability of water, and ability to spread horizontally across a substrate.

Figure 24. *Barbula unguiculata*, an **acrocarpous** moss. Setae originate at the apex of the previous year's growth. Photo by Michael Lüth, with permission.

Figure 25. *Neckera urnigera*, a **pleurocarpous** moss showing the origin of the setae on short side branches. Photo by Michael Lüth, with permission.

The upright or sprawling stems of the gametophyte produce **antheridia** (sperm-containers; Figure 26) and **archegonia** (egg-containers; Figure 28). In mosses, antheridia and archegonia may be located at the end of the main stem (Figure 29), at the ends of lateral branches, or along the main stem, either at the ends of very short branches (Figure 30) or nearly sessile (Figure 103). One can determine the position of archegonia most easily by finding the base of the seta. Often the chloroplasts of the antheridial jacket cells are converted into chromoplasts as the antheridia mature, causing the characteristic red-orange color (Figure 29) (Bold *et al.* 1987).

Sperm Dispersal

Crawford *et al.* (2009) found that there seemed to be no evolutionary support for a relationship between asexual reproduction and the separation of the sexes. Hence, they reasoned that the evolution of the sexual system is influenced by mate availability and gamete dispersal.

Release of Sperm from the Antheridium

The release of the sperm from the antheridium is an interesting phenomenon. In *Mnium hornum* (Figure 31), within about four minutes of placing water into an antheridial cup, dehiscence will occur (Muggech & Walton 1942). The **spermatocytes** (cells in which sperm have differentiated) emerge in a banana-shaped packet (Figure 27, Figure 33) into the water surrounding the antheridium, usually within 4-10 minutes.

Figure 26. *Hypnum cupressiforme* paraphyses and antheridia. In this species, antheridia occur long the stem. Photo by Kristian Peters, with permission.

Figure 27. *Aloiina ambigua* sperm release, looking like white, gelatinous clouds. Photo courtesy of Llo Stark.

Figure 28. Pleurocarpous moss *Pleurozium schreberi* showing archegonia on short branch along stem. Photo by Janice Glime.

Then, when (or if) that packet connects with the water-air interface, the sperm spread apart rapidly to form a surface layer of regularly spaced sperm (Muggoch & Walton 1942). This movement of sperm emerging from an antheridium is shown in a film by Serge Hoste <<http://users.pandora.be/serge.hoste1/>>. This spreading suggests that some substance with a low surface tension might be present in the sperm packet because the mass spreads much like an oil spill. The behavior suggests that there is a small amount of fat present in the sperm mass.

Figure 31. *Mnium hornum* male splash cups. Photo by David T. Holyoak, with permission.

Cronberg *et al.* (2008) filmed various stages in the life cycle of *Bryum argenteum*. They found that this species expels its sperm in a mass (Figure 32-Figure 37). The upper cells of the antheridium are expelled and the sperm mass is released. This is a rapid occurrence, followed by a slower activity of sperm escaping from the mass. The sperm have a density close to that of water and thus are easily transported by moving water. When the sperm mass reaches the air surface, the mass disintegrates almost instantly as the mass and surface tension of water react. The surface tension causes a passive dispersal of the sperm for ~2 cm. After 30 minutes, about half the sperm are dead. All are dead after 60 minutes. This might differ in nature where the water chemistry is different.

Dispersal to the Archegonium

Some bryophytes seem to have no special means of dispersing their sperm, relying on the water film that surrounds the bryophytes when it rains. Others have developed splash cups or splash platforms that aid in the dispersal of sperm. Andersson (2002) filmed the splashes on splash cups in the moss *Plagiomnium affine* (Figure 41). Andersson observed that water fills the splash cup capillary spaces among the antheridia and paraphyses up to the bottom of the cup. He determined that for a striking raindrop to have the space needed to develop, the diameter of the drop should be 1 mm or less, a size common in most rain showers. The impact of the drop causes the ripe antheridia to rupture, causing the spermatozoids to reach the bottom of the splash cup through the capillary spaces created by the heads of the paraphyses. The drop of rain incorporates water from the bottom of the splash cup, thus including the spermatozoids that are entering the cup. These droplets can travel 100 mm or more as they rebound from the cup, thus effecting fertilization of nearly all female gametangia within about 80 mm. Since the fertilization period in southwestern Sweden lasts about three weeks, this is usually sufficient time for one or more appropriate rainfalls to occur and facilitate dispersal.

Figure 41. *Plagiomnium affine* splash cups. Photo by Peter Gigiegl. Permission pending.

Duckett and Pressel (2009) demonstrated that falling raindrops on the antheridiophores of the liverwort *Marchantia polymorpha* were not very effective, so the even softer splash platforms of mosses may be even less effective, or certainly not any better. Measurements from fertilized females to nearest male have provided us with some estimates, as for example that of *Plagiomnium ciliare* (Figure 42) for 5.3 cm (Reynolds 1980). But Reynolds did find that artificial rainfall could splash over 10 cm and concluded that measurements to nearest male most likely underestimated the distances sperm could travel from a splash cup or platform.

Figure 42. *Plagiommium ciliare* with splash platforms. Photo by Robert Klips, with permission.

Until somewhat recently we have assumed that in most bryophytes sperm reached the archegonia by splashing or swimming from the antheridia to a landing spot, then swimming the remainder of the way. Closer observation by recent researchers indicates that such an inefficient and unsafe method may not be the case for some bryophytes, and that we should examine others more closely for secrets in their sperm dispersal. Muggoch and Walton (1942) considered the presence of fat in the sperm mass to be a widespread phenomenon, perhaps true of all mosses, and that it was important in permitting insects to carry sperm to female plants. However, there seem to be few observations of such insect dispersal except in *Polytrichum* (Class **Polytrichopsida**; Figure 43) and *Ptychostomum capillare* (syn. = *Bryum capillare*; **Bryopsida**; Figure 29).

The idea that invertebrates may disperse sperm is not entirely new. Harvey-Gibson and Miller-Brown (1927) observed various invertebrates visiting the fertile shoots of *Polytrichum commune* (Figure 43). As the invertebrates crawled about the male splash cups, they picked up mucilage and sperm. The researchers then observed that the same insects would appear on female plants with abundant sperm smeared on their bodies and legs in the mucilage. The invertebrates seemed to consider mucilage to be a source of food as they "greedily" lapped it up and also licked at saline crystals on the perichaetial leaf margins.

It appears that *Ptychostomum capillare* (Figure 29) may indeed be fertilized, at least some of the time, by animals. When covered by a fine net to discourage winged insects and other creatures, females were not fertilized, but when the net was removed, fertilization occurred 2 m(!) from the nearest males (Gayat 1897). However, it is difficult to rule out the possibility of raindrops in this case, or even squirrels, for that matter. Raindrops are likely to trap the mucilage with its sperm load in the tiny capillary spaces of the net. The success of fertilization would depend on the success of these drops getting bounced from one plant to another, and that bounce would surely be inhibited by such a filter to diminish the impact and retain the mucilage.

Figure 43. *Polytrichum commune* males with splash cups. Photo by Li Zhang, with permission.

Observations on *Bryum argenteum* (Figure 44-Figure 45) are more conclusive. Cronberg *et al.* (2006), in an experiment in which male and female plants were separated by 0, 2, and 4 cm, demonstrated that help from such agents as invertebrates are essential. These treatment distances were combined either with no animals, or with mites (Acarina: *Scutovertex minutus*; see Figure 46) or springtails (Collembola: *Isotoma caerulea*, Figure 47) (Cronberg *et al.* 2006; Milius 2006). After three months, those females in contact with male plants (0 cm) produced sporophytes. Those without this contact (2 or 4 cm) and without either animal group produced no sporophytes. But those housed with springtails or with mites produced numerous sporophytes, with springtails being the more effective conveyor. Springtails are more mobile than mites, and in this experiment, more sporophytes were produced at greater distances when springtails were available as dispersal agents.

Figure 47. *Isotoma caerulea*, a springtail that is instrumental in fertilizing *Bryum argenteum*. Photo by Katrina Hedlund, with permission.

But how do these springtails find the mosses? Flowers provide odors and colors to attract their pollinators. It appears that these mosses also have a way to attract their dispersal agents. When springtails and mites were given choices of plants with mature gametangia vs those that were sterile, fertile plants were chosen over non-fertile ones about five times as often (Beckman 2006) in the cases of both male and female mosses and by both arthropod organisms. Cronberg *et al.* (2006) suggest that fertile

plants may attract the invertebrates with sucrose (Pfeffer 1884), starch, fatty acids, and/or mucilage (Harvey-Gibson & Miller-Brown 1927; Paolillo 1979; Renzaglia & Garbary 2001). Ziegler *et al.* (1988) demonstrated the presence of sucrose in the archegonium exudate of *Ptychostomum capillare* (Figure 29). Llo Stark has captured images of this exudation in *Aloina ambigua* (Figure 48-Figure 50).

A small flurry of research followed this exciting finding (Cronberg 2012). Both *Bryum argenteum* (Figure 45) and *Ceratodon purpureus* (Figure 51) sperm are transported by tiny springtails (*Folsomia candida*; Figure 52) (Rosenstiel *et al.* 2012). Rosenstiel and coworkers (2012) used *Ceratodon purpureus* to examine what attracts sperm dispersers. They found that this moss species produces volatile compounds – some of those secondary compounds that have evolved tremendous varieties in bryophytes. They were able to demonstrate that some, perhaps many, of these compounds attracted the springtail *Folsomia candida* (Figure 52). The volatile compounds are sex-specific (Figure 53) and definitely increase the rate of fertilization, even when splashing water is provided to facilitate sperm transfer (Figure 54). Although fertilization rates were about the same in treatments of water spray alone and springtails alone, the presence of both more than doubled the rate of using either alone.

Splash cups and splash platforms help to launch the sperm in many acrocarpous taxa, with spreading upper leaves serving to facilitate the launch. Richardson (1981) estimated that raindrops could splash these sperm only about 5 cm in small mosses, but up to 2 m in large ones. In mosses without antheridial splash cups or platforms, dispersal distances are typically short. Pleurocarpous mosses are not arranged in such a way as to offer much of a boost to raindrops containing sperm. In *Hylocomium*

splendens (Figure 55), sperm have a long distance record of only 11.6 cm (Rydgren *et al.* 2005).

Figure 55. *Hylocomium splendens* in autumn. Photo by Petr Brož, through Wikimedia Commons.

Insect dispersal of sperm is not unique to *Ceratodon purpureus* (Figure 52). Ignatov (1921) reported that the luminous moss, *Schistostega pennata* (Figure 56), has several kinds of visitors who facilitate sperm dispersal. This species is **cladoautoicous** (male and female reproductive structures on separate stems, connected only by the protonema; Figure 57-Figure 59). Thus, the sperm must be dispersed to a different stem. In addition to movement in a drop of water when the antheridium bursts (Figure 60), in the Moscow Province of Russia this dispersal is facilitated by a variety of small arthropods, including mites in the families **Damaeidae** (e.g. *Damaeus lengersdorfi*, Figure 61, Figure 62) **Oribatulidae** (e.g. *Oribatula tibialis*, Figure 63-Figure 64), **Astegistidae** (e.g. *Furcoribula furcillata*, Figure 65), and **Ceratozetidae** (e.g. *Melanozetes mollicomus*, Figure 66), and springtails *Orchesella bifasciata* (Figure 67) and *Entomobrya nivalis* (Figure 68) in the family **Entomobryidae**. The arthropods use the antheridial contents as food. This activity is facilitated by the barely hidden antheridia of *Schistostega pennata*, unlike those of most mosses that are well protected by perigonia.

Anderson (2000) managed to catch the dispersal of *Plagiommium affine* (Figure 41) on video to see the effectiveness of the splash platform of that moss. Although many drops will miss the tiny platform completely, a few manage full hits. Impact causes a "crown" of water to

form, like dropping a rock into a lake. The capillary spaces between the antheridia and adjoining **paraphyses** (sing. **paraphysis**: sterile filaments located among reproductive organs; Figure 69, Figure 101, Figure 103) fill with water.

The impact of the drop causes the swollen antheridia to burst, releasing the swimming sperm. For the splash to be effective in making the crown, the diameter of the drop should be 1 mm or less, a common size in most rain showers. The rim of the crown has small droplets that are propelled away by the action. Since these droplets include water from within the splash platform, they also contain the sperm and thus propel them away from the plant. These droplets can travel 100 mm or more and manage to fertilize most of the females within 80 mm. The dioicous liverwort *Marchantia* has a splash platform that performs a similar function.

Figure 69. Mature **antheridia** and **paraphyses** of the moss *Rhizomnium* sp. Photo by Janice Glime.

Splash cups and platforms seem to be rare in monoicous taxa [exceptions include species of *Brachymerium* (Figure 70) and *Rosulabryum* (Figure 71) per John Spence], suggesting fertilization is accomplished with close neighbors. For most **Bryopsida**, however, there is no antheridial splash cup or platform, so seemingly sperm must swim all the way.

Figure 70. *Brachymerium* sp. showing splash platform. Photo by Michael Lüth, with permission.

Figure 71. *Rosulabryum laevifilum* with splash platform. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

However, other things can create splash. Jonathan Shaw (pers. comm.) has considered that *Funaria hygrometrica* (Figure 72) has wide-spreading bracts surrounding the antheridia and the flexible nature of these bracts permits them to bend back and create an effective cup from which sperm in that species might be splashed. Angela Newton (pers. comm.) has suggested that platform surfaces among the more dendroid and shelf-forming taxa could be viewed as water-trapping mechanisms that would promote surface flow and dripping to the next level down as a mode of transporting sperm between individual plants or parts of plants. One complication in this arrangement is that the complex texture would act to trap water drops rather than encouraging them to splash out and away. However, in some of the plants with large smooth leaves, these leaves might act as springboards, but Newton considered that in such a case the water drops would be unlikely to carry sperm, although they might carry the smaller kinds of vegetative propagules. Nevertheless, sperm that had gotten as far as a leaf might benefit from this splash as well.

Figure 72. *Funaria hygrometrica* males showing splash apparatus. Photo by James K. Lindsey, with permission.

Now it would seem that monoicous taxa might not need a partner since they have one built in. For example, *Desmatodon randii* and *D. urainicus* are both self-compatible when grown from a single spore (Lazarenko & Lesniak 1972; Lazarenko 1974). *Desmatodon randii*

retained vigorous fertility for 15 generations of self crossing in the lab (Lazarenko 1974). On the other hand, it also gave rise to a spontaneous **apogamous** (development of sporophyte without gamete union) haploid line that continued the line vegetatively.

The suggestion of selfing is even supported by the scarcity of splash platforms in monoicous taxa. And in desert habitats, the monoicous condition prevails, presumably due to the scarcity of water for sperm dispersal (Stark 1983). Nevertheless, means exist to ensure at least some cross fertilization in monoicous taxa (Longton & Miles 1982; Ramsay & Berrie 1982). Such means include having antheridia placement below the archegonia on the same stem (Longton & Miles 1982) or on different stems or branches, and differences in timing of maturity of male and female gametangia. Despite the greater opportunity for selfing, Lefebvre (1969) found evidence in the **Plagiotheciaceae** that not only do monoicous species have a wider distribution, they also have greater phenotypic variability than that found in dioicous species in the family.

Longton and Miles (1982) suggest that the greater distance between male and female gametangia in **autoicous** (male & female gametangia in separate clusters) species provides a greater opportunity for out-crossing. But a close neighbor is likely to be part of the same clone or grown from a spore from the same parent. Nevertheless, this permits mutations to be remixed and passed to a new generation and thus provide at least some genetic mixing.

Lazarenko and Lesniak (1972) found that *Physcomitrella patens* from wild strains was self compatible, but certain mutant strains were self incompatible. On the other hand, they found that monosporic cultures of *Desmatodon cernuus* were sterile when grown in 24-hour light (these are long-day plants preferring 16 hours daylight), demonstrating the importance of environmental conditions, especially in new locations.

Ashton and Cove (1977) have also demonstrated possible mechanisms of compatibility by using mutants. They have shown that many **auxotrophs** (requiring an additional nutrient) of *Physcomitrella patens* are self-sterile. They obtained a diploid strain by aposporus regeneration from a hybrid sporophyte and the progeny accomplished self-fertilisation. Outcrossing would most likely supply the right genes to complement the missing one(s), but half the forthcoming spores would still be expected to carry the mutation. There would be a quick selection against the mutants in the next generation of gametophytes if the missing or mutant gene was needed by the gametophyte. The big advantage for monoicous taxa is that their nearest neighbors can always provide gametes of the opposite sex. (See fuller discussion in Chapter 3-4 of this volume.)

Whereas flowering plants frequently rely on animals, especially insects, to transport their male gametophytes, and ultimately the sperm, to the female reproductive organ, this seems rarely to be the case in bryophytes. Surprisingly, until recently it appears that the only documented case of such animal transport of sperm was in *Polytrichum commune* (Polytrichopsida; Figure 73), which has well-developed splash cups (Figure 73) for the purpose of sperm dispersal. Nevertheless, it was in this species that Harvey-Gibson and Miller-Brown (1927) found motile

sperm on the bodies of small arthropods (flies, leafhoppers, mites, spiders, and springtails) on both male and female reproductive inflorescences. Schofield (1985) suggests that mucilage produced in both the **perigonia** (modified leaves enclosing male reproductive structures; Figure 74) and **perichaetia** (modified leaves enclosing female reproductive structures; Figure 75) sometimes attract invertebrates.

Figure 73. *Polytrichum commune* antheridial splash cups. Photo by Michael Lüth, with permission.

Clayton-Greene *et al.* (1977) used laboratory tests to determine the distance sperm could travel from the large moss *Dawsonia longifolia* (= *D. superba*) (Figure 76). Field investigations indicated that this species uses a splash cup mechanism. Field data of sporophyte production indicated that capsules seldom develop on females located more than 1.5-2 m from any male. They found similar results in the lab when they dropped water from a height of up to 3.3 m. In experimental heights ranging from 150 to 330 cm, travel distances ranged from 105 to 230 cm, indicating that height of water drop positively affects dispersal distance. But in the smaller *Polytrichum ohioense* (Figure 77), sperm in experiments only landed up to 61 cm from the source when water was dropped from ~1 m (Clayton-Greene *et al.* 1977). Clayton-Greene *et al.* suggested that smaller drops could act like an aerosol spray and float in air, achieving greater distances.

Figure 76. Female *Dawsonia longifolia* (= *D. superba*). Photo by Jan-Peter Frahm, with permission.

Figure 77. *Polytrichum ohioense* males with new growth from old splash cups. Photo by Janice Glime.

One might expect that many antheridia burst as they and their surrounding **paraphyses** (Figure 78) swell from a desiccated state to a hydrated state during early minutes of a precipitation event. Could it be that the same external capillary forces that carry water rapidly to other parts of the plant could move sperm, thus reducing the energy requirements for getting these tiny cells to their destinations? Or are these forces to be reckoned with, forcing the sperm to swim against a current?

Figure 78. Antheridia and paraphyses of *Rhizomnium* sp. Photo by Janice Glime.

If sperm swim so slowly, how do they ever reach their goal in the absence of an accurate splash? One aid to this dispersal in at least some bryophytes is that the antheridia release fatty materials that cause a rapid dispersal of sperm upward in a continuous film of water (Muggoch & Walton 1942). But apparently this mechanism is not available to all bryophytes, nor are conditions always suitable for it to work.

If animal dispersal is so rare, then how, in this vast world, does an unintelligent sperm find an archegonium and an egg? Fortunately for the moss, the archegonium at this time has dissolved the **neck canal cells** (entry canal through neck to egg in base of archegonium; Figure 79; Figure 103) leading down to the **egg** in the **venter** (Figure 79), and the resulting liquid provides a chemical attractant for the sperm.

Meanwhile, the egg exudes mucilage into the cavity of the venter (Lal *et al.* 1982). When the canal opens, the liquid exudes from the opening of the neck (Figure 48-Figure 50), creating a chemical gradient. The sperm follows the concentration gradient toward the archegonium and finally swims down the **neck canal** (Figure 79) of the archegonium to the egg. The exact nature of this liquid is unknown, but it seems that sugars (Harvey-Gibson & Miller-Brown 1927) and sometimes boron are necessary. It seems also likely that something specific, perhaps a protein, might guide the sperm to the correct species. Otherwise, it would seem that in spring, when so many species are producing sexual structures, some of these sperm would find their way into the wrong archegonium – or perhaps they do!

Gayat (1897 in Clayton-Greene *et al.* 1977) experimented with *Ptychostomum capillare* (Figure 29) and found that when the plants were covered with a fine net, female plants located 2 m from males had no fertilization, but when the net was removed, giving insects access to the females, these same plants did have fertilization. Harvey-Gibson and Miller-Brown (1927) found that in *Polytrichum commune* (Figure 73-Figure 75) the paraphyses (Figure 79) of both males and females exuded mucilage, but contained no sugar. These gametangial areas were "constantly" visited by oribatid mites, two species of *Collembola* (springtails), a small midge (*Diptera*), a leaf hopper (*Cicadidae*), an aphid, and a spider. They found that the insects "greedily" lap the mucilage and their body parts become smeared with the

mucilage excretion. This adhering mucilage contains actively motile sperm. These sperm-carrying invertebrates were also located on female plants.

Archegonial Reception

Cronberg *et al.* (2008) described the opening of the archegonium in *Bryum argenteum* (Figure 44) as sudden. The top of the archegonium ruptures and the upper cells fold outward, creating a small funnel leading to the neck canal (e.g. Figure 80-Figure 81). At the same time, the archegonium releases a fluid.

Sexual strategies are covered in Chapter 3-1 of this volume.

Embryo Development

When a sperm reaches and fertilizes an egg, the resulting **diploid** (having two sets of chromosomes; $2n$) **zygote** begins dividing by **mitosis** to form an **embryo** that starts to stretch the archegonium (Figure 83). But the archegonium cannot stretch indefinitely, and as the embryo gets larger, the archegonium finally tears. Here, mosses and liverworts differ. In most mosses, part of the archegonium remains perched on top of the developing **embryo** (young sporophyte). This separated piece of archegonium is the **cap** you often see on top of the capsule and is now called a **calyptra** (Figure 103). So the calyptra is a $1n$ covering over the $2n$ capsule.

The emerging embryo grows into the sporophyte of the moss. The mature sporophyte has a **capsule** and **stalk** (**seta**), with a **foot** embedded into the gametophyte tissue (Figure 84). **Meiosis** occurs in the mature capsule, producing haploid ($1n$) spores, as in all plants. Note that this is a major difference from meiosis in animals, which results in gametes. These spores are dispersed from the capsule by wind (or in a few cases – *e.g.* Splachnaceae – by insects) and grow into new gametophytes.

Figure 83. Development of calyptra of a moss. **a.** egg in archegonium, with neck canal cells not yet disintegrated. **b.** archegonium after fertilization and early development of embryo, showing elongation of archegonium as embryo grows. **c.** elongated seta with calyptra perched on top of it before capsule has developed. **d.** mature capsule with calyptra and fully elongated seta. **c & d** indicate remains of venter of archegonium at base of sporophyte. Drawings by Janice Glime.

Figure 84. *Aloina rigida* with stalk and capsule and with foot imbedded in gametophyte tissue. Photo by Michael Lüth, with permission.

The **calyptra** (Figure 85) that covers the capsule of mosses most likely plays multiple roles. We know that in many species, normal development ceases if the calyptra is removed (Paolillo 1968; French & Paolillo 1976a, b). One could assume that it provides protection from UV light and other environmental influences, as well as changing the internal environment, and that these influences are important in shaping the further development of the capsule, as will be discussed in another chapter.

Capsule Development

In mosses, once the calyptra (Figure 85) has been shed, the **operculum** (lid) of the capsule is exposed (Figure 86). As a result of this exposure, the environment is considerably changed for remaining development. Gas exchange could be easier, moisture relations can change, and the constraining effect of the size and shape of the capsule might change.

Figure 85. *Polytrichum* sp. with calyptra covering the capsule. Photo by George Shepherd, through Creative Commons.

Figure 86. *Polytrichum* sp. capsule with calyptra removed, showing operculum. Photo by George Shepherd, through Creative Commons.

The exposed operculum must come off before the spores can be dispersed. The **dehiscence** of the operculum is usually facilitated by drying of the capsule that causes it to shrink and compress the contents. This creates a distortion that forces the operculum to pop off, at least in some species. But a few are **cleistocarpous** (indehiscent; lacking a regular means of opening; Figure 87), thus lacking an operculum (Figure 89). Capsules in these taxa open by irregular breakage of the capsule. Llo Stark (pers. comm. 22 March 2023) describes this in *Physcomitrella patens* as highly fragile capsule walls that break up very quickly after the capsules are mature.

Figure 87. *Pleurophascum grandiglobum* with cleistocarpous capsules. Photo by Yordle Ziggs, through Creative Commons.

Figure 88. *Physcomitrella patens* cleistocarpous capsule opening. Photo by Hermann Schachner, through Creative Commons.

Just under the lid of most moss capsules you will find the **peristome teeth** (in mosses, fringe of teeth around opening of capsule, involved in spore dispersal; Figure 90-Figure 98). These are usually **hygroscopic** (responding to humidity changes) and may flex back and forth in response to moisture changes to aid in gradual dispersal. In most cases, these function best as the capsule is drying, but in some taxa moisture actually facilitates dispersal. Perhaps their best role is in preventing the spores from all exiting the capsule at the same time, as happens in the liverworts and *Sphagnum* and most likely also in the mosses with valvate capsules. They often form spaces between the teeth, creating a salt shaker appearance (Figure 96). The sporophyte capsule usually has a **columella** (Figure 93, Figure 97) that is columnar like those in Polytrichopsida, providing structure. Most mosses also have an **annulus** (Figure 91) just below the peristome. This annulus aids in dehiscence of the operculum.

A very recent study by Zanatta *et al.* (2018) has revealed that some mosses are **xerochastic** (and others are **hygrochastic** (**hydrochastic**; **hydrochastique**). That is, some peristome teeth flex and open as the surrounding moisture decreases (**xerochastic**) and others respond and open in response to increasing moisture (**hygrochastic**). In their study of 16 species, they found that all nine species with **perfect peristomes** [having both **endostome** (inner peristome) and **exostome** (outer peristome); Figure 96] exhibited xerochastic behavior, opening at around 90% RH upon drying, but initiating closing (exostome teeth bending inward toward endostome) around 50-65% RH as humidity increased. On the other hand, five species with specialized peristomes displayed hygrochastic behavior, opening as RH increased and closing as it decreased. Opening started at about 70% RH; closing started when humidity decreased below about 94%. But *Pseudoamblystegium subtile* possesses a specialized peristome while exhibiting xerochastic behavior. Behavior of the peristome in *Orthothecium rufescens* could not be classified as it was unclear whether teeth were clearly closing or opening. In three species, the humidity initiating position changes was dependent on age. These interesting observations need to be expanded to many more species from a wide range of habitats to determine if there is any relationship to habitat.

Unlike the valvate capsules of liverworts and some moss classes, the sporophytes of the Bryopsida are photosynthetic (Figure 99). The same pigments often occur in both generations: chlorophylls *a* and *b*, carotene, lutein, violaxanthin, and zeaxanthin (Freeland 1957). Even the ratio of chlorophyll *a* to *b* is approximately the same – about 2.5:1 (Rastorfer 1962). Nevertheless, the gametophyte contains a higher chlorophyll concentration than does the sporophyte and the ratio of photosynthesis to respiration is likewise higher in the gametophyte. Despite its photosynthetic abilities, the sporophyte still depends on the gametophyte for some of its carbohydrates (Krupa 1969).

The stages of the life cycle are summarized in Figure 100 and Figure 101. Structures involved in the life cycle and in general morphology are illustrated in Figure 102- Figure 105.

Summary

The **Bryopsida** is the largest and most diverse class of **Bryophyta**. In **Bryopsida**, as in **Polytrichopsida**, an **operculum** usually covers **peristome** teeth that often aid dispersal. **Bryopsida** have **arthrodontous** peristome teeth, separating them from the **Polytrichopsida**, which have **nematodontous** teeth. All other classes of **Bryobiotina** lack peristomes.

The life cycle of **Bryopsida** involves a **protonema** that is usually threadlike and develops from the germinating spore, developing numerous **buds** and **gametophores**. Gametophores produce **archegonia** and/or **antheridia**. Sperm escape as a mass when the antheridium bursts. In some species, arthropods facilitate transfer of sperm from the antheridium to the archegonium. The **embryo** develops within the archegonium.

Sporophytes remain attached to the gametophyte and produce **spores** by **meiosis**. As in all Bryophyta, **Bryopsida** produce spores from the sporophyte only once. A **perfect peristome** has two rows of teeth and seems to respond to drying by opening the teeth. The **specialized peristomes** tested generally respond to drying by closing the teeth.

Vegetative reproduction is common among bryophytes. **Bryophyta** can reproduce by **fragments** as well as specialized asexual structures and thus add a new dimension to life cycle strategies.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading and life cycle diagrams. Betsy St. Pierre has been taking pictures for me and contributed several for this chapter. Llo Stark kindly offered his images of archegonial exudate and sperm packet release; he also has provided a review and valuable comments on this chapter.

Summary

The traditional bryophytes are classified into three phyla (Marchantiophyta, Bryophyta, Anthocerotophyta) that can be placed in the subkingdom Bryobiotina. **Anthocerotophyta** (hornworts) differ in having a sporophyte that is shaped like horn and continues to grow at the base as spores mature and are dispersed at the apex.

Anthocerotophyta have a **dominant gametophyte** generation. Gametophytes produce **archegonia** and/or **antheridia** and the **embryo** develops within the archegonium.

Sporophytes remain attached to the gametophyte and produce **spores** by **meiosis** over a prolonged period of time, with the youngest spores at the base. **Pseudoelaters** are produced along with the spores, but are formed by mitosis and remain $2n$. **Capsules** split longitudinally and peel backward from the tip.

Acknowledgments

I appreciate the comments and suggestions of Karla Werner, who offered a beginner's perspective. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading. Eugenia Ron Alvarez and Tom Sobota offered use of images at the PlantActions web site and provided me with high resolution images.

CHAPTER 2-8

ANTHOCEROTOPHYTA

Figure 1. *Notothylas orbicularis* thallus with involucre. Photo by Michael Lüth, with permission.

Anthocerotophyta

These plants, once placed among the bryophytes in the Anthocerotae, now generally placed in the phylum **Anthocerotophyta** (hornworts, Figure 1), seem more distantly related, and genetic evidence may even present them as more like ferns as we understand them better (Hori *et al.* 1985; Sherman *et al.* 1991; Nickrent *et al.* 2000; Knoop 2004; Groth-Malonek 2005). Yet other chemical evidence places them close to the liverworts (Hanson *et al.* 1999); they lack isoprene emission, as do liverworts, whereas mosses and ferns possess it. However, such characters may prove to be retained or lost adaptively and contribute little to phylum level relationships.

The hornworts are divided into two classes (Stotler & Crandall-Stotler 2005), a concept supported by molecular data (Frey & Stech 2005). **Anthocerotopsida** is the largest and best known of these, with two orders and three

families. The second class is **Leiosporocerotopsida**, a class with one order, one family, and one genus. The genus *Leiosporoceros* differs from members of the class **Anthocerotopsida** by having the Cyanobacterium *Nostoc* in longitudinal canals. In the other hornworts, the *Nostoc* colonies are scattered in discrete globose colonies (Villarreal A. & Renzaglia 2006).

As in other Bryobiotina, the gametophyte in the Anthocerotophyta is the dominant generation, but then, there are a few ferns in which the gametophyte might also be considered dominant. Hornworts differ from Marchantiophyta in having typically only **one chloroplast per cell** in the thallus, **lacking oil bodies**, and possessing a **pyrenoid** (a proteinaceous body serving as a nucleus for starch storage and common in green algae) (Figure 2).

Figure 2. Hornwort cells showing single chloroplast, doughnut-shaped pyrenoid in center, and absence of oil bodies. Photo by Chris Lobban, with permission.

Some **Anthocerotophyta** have interesting adaptations to help them get the most from their environmental resources. The **pyrenoid**, present in many taxa, has a concentration of Rubisco, and this permits it to concentrate CO₂ (Hanson *et al.* 2002). Furthermore, the thallus typically has colonies of *Nostoc* (Figure 3-Figure 5), a member of the Cyanobacteria, embedded within the tissues and providing a conversion of atmospheric nitrogen into a form the hornwort can use. This fixed nitrogen is transferred from the gametophyte thallus to the sporophyte. Furthermore, if the gametophyte happens to be grown in the dark, and the sporophyte is illuminated, it can transfer the photosynthate to the gametophyte (Bold *et al.* 1987). And that sporophyte can have twice the photosynthetic carbon fixation of the gametophyte (Thomas *et al.* 1978)!

Figure 3. Probably *Megaceros* with *Nostoc* colonies. Photo by Chris Lobban, with permission.

Figure 5. *Nostoc* from *Anthoceros agrestis*. Photo by Ralf Wagner at <www.dr-ralf-wagner.de>, with permission.

At least some members have associated fungi. Ligrone (1988) reported fungi in association with *Phaeoceros laevis*. The fungus colonized the parenchyma cells except at the growing tips of the thallus and epidermal cells. The infected cells increased their cytoplasmic contents, but the chloroplast lost starch and the pyrenoids disappeared. The chloroplast became branched and these branches intermingled with the arbuscular fungal hyphae.

The sporophyte is like that of *Sphagnum* in **lacking a sporophyte stalk** (seta) on the capsule (Figure 6) and like the Bryophyta in having a **columella** (Figure 7-Figure 8) that is not in liverworts. The capsule also has **stomata** surrounded by two kidney-shaped **guard cells** (Figure 9), characters shared with Bryophyta. Instead of elaters, they have **pseudoelaters** (arising from division of a pseudoelater mother cell and outnumbering spores; Figure 10) of one, two, or four cells, usually with **no spiral thickenings** [except *Megaceros* and *Dendroceros* (Renzaglia 1978)] (Figure 11). The pseudoelaters probably provide nutrition, at least initially, but at maturity they twist, contributing to dehiscence and dispersal (Renzaglia 1978).

Meiosis is **continuous**, occurring at the base of the capsule, causing the tip of the sporophyte to have more mature spores than the base (Figure 12-Figure 14), a feature unique to the Anthocerotophyta. Dispersal results as the **capsule splits** into valves from the top down (Figure 25), and consistent with its development, this peeling back of the capsule occurs slowly over time, retaining the lower spores while dispersing the upper ones. The valves twist in response to moisture changes, perhaps aiding in dispersal. The **spores mature progressively** from top to bottom of the capsule (Figure 13) as the capsule splits and **continues**

to grow at its base, unlike any other Bryobiotina (Figure 26).

Dendroceros is a tropical genus that is unusual among the Anthocerotophyta by growing on tree bark and leaves. Furthermore, it produces multicellular green spores (Figure 15) (Schuette & Renzaglia 2010). Schuette and Renzaglia suggest that the precocious development of the spore, resulting in **endospory**, permits it the time and resources necessary to survive the desiccating habitat where it lives.

Figure 15. *Dendroceros tubercularis* endospores. Photo by Karen Renzaglia, with permission.

Spores in **Anthocerotophyta** germinate to form a short **protonema** that does not remain threadlike, but gets areas that are more three-dimensional, resembling a tuber (Figure 16).

Figure 16. *Anthoceros dichotomus* protonema. Photo from Plant Actions through Eugenia Ron Alvarez, with permission.

The mature gametophyte thallus resembles that of a club moss (Lycopodiophyta) in that the **antheridia** may occur in groups within a chamber (Figure 17-Figure 23). The archegonia are likewise embedded within the thallus, again like those of the club mosses. The structure of the archegonium is illustrated in Figure 24.

Table 1. Comparison of the phyla of Bryobiotina. Amplified from Crandall-Stotler (1996) and Gradstein *et al.* (2001).

Character	Marchantiophyta	Bryophyta	Anthocerotophyta
Protonema	Mostly globose or thalloid, forming one bud; no gemmae	Filamentous, forming many buds; may produce gemmae	Globose, forming one bud; no gemmae
Gametophyte form	Leafy shoot or thallus; thallus simple or with air chambers; dorsi-ventral	Leafy shoot	Simple thallus; dorsi-ventral
Branches	Developing from leaf initial cells or inner stem cells, rarely stem epidermis	Developing from stem epidermis	
Leaf origin	2 initial cells (1 in Calobryales & Metzgeriales)	1 initial cell	
Leaf arrangement	Leaves in two or three rows, ventral row usually of different size	Leaves usually in spirals	Not applicable
Leaf form	Leaves unistratose, divided into 2+ lobes, no costa	Leaves unistratose in most, undivided, costa present in some	Thallose
Leaf/thallus cells	Usually isodiametric, have trigones; numerous chloroplasts	Often elongate, rarely possess trigones; numerous chloroplasts	No trigones; 1-4 large chloroplasts
Special organelles	Complex oil bodies often present	Simple, small oil bodies or none	Single plastids with pyrenoids
Gemmae	Common on leaves	Common on leaves, stems, rhizoids, or protonemata	Absent
Water conducting cells	Present only in a few simple thalloid forms	Present in both gametophytes and sporophytes of many	Absent
Rhizoids	Hyaline, one-celled	Brown, multicellular	Hyaline, one-celled
Gametangial position	Apical clusters (leafy forms) or on upper surface of thallus	Apical clusters	Sunken in thallus, scattered
Paraphyses	Usually lacking; often have mucilage filaments	Usually associated with antheridia & archegonia	Lacking
Growth of sporophyte	Apical	Apical	Grows continuously from basal meristem
Stomata	Absent in both generations, but pores present on some gametophyte thalli	Present on sporophyte capsule	Present in both sporophyte and gametophyte
Seta	Hyaline, elongating just prior to spore release, rigid when turgid, deliquescent	Photosynthetic, emergent from gametophyte early in development in Bryopsida & Polytrichopsida, rigid due to cell structure, persistent; not elongating in Sphagnopsida – pseudopodium present	Absent
Calyptra	Ruptures & remains at base of seta, lacks influence on capsule shape	Ruptures & persists at apex of seta & capsule, influences capsule shape	Lacking
Capsule	Undifferentiated, spherical or elongate; jacket uni- or multistratose; often with transverse or nodular thickenings	Complex with operculum, theca and neck; jacket multistratose; lack transverse or nodular thickenings	Undifferentiated, horn-shaped; jacket multistratose
Sterile cells in capsule	Spirally thickened elaters	Columella	Columella and pseudoelaters
Capsule dehiscence	Into 4 valves; spores shed simultaneously	At operculum & peristome teeth in Bryopsida & Polytrichopsida, spores shed over extended period; valvate in Takakiopsida, Andreaeopsida, & Andreaebryopsida; lacking peristome in Sphagnopsida	Into 2 valves; spores mature & shed over extended period
Chemistry	Monoterpenes, sesquiterpenes, & diterpenes; lunularic acid	Triterpenes; ABA	Terpenoids(?)

CHAPTER 3-1

SEXUALITY: SEXUAL STRATEGIES

Figure 1. Depiction of the *Marchantia* sexual life cycle in a chalk drawing by Gerald W. Prescott. Photo by Janice Glime.

Expression of Sex

Understanding sexuality is fundamental to understanding evolution, and by extension, to understanding the ecology of species. The topic of sexual expression has led to interesting discussions for many centuries and still perplexes us. On Bryonet, 14 February 2016, Ken Kellman asked several pertinent questions that remain with incomplete answers. His questions included the role of auxins or other hormones in the **perigonium** (leaves surrounding male reproductive structures) and **perichaetia** (leaves surrounding female reproductive structures) formation. How does **polyploidy** (condition of multiple sets of genes) relate to separate sexes? How many totally asexual species are there? (In California Kellman is aware that only *Dacryophyllum falcifolium* is never known to form gametangia). And some species are sexual in Europe, but not in North America, e.g. *Hennediella stanfordensis* (Figure 2), or male in Europe and female in North America, e.g. *Syntrichia pagorum* (Figure 3).

Figure 2. *Hennediella stanfordensis*, a species that is sexual in Europe but not in North America. Photo by Martin Hutten, with permission.

Figure 3. *Syntrichia pagorum*, a species that is male only in Europe, female only in North America, and both sexes occur in Australia. Photo by Michael Lüth, with permission.

Figure 5. *Campylopus gracilis* showing caducous tips by which it reproduces. Sexual plants are unknown. Photo by Michael Lüth, with permission.

But it turns out that Ken Kellman's example from California is only a drop in the bucket – many species in Europe are not known to reproduce sexually, including *Bryoerythrophyllum caledonicum*, *B. ferruginascens* (Figure 4), *Bryum dixonii*, *Campylopus gracilis* (Figure 5), *Didymodon maximus* (Figure 6), *Ditrichum plumbicola* (Figure 7), *Leptodontium gemmascens* (Figure 8), *Pohlia scotica*, *Thamnobryum cataractarum* (possibly a form of *T. alopecurum*), and *Tortella limosella* (Christopher Preston, Bryonet 15 February 2016). To these, Misha Ignatov (Bryonet 15 February 2016) added *Limnophyllum muzushimae*, a rare pleurocarpous species in Kamchatka, Kurils, and Japan. Johannes Enroth, Bryonet 16 February 2016 added *Caduciella mariei*, a species that occurs in eastern Africa, SE Asia, Queensland, and New Britain; it seems to reproduce only by caducous branch leaves. Liverworts include *Mastigophora woodsii* (Figure 9), *Plagiochila norvegica*, *Riccia rhenana* (Figure 10), *Scapania nimbosa* (Figure 11), *Herbertus borealis* (Figure 12), *H. noreus*, *Lophozia wenzelii* (Figure 13-Figure 14), *Protolophozia herzogiana*, *Anastrophyllum alpinum* (Figure 15), and *Marsupella arctica* (Jeff Duckett, Bryonet 15 February 2016). But as Nick Hodgetts pointed out (Bryonet 16 February 2016), some may reproduce by sexual union only rarely and "bryologists are unfortunately likely to miss the event!"

Unisexual and Bisexual Taxa

Jesson and Garnock-Jones (2012) attempted to provide a single classification of functional sex that could be used for all land plants. They divided the strategies into three categories: sporophyte (and gametophyte) **dimorphic** (having two forms); sporophyte-**cosexual** and gametophyte-dimorphic; gametophyte (and sporophyte) **cosexual** (having both sexes). Bryophytes exhibit only the latter two of these, always having sporophytes that are cosexual and never dimorphic. The gametophyte is always dimorphic in seed plants. [Note that in seed plants, the female gametophyte is embedded in the sporophyte tissue and the male gametophyte is a pollen grain; hence gametophyte sexes are always on separate gametophyte individuals.] Despite this simplistic approach, Jesson and Garnock-Jones consider that there are many variations within these three categories and that closer examination should reveal that bryophytes have as many variations in strategy as do more complex seed plants.

In bryophytes, it is the gametophyte ($1n$, **haploid**) plant that exhibits the **bisexual (monoicous)** trait. To the seed-plant botanist, the terms **monoecious** and **dioecious** are familiar, referring to having male and female organs on one sporophytic individual or on separate individuals, respectively, but the terms are legitimately restricted to sporophytes (Magill 1990). The counterpart to these terms for bryophytes, applied to the gametophyte, are **monoicous** and **dioicous**. Nevertheless, the sporophyte terms are often applied, as are the terms leaf and stem, but the oicy terms

emphasize important differences in bryophyte sexuality (Zander 1984; Allen & Magill 1987; Magill 1990). Their root words are the same, derived from the Greek *mónos* (*mónos*), single, or *di-* (*di-*), twice, double, and *oikos* (*oikos*) or *oikía* (*oikía*), house. In other words, one house for sperm and egg on one plant (**monoicous**) or two houses for sperm and egg on different plants (**dioicous**).

Bryophytes have an unusually high number of **dioicous** taxa (male and female gametangia on separate individuals) among green land plants. Ramsay and Berrie (1982) reported that about 42% of bryophyte genera are exclusively dioicous, 49% of the genera include both dioicous and monoicous species, and only 9% are exclusively monoicous. Hedenäs and Bisang estimated roughly 60% of all bryophyte species are dioicous. Villarreal and Renner (2013a) estimated 57% in mosses and somewhat higher in liverworts (68%), although McDaniel and Perroud (2012) consider them to be about equal. This may differ somewhat by geographic distribution, but more careful analysis is needed. By contrast, in seed plants only 4-6% of the species are dioecious (Renner & Ricklefs 1995; de Jong & Klinkhamer 2005) and the sex ratio is more likely to be male-biased (Sutherland 1986; Delph 1999; Barrett *et al.* 2010).

Cross fertilization in monoicous **Bryophyta** is insured in many species by having differences in maturity times of male and female gametangia. Other furtherance of outcrossing is accomplished by the placement of gametangia on the plants. Bryophytes exhibit all sorts of arrangements of sexual organs on their **monoicous** species (having male and female gametangia on same individual), providing them with various strategies for outbreeding. These include having male and female gametangia on separate stems or branches and having male gametangia below female gametangia on the same branch or stem. When male and female organs are on separate individuals (Figure 1), outbreeding is ensured whenever sexual reproduction occurs; opportunities for fertilization decrease and opportunities for genetic variation increase.

One of the major problems for dioicous species is that one sex may arrive in a new location without the other, as seems to be the case of *Syntrichia pagorum* (Figure 3) in North America (female only) and Europe (male only). *Didymodon nevadensis* (Figure 16) is endemic in North America, occurring on the gypsiferous ridges of Nevada and only female plants are known (Zander *et al.* 1995). Llo Stark (pers. comm. 28 March 2023) considers that males have become extinct here. Nevertheless, with a variety of vegetative reproductive means, the species can persist.

Figure 16. *Didymodon nevadensis*. Photo by Theresa Clark, with permission.

Among the bryophytes, it is well known that many taxa with separate sexes never produce capsules [e.g. *Sphagnum* (Cronberg 1991)], presumably due to absence of the opposite sex or to inability of the sperm to reach the female plant and its reproductive structures successfully. For example, in a population of *Cyathophorum bulbosum* (Figure 17) in New Zealand, where male plants were located nearly a meter above the females, sporophytes existed in several developmental states, but on a nearby bank the entirely female population was completely barren (Burr 1939). In studies by Grebe (1917) on 207 German mosses and Arnell (1875) on 177 Scandinavian mosses, 200 of the 220 taxa that seldom produced capsules were dioicous. So one must ask what is the genetic mechanism that underlies the sexual differences in these unisexual taxa (taxa having only one sex on an individual; **dioicous**) and just what permits these unisexual taxa to persist?

Sex Chromosomes

Bryologists are the proud discoverers of X and Y sex chromosomes (Figure 18) in plants (Anderson 2000), first discovered in the liverwort genus *Sphaerocarpos* (Figure 19) (Allen 1917, 1919, 1930). And it is fitting that one of the first sex markers in bryophytes was likewise found in *Sphaerocarpos* (McLetchie & Collins 2001), although this was predated by identifying the tiny X and Y chromosomes in the female and male liverwort *Marchantia polymorpha* (Figure 20-Figure 21) (Okada *et al.* 2000; Fujisawa *et al.* 2001). These researchers have determined that the Y chromosome of the dioicous *Marchantia polymorpha* has unique sequences that are not present on the X chromosome or on any autosomes. Note that these individual haploid plants each have only one sex chromosome. To emphasize differences between **haploid** and **diploid** sex determination, the haploid single sex chromosomes have recently been distinguished as U (female) and V (male) chromosomes (Bachtrog *et al.* 2011; Olsson *et al.* 2013).

Figure 17. *Cyathophorum bulbosum*, a species that can readily be fertilized when males are above females, but not when females are isolated on a nearby substrate. Photo by Niels Klazenga, with permission.

Figure 18. Chromosomes of *Sphaerocarpos donnellii*. a & b: Chromosomes from female gametophyte. c & d: Chromosomes from male gametophyte. From Allen 1919.

Figure 19. *Sphaerocarpos michelii*, member of the genus where X and Y sex chromosomes were first discovered. Photo by Jan-Peter Frahm, with permission.

Figure 20. *Marchantia polymorpha* male with antheridiophore, first bryophyte species in which sex markers were found and unique sequences found on males that were not present on females. Photo by David T. Holyoak, with permission.

Figure 21. *Marchantia polymorpha* females with archegoniophores, the first bryophyte species in which sex markers were found. Photo by Janice Glime.

But the presence of sex chromosomes does not mean that all bryophytes have separate sexes, or even that all bryophytes have sex chromosomes, so we must ask what determines the sexual differentiation. Ramsay and Berrie (1982) discussed the mechanisms of sex determination in bryophytes, including physiological and genetic regulation of sexuality. They considered that genetic sex is determined at the spore stage, but Bachtrog *et al.* (2011) consider that it is determined at meiosis. Even within the same genus, some bryophytes may be **unisexual** (Figure 22-Figure 25), others **bisexual** (having both sexes on the same individual; monoicous) (Figure 26-Figure 30). Clearly we need more research to discover how some of these determinations are made.

Figure 22. Clonal colony of male *Philonotis calcarea*. Note innovation branches below the male splash cups. Photo by Michael Lüth, with permission.

Figure 24. Female plants of the dioicous *Philonotis calcarea*, distinguishable by their sporophytes. Photo by David T. Holyoak, with permission.

Figure 25. Colony of non-expressing or female plants of the dioicous *Philonotis calcarea*. Archegonia are hidden among perichaetial leaves at the tip of the plant and are often difficult to distinguish without destroying the tip of the plant. Photo by David T. Holyoak, with permission.

Figure 26. **Antheridia of *Funaria hygrometrica*.** This is a special case of monoicous termed **autoicous**. Both male and female gametangia are on the same plant, but in separate places. Here the antheridia are at the base of a leaf. The white-knobbed structures with them are **paraphyses**. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Renner *et al.* (2017) reported a different combination of sex chromosomes. In *Frullania dilatata* (Figure 28), there are two U chromosomes and one V chromosome. In *Plagiochila asplenioides* (Figure 29), there are one U chromosome and two V chromosomes. They discuss the many things we don't understand in bryophyte sexual genetics. There is a lack of high-throughput sequencing, quantification, or *in situ* study of repetitive DNA, organellar DNA, or transposable elements. The causes of size differences in U and V chromosomes is unknown. Even though heterochromatin was first discovered in bryophytes, its role in sex regulation of these organisms remains unknown. The only sequencing of sex chromosomes is that of the V chromosome in *Marchantia polymorpha* (Figure 20-Figure 21), a species with 8 autosomes and 1 sex chromosome.

Figure 27. *Frullania dilatata* on tree trunk, a species with two U chromosomes and one V chromosome. Photo by Claire Halpin, with permission.

Figure 29. *Plagiochila asplenioides*, a species with one U chromosome and two V chromosomes. Photos by Claire Halpin, with permission.

An Unusual Y (=V) Chromosome

An active "Y"-chromosome-specific gene has been unknown in plants, although mammals such as humans do have specific genes on the Y chromosomes (Okada *et al.* 2001). But Okada *et al.* found that the bryophytes, or at least *Marchantia polymorpha* (Figure 20-Figure 21), have at least one such gene. This gene is unique and is expressed specifically in the male sex organs.

Since that earlier discovery, Yamato *et al.* (2007) have identified 64 genes on the V (male) chromosome of *Marchantia polymorpha* (Figure 20-Figure 21). Of these, 14 occur only in the male genome and have been linked exclusively to expression in reproductive organs. Although their individual functions are still not known, this relationship suggests that they participate in the reproductive functions of the male. Additional genes (40 genes) on the V chromosome are expressed in both male sexual organs and male thalli, suggesting that they have cellular functions unrelated to reproduction.

Figure 30. *Funaria hygrometrica* with both undeveloped and nearly mature capsules on female plant portions. Photo by Robert Klips, with permission.

Figure 31. *Orthotrichum pusillum*, an **autoicous** species with capsules. Photo by Robert Klips, with permission.

Gametangial Arrangement

There are multiple configurations of gametangia among the various bryophytes. The monoicous condition of sexuality among mosses can be further divided into **autoicous**, **paroicous**, and **synoicous**. In the **autoicous** condition, the male and female gametangia are in separate clusters, as in *Orthotrichum pusillum* (Figure 31-Figure 33). In the **paroicous** condition, the male and female gametangia are in separate groupings but in a single cluster, as they are in a number of species of the liverwort *Lophozia* (Figure 34) (Frisvoll 1982). The **synoicous** condition is one in which the male and female gametangia occur intermixed in the same cluster, as in *Micromitrium synoicum* (Figure 35), a condition unusual enough to be used in the specific name. Whereas archegonia in acrocarpous mosses are always terminal, pleurocarpous mosses grow horizontally, and the female and male sex organs occur at the apex of specialized short branches, **perichaetia** and **perigonia**, respectively. In dioicous taxa, antheridia of acrocarpous mosses are in various positions, whereas archegonia are terminal. The same arrangements into perichaetia and perigonia is true for both monoicous and dioicous species.

In **Jungermanniopsida**, the antheridia are arranged behind the growing point (Figure 36-Figure 38). In most of the leafy **Jungermanniopsida** the archegonia occur in perianths (Figure 36, Figure 39) that may be terminal on stems and branches or located along these. In the **Metzgeriales** (**Jungermanniopsida**), the archegonia appear along the midrib of the thallus, thus permitting continued apical growth (Figure 40). In the **Marchantiopsida** the antheridia occur in clusters on the thallus (Figure 41) or elevated on a stalk (Figure 42), with similar arrangements for archegonia (Figure 42-Figure 43). In **Anthocerotopsida** the antheridia are imbedded in the thallus (Figure 44-Figure 45) and archegonia are single and surrounded by involucre (Figure 44).

Origin of Bisexuality in Bryophytes

As already noted, the number of dioicous species of bryophytes is greater than the number of monoicous species (Hedenäs & Bisang 2011), with 68% of liverworts, 57% of mosses, and 40% of hornworts being dioicous (Villarreal & Renner 2013a). Longton and Schuster (1983) recognized 205 liverwort taxa as dioicous, 112 as

monoicous in New Zealand. In Guatemala, 161 taxa are dioicous compared to 145 monoicous. Une (1986) found 613 (62.2%) of the bryophyte species in Japan were dioicous and 356 (36.2%) were monoicous. This prevalence of dioicous taxa is an unusual situation among plants and raises questions about its significance. The switch to monoicy has previously been suggested to be a derived character in bryophytes (but see below under Monoicy as a Derived/Advanced Character?), and in many genera it drives speciation through doubling of some or all of the chromosomes. One must then ask, how do so many dioicous taxa survive and spread?

Monoicy as a Derived/Advanced Character?

Ando (1980) suggested seven reasons to consider monoicy as advanced over dioicy in bryophytes, based on concurrent knowledge on bryophyte systematics, distributions, and life histories:

1. Frequently the strain with the haploid chromosome number is dioicous and the monoicous one is diploid.
2. Monoicous taxa seem to have more limited distribution, despite their higher frequency of producing sporophytes and spores.
3. Bryophytes of specialized, more recent habitats such as on decaying wood or living leaves of tracheophytes include many monoicous taxa.
4. Taxa with small gametophytes are more commonly monoicous.
5. Most annual bryophytes are monoicous, e.g. Ephemeraceae, Funariaceae, and Splachnaceae.
6. More advanced groups such as Marchantiales and Anthocerotophyta include many monoicous taxa. [This statement does not fit with 2016 thinking about the phylogenetic position of these groups.]
7. Monoicous taxa have several means to prevent self-fertilization and may have evolved by hybridization.

This suggested direction of evolution is in line with the recent study in hornworts, discussed below, which revealed a transition rate from dioicy to monoicy that was twice as high as in the opposite direction (Villarreal & Renner 2013a, b). Devos and coworkers (2011) consider genetic history in their treatise on the evolution of sexual systems in the mostly epiphytic liverwort genus *Radula* (Figure 46). They also found that shifts from dioicy to monoicy in that genus occurred multiple times, with some epiphytes having facultative shifts.

However, recent studies using modern comparative phylogenetic analyses and large scale phylogenies of mosses (McDaniel *et al.* 2013) and liverworts (Laenen *et al.* 2016) found that transitions in sexuality are biased towards dioicy. Furthermore, they found that there seem to be higher rates of diversification among the monoicous moss taxa than among the dioicous ones. In liverworts,

bisexuality evolved multiple times. It is nonetheless associated with certain clades in the liverwort tree, which suggests that it might be a response to environmental conditions (Laenen *et al.* 2016). The distinct phylogenetic signal in sexual systems across the liverwort phylogeny contrasts with the high lability of sexual systems in mosses and hornworts. McDaniel and coworkers (2013) suggest that dioicy works best when separate sexes derive some advantage in their different morphologies.

Figure 46. *Radula complanata* growing epiphytically and exhibiting numerous sporophytes. Photo by David Holyoak, with permission.

One might look for these dioicy advantages in genera such as *Diphyscium* (Figure 47) where males and females have very different morphologies, or in those taxa with **dwarf males** (See Dwarf Males in Chapter 3-3). But even more likely are sexual differences in physiology – phenomena that have barely been explored (see discussions for *Syntrichia caninervis* and *Marchantia inflexa* in section on Environmental and Geographic Differences in Chapter 3-2).

Figure 47. *Diphyscium foliosum* females with capsules surrounded by perichaetial leaves and photosynthetic males (green leaves in foreground). Photo by David T. Holyoak, with permission.

It seems that it still remains for us to unravel the selection pressures and evolutionary processes behind this dioicous phenomenon, but this unravelling is promising with current molecular techniques. It is likely that further phylogenetic analyses as well as the thorough study of

genome evolution will shed light on the evolution of sexual systems in bryophytes (Crawford *et al.* 2009; Laenen *et al.* 2016; McDaniel & Perroud 2012; McDaniel *et al.* 2013; Villarreal & Renner 2013a, b).

Multiple Reversals

The hornworts (**Anthocerotophyta**) are unique in many ways, and among these are their sexual systems. Villarreal and Renner (2013a, b) contend that hornworts underwent numerous transitions between dioicy and monoicy, with a transition rate from dioicy to monoicy that was twice that from monoicy to dioicy. But a seemingly strange occurrence is that monoicous groups of hornworts have higher extinction rates. This might be explained by the fact that in the hornworts, diversification rates do not correlate with higher ploidy levels as they do in some mosses (*e.g.* Lowry 1948 for **Mniaceae**). Rather, in hornworts polyploidy in monoicous taxa is rare, occurring in only one (*Anthoceros punctatus*, Figure 48-Figure 49) of 20 species that have been assessed (Villarreal & Renner 2013a). Crawford *et al.* (2009) consider the evidence for simultaneous transitions in chromosome ploidy numbers and sexual systems to be inconclusive in mosses as well. And in liverworts, only about 5% of the species are polyploid whereas 30-40% of the species are monoicous (Fritsch 1991 in Laenen *et al.* 2016).

Figure 48. *Anthoceros punctatus* with sporophytes. Photo by Des Callaghan, with permission.

Villarreal and Renner (2013a) examined the sexual systems of 98 of the 200 known species of hornworts. Knowing that a relationship between dioicy and small spores exists in mosses, they looked for a similar relationship in hornworts. Using Bayesian techniques, they found at least a weak support for this correlation in hornworts. More to the point, they showed that the sexual system depends on spore size, but that the reverse relationship is not true. They reasoned that dioicous species would be more successful with small spores by providing dense carpets of gametophytes for reproduction. It would seem that this character also permits them to occupy their disturbed and ephemeral habitats where they can thrive without competition.

Figure 49. *Anthoceros punctatus* antheridial pit. Note the bluish *Nostoc* colony to the left of the antheridial pit. Photo by Des Callaghan, with permission.

The Monoicous Advantage

The effects of these oicy differences on bryophyte ecology and biology are impressive for this gametophyte-dominant group. As in other plants, monoicous species might appear at a competitive advantage, as all individuals in a population can potentially produce offspring. Moreover, monoicous species in general also reproduce by spores more frequently than do dioicous taxa (Longton & Schuster 1983), although this is not always the case. In 1950, Gemmell published vice-county records for the sexual condition of British mosses, using Dixon's The Student's Handbook of British Mosses, and supported the concept that mosses with the monoicous condition are more successful at producing capsules than those of the dioicous condition (Figure 50). Although a much higher percentage (97% compared to 58% in dioicous taxa) of the monoicous group has capsules frequently (Figure 50), presumably because of greater opportunity for fertilization, the dioicous group occupies a greater proportion of the vice-county observations compared to the number of monoicous species (Figure 51).

Figure 50. Frequency of producing capsules in dioicous and monoicous mosses and frequency of non-expressing species in vice-counties of Great Britain. The total number of species is 573, and the bars represent the relative frequency of the three types. Based on table in Gemmell 1950.

Heegaard (2001) illustrates the problem of dioicy in *Andreaea* (Figure 52-Figure 55). Both monoicous and dioicous species occur in western Norway, permitting us to compare genetically similar sibling taxa from a limited geographic range. The only dioicous species, *Andreaea blyttii* (Figure 52), had a lower percent (38%) of sporophytes on cushions bearing **perichaetia** (leaves surrounding archegonia) than did the three monoicous taxa (60-86%). Nevertheless, even among monoicous taxa, *A. nivalis* (Figure 53) and *A. obovata* var. *hartmannii* (Figure 54) rarely produced capsules. The production of capsules in monoicous *A. rupestris* var. *rupestris* (Figure 55) was highly correlated with the environment, with one group having capsule production that was strongly correlated with altitude and slope, corresponding with **perichaetial** development, and a second group where there was no correlation with perichaetial development, but sporophyte production correlated with gradients of flushing and snow cover. Yet another group produced sporophytes throughout its environmental range. Coordination between the sexes for timing of formation and maturation of the sexual structures, influenced by the environment, could add to the problems of both monoicous and dioicous taxa.

Figure 51. Effect of sexual group on relative frequency of bryophytes in British vice-counties. Total number of species is 573. Percent of flora was obtained by dividing number of species in the category by total number of species. Percent of observations was obtained by dividing total number of vice-county observations by number of species in the category and converting to percent. Based on table in Gemmell (1950).

In comparing taxa that commonly produce capsules, Longton and Schuster (1983) reported only 22 British dioicous mosses, compared to 134 monoicous taxa, commonly have capsules; 154 dioicous taxa rarely or very rarely have capsules, compared to 12 monoicous taxa. It is apparent, then, that factors other than sexual reproduction contribute to the success of dioicous taxa.

Nishimura and Une (1989) examined sporophyte production in **pleurocarpous** mosses (horizontally growing taxa with reproductive organs on short side branches;

Figure 56) of the Hiruzen Highlands in Japan. Out of 22 **autoicous** (monoicous with antheridia and archegonia in different clusters) species, 20 produced sporophytes (91%). However, out of 49 dioicous species, including 5 with **dwarf males** (**phyllodioicous** – see Dwarf Males in Chapter 3-2), only 27 produced sporophytes (55%). Studies like this suggest that there is a sexual reproductive advantage to being monoicous. But they still beg the question of better survival.

One possible consequence of being dioicous and spreading to new locations is the total absence of sporophytes for some species in part of their geographic range. This appears to be the case for the entire genus of *Sphagnum* in California, USA (Carl Wishner, Bryonet 14 August 2012; Norris & Shevock 2004). McQueen and Andrus (2007), in *Flora of North America* vol. 27, report that most, if not all, of the species known from California are dioicous. Yet, for the typically dioicous *Sphagnum russowii* (Figure 57), Shaw *et al.* (2012) report that some specimens are apparently monoicous. The common presence of sporophytes for some California species [*e.g.* *S. capillifolium* (Figure 58), *S. angustifolium* (Figure 59)] when they occur elsewhere suggests that there may be a **founder principle** at work (Carl Wishner, Bryonet 14 August 2012) wherein only one sex arrived to colonize a particular location. This was also suggested for *S. palustre* (Figure 60) in Hawaii where sporophytes are not known to occur (Karlin *et al.* 2012). But without genetic evidence, we cannot rule out the possibility of a climate that is not suitable for expression of one of the sexes or that makes the two sexes mature at different times.

Herbarium records are frequently the basis for descriptions of bryophytes and frequency of sporophytes. One must view herbarium collection records for such factors as male:female ratios and sporophyte production with caution, however, due to collection bias. As Harpel (2002) demonstrated for bryophytes collections for the western U.S., bryologists are more likely to collect the unusual, creating a bias toward over-collecting the rarer species and those with capsules, while ignoring the common.

Stark (1983) suggests that monoicy is advantageous in the desert because of limiting water supplies. However, when he tested the hypothesis in the field in New Mexico, USA, he was unable to support the hypothesis (Stark & Castetter 1987). As found by others, Stark and Castetter found patterns of monoicy correlation with sporophyte production. Nevertheless, Stark considers that at the species level, monoicy provides advantages in the desert habitat.

Or the Dioicous Advantage?

To their potential detriment, monoicous taxa frequently experience **selfing** (being fertilized by sperm from the same plant; see Reproductive Barriers in Chapter 3-4), despite having neighbors that can produce gametes of the opposite sex (Eppley *et al.* 2007). This results in significantly fewer heterozygous fertilizations than that found in dioicous taxa. Furthermore, these monoicous near-neighbors typically belong to the same clone, produced through vegetative reproduction, or have developed from spores from the same parent. This results in a deficiency of heterozygous sporophytes among monoicous taxa. Could it be that the heterozygous condition might itself drive the "mistakes" that result in having two sex chromosomes in one spore, resulting from a misalignment of chromosomes during meiosis? This would drive the bryophytes toward monoicy.

As suggested for the California *Sphagnum* species (see The Monoicous Advantage above), total absence of the opposite sex in dioicous taxa can force species to survive vegetatively in many isolated regions and margins of distribution. Because of the success of **vegetative propagation** (reproduction by asexually produced pieces or branches of the plant) (Figure 61-Figure 62), entire single-sex populations of dioicous taxa may exist and expand over large areas without ever producing capsules. Such is often the case with aquatic taxa like *Fontinalis* (Figure 63) and in parts of its distribution for *Pleurozium schreberi* (Figure 64) (Longton & Greene 1969).

Figure 61. *Syntrichia pagorum* exhibiting gemmae. These are one means of asexual reproduction. Photo by Paul Davison, with permission.

Figure 63. *Fontinalis duriaei* showing its flowing growth of a single clone. It is unlikely a female in this position would ever get fertilized and produce capsules unless a male clone became intermixed. Photo by Janice Glime.

Figure 64. *Pleurozium schreberi*, seen here with capsules in Baraga County, Michigan, USA, is barren northward in Ontario where apparently only one sex exists. Photo by Janice Glime.

As a result of being dioicous it may be possible to harbor more genetic variation than that of monoicous species. Both mating systems permit species to reproduce asexually by **ramets** (individual members of clone, arising vegetatively), but the greater percentage of species with asexual diaspores permits those dioicous species to carry non-functional or non-lethal genes as potential pre-adaptations without the selection step that often occurs during failed pairing in meiosis.

Shaw (1991) found that the monoicous moss *Funaria hygrometrica* (Figure 30) never had heterozygous sporophytes for 14 allozyme loci, *i.e.*, it had a high level of heterozygote deficiency. The dioicous moss *Polytrichum juniperinum* (65), on the other hand, had extremely high levels of heterozygosity based on six allozyme loci (Innes (1990).

In short, monoicous taxa do not always gain the advantages of cross-breeding, although their chances for cross-breeding may in some cases be equal to or greater than that of dioicous taxa. This cross-breeding opportunity assumes that spores of another genotype of a monoicous taxon have equal chances of germinating and growing near that taxon compared to spores of a dioicous taxon growing close enough for fertilization of a plant of the opposite sex of that taxon.

65. *Polytrichum juniperinum*, a dioicous moss shown here with prolific capsule production. Photo by Daniel Mosquin, through Creative Commons.

In fact, the opportunities for cross fertilization in monoicous taxa should be greater than those of dioicous taxa because any spore of the species that germinates near another of the same species should be able to cross with it, whereas the dioicous taxon must have a pair of sexes. On the other hand, if the archegonia of a monoicous taxon lack any protection against self-fertilization, their own sperm have the greater chance of reaching them due to the shorter distances. Thus, taxa of both mating systems have opportunities for different individuals nearby to fertilize them. At present we do not have enough data to generalize about the numbers of cross-fertilizations that occur in monoicous taxa. Due to the higher number of total successful fertilizations, monoicous taxa have much better

dispersal through spores, increasing the possibility of a different genotype nearby and providing it a source of cross-fertilization. The likelihood of cross-fertilization with a different genotype in both sexual strategies is complicated by arrival times, competition, leakage of inhibitory substances, and the degree of self-incompatibility (See Chapter 3-4 in this volume). But dioicous taxa have the advantage of more frequent asexual reproduction and guaranteed mixing of genes when they do reproduce sexually, creating the variability for the species to survive throughout environmental changes.

Origins of Polyploidy

The monoicous condition in mosses may be the result of **polyploidy** (in bryophyte gametophytes, having more than one complete set of chromosomes). Polyploidy is a common occurrence among plants, being rare only among the gymnosperms (Ahuja 2005). Bryophytes seem to have multiple avenues by which to become polyploids. This increase in ploidy is often considered to make the monoicous condition possible by providing an extra set of chromosomes. But in this group where sex chromosomes have been identified in at least some species, the understanding of how all of these possible origins work is complex. See Monoicy as a Derived/Advanced Character? above and examples below.

Sporophytes from Fragments

It is still unclear how the majority of monoicous taxa arose. We know that it is possible in the lab to grow $2n$ (**diploid**) protonemata and leafy gametophores from bits of sporophyte tissue, producing monoicous plants (Crum 2001). Marchal and Marchal (1907, 1909, 1911) grew nineteen species of diploid moss gametophytes from setae in the lab. Since then, many others have succeeded in producing diploid moss gametophytes without spores (Crum 2001). Lorbeer (1934) induced diploid gametophytes from capsules and setae in 52 species of liverworts. But this development of sporophyte tissue into a gametophyte has been observed only once (*Funaria hygrometrica*, Figure 26-Figure 30) in nature (Brizi 1892; Crum 2001).

Sporophytes have also been developed from gametophyte tissues. The first was produced as outgrowths from $2n$ leaves and stem tips of *Tortula acaulon* (= *Phascum cuspidatum*) (Marchal & Marchal 1911; Springer 1935). These were initially misinterpreted by Marchal and Marchal as asexual reproductive structures, but later Springer (1935) interpreted them as apogamous sporophytes. These seemed to be the result of altered, mostly dry, conditions. However, these pseudosporophytes failed to produce normal capsules and never produced spores. More recently El-Saadawi *et al.* (2012) discovered what appears to be an apogamous sporophyte – one that lacks any evidence of an archegonium at its base, in *Fissidens crassipes* subsp. *warnstorffii* (Figure 66). It likewise never produced spores. It originated at the base of

the stem, whereas this species normally produces its sporophytes at the apex.

It is unlikely that these vegetative anomalies have contributed much, if any, to the creation of monoicous taxa. On the other hand, the accidental fusion of haploid gametophyte cells other than gametes can result in capsules with at least some viable spores. This suggests that cases might exist where cells join but remain as gametophyte, possibly becoming polyploid monoicous plants.

Figure 66. *Fissidens crassipes* showing an apogamous sporophyte (1 & 2) compared to a normal sporophyte (3) and the vaginula at the base of the normal sporophyte (4), but absent on the apogamous sporophyte. Photo from El-Saadawi *et al.* (2012). Permission pending.

Genome Doubling in Mosses

Genome doubling seems to occur commonly in mosses [76% polyploidy (Przywara & Kuta 1995)], but seemingly less often so in hornworts (Villarreal & Renner 2013a) and liverworts [10% (Newton 1983); 5% (Fritsch 1991 in Laenen *et al.* 2016) (this can include ancient polyploidism and subsequent chromosome loss). Polyploidy might be coupled with a change in sexual system from dioicous to monoicous, but not necessarily so (Jesson *et al.* 2011). Both **autopolyploidy** (self-doubling of chromosomes within a single bryophyte) and **allopolyploidy** (**hybridization**) are known to be present among bryophytes in nature (Natcheva & Cronberg 2004; see also 3.4, Hybridization).

Autopolyploids – Although **autopolyploidy** was once considered the primary source of polyploidy in mosses (Boisselier-Dubayle & Bischler 1999), this may not be the case. Košnar *et al.* (2012) were able to use genetic markers to demonstrate autopolyploid origin of several lineages in

the *Tortula muralis* (Figure 67) complex, making them the first group of mosses in which autopolyploidy was demonstrated with molecular markers. Google Scholar, when searched for bryophyte autopolyploidy, listed mostly allopolyploidy references. In one species that does exhibit autopolyploidy, *Targionia hypophylla* (Figure 68), its triploidy seems to actually be a combination of autopolyploidy and allopolyploidy (Boisselier-Dubayle & Bischler 1999).

Figure 67. *Tortula muralis* with capsules. Photo by Derek Christie, with permission.

Figure 68. *Targionia hypophylla* showing black marsupial pouches that house the archegonia and sporophytes. Photo by Martin Hutten, with permission.

Allopolyploids – allopolyploids can be achieved by **hybridization** (crossing of non-identical genomes, as in a different strain or species) and has been demonstrated in a number of bryophyte species. For example, Wyatt *et al.* (1988, 1992) showed that *Plagiomnium medium* (Mniaceae; Figure 69) arose from a cross between *Plagiomnium ellipticum* (Figure 70) and *Plagiomnium insignis* (Figure 71-Figure 72), resulting in **allopolyploids** (having two or more complete sets of chromosomes that

derive from more than one species). Not only did it happen, but it happened multiple times! *Plagiomnium cuspidatum* (Figure 73-Figure 75) is likewise an allopolyploid, but one of its parent species is unknown (Wyatt & Odrzykoski 1998). *Cinclidium stygium* (Figure 76) ($n=14$), also a member of Mniaceae, is a monoicous polyploid closely related to *C. arcticum* (Figure 77) and *C. latifolium* (Figure 78), both having $n=7$ (Wyatt *et al.* 2013). *Cinclidium stygium* appears to have an **allopolyploid** origin from these two close relatives. Also *Cinclidium subrotundum* (Figure 79) is a monoicous polyploid ($n=14$) that exhibits strong evidence for allopolyploidy, having 7 fixed heterozygous loci out of 17 scored (Mogensen 1973).

In cases when monoicous taxa are polyploids developed from dioicous taxa, we could hypothesize that the monoicous taxa should have more variability and thus

better survival. Natcheva and Cronberg (2004) report that the spontaneous hybridization among bryophytes is sufficient to have a significant evolutionary significance, with the many allopolyploid taxa supporting this contention. (See Chapter 3-4, Sexuality: Reproductive Barriers and Tradeoffs).

Relationship of Polyploidy and Monoicy in *Atrichum*

In an *Atrichum undulatum* (Polytrichaceae, Figure 82) complex from a study in New Brunswick, Canada, monoicous plants were either diploid or triploid, with the number of monoicous individuals increasing as the number of triploids increased (Figure 80; Jesson *et al.* 2011). Many diploid populations, on the other hand, were dioicous (Figure 81). Jesson and coworkers found that male and female gametophytes were represented by haploid, diploid, and triploid individuals (Figure 81). Perley and Jesson (2015) examined the association between polyploidy and sexual system further in the genus, including species of different ploidy-levels. In the haploid state, this genus has either a female U chromosome or a male V chromosome. Using genetic markers, they determined that certain gene sequences are consistent with independent **allopolyploid** origins of **diploid** (2 sets of chromosomes) and triploid (3 sets of chromosomes) species. In the **triploid** *Atrichum undulatum* (Figure 82-Figure 84), and possibly the diploid *A. altecristatum* (Figure 85-Figure 86) as well, hermaphroditism appears to be a result of allopolyploidy. However, in the diploid *A. crispulum* (Figure 87), this allopolyploid event did not result in the hermaphrodite condition. This tells us again that the creation of monoicy (hermaphroditism) is more complex than simply doubling the chromosome number. (See more in Chapter 3-4, Reproductive Barriers: Selfing and Hybrids.)

Figure 80. Relationship between percentage of triploid individuals and monoicism in 21 randomly sampled populations of the *Atrichum undulatum* complex in New Brunswick, Canada. Five populations were not sampled for ploidy determination. Eight populations exhibited no hermaphrodites and no triploids. Modified from Jesson *et al.* 2011.

Pseudodioicy

As its name implies, **pseudodioicy** is a condition which appears to have separate sexes, but in fact they originate from one plant with separate sexual branches. The best known examples of the pseudodioicous condition typically arise when a male branch breaks off or becomes separated by decay. However, that male branch typically remains in proximity of the original plant, which often appears to be only female. The second type is more difficult to observe and can arise when male and female buds from a protonema become separated, causing separate plants to form.

The first record of pseudodioicy I could find is that of Barnes (1887). He noted the condition in *Fissidens closteri* (Figure 88), *F. incurvus* (Figure 89), and *F. pallidinervis* (Figure 90). He described *F. closteri* as male gemmiform, attached to the female by rhizoids or separate. For *F. incurvus*, he writes "male gemmiform, at the base of stems from which they sometimes separate." For *F. pallidinervis*, he hedges and says "probably pseudodioicous."

Figure 90. *Fissidens pallidinervis* with capsules, a species with pseudodioicy. Photo by Frederick B. Essig, with permission.

Fissidens seems to have the most recorded observations of the pseudodioicous condition. Hill (1907) reported that *F. minutulus* (Figure 91) had male "flowers" that form little stems among the rhizoids of fertile plants. As the plants age, the connection with the parent plant ceases to exist. Hill suggested that male organs may start in the leaf axils of fertile stems as buds, later becoming independent. Whittier and Miller (1967) described *Fissidens mangarevensis* (Figure 92) from the Society Islands as sometimes being pseudodioicous, but they found no antheridia to verify that.

Figure 91. *Fissidens minutulus*, a species with pseudodioicy. Photo by Jan-Peter Frahm, with permission.

Figure 92. *Fissidens mangarevensis*, a species with pseudodioicy. Photo by Yang Jia-dong, through Creative Commons.

The fascinating cave moss *Schistostega pennata* (Figure 93) likewise can be pseudodioicous (Mežaka *et al.* 2011). Jeff Duckett (pers. comm. 3 December 2019) tells me he has confirmed this in freshly collected material. Hill *et al.* (1994) describe it as pseudodioicous with male and female plants arising separately from the same protonema. Thus, this species fits the second type of pseudodioicy. It is likely that this separation occurs frequently in species with male and female buds on one protonema, but it is difficult to document, and it is likely that these species have been treated as dioicous, as is the case for *S. pennata* in Crum's 1983 description.

Other cases of pseudodioicy have been reported in both leafy and thallose liverworts. Some of these are guesses, based on finding what appear to be both autoicous and dioicous plants, as in the leafy liverwort *Lophonardia jamesonii* (Vána & Watling 2004).

Several thallose liverworts become pseudodioicous when the thallus decays from its base and leaves male and female gametangia in separate thalli. Such is the case for *Reboulia hemisphaerica* (Figure 94) (Puglisi *et al.* 2018).

In this species the branches can also be easily separated by age, but also during preparation. *Mannia californica* (Figure 95) can produce its gynoeceia on ventral branches, but at least in Japan, terminal autoicous female branches occur (Borovichev *et al.* 2014). Decaying thallus bases make the species appear to be dioicous, but they are in fact pseudodioicous. Among Canadian specimens of *Metzgeria conjugata*, Brinkman (1931) found several pseudodioicous specimens in this monoicous species. Borovichev *et al.* (2012) described pseudodioicous plants of *Sauteria alpina* (Figure 96) from Russia, earlier described from Greenland by Schuster (1992).

Figure 93. *Schistostega pennata* capsules, a species with pseudodioicy. Photo by Martin Hutten, with permission.

Leafy liverworts also exhibit this trait among several species. *Cephaloziella crassigyna* can be found in an autoicous or pseudodioicous state (Beveridge *et al.* 2017). Watson (1913) reported that Macvicar considered *Cephalozia lammersiana* as pseudodioicous; the taxonomic affinities of the species were unclear, but it does seem to represent the condition in some specimens of *Cephalozia*.

Ploidy and Spore Size

Stebbins (1950) concluded that cell size of constant-form cells such as spores was the best indicator of hybridization and polyploidy in plants. We know from studies in ferns that polyploidy can result in larger cells (Lawton 1932). Subsequent studies indicated a similar relationship in spores size in ferns (Hagenah 1961; Wagner 1966; Schneller 1974). Kott and Britton (1983) suggested that spore size could be used to characterize a species as long as at least 20 spores were measured.

But Britton (1968) found that such a correlation does not seem to exist in the fern genus *Dryopteris*, a finding later corroborated by Wagner (1971) for the same genus. Other factors contribute to selection for spore size, making the ploidy relationship unreliable in at least some cases. For example, Carlquist (1966) demonstrated that small spore size increases likelihood of spore dispersal to greater distances, whereas on islands spore size increases because of absence of suitable habitat at greater distances. Barrington *et al.* (1986) noted the absence of statistical data and statistical analyses in studies of spore size-ploidy relationships. Voglmayr (2000) demonstrated, using 138 different moss taxa, that variation in DNA contents has a much lower range of variation than that of tracheophytes (12-fold compared to 1000-fold). However, the possible correlation of spore size and ploidy level does not seem to be explored in bryophytes.

So what evidence do we have that bryophytes exhibit any relationship of larger spores in polyploid individuals? I decided to examine the possibilities in the **Mniaceae**, a family known to have polyploid species. I was not surprised to find a complicated relationship (Table 1).

Although these data suggest possibilities, they do not supply the necessary link between spore size and chromosome number. Furthermore, as Des Callaghan reminded me, descriptions often fail to indicate true variation. Spore sizes vary a lot; he recommended a mean of 50 spores (10 spores from a capsule and five capsules from different populations).

Table 1. Comparison of spore size with number of chromosomes in several genera of **Mniaceae** in the Great Lakes region of North America (from Crum 1983).

Species	Spore Size	Number of Chromosomes
<i>Mnium stellare</i>	20-29 μ m	n=6 + m, 7
<i>Mnium lycopodioides</i>	19-29 μ m	n=6
<i>Mnium marginatum</i>	22-32 μ m	n=12
<i>Mnium thomsonii</i>	20-31 μ m	n= 6, 8
<i>Mnium spinulosum</i>	28-21 μ m	n=8
<i>Plagiomnium cuspidatum</i>	24-31 μ m	n=6, 12
<i>Plagiomnium drummondii</i>	18-24 μ m	n=6
<i>Plagiomnium affine</i>	26-29 μ m	n=6
<i>Plagiomnium medium</i>	24-29 μ m	n=12
<i>Plagiomnium rostratum</i>	22-33 μ m	n=7, 12, 14, 21
<i>Pseudobryum cinclidioides</i>	31-40 μ m	n=6,7
<i>Rhizomnium punctatum</i>	29-41 μ m	n=6, 7; 2n=14
<i>Rhizomnium pseudopunctatum</i>	28-48 μ m	n=13-14

Variation within a species can be enormous. For example, within *Cinclidium stygium* (Figure 76), spore size may range from 31-68 μm within the same capsule, with a ploidy number of $n=14$ (Crum 1983). Mogensen (1981) demonstrated that multiple spore sizes can occur in the same capsule in mosses, and Glime and Knoop (1986) showed that in *Fontinalis squamosa* (Figure 97) two spore sizes can be present in the same capsule (Figure 98-Figure 99), apparently resulting from arrested development and progressive death of spores. The latter phenomenon can make more space for the remaining spores and perhaps permit them to develop to a larger size before leaving the capsule.

This leaves us with little to suggest whether more chromosomes, *i.e.* a higher ploidy number, would result in larger spores in bryophytes, adding this to the many questions still unanswered about bryophytes.

Cross Fertilization

Certain mixing of genes results from cross fertilization, a condition widely accepted among botanists as providing genetic variability and greater chances for the species to survive changing conditions. For sexual reproduction to be successful, the sperm must reach the egg. For bryophytes, this could be an easy task in **synoicous** taxa (monoicous with antheridia and archegonia in same cluster), but quite difficult in dioicous taxa. (See above in The Monoicous Advantage.)

Some bryophytes can alter their life cycle depending on the density of the population – a strategy reminiscent of maple (*Acer*) trees. The moss *Tetraphis pellucida* reproduces asexually with gemmae at low densities and has a female-biased sex ratio (Kimmerer 1991). As the density increases, there is an increase in sexual reproduction and sporophyte production. The proportion of males also increases as the population size increases, but this greater density also causes the onset of senescence. The strategy is beneficial to a species such as this that lives in unstable or short-lived environments.

Sperm Dispersal

Sperm transfer is a problematic aspect of fertilization for bryophytes. It must be accomplished within the life of the sperm, keep the sperm hydrated, and find an archegonium of the right species at the right maturity stage. A good release mechanism can start the sperm on their journeys.

The release of sperm in bryophytes is not a simple bursting of the antheridial wall with swimming sperm free to travel their own way. Rather, it typically occurs as the release of **spermatocytes** as a mass (Muggoch & Walton 1942). Meanwhile, as water accumulates at the base of the antheridium, it pushes this mass outward and away from the antheridium. As the spermatocytes reach the air-water interface, they spread apart rapidly to form a regular spaced arrangement on the surface. Muggoch and Walton concluded that this spreading and spacing correlated with the presence of fat from the spermatocyte mass. As the fat

lowers the surface tension, the spermatocytes gain their freedom and spread. In some bryophytes, such as *Sphagnum* and some liverworts, fats seem to be absent and surface spreading likewise is absent. Muggoch and Walton further concluded that it is the surface spreading that makes the sperm susceptible to dispersal by invertebrates in dioicous taxa – a rather astute observation so long before we had actual proof that invertebrate dispersal occurs.

Once freed, the sperm are able to swim rapidly, and if they are near enough they may be attracted to the female gamete chemotactically. Pfeffer (1884) found chemotaxis involved in sperm locating archegonia of *Marchantia polymorpha* (Figure 43) and *Radula complanata* (Figure 46). Lidforss (1904) found that the proteins albumin, hemoglobin, and diastase were each able to attract sperm of *Marchantia polymorpha* to a capillary tube that contained them. Chemotaxis of sperm still needs clear verification and some studies suggest there is no chemotaxis (Showalter 1928). Diversity among the species is likely, but it leaves us with the question of how the sperm finds the archegonium if no attractant is present.

Walton (1943) observed the spreading of sperm in the monoicous thallose liverwort *Pellia epiphylla* (Figure 100-Figure 101). In his observations, archegonia were only 5-10 mm from antheridia. Whereas freed sperm in the dioicous liverwort *Aneura* (Figure 102) took several hours to travel only 10 mm, those in many moss and liverwort taxa spread rapidly by surface tension over free water at a rate of ~20 mm per minute. Walton found that *Pellia epiphylla* sperm behaved like these fast-moving moss and liverwort sperm, extruding in grey masses into water, breaking apart when they reached the surface, and dispersing over the wet surface rapidly. Once released, they were able to reach archegonial involucre in only ~15 seconds. The more lengthy process was emergence of sperm from spermatocytes, which required ~15 minutes. Walton concluded that if the sperm had to swim it would require several hours, but that the surface tension carried them rapidly to their destination. This leaves us with the question of how transfer is accomplished in dioicous taxa with longer distances to traverse.

Sperm Travel Distances

One reason for the observed genetic variability in bryophytes is that cross-fertilization may extend greater distances than we had supposed (Table 2). Anderson and Lemmon (1974) considered the maximum distance for sperm to travel in acrocarpous mosses to be 40 mm, with a median dispersal distance of about 5 mm. Pleurocarpous mosses were assumed to have even shorter dispersal distances due to the total lack of splash cups or platforms (see below under Splash Mechanisms) (Anderson & Snider 1982). But as seen in Table 2, known (implied?) distances range up to 230 cm.

Reynolds (1980) found that splashing water on the platforms of the moss *Plagiommium ciliare* (Figure 103) indicated greater travel distance (50+ cm) than that to the nearest male (5.3 cm). In the thallose liverwort *Marchantia chenopoda* (Figure 104), fertilization distances seem to range 0.7-65 cm (Moyá 1992), a range that suggests microhabitat factors may play a role in dispersal distance. Differences in dispersal mechanisms

can account for wide ranges. Earlier chapters on **Marchantiophyta** and **Bryophyta** have discussed these mechanisms, including splash cups and platforms, flowing water, and arthropods.

Table 2. Maximum known distances for sperm dispersal. Those in bold have splash cups or splash platforms. Distances mostly from Crum 2001.

<i>Splachnum ampullaceum</i>	5-15 mm	Cameron & Wyatt 1986
<i>Breutelia arcuata</i>	2.5 cm	Bedford 1940
<i>Weissia controversa</i>	4 cm	Anderson & Lemmon 1974
<i>Climacium dendroides</i>	7 cm	Bedford 1938
<i>Pleurozium schreberi</i>	10 cm	Longton 1976

Figure 104. *Marchantia chenopoda*, with males on **left** and females on **right**. Female archegoniophores elongate after fertilization. Photos by Janice Glime.

Maggot and Walton (1942) demonstrated experimentally that some bryophyte sperm can move 0.1-0.2 mm per second and continue movement for several hours, suggesting they could swim for 35 cm. Rosenstiel and Eppley (2009) and Shortlidge *et al.* (2012) provided further evidence of the possibility of greater sperm dispersal distances based on longevity (see below under Sperm Longevity).

Explosive Help in Thallose Liverworts

As discussed in Chapter 2-3 on **Marchantiophyta**, *Conocephalum conicum* (Figure 105) releases its sperm into a mist that makes them airborne (Benson-Evans 1950; Shimamura *et al.* 2008; see Chapter 2-3), suggesting that this could result in greater dispersal distances. Benson-Evans (1950) describes her experience with dried males of this species in the lab, the result of a hot week-end. Upon rewetting, the plants emitted a fine mist. She paid little attention to this until she noticed that "the mist was being emitted from the antheridial heads in regular puffs. Removal into direct sunlight increased the activity and the particles which were being ejected were visible to the naked eye, so that the puffs were obviously composed of distinct granules." A similar "explosion" is known from a number of other Marchantiales taxa (Peirce, 1902; Cavers 1903, 1904a, 1904b; Andersen 1931; Benson-Evans 1950).

Sperm Dispersal Vectors – After Release

Water has been presumed to be the primary dispersal vector in bryophytes. But interesting mechanisms accompany this water dispersal and still others rely on other organisms to accomplish the task.

I have suggested (Glime 1984) that species of the dioicous aquatic moss *Fontinalis* could accomplish fertilization when females are wet but above the water level in streams or lake margins. In streams, this would typically be on emergent rocks, and emergent rocks can create water spray. Once released the sperm could then travel in these drops of water to land on the moist female plants. The timing of their gametangial maturation in autumn when plants are often emergent supports this hypothesis. And if splash from the stream is not effective, autumn rains splashing on emergent males could accomplish the mission.

Splash Mechanisms

Bryologists have been interested in the use of splash mechanisms in bryophytes for dispersal of sperm. Clayton-Greene *et al.* (1977) found that both field studies and lab tests support the hypothesis that antherozoids of *Dawsonia longifolia* (= *D. superba*; Figure 106) are dispersed by a splash mechanism. They found that females up to 1.5 m from males were fertilized, a distance only slightly less than the distance travelled by water drops released at 3.3 m above the splash cups.

Figure 106. *Dawsonia longifolia* male plant with splash cup. Photo by Allan Fife, with permission.

Andersson (2002) used a more sophisticated approach by making a video of splashes of rain on the splash platforms of the moss *Plagiomnium affine* (Figure 107). He discovered that a crown forms upon impact of water. Small droplets are propelled away from the rim of this crown. For this to be effective, the diameter of the drop should be 1 mm or less to permit the crown to form, a size common in most showers. Upon impact of the drop, the antheridia rupture. Water fills the capillary spaces between the antheridia and the paraphyses, permitting the spermatozoids to reach the bottom of the splash cup. When the crown forms, it incorporates water from the bottom of the splash cup and hence includes the spermatozoids. These entrapped spermatozoids are ultimately released from the splash cups as the small droplets propel away from the splash cups. Such droplets are known to travel more than 100 mm, fertilizing most of the females within an 80 mm radius.

Among the best known splash platforms among bryophytes is that of *Marchantia polymorpha* (Figure 20-Figure 21). But Duckett and Pressel (2009) inform us that the widely told dispersal story is not entirely correct. Traditional description since the accounting by Goebel (1905) has been that fertilization occurs when the archegoniophore stalks are still young and short, at which time the archegonial necks still point upward. The antheridiophores, developing first, tower over these,

permitting sperm to travel downward by splashing or dripping during rainfall. But it is likely that the sperm actually disperse as they do in *Conocephalum conicum* (Figure 105), discharging into the air up to 15 cm above the antheridial heads (see Sperm Dispersal by the Bryophyte above). This can explain why both Parihar (1970) and Crum (2001) reported that the archegonia continued to be fertilized after the stalk elongated. Furthermore, when female thalli were placed in dye, the coloring reached archegonial heads in 30-60 minutes (Duckett & Pressel 2009), suggesting that capillary action and surface tension movement could carry the water and accompanying sperm from the antheridial splash cups upward to the archegonial heads and archegonia.

Figure 107. *Plagiomnium affine* showing splash platforms of male plants. Photo by Janice Glime.

The splash mechanism in the dioicous *Fontinalis* (Figure 108) requires a suitable location within a rapid stream. When female plants are elevated above the water and male plants or their rock substrate are obstructing flow to create splash, sperm may be able to go about 2 m (personal estimate based on distance between male plants and females with capsules) in a rocky stream. This takes advantage of the splashing of rapid water, whereas when the antheridia and archegonia are under water, the highly diluted sperm will be swept away, most likely never being able to enter the neck of an archegonium (Goebel 1905).

Figure 108. *Fontinalis dalecarlica* with immature, green capsules. This clump is located in a rapid stream where rocks are covered with this species. Photo by Janice Glime.

Invertebrate Dispersal

Clayton-Greene *et al.* (1977) reported on the use by Gayet (1897) of netting over *Rosulabryum capillare* to demonstrate that some outside force was needed for fertilization. With fine nets over the plants, fertilization failed, but when the netting was removed, fertilization occurred over distances of 2 m. Although this may suggest that invertebrates were denied access, hence being prevented from fertilizing the females, it does not eliminate the possibility of the netting affecting the splashing of raindrops.

As early as 1927, Harvey-Gibson and Miller-Brown found that the paraphyses (Figure 26) of both males and females in *Polytrichum commune* (Figure 109) exuded a mucilage, but that mucilage did not contain any sugars. Nevertheless, **oribatid mites**, **springtails** (Collembola), **midges** (Diptera), **leaf hoppers** (Cicadellidae), **aphids**, and **spiders** visited these structures and lapped up the mucilage. Their body parts carried the mucilage, and thus they might easily have carried the sperm. But this possibility seemed to be ignored by most bryologists until recently.

Figure 109. *Polytrichum commune* with capsules. Photo by David Holyoak, with permission.

Cronberg *et al.* (2006) experimentally demonstrated that **springtails** and **mites** were able to transport sperm over distances of up to 4 cm, but it is possible that under the right circumstances transport could be much farther. Rosenstiel *et al.* (2012) also described one of the more remarkable cases of sperm dispersal in the mosses *Bryum argenteum* (Figure 110-Figure 111) and *Ceratodon purpureus* (Figure 112). These species can have their sperm dispersed from male to female by the springtail *Folsomia candida* (Figure 112). Rosenstiel and coworkers showed that the springtails chose significantly more female mosses than male mosses in *Ceratodon purpureus* (Figure 113) and that their presence facilitated fertilization (Figure 114). This preference was supported by verifying that the volatile compounds differed between the two sexes in *C. purpureus* (Figure 115-Figure 116).

Sperm Longevity

Few studies have included the life of the sperm or experimented with conditions necessary for their survival. It has always been assumed that sperm had a short life span and were unable to survive desiccation. However, Rosenstiel and Eppley (2009) experimented with sperm from geothermal populations of the **paroicous** (having reproductive organs beside or near each other) moss *Pohlia nutans* (Figure 117-Figure 118) and found that this is not the case, at least for this ubiquitous species. Sperm in this species were not affected by temperatures between 22 and 60°C and only showed increased mortality at temperatures above 75°C. Dilution also contributed to their mortality (Figure 119), suggesting that they might protect each other. Moreover, within their safe temperature range 20% survived for more than 200 hours (Figure 120). If this trait has been retained in a paroicous moss, we are likely to find some surprisingly tolerant and long-lived sperm in dioicous bryophytes.

Figure 114. Effect of spray and the springtail *Folsomia candida* presence on sporophyte production in *Ceratodon purpureus* / *Bryum argenteum* microcosms, showing mean and error bars. + and - represent presence or absence of **springtails** or water spray; $n=108$ microcosms; * $P<0.05$. Redrawn from Rosenstiel *et al.* 2012.

Shortlidge *et al.* (2012) demonstrated that in *Bryum argenteum* (Figure 110-Figure 111), *Campylopus introflexus* (Figure 121), and *Ceratodon purpureus* (Figure 112) some of the sperm were able to survive environmental desiccation for extended periods of time. The tolerance seemed to be independent of both species and dehydration conditions. Furthermore, the addition of sucrose during drying improved their recovery. Despite the lack of variation among species, there was considerable variability among individuals within a species.

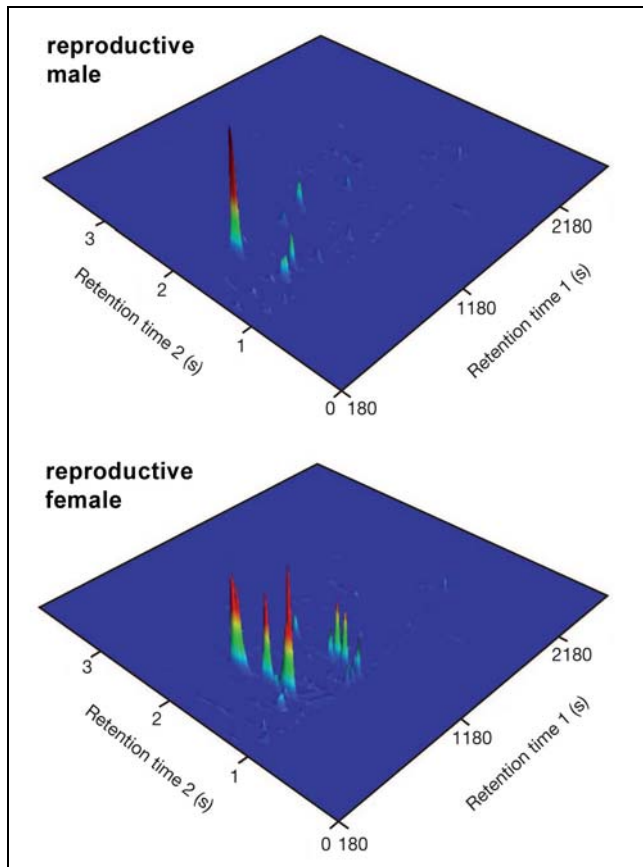

Figure 115. Comparison of profiles (two-dimensional GC3GC-TOFMS chromatograms) of volatile compounds in a male and a female shoot of reproductive *Ceratodon purpureus*. Colors indicate relative measures of compound abundance; red indicates compounds that are greater than 50% of the largest individual peak area. Modified from Rosenstiel *et al.* 2012.

Figure 121. *Campylopus introflexus* with water drops. Such drops can greatly aid fertilization. Photo by Michael Lüth, with permission.

Stark *et al.* (2016) revealed that moss antheridia are desiccation tolerant. Noting that free-living sperm are partially desiccation tolerant, they hypothesized that the mature antheridia should also be tolerant. They further hypothesized that rehydration to partial turgor or full turgor before immersion in water is required for full recovery from the damaging effects of desiccation. They cultured *Bryum argenteum* until it produced mature perigonia with antheridia, then dried them slowly over ~36 hours, equilibrating them with 50% relative humidity. To test their hypothesis, they prehydrated them in a saturated atmosphere or rehydrated them in saturated media in a range of times from 0 to 1440 minutes. Following these treatments they immersed them in sterile water. When they were prehydrated for at least three hours before their immersion, the antheridia functioned like those of the controls that had not been dried. They found that prehydration did not improve on the recovery compared to rehydration. After three hours of rehydrating before immersion, the antheridia have full recovery.

Factors for Successful Fertilization

Multiple factors contribute to the successful fertilization of bryophytes, including sex expression of both sexes, distance to nearest mate, suitable sperm dispersal mechanism (see above), and appropriate weather conditions, especially temperature and water availability. But assessing the relative importance of multiple factors in a single study has rarely been done. Rydgren *et al.* (2006) used generalized linear modelling (GLM) to assess three factors for the dioicous perennial moss *Hylocomium splendens* (Figure 122). They found that most sporophytes (up to 85%) were located within 5 cm of a male, with the longest distance measured being 11.6 cm. But year was an even better predictor of success than distance, attesting to the importance of weather and probably past history, although female segment size as well as distance to closest male were both highly significant. They emphasized the importance of using multiple factors as predictors of reproductive success.

Figure 122. *Hylocomium splendens* with capsules. This dioicous species forms colonies with only one sex, hence not producing sporophytes from fertilization by its neighbors. Photo by Janice Glime.

Bisang *et al.* (2004) took the distance question further to see if increasing the availability of mates would increase the success of fertilization. They selected two dioicous pleurocarpous mosses, *Hylocomiadelphus triquetrus* (= *Rhytidiadelphus triquetrus*; Figure 123) and *Abietinella abietina* (Figure 124) and transplanted individual male shoots into non-sporophyte-bearing female colonies.

Figure 123. *Hylocomiadelphus triquetrus* with capsules. Photo by David T. Holyoak, with permission.

Figure 124. *Abietinella abietina* in Europe. Photo by Michael Lüth, with permission.

They determined that the number of sporophytes produced depended on the distance from the male mate, *i.e.* spermatozoid source. Furthermore, differences between species were evident, with *Hylocomiadelphus triquetrus* (Figure 123) being more successful than *Abietinella abietina* (Figure 124). They estimated that in *H. triquetrus* the maximum fertilization distance was 34 cm, considerably more than the 3-6 cm previously reported (Riemann 1972). Bisang *et al.* (2004) found that in *H. triquetrus* the number of female reproductive branches significantly affected the number of sporophytes. By contrast, in *A. abietina* the number of female reproductive branches per plot did not affect sporophyte production. Both species were mate limited.

As one might expect, for both species, when male plants were uphill from female branches, the number of sporophytes was significantly greater than when their positions were reversed, presumably because the sperm were able to travel farther, possibly carried or splashed down the slope by rain (Bisang *et al.* 2004). In *Hylocomiadelphus triquetrus* (Figure 123), a mean of 40 sporophytes per plot ($n=25$ plots) occurred on sloping substrata compared to 22 on horizontal surfaces. Upslope distances for this species had a mean of 6.2 cm above transplanted males (max=16 cm) and 10.2 cm downslope (max=34 cm). In *Abietinella abietina* (Figure 124), the downslope distances (mean=3.3 cm) were also significantly greater than upslope (mean=1.9 cm) distances, but in this species both the distance travelled and the successful production of sporophytes (mean=2.4 per plot) were considerably less than in *H. triquetrus*. Genes matter.

Figure 125. *Anomodon viticulosus* in a seepage area of England. Photo by Janice Glime.

Granzow de la Cerda (1989) demonstrated movement of sperm in seepage water by transplanting male *Anomodon viticulosus* (Figure 125) to a position at least 25 cm above female plants, a move that resulted in production of sporophytes.

Multiple Fertilizations

Wyatt *et al.* (2022) used isozyme markers to estimate incidence of multiple paternity in the dioicous, haploid, leafy liverwort *Porella platyphylloidea* (Figure 126). They found that 12.6% of the plants were non-sex-expressing, 13.4% were females without sporophytes, 31.9% were males, and 42% were females with sporophytes. The sex ratio was female biased at 1.74:1. Using the criterion that only females with two or more sporophytes with different genotypes had experienced multiple paternity, they estimated 57% of female plants had been fertilized more than once. Plants on the lower parts of trees were significantly larger, but the larger size of females seemed to account for this difference.

Summary

The liverwort genus *Sphaerocarpos* was the first genus in which sex chromosomes were known in plants. Many bryophytes possess sex chromosomes (X & Y chromosomes, or designated U & V to refer to their haploid condition) which may play a role in sex

determination. Bryophytes can be **monoicous** (bisexual) or **dioicous** (unisexual). Gametangia in monoicous bryophytes can be **autoicous** (♂ & ♀ gametangia in separate clusters), **paricous** (♂ & ♀ gametangia in separate groupings but one cluster), or **synoicous** (♂ & ♀ gametangia intermixed in same cluster). **Monoicy** may have arisen through **hybridization** and **polyploidy**. Transitions from monoicy to dioicy and vice versa have happened multiple times. There seem to have been more changes from monoicy to dioicy than the reverse in mosses, whereas the opposite was the case in hornworts, but this pattern appears to depend on those taxa included in the study and is not a settled relationship. McDaniel *et al.* suggested that dioicy works best when there are advantages to both sexes for being separate.

At least some antheridia can tolerate desiccation, but survival is improved by rehydration before submersion. Sperm dispersal begins with bursting of the antheridium, often accompanied by movement with surface tension of water drops. In thallose liverworts, sperm are often expelled explosively into the air. Sperm dispersal is usually accomplished by movement through a water film or by splashing and is sometimes aided by gravity. But some species have their sperm dispersed by invertebrates, including insects and mites. Dispersing sperm are known to survive as much as 200 hours and travel distance is known up to 230 cm. Travel distance and weather seem to be the most important factors in determining the success of fertilization in bryophytes.

Acknowledgments

We greatly appreciate the numerous comments and suggestions of Lars Hedenäs who provided a critical review of an earlier draft of the chapter and gave me encouragement. Heino During asked probing questions, challenged me to do more, and provided me with references to do it. Karla Werner offered a beginner's perspective and suggested the internal summaries. Noris Salazar Allen offered constructive criticisms on the taxonomic descriptions and helped with the proof reading of a very early draft. Des Callaghan provided the inspiration for including the section on spore size and polyploidy and commented on that text. Bryonettors have been especially helpful in providing examples and observations to answer questions arising during the preparation of this chapter. As always, many people have contributed images, as noted in the captions. Jeff Duckett asked me about species with pseudodioicy, and I decided I should include the subject here. Llo Stark has provided valuable suggestions on the chapter.

CHAPTER 3-2

SEXUALITY: SEX RATIO AND SEX EXPRESSION

Figure 1. *Marchantia polymorpha* developing archegoniophores and antheridiophores on separate thalli. Photo by Bob Klips, with permission.

Sex Ratio

We tend to expect the number of males and females to be about equal (Figure 1), as they are in humans, but many plants and animals have not evolved that way. In bryophytes, it has seemed that mature populations of dioicous species were typically female-biased (Bisang & Hedenäs 2005), and this bias is often huge (but see When Males Are Dominant below). Sex ratios are likely to affect fertilization and thus sporophyte frequency. For example, in *Syrrhopodon texanus* (Figure 2) in the USA central plains, males are very rare (Reese 1984). However, wherever males are found, there are also females bearing sporophytes. These sex ratio imbalances can result from a number of factors, including developmental factors, age, environment, weather, neighbors, and genetic factors.

Figure 2. *Syrrhopodon texanus* in North Carolina, USA. Photo by Janice Glime.

The Bryophyte Female Bias

Stark (2002) reports, based on literature values, that 20 out of 30 species of dioicous bryophytes in those reports have a female bias; 5 have a male bias, and the other 5 seem to have no bias. Bisang and Hedenäs (2005; Bisang, pers. comm. December 2014) reviewed the expressed sex ratios in 143 taxa of dioicous bryophytes (89 mosses, 54 liverworts) based on their own studies and literature data. They used both herbarium specimens and field patches as one category (1) and field studies of individual shoots or thalli (2) as a second. Their study provides us with a cautionary warning that methods can skew the study. They found that for category 1, 85% had a female bias, whereas for category 2, 82% had a female bias. In herbarium studies, the exact bias may be slightly obscured by the tendency of bryologists to collect plants with capsules whenever possible. This is further complicated by the clonal nature of bryophytes, so that it is likely that one small patch is all one clone.

Spore Sex Ratios

In a **dioicous** species, the expectation for a **sporogenous** (giving rise to spores) cell at the onset of meiosis is that it will have one set of chromosomes containing a male chromosome and one set containing a female chromosome. If all proceeds normally during meiosis, a sporogenous cell will produce 4 daughter cells, 2 female and 2 male. But often things do not proceed "normally."

Spore sex ratio has been examined in only a few species so far, by means of cytological evidence (Allen 1919; Newton 1972) or by cultivating plants from spores to sexual maturity (Allen 1919; McLetchie 1992; Shaw & Gaughan 1993; Shaw & Beer 1999; Stark *et al.* 2010). Newton (1972) and Allen (1919) argued for unbiased spore sex ratios in *Plagiomnium undulatum* (Figure 4) and *Sphaerocarpos donnelli*, based on segregation patterns. Also Stark *et al.* (2010) recounted a 1:1 spore sex ratio in *Bryum argenteum*, while ignoring the portion of late-germinating spores. Large fractions of non-germinated spores are also reported for the species investigated in the other cultivation studies, which makes it difficult to assess the actual spore sex ratios in these. This also holds true for the study of the meiotic sex ratio variation in the moss *Ceratodon purpureus* (Figure 3), using a PCR method (Norrell *et al.* 2014). Spore viability varied strongly among sporophytes (0.04 to 0.69) in 9 subsamples each from 11 sporophytes; overall, 63% of the spores did not germinate. Among the germinated spores, the sex ratio at the completion of meiosis was variable, more often female-skewed (proportion of males 0.17-0.72, overall mean 0.41), but not related to spore viability. In contrast, McDaniel *et al.* (2007) found that the EC-NY population cross of *Ceratodon purpureus* had a male-biased sex ratio. They suggested that this was caused by lethal genetic interactions between the sex-linked loci and those of the pseudo-autosomal loci. Nothing like having your genes fight with each other!

While most of the attempts to reveal spore sex ratio so far included easily cultivated ruderals that rapidly express sex in the laboratory, Bisang *et al.* (2017) recently investigated the rarely sexually reproducing perennial dioicous moss *Pseudocalliergon lycopodioides* (Figure 8).

They used single-spore cultures from field-collected sporophytes, and a molecular sex-associated marker to determine the sex of individual sporelings. They achieved a near-complete or complete spore germinability. In line with cytological evidence in the species mentioned above, spore sex ratio was balanced. However, it differed strongly from the female-skewed adult genetic sex ratios observed in the regional natural populations where the sporophytes were collected, as well as from the sex ratio in the European population established on the basis of a herbarium collection survey (Bisang *et al.* 2013; see also below, Genetic vs Expressed Adult Sex Ratio).

Provided that the observed sex ratios in *Ceratodon purpureus* (Figure 3) correspond to the actual sex ratios in the entire spore population, Norrell *et al.* (2014) may conclude that the noted variability in viability and sex ratio is due to genetic variations within populations. As spore viability and sex ratio were not related, factors other than **sex ratio distorters** (cytoplasmic element such as infection may replace nuclear gene as sex-determination mechanism; see Taylor 1990) may account for sex ratio variation. In this case, and in the case of even spore sex ratios as in *Drepanocladus lycopodioides* (Figure 8) that differ from adult sex ratio biases, other possible causes need to be explored, for example sexual dimorphism in life histories or in eco-physiological requirements, which selectively favor females. Norrell *et al.* (2014) further suggested that the sex ratio might be affected by genetic conflict over meiotic segregation and that this affects the fitness variation in the species.

Figure 3. *Ceratodon purpureus*, a species in which the sex ratio differs among populations. Photo by Michael Lüth, with permission.

Genetic vs Expressed Adult Sex Ratio

Are females truly more abundant, as suggested when counting populations or individuals with sexual structures? Even in female-biased populations male bryophyte plants can be more abundant among non-sex-expressing plants than many counts of plants forming sexual organs would indicate. It is crucial to separate an observed sex ratio pattern into its two elements, namely 1) genetic sex ratio, and 2) differential sex expression among sexes. Knowledge of both components is necessary to understand the underlying mechanisms of sex ratio variation, and to determine when and how observed sex ratio biases are established during the life cycle.

Genetic sex ratios have been studied in relatively few bryophytes to date, and both agreement and differences exist between phenotypically expressed and genetic sex ratios. Newton (1971) pioneered the genetic approach by comparing plants of *Plagiomnium undulatum* (Figure 4) with large **heterochromatin bodies** with those having smaller bodies, using heterochromatin body size as a sexual marker. She found that among 239 non-expressing plants examined (34 gatherings) the ratio was 6.5 females to 1 male, but when only the 156 sex-expressing plants in bisexual populations were considered, the ratio was only 3.9♀:1♂. Newton concluded that using only fertile plants underestimates the abundance of male plants. She determined that the non-expressing males of *Plagiomnium undulatum* were rarer than non-expressing females, but not as rare as in the expressing male to female ratio. Using this ratio change, Newton suggested a lower sex expression rate for males than for females. This could also suggest a narrower range of environmental conditions in which sex expression is able to occur. Newton (1972) demonstrated in *P. undulatum* that the environmental conditions for production of antheridia were more restricted than those needed for production of archegonia. However, she could find few differences between the sexes for the environmental parameters she tested. In at least some taxa male plants may be less fit, surviving in a narrower range of conditions than do females. The balance of conditions is complicated in bryophytes by the fact that antheridia typically take longer to develop than do archegonia, thus requiring different conditions to initiate them and needing to survive for a longer time under a greater range of conditions.

Figure 4. *Plagiomnium undulatum*, a species where antheridial expression requires a narrower set of environmental conditions than those required for archegonial expression. Photo by David T. Holyoak, with permission.

Cronberg *et al.* (2003) used electrophoresis to identify **genets** [genetic individual that develops from the zygote and produces **ramets** (any physically and physiologically independent individual plants, whether sexually produced or derived by vegetative reproduction) of the same genotype vegetatively] in *Plagiomnium affine* (Figure 5), reducing the number of plants with unknown sex to 10%. At the ramet level, the overall sex ratio had a slight female bias, but at the genet level it was close to 1:1. Cronberg *et*

al. (2006) found a sex ratio in five plots of *Hylocomium splendens* (Figure 27) to be female biased at the ramet level (2.6 female to 1 male), but it was male biased at the genet level (1 female to 3 males).

Figure 5. *Plagiomnium affine*, a species that invaded European forests multiple times. Photo by Hermann Schachner, through Creative Commons.

More recently, cultivation approaches and novel techniques of molecular sex markers have been used to reveal genetic sex ratios (see below, Sex Expression and the Shy Male Hypothesis).

Causes of Female Bias

There have been many efforts to explain this female bias (Longton & Schuster 1983; McLetchie & Puterbaugh 2000; Crowley *et al.* 2005; Bisang *et al.* 2006; Rydgren *et al.* 2010; Stark *et al.* 2010; Horsley *et al.* 2011, and many more), to date usually the expressed female bias. In fewer cases the underlying genetic sex ratio has been approached. We ask, if it is real, what evolutionary forces drive a female bias? Henceforth we present a number of studies that have examined bryophyte sex ratios, its variation, and discuss possible explanations for the observed patterns.

Sex Expression and the Shy Male Hypothesis

As already mentioned, our methods so far are usually indirect, such as using capsules, perichaetia, and perigonia to assess sex, and few studies involve a direct count that provides a ratio under field conditions. In most cases to date, we are unable to determine the sex of plants not producing sexual organs. Several factors could cause a disproportionate phenotypically expressed sex ratio. Might males take more time to develop and express sexual maturity? Or is the unbalanced observed sex ratio merely a consequence of differential sex expression, as Newton (1971) suggested for *Plagiomnium undulatum* (see above; Figure 4)?

Hedenäs *et al.* (2010) examined the question of sex ratio in non-expressing females of *Pseudocalliergon trifarium* (= *Drepanocladus trifarius*) (Figure 6) using a new technique of genetic sex-targeting markers. They estimated the European population sex ratio to be 1.93:1 (female:male) (Hedenäs *et al.* 2010). There were no

significant differences among expressed, non-expressed, and population sex ratios, and thus no differences in expression rates between the sexes.

Figure 6. *Pseudocalliergon trifarium*. Photo by Andrew Hodgson, with permission.

The "shy male hypothesis" suggests that males express sex less frequently than do females (Stark *et al.* 2010). Those individuals that have no sexual structures are often referred to as "sterile," but sterile implies that they are incapable of producing sexual organs. The preferable terminology, therefore, is "non-expressing" or "non-sex-expressing" (Bowker *et al.* 2000).

Using *Bryum argenteum* (Figure 7), Stark *et al.* (2010) tested both the "shy male" hypothesis and the hypothesis that sex ratios of sporelings are biased (for the latter, see above, Spore Sex Ratios). They used both sex-expressing and non-expressing collections from the field and shoots grown from spores in the lab. Field collections revealed a greater than 80% female bias among 154 collections in the USA, with male expressions being even more rare (as little as 2%) in arid habitats of the Mojave Desert and California chaparral. They grew non-expressing shoots from mixed-sex populations until they reached sexual expression and found that the ratio of males to females did not differ significantly from that of sexually expressing field populations. Hence, the "shy male hypothesis" lacks support in *Bryum argenteum*. Populations grown in the lab from spores, on the other hand, had a 1:1 sex ratio. This leads us to the conclusion that in this species there are factors between sporeling and mature gametophyte that differentially affect the two sexes.

Using herbarium samples from a wide geographic range, Bisang and Hedenäs (2013) assessed the sex ratio in expressing and non-expressing *Pseudocalliergon lycopodioides* (Figure 8), using a sex-associated molecular marker to identify the sex of non-expressing plants. They determined that the true genetic population sex ratio (non-expressing plants included) was the same (2.6:1 female bias) as that when non-expressing plants were not included, thus refuting the "shy male" (non-expressing male) hypothesis also in this species. This distinct female genetic sex ratio bias in the adult population differs from the balanced spore sex ratio (see above, Spore Sex Ratios; Bisang *et al.* 2017). As in *Bryum argenteum* (Figure 7), biased population sex ratios in *Pseudocalliergon lycopodioides* seem to arise at life cycle stages after spore germination. In any case, simply refuting the "shy male"

hypothesis in a species does not answer our question regarding the unequal adult sex ratio.

Figure 7. *Bryum argenteum*, a species with 80% females in montane and disturbed habitats in western USA and up to 98% females in native lowland desert and chaparral, but with a 1:1 ratio of plants grown in the lab from spores. Photo from India Biodiversity Portal, through Creative Commons.

Figure 8. *Pseudocalliergon lycopodioides*, a moss with a 2.6:1 female-biased sex ratio among both non-expressing and fertile plants. Photo by David T. Holyoak, with permission.

Eppley *et al.* (2018) set out to understand the origin of biased sex ratios in *Ceratodon purpureus* (Figure 3). They started with equal populations of male biased and female biased sex ratios to test the hypothesis that male-biased populations would become female-biased and that stress could increase the transition. After 18 months there was no significant change in the originally female-biased populations. However, the male-biased populations became more female. This provides concrete evidence that sex ratio change can occur during the gametophyte generation. Furthermore, sporophytes were produced only in female-biased populations. Eppley and coworkers suggested that females in male-biased populations may have invested energy in producing ramets, thus increasing the number of females. They noted that these results, combined with previous work, indicate that both the gametophyte and the sporophyte operate in determining the sex ratio in *Ceratodon purpureus*. Yes, for than one mechanism exists in a single species!

Brzyski *et al.* (2013) cultivated *Marchantia inflexa* (Figure 9) from different environments. In contrast to *B. argenteum* (Figure 7), they found that in the roadside habitat the males were 4.7 times more likely to express sex than were females, despite the better growth for females in that habitat.

Figure 9. *Marchantia inflexa* thallus, a liverwort where males and females have different environmental stressors. Photo by Scott Zona, with permission.

Germination Patterns and Spore Mortality

But if we examine what might explain such a biased expressed ratio, we know that meiosis in a dioicous plant such as *Sphaerocarpos texanus* (Figure 10), known to have X and Y chromosomes (now called U and V), should result in an equal number of male and female spores, as found in *Bryum argenteum* (see above). Nevertheless, also McLetchie (1992) found numbers that support female dominance in sex expression of the liverwort *Sphaerocarpos texanus*. In both the field and in culture, *Sphaerocarpos texanus* produces a greater number of pure female clumps, followed by mixed sexes and then pure males. McLetchie interpreted this to mean that males have a lower survival rate than females, both before germination and while growing. The first loss of males, leading to an unequal germination rate, assumedly results from unequal survival and germination capability of spores. This abortion can start immediately after meiosis (Figure 11). These differences can result from a difference in allocation of resources to male and female spores, leading to reduced viability and germination success in the males (McLetchie 1992). McLetchie (1992, 2001) also found that there was a sex-specific determination at germination in *Sphaerocarpos texanus*, with more female than male germinations. Could it be, as suggested by Schuster (1983) for *Sphaerocarpos* (Figure 10), that small spores become male plants and that their poor nutrient conditions as spores give them an inferior start in life, causing them to die soon after producing sperm?

McLetchie (1992) suggests that even after germination, males may have inferior competitive ability or be more susceptible to unfavorable environmental conditions. In mixed clumps, females may provide added protection that permits more males to survive, and both benefit from the increased sexual reproductive success.

Figure 10. *Sphaerocarpos texanus* showing female population. Photo by Michael Lüth, with permission.

Figure 11. SEM image of spores of *Fontinalis squamosa* showing abortion of two spores in the tetrad. Photo by Janice Glime.

Even where spores are retained in tetrads and thus travel together, as in *Riccia* (Figure 12), females of *Riccia frostii* (Figure 13) outnumber males (Pettet 1967). In this case, at least one factor is greater mortality of males under conditions of rapid desiccation. In *Cryptothallus* (Figure 14), where sex is determined by sex chromosomes, females outnumber the males 5:1 (Shaw 2000). It appears in this genus that some spores of the tetrad are inviable.

Figure 12. *Riccia sorocarpa* spore tetrads ready for dispersal. Photo by Des Callaghan, with permission.

It would be helpful to know the number of males and females at all life cycle stages to elucidate further the causes of biased sex ratios. Modern molecular techniques (see e.g. Pedersen *et al.* 2006; Bisang *et al.* 2010; Bisang & Hedenäs 2013) or cultivation methods (e.g. Stark *et al.* 2010) make this possible, albeit very time-consuming.

Environmental and Geographic Differences

Bell (1980) stressed the importance of life history in understanding evolutionary theory. Although he focussed on animals, his principles can apply to bryophytes. He posited that "once reproductive costs are introduced, reproduction will be optimized rather than being merely maximized. The 'survival cost' is the decrease in the rate of adult survival which accompanies a given increase in fecundity." Sex ratio can be influenced by these life history principles.

In the Bisang and Hedenäs (2005) study, expressed sex ratio variation not only occurred among species, but also within species. The latter variation was related to geographic region, elevation, year, substratum, and plant/clone maturity. It was interesting that Bisang and

Hedenäs did not find a direct relationship between the sex ratio and the proportion of sporophytic samples or shoots across species. This suggests that the bryophytes may have evolved to optimize the sex ratio for the conditions where they grow. But Bisang and Hedenäs contend that the "data do not support a generalization that the most strongly female-biased sex ratios among dioicous bryophytes occur in 'extreme environs.'" Rather, they suggest that phylogenetic history may explain at least some of the species-wide sex ratios better than current habitat conditions (Bisang *et al.* 2014).

It is likely that both phylogenetic history and extreme environments play a role in determining sex ratio, depending on the species and location. Stark *et al.* (2001) provide supporting data that the greatest departure from a 1:1 sex ratio in mosses is seen in the extreme desert environment (high temperatures and extreme drought) and always leads to male rarity. In fact, there are four species in the Mojave desert that are known there only from females (Llo Stark, pers. comm. 28 March 2023).

In *Marchantia inflexa* (Figure 9), habitat seems to play a strong role in the performance of the sexes (Brzyski *et al.* 2013). Females had both higher growth rates and more asexual reproduction among road-collected plants whereas males tended to have better growth and asexual reproduction (but not significantly) in river-collected plants.

Environmental differences can occur even within short distances. Although the sexes of *Marchantia inflexa* (Figure 9) are spatially separated within populations, they overlap in habitat use and their distributions are not correlated with an environmental gradient (Fuselier & McLetchie 2004). Males collected on the island of Trinidad tend to occur in a wider range of light conditions than do females (Fuselier & McLetchie 2002, 2004). Groen *et al.* (2010a), using five locations in Trinidad, found that males in *M. inflexa* occur where there is more tree-canopy openness than that found in locations where females occur. Groen and coworkers (2010a, b) also found that males of this species had lower chlorophyll *a* to *b* ratios compared to females, the opposite of what one would predict for plants in more open areas. On the other hand, in populations from Granger County, Tennessee, USA, Fuselier (2004) found that laboratory-grown and field-grown males showed little difference in their responses to moisture and light levels.

Fuselier and McLetchie (2002) tested the influence of selection on asexual and sexual fitness components in *Marchantia inflexa* (Figure 9) using a field study on natural selection. They grew replicates of female and male genotypes from Trinidad under two different light environments in a greenhouse. Not only did they find that the timing for the onset of asexual reproduction and the determination of size of the plant during early development were under sex-specific selection in low light, but for females, there was also an apparent cost for plasticity in the timing of their asexual reproduction in high light. Selection pressures favoring asexual fitness tended to favor monomorphism (both sexes looked the same) rather than sexual dimorphism. But if the female morphology was expressed, then selection acted on sexual fitness rather than on morphology, hence favoring females.

McLetchie and Puterbaugh (2000) also explored the relationship of male and female numbers, using the thallose liverwort *Marchantia inflexa* (Figure 9) in Trinidad. They found that among 209 individual patches of this liverwort along a stream, 83% were not expressing sexual characters at all, 9% had both male and female thalli, and the remainder were 4% all male and 4% all female. In bisexual patches, the proportion of males ranged 22-80%. This is hardly an image of sexual dominance by either sex and is one of the examples of infraspecific variation mentioned by Bisang & Hedenäs (2005). Furthermore, when gemmae from non-sex-expressing field collections were planted, the resulting ratio of plants was 10 females to 8 males.

But in those 209 patches of *Marchantia inflexa* (Figure 9), the role of environment in affecting sex expression began to emerge (McLetchie & Puterbaugh 2000). Those patches with the lowest canopy openness, *i.e.* less light, exhibited less sex expression. And, growth patterns of male and female plants differed. The female plants grew faster and produced more meristematic tips, but they had lower levels of asexual reproduction (gemmae) than did the male plants. In fact, asexual reproduction was negatively correlated with the number of meristematic tips (see also 3.4, Reproductive Trade-off). This suggests that the female plants might be more competitive through more rapid growth and soil coverage, but male plants might have greater ability to disperse and occupy new ground. And, this behavior could lead to large numbers of single-sex patches and biased sex ratios among mature, sex-expressing plants.

In the Mojave Desert of southern Nevada, USA, the female-biased desert moss *Syntrichia caninervis* (Figure 15) is a dominant moss in the blackbrush (*Coleogyne ramosissima*) community. Bowker *et al.* (2000) demonstrated that microhabitat can play a major role in sex expression in this xerophytic dioicous moss. On one 10-ha site, sex-expressing female ramets dominated males 14:1 (890 samples). In this harsh environment, it is not surprising that 85% of the ramets did not show sexual expression during their entire life span. Demonstrating responses similar to those of *Sphaerocarpos texanus* (Figure 10), *Syntrichia caninervis* showed more sexual expression in shaded sites, where there was more moisture and plants were taller. Predictably, ramet height was positively correlated with soil surface moisture in more exposed sites. Male ramets were restricted to shaded sites, whereas female ramets and populations occurred in both shaded and exposed locations. There were no mature sporophytes in the ramets sampled, and only 3% of the populations overall had any mature sporophytes. Among the reasons for the success of females are their greater ability to produce biomass and to produce new protonemata and shoots from detached leaves that have experienced desiccation (Figure 16-Figure 17), an inevitable event in this habitat (Stark *et al.* 2005). In this case it appears that there is a strong selection pressure, based on available moisture, against males in some environments and that females are more tolerant of exposed, desiccating conditions.

Figure 16. Effect of varying numbers of desiccation cycles on biomass accumulation rates in males and females of *Syntrichia caninervis* leaves. Values are means ($n=20$) \pm 1 SE. Cycles with different letters are significantly different ($P < 0.05$, Tukey's multiple comparison). Graph modified from Stark *et al.* (2005).

Figure 17. Shoot production from regenerating leaves of males and females of *Syntrichia caninervis* subjected to varying numbers of desiccation cycles. Values are means ($n=20$) \pm 1 SE. Cycles with different letters are significantly different ($P < 0.05$, Tukey's multiple comparison); data were log-transformed before analysis. Graph modified from Stark *et al.* (2005).

Sex-expressing males of *Syntrichia caninervis* (Figure 15) are restricted to higher elevations in the Mojave Desert where they are tucked under shrubs (Stark *et al.* 2005). Female plants, on the other hand, have no such habitat restriction and are relatively widespread along the elevational gradient. Whenever only one sex is expressed, it is always the female. Stark *et al.* (2005) found that the greatest stress results from rapid drying cycles (Figure 16). The plants need 72 hours to dehardening after a gradual drying event. In their desert habitat, they experience 40-70°C temperatures in a dry condition, but may experience 30-40°C while still hydrated. Differential abilities to handle such stress can have severe effects on sex ratios.

Blackstock (2015) investigated sex expression rate, sporophyte frequency, and sex ratios of the dioicous liverwort *Frullania tamarisci* (Figure 18) in western Britain, comparing woodland populations with exposed coastal colonies. Whereas the former were highly fertile, the coastal population exhibited a distinct female sex ratio bias, spatial segregation of the sexes, and male scarcity, which appear to limit sporophyte formation.

Figure 18. *Frullania tamarisci*, a species in which habitat affects the sex ratio. Photo by Hermann Schachner, through Creative Commons.

As seen in the moss genus *Macromitrium* (Figure 19), both geographic and ecological differences are present (Une 1985). Dwarf males (see Chapter 3-3, Dwarf Males, in this volume) of the isosporous species *M. gymnostomum* and *M. japonicum* are widely distributed in Japan, whereas normal males are rare and occur only in low altitudes and latitudes on the Pacific Sea side of Japan. Experimental results suggest that this difference is due to suppression of growth of males at low temperatures, whereas females and dwarf males are less affected by the cold.

Hassel *et al.* (2005a) compared mountain and lowland populations of *Pogonatum dentatum* (Figure 20) in Fennoscandia. They found differences in age of maturation, with females in the lowlands producing spores in their second year, whereas those in the mountains required three years. Nevertheless, both populations produced sex organs in the second year.

Figure 19. Neotropical *Macromitrium* sp. with capsules. Photo by Michael Lüth, with permission.

Fisher (2011) examined differences between sex ratios at the edges vs the centers of distributions in *Syrrophodon involutus* (Figure 21). In this species, she found that female sex expression was significantly lower at the margins than in central areas of the species complex. Furthermore, the margins had a higher proportion of non-sex-expressing individuals. On the other hand, the proportion of male-expressing plants did not differ significantly between marginal and central areas. Nor did the percentage of female-expressing successfully producing sporophytes plants differ between margins and the centers of distribution. Fisher concluded that this indicates the availability of males constrains sporophyte production for this species in both the margins and the centers of distribution. Could it also mean that the two sexes are more likely to differ genetically on the margins?

Figure 20. *Pogonatum dentatum* in Norway. Photo by Michael Lüth, with permission.

Figure 21. *Syrrophodon involutus*. Photo by Jan-Peter Frahm, with permission.

The only study so far that explores the association between genetic adult sex ratio and environmental factors was conducted with the wetland moss *Pseudocalliergon trifarium* (Figure 6), a species that rarely produces sexual structures or sporophytes (Bisang *et al.* 2015). In a total of 277 shoots representing 214 locations, Bisang and coworkers determined sex using a female-targeting molecular marker. They found that the sexes did not differ in shoot biomass. The sexes were randomly distributed and environmental factors associated with the localities of the two sexes did not differ. Nevertheless, the sex ratio had a strong female bias of 28:1! In this case, the environment does not appear to be the cause of the biased genetic sex ratio.

When Are Some Males More Stress Tolerant?

Loss of males due to stressful environments is not true for all species. Cameron and Wyatt (1990) found that males of *Splachnum* are able to survive in more stressful habitats than are females. Using experimental cultures, they found that for *S. ampullaceum* (Figure 22), *S. rubrum* (Figure 23-Figure 24), and *S. sphaericum* (Figure 25), low light and low pH favored production of males over females, whereas good nutrition seemed only to affect *S. ampullaceum*. Nevertheless, the sexes are highly clumped and the sex ratio is typically 2:1 female to male.

Other Differences between Populations

Even within a species complex (based on isozyme analysis), the ratios can vary in size and bias. For example, in the liverwort *Aneura pinguis* (Figure 26) complex, in one cryptic species there were equal frequencies of males and females, in one male plants numbered more, and in a third female plants were more numerous (Buczkowska *et al.* 2006). In *Ceratodon purpureus* (Figure 3) cultivated from spores to maturity, the sex ratio is also heterogeneous (Shaw & Gaughan 1993), but a female bias occurred in more than half of the eleven studied populations.

Figure 26. *Aneura pinguis* with perianths and one black capsule. Photo by Dick Haaksma, with permission.

Another possibility might be that dispersal and germination success differ between male and female propagules, causing more females to colonize. Such a difference would not present itself in experiments on germination of spores from individual capsules or other propagules because these would not have been subjected to the stresses of long-distance dispersal. Males and females would then not arrive and / or establish together and long periods of time may elapse before both sexes are present. And these sexes may represent different cryptic species. Using allozyme electrophoresis, Cronberg (2002) showed that *Hylocomium splendens* (Figure 27) presented 103 haplotypes in a sample of 694 shoots on 10 Baltic islands. The number of clones, sex expression, and sporophyte frequency increased, and sex ratios became more balanced with the age of the islands.

Frequency and Timing of Sex Expression

Functional sex ratio is dependent on the frequency with which it is expressed and whether sequential sex changes ever occur. Do males express sex only once, or do they continue to do it year after year? Likewise, are females able to repeat their high-cost sexual endeavors?

Zoologists have named two strategies of sexual frequency as **iteroparity** and **semelparity**. The story behind the term **semelparity** helps one to remember its meaning. *Semel* comes from the Latin *semel*, meaning once, a single time. *Parous* is derived from *pario*, meaning

to beget. The origin seems to be in Greek mythology, where Semele, daughter of Cadmus and Harmonia, was the mortal mother of Dionysus by Zeus. In the myth, Semele asked Zeus to reveal himself as his true entity. Because he had promised to grant her a boon, he could not break his promise, revealing himself as the lightning bolts he represented, and that cause any human that views them to incinerate. Hence, Semele could bear a child only that once, then died.

The terms semelparity and iteroparity have been applied to plants, as for example the century plant that blooms only once, then dies, certainly an example of semelparity. But the terms are rarely used for bryophytes. Hassel *et al.* (2005a) used it in relation to the populations of *Pogonatum dentatum* (Figure 20) in the mountains vs lowlands of Fennoscandia to describe their differences in sexual parity. Among mountain females, 41% of the shoots branched following reproduction the first time, a condition known as **iteroparous** (having sexual crossing in iterations, *i.e.*, successive years). On the other hand, the lowland female populations did not produce branches, thus being unable to produce sexual organs the next year, a behavior one could call **semelparous** (having sexual crossing only once), assuming it never produces such innovations. On the other hand, new plants might arise from rhizomes.

More likely representatives of semelparity are the **Splachnaceae** (Figure 28-Figure 29). As they mature, their habitat changes. They produce capsules and their substrate is no longer able to support the early stages of the life cycle, nor do they produce additional sporophytes in subsequent years.

Figure 28. *Splachnum rubrum* females with young sporophytes. Photo by Michael Lüth, with permission.

Figure 29. *Splachnum rubrum* females with mature capsules. Photo by Michael Lüth, with permission.

Among **pleurocarpous** plants, both males and females continue to produce ramets or side branches where new gametangia can form, making them **iteroparous**. But what is the general case in **acrocarpous** mosses? Observations of clumps suggest that individual sporophytes are produced annually, but do these come from the same branches or from new plants formed within the clump? For example, in *Weissia* spp. (Figure 30) most shoots are **unisexual** (only male or female) during a given reproductive cycle (Anderson & Lemmon 1973, 1974). To answer these questions we must understand the differences in growth habits among the bryophytes.

Figure 30. *Weissia controversa* with capsules. Photo by J. C. Schou, with permission.

Branching Patterns and Gametangial Location

Among mosses there are two overall branching patterns: **sympodial** for **acrocarpous** mosses and **monopodial** for **pleurocarpous** mosses (with some exceptions). **Sympodial** growth is growth in the absence of apical dominance, *i.e.*, apical growth is terminated (in acrocarpous mosses it is terminated by the gametangia) and the main axis produces branches by innovations or produces ramets at the base. **Monopodial** growth is growth with apical dominance wherein new apical stem and leaf tissue continues to be added. In pleurocarpous mosses, the primary axis produces side branches where the gametangia develop, while the primary axis continues growth. In acrocarpous mosses, growth appears at first to be monopodial, but once gametangia occupy the apex, new growth of that axis ceases. (See Mishler & De Luna 1991 for a discussion of branching in mosses.)

The family **Polytrichaceae** exhibits both of these branching patterns, often in the same species. In *Polytrichum* (Figure 31), we know that new growth originates in the antheridial splash cup and that new splash cups are produced in successive years on the primary axis. In his studies on *Pogonatum dentatum* (Figure 20), Kristian Hassel (pers. comm. 24 January 2014) found that both male and females were able to produce innovations just below their gametangia, but this behavior seemed to be affected by the environment. Furthermore, in Scandinavia he found that production of innovations varied among species in **Polytrichaceae** as well as between males and females. For example, Hassel never observed innovations on shoots of *Polytrichum commune* (Figure 31) that had sporophytes, but in *Polytrichastrum alpinum* (Figure 32) and *Pogonatum urnigerum* (Figure 33) such innovations are common. Males of these species usually produce new antheridial splash cups on the primary axis year after year, reliably enough that these have been used as growth markers. In the genus *Atrichum* (Figure 59-Figure 61), sex expression occurs via branching (Linley Jesson, unpubl., pers. comm. 25 January 2014).

Figure 31. *Polytrichum commune* with capsules, a species where innovations apparently do not occur. Photo by David T. Holyoak, with permission.

Figure 34. *Philonotis fontana* with antheridia and innovations. Photo by Michael Becker, through Creative Commons.

Figure 33. *Pogonatum urnigerum* males with splash cups. Photo by David T. Holyoak, with permission.

But it appears that among **acrocarpous mosses** in the **Bryopsida**, the formation of archegonia at least terminates the apical growth, requiring subapical innovations for further extension of that gametophore. For example, in *Philonotis* (Figure 34), new male inflorescences can appear on innovations in successive years. Mishler and Oliver (1991) reported that female gametangia terminated growth of annual innovations in the dioicous acrocarpous moss *Syntrichia ruralis* (Figure 35). Bisang and Ehrlén (2002) have observed perichaetia terminating each annual innovation of female stems of *Dicranum polysetum* (a species with dwarf males; Figure 36-Figure 38). *Tortella rigens* (Figure 39) females have similar innovations, although the perigonia could not be located (Lars Hedenäs, pers. comm. 23 January 2014). The multiyear behavior in males seems to be less obvious, although the **Polytrichaceae** demonstrate the possibility for growth to continue apically, even when a splash cup is present (Figure 40).

Figure 35. *Syntrichia ruralis* with sporophytes arising from archegonia that terminate its apical growth. Photo by Peggy Edwards, with permission.

Figure 36. *Dicranum polysetum* showing multiple sporophytes in one apex. The apical production of archegonia stops growth of that apex (see Figure 37). Picture by Janice Glime.

Also those acrocarpous mosses that have horizontal growth forms much like those of pleurocarpous taxa do produce antheridia and archegonia in multiple years, but usually not at the original apex. In fact, it is the innovations, growing horizontally, that make them look pleurocarpous. This group includes such taxa as *Racomitrium* (Figure 41), *Hedwigia* (Figure 42) (Sean Edwards, pers. comm. 23 January 2014), and some members of the **Orthotrichaceae** (Figure 43). For example, Arno van der Pluijm (pers. comm. 23 January 2014) tells me that his search for males of the dioicous acrocarpous *Zygodon* (*Zygodon viridissimus*, Figure 43) in **Orthotrichaceae** in old herbarium collections revealed male plants with multiple male buds on the same stem. He found that one or two innovations can develop directly below the perigonium, make a new perigonium, then branch again. He was able to observe up to five generations of male buds in 19th century collections. This family has members that often appear to be pleurocarpous, with predominantly horizontal growth like that of *Macromitrium* (Figure 19).

Figure 42. *Hedwigia ciliata* with capsules. Photo by Robert Klips, with permission.

Figure 43. *Zygodon viridissimus* var *viridissimus* with capsules. Photo by David T. Holyoak, with permission.

In **thallose liverworts**, the apex typically continues to grow or divides to produce two branches for the succeeding year. For example, in perennial *Riccia* (Figure 44-Figure 45) species, the apex continues growing, and if fertilized, leaving successive sporangia to mature – and decay – behind (Rod Seppelt, pers. comm. 23 January 2014). Similarly, in Australia populations of fertilized *Lunularia cruciata* (Figure 46) produce white scale-like conical structures on the upper surface of the thallus. These enclose fully developed sporangia with spores and elaters as well as the **carpocephalum** (sporangial receptacle in most thallose liverworts). When autumn rains arrive, the stalks suddenly elongate to elevate the mature sporangia. It appears that in thallose liverworts, growth continues at the apex following gametangial formation and new gametangia later arise near the new apex.

Leafy liverworts have a growth pattern in which most species have terminal perianths surrounding the archegonia and sporophytes, but with antheridia in leaf axils along the branches. This pattern permits the male branches to continue growing at the apex, but alas, the female has a terminator in the presence of the perianth and archegonia, whether it is terminal on the stem or terminal on a branch. Hence, only new branches can form subsequent archegonia.

It is likely that we should find examples where bryophytes expend so much energy on capsule development that they must wait a year or more to provide enough energy for another sexual endeavor. A negative relationship between sporophyte production and future perichaetia initiation was actually demonstrated in *Dicranum polysetum* (Figure 36-Figure 38) (Bisang & Ehrlén 2002; see also Chapter 3.4, Reproductive Trade-

off). If we are to use growth increment markers such as splash cups, we need to understand this relationship lest we underestimate the age of the plants.

Protogyny and Protandry

Protogyny, the maturation of female reproductive structures before those of the male, and **Protandry**, the maturation of male reproductive structures before those of the female, are not commonly reported in the bryophytes [but see for example Lackner 1939; Crum 1972 for *Atrichum undulatum* (Figure 59-Figure 58) and *Funaria hygrometrica* (Figure 47); Longton & Schuster 1983; Stark 2002]. That does not mean they are effectively absent or even rare. One of the problems in identifying maturation of the male and female sexual organs at different times is that this may occur even in different years and give the appearance of having the two sexes on separate plants. Deguchi (1978) sums this up well in his study of *Grimmia* (Figure 48): "When successive branchings, including subfloral innovations, continue, and lower, older branches are decomposed in time, the upper newer branches, with different sexual organs, appear to be of different individuals. This circumstance often leads bryologists to a misunderstanding of the sexuality."

Figure 47. *Funaria hygrometrica*, a monoicous annual shuttle species that produces prolific capsules with long-lived spores, shown here growing on fresh charcoal. Photo by Janice Glime.

Figure 48. *Grimmia affinis*, a species that produces mature antheridia and archegonia at different times. Photo by Michael Lüth, with permission.

Ken Kellman (Bryonet 17 April 2014) excitedly reported the discovery of a plant that had been thought to be dioicous, but that in reality was synoicous and protogynous, an undescribed species of *Bryum* (*Gemmabryum*). The antheridia are produced after the archegonia have senesced. As he aptly pointed out, this is an effective mechanism to prevent selfing in monoicous species, while retaining the advantage of a clone that contains both sexes and achieves adequate spore dispersal for later mixing of genes.

This discovery by Kellman brought other Bryonetters to report their observations. Brent Mishler (Bryonet 18 April 2014) reported that in *Syntrichia princeps* (Figure 49) mature archegonia are present while antheridia in the same inflorescence are just beginning their development. We can't be certain whether this is maturing of archegonia first, or if the antheridia of that year have already matured and disintegrated, but one would assume that since they are in the same inflorescence this is protogyny. Stark (1985) likewise found evidence of brief protogyny in both species of *Forsstroemia* (Figure 50) in Virginia, USA. The monoicous *Phaeoceros carolinianus* (Figure 51) is an example of a typically protandrous hornwort.

Figure 51. *Phaeoceros carolinianus* with sporophytes, a protandrous hornwort. Photo by Hermann Schachner, through Creative Commons.

Age-related Differences

Could differences be due to fewer males expressing sex in their lifetimes, or do they take longer to reach sexual maturity? Since antheridia frequently require a longer time to develop than do archegonia (Clapham & Oldroyd 1936; Miles *et al.* 1989; Stark 1997, 2002; Milne 2001), it seems logical that males might require more maturity before they produce their first antheridia.

In *Anastrophyllum hellerianum* (Figure 52), Pohjamo and Laaka-Lindberg (2004) found that a **threshold size** exists not only for sexual reproduction, but also for asexual reproduction. Stark *et al.* (1998) also report a threshold size for sex expression in *Syntrichia caninervis* at 2.1 mm height; this usually is reached at about 6 years. This threshold could account for a large number of non-expressing plants in some populations and some species might even exhibit a different threshold for male and female expression.

Figure 52. *Anastrophyllum hellerianum* with gemmae. Photo by Michael Lüth, with permission.

Sexual Plasticity

It seems that bryophytes may have their own version of the alligator and crocodile story. In these reptiles, and some other animals, the temperature during development of the embryo determines the sex. At high temperatures ca 34°C all the hatchlings are males and when it is ca 30°C, all are female (Woodward & Murray 1993). In this case, there are no sex chromosomes, so temperature during incubation is a crucial factor in sex determination. The

planktonic microcrustacean *Daphnia* is dependent on environmental triggers for sex determination of its progeny (Innes & Dunbrack 1993; Tessier & Cáceres 2004).

Bisexual through Ramets and Rhizautoicy

Dioicous plants may not always be what they seem. Stark and Delgadillo (2001) became curious when the Mojave Desert moss *Aloina bifrons* (Figure 53), reputedly dioicous, appeared frequently with sporophytes. This was most unusual for a xerophytic, dioicous moss. Upon further investigation, they found that **ramets** (individual members of a clone) (Figure 54-Figure 55) of the same clone could on some individual ramets bear **perichaetia** (modified leaves enclosing archegonia) (Figure 56) and on others bear **perigonia** (modified leaves enclosing antheridia) (Figure 57), but that underground these ramets were connected by single rhizoids, rhizoid strands, or masses of rhizoids (Figure 54-Figure 55). In an experimental approach, Stark & Brinda (2013) recently confirmed **rhizautoicy** in this species, *i.e.* the sexual condition of separate male and female shoots connected by protonemata (Crandall-Stotler & Bartholomew-Began 2007) (or rhizoids), often beneath the substrate surface. Such a strategy, apparently from a single spore, would increase the probability of fertilization while permitting a somewhat greater chance for somatic variation between the sexes.

Figure 56. *Diphyscium foliosum* females with capsules and perichaetial leaves. This species is dioicous (the male and female sexual organs occur on separate individuals), with photosynthetic males with leaves and females that consist of only a protonema and perichaetial leaves that surround the archegonia and subsequent sporophyte. Photo by David Holyoak, with permission.

One example of possibly environmentally determined sex in bryophytes is that of *Splachnum ampullaceum* (Figure 22). In this species a protonema from a single spore can produce both male and female shoots (Cameron & Wyatt 1990), fitting the definition of rhizautoicy. The spores are bisexual, but the individual gametophores are unisexual. Therefore, it appears that selection against female-expressing plants is determined later in the developmental stage, although field conditions might cause quite different responses from those in the lab. What is it that determines the sex in these gametophores? Could density of the population in the dung habitat influence sexual differentiation or survival in this functionally dioicous moss? Or could presence of external hormones in the dung habitat influence sexual differentiation or survival? Such factors as ethylene concentrations,

regulated by population density or other environmental factors, could alter the sex ratio. For example, in the flowering plant *Cucurbita texana*, an injection of ethylene into the stem resulted in a greater proportion of female-expressing flowers (Krupnick *et al.* 2000). It is possible that bryophytes, like flowering plants (Lebel-Hardenack & Grant 1997), have environmental means of sex determination. But, alas, it seems we know little about the ability of a single protonema to produce gametophores of different sexes and what might control those differences.

Figure 57. **Perigonial leaves** and antheridia of *Diphyscium foliosum*. Photo from Botany 321 website at the University of British Columbia, with permission.

How common is rhizautoicy in bryophytes? Is this a facultative trait that responds to absence of the opposite sex? Does it involve genetic mutations on the branches, or suppression of genes? And what environmental stimuli are involved in triggering the formation of each sex? Does the environmental trigger cause a physiological response that changes the sex of a newly developing ramet? What is the role of hormone concentration in determining sex expression? Do these rhizautoicous plants retain their sex, or can they switch from year to year based on their stored energy or growing conditions or even age? Is rhizautoicy involving rhizoid connections really the same phenomenon as the production of separate male and female gametophores produced from a single protonema in *Splachnum ampullaceum*?

Sex Reversal

This brings us to attempting to answer the question of sex change in bryophytes. Do bryophytes behave like the Jack-in-the-pulpit (*Arisaema triphyllum*) and remain non-expressing until they have sufficient energy, then change sex in a pattern determined by their sizes? This species does not flower when it is small, produces males flowers when somewhat larger, and produces female flowers in its largest size range (Bierzchudek 1982). Hence, as these perennial plants increase or decrease in size from year to year, they also may change sex.

This model would seem only to work for perennials with underground overwintering structures like the Jack-in-

the-pulpit, but consider another scenario. Annual growth of an innovation after sporophyte production can decrease due to energy transfer to the sporophyte, as seen in *Dicranum polysetum* (Figure 36-Figure 38) (Bisang & Ehrlén 2002). Then the new branch would represent the shorter "plant." In *D. polysetum* sporophyte development reduced the probability of development of future perichaetia and/or reduced the mass of new perichaetia. In short, it exhibited an energy tradeoff much like the Jack-in-the-pulpit, but there is no sex change involved.

Is there evidence that any bryophytes can change sex in response to stored nutrients or nutrient availability? Crum (1976) reports that *Atrichum undulatum* (Figure 59-Figure 58) behaves this way in Michigan, USA. He observed that this species does not produce male and female gametangia on the same plant at the same time, but that at least some populations produce antheridia the first year and archegonia the next (Braithwaite 1887-1905; Dixon 1924; Nyholm 1954-1969; Smith 1978). Thank you to Bryonettors, we can cite further personal observations to shed light on this matter. Linley Jesson, in response to my question on Bryonet in January 2014, shared her observations that in *Atrichum* (Polytrichaceae; Figure 59-Figure 61), because new innovations arise after sex expression, sex indicators remain over 2 or sometimes 3+ years. In triploid *Atrichum undulatum* (Figure 59-Figure 58) and diploid *Atrichum altecristatum* (Figure 60-Figure 61; or possibly *A. undulatum*) it appears that sequential sex expression occurs. Often the first gametangia produced are male and in the next year either female or both gametangia appear. The age of reproduction in both sexes certainly needs further investigation.

Figure 58. *Atrichum undulatum* with capsules. Photo by Michael Lüth, with permission.

This leaves us with two pieces that we have not been able to connect in bryophytes. *Dicranum polysetum* (Figure 36-Figure 38) demonstrates the tradeoff due to energy cost, with innovations behaving like the subsequent year of growth from the Jack-in-the-pulpit rhizome. *Atrichum undulatum* (Figure 59-Figure 58) demonstrates the ability to change sex in subsequent years. But we lack

the link to demonstrate that energy/nutrient availability cause a change to the less costly sex.

Figure 61. *Atrichum altecrisatum* in its first year of invasion. There was no evidence of sexual structures. Photo by Eric Schneider, with permission.

Dan Norris, in his discussion on Bryonet (2 May 2003), helps to answer this question. He expressed his observations on the variability of sexual type within species: "I find myself very skeptical about published data

on dioicy and monoicy. As I write my own manual of California mosses with all descriptions based upon observation of actual specimens, I have found too many contradictions to published reports... I have found the **Polytrichaceae** is so often male in early few years of its life and female later. Too many presumed **cladautoicous** (having archegonia and antheridia on different stems of the same plant) specimens can only be guessed as such because actual connections of the stems cannot clearly be demonstrated...The frequency of sporophytes is hardly a reliable indication of sexuality; *Orthotrichum lyellii* (Figure 87) in my California region seems to be dioicous, as universally reported, but nearly all bunches of the plant – bunches I first thought to be clones – contain both sexes and are almost always with sporophytes."

Even in the well-known dioicous *Polytrichum* (Figure 40) and *Atrichum* (Figure 59-Figure 58), both archegonia and antheridia can occur on the same plant, either mixed together or in separate locations, a condition known as **polyoicous** or **heteroicous** (Vitt 1968). We have much to learn about sex determination in bryophytes!

Mechanisms of Labile Sex Expression

Korpelainen (1998) compared the **lability** (flexibility) of sex expression among the plant phyla and found that while it exists in all the major plant phyla, it is the rule only among homosporous ferns. Furthermore, most of the plants that have labile sex expression are perennials with long life cycles. She found that environmental stresses such as low light, nutrition, unfavorable weather, and too much or too little moisture often favor male expression. Unfortunately, we know little of these mechanisms in bryophytes.

In the monoicous *Tetraphis pellucida* (Figure 63-Figure 62), density affects sex expression, with male shoots dominating when densities are greater (Kimmerer 1991). Selkirk (1979) found that nitrate levels affected sexual expression in *Riccia duplex* (Figure 64), but she did not show differences between male and female expression. In *Riccia rhenana* (Figure 65), some clones produced archegonia in both soil and nutrient solutions, whereas others did not produce any sexual structures during the same six-month cultivation period, suggesting that either they differed genetically or that their past history (e.g. age, environmental conditions, time since last production of sporophytes) affected their ability to respond.

Figure 65. *Riccia rhenana*, a species for which sexual expression is not affected by nitrates. Photo by Jan-Peter Frahm, with permission.

Hormones undoubtedly contribute to sex expression and we might expect their concentrations to be subject to environmental conditions. When experimenting with the mostly vegetative liverwort *Riccia crystallina* (Figure 66), Chopra and Sood (1973) found that **gibberellin** and **ethrel** enhanced antheridial formation, whereas **glycocol** enhanced archegonial formation. In the dioicous *Bryum argenteum* (Figure 7), Bhatla and Chopra (1981) stimulated expression of male gametangia with **auxin** and **gibberellin**, whereas these same hormones inhibited development of female gametangia. Instead, **cytokinins** stimulated the development of female gametangia, slightly inhibiting development of gametangia in male clones. Studies such as these suggest that hormones could control sex expression either by genetic control or environmental control on gene expression. Furthermore, gaseous hormones such as **ethylene** or fungal exudates such as **gibberellin**, present in the environment, could influence sexual expression, differing between years and environments and causing the differences and changes in sexual expressions that have been observed in some species.

Figure 66. *Riccia cf. crystallina*, a species in which **gibberellin** and **ethrel** enhance antheridial formation, whereas **glycocol** enhances archegonial formation. Photo by Michael Lüth, with permission.

We cannot overlook the importance of hormonal interactions on development (see Chapter 5-1 of this volume, Ecophysiology of Development: Hormones). In their experiments with *Bryum argenteum* (Figure 7), Bhatla and Chopra (1981) showed that **IAA** and **cytokinin** could counteract each other's individual hormonal inhibitory effects on the female and male clones, respectively. **ABA**, known as a stress hormone, inhibited both sexual expression and vegetative growth in this species, with sexual induction in the female being more sensitive. In addition to interactions, concentrations are important in developmental control.

Plasticity vs Genetic Differentiation

Transplant experiments can be used to help us understand plasticity that permits environmentally induced changes vs genetic characters that may prevent living in some environments. Hassel *et al.* (2005b) used *Pogonatum dentatum* (Figure 67) transplants to demonstrate such plasticity. They found that vegetative growth was greater in the mountain areas than in lowland areas. Furthermore, reproductive investment was greater in

the lowland areas. But lowland plants tended to produce larger sporophytes than those from the mountain when grown in the same environment, suggesting a genetic difference between the two populations. What is interesting is that the transplanted shoots often outperformed the native ones by growing larger and producing larger sporophytes. They suggested that plasticity may have permitted the range expansion of *P. dentatum*.

Figure 67. *Pogonatum dentatum*. Photo by Michael Lüth, with permission.

Using reciprocal transplants, Hedderson and Longton (2008) likewise found both genetic variation and plasticity in life history traits in upland and lowland sites of several other **Polytrichaceae**: *Pogonatum aloides* (Figure 68–Figure 69), *Polytrichum commune* (Figure 31), and *P. juniperinum* (Figure 40, Figure 70). These differences were apparent in male reproductive effort and investment in vegetative shoots by females. Variation included tradeoffs between number and size of spores and between vegetative reproduction and spore production.

Is There an Asexual Role for Males?

Is it possible that male bryophytes may have more vegetative reproductive success while females have the primary sexual reproductive role? A sexually reproducing female bryophyte needs to nurture the developing sporophyte (see Chapter 3-4, Reproductive Trade-off). Reproductive output may be increased if the female individual is large, increasing fitness by permitting that female to occupy more space and obtain more light, and possibly more water and nutrients. But a male may be able to maintain the population, and enlarge it, through asexual means.

Figure 68. *Pogonatum aloides* males. Photo by David Holyoak, with permission.

Figure 70. *Polytrichum juniperinum* males showing old antheridial splash cups (arrows) with new growth and splash cups above that previous apex. Photo by Jan-Peter Frahm, with permission.

As discussed above (Genetic vs Expressed Sex Ratio), in *Marchantia inflexa* (Figure 9) the growth patterns of males and females differ, with the females in some habitats producing more meristematic tips, but the males producing more gemmae (Brzyski *et al.* 2013), giving the females more coverage in the immediate area and more chance for long-distance dispersal through spores, but giving males more opportunity to spread locally away from the immediate clump.

Among mosses in Great Britain about 18% (Longton 1992) to 29% (Hill *et al.* 1991, 1992, 1994) produce specialized vegetative propagules, and there are significantly more of these in dioicous mosses than in monoicous taxa (Longton 1992; During 2007). Among Belgian and Dutch liverworts, 69% of the dioicous species produce vegetative propagules, compared to 54% for monoicous taxa (During 2007). Such a strategy of asexual reproduction in males could be cost effective in dioicous taxa, permitting the females to put energy into producing spores while males could maintain the local population through asexual means (see *e.g.* Laaka-Lindberg *et al.*

2000). Even if both sexes produce vegetative propagules, this may be suppressed while sexual reproductive processes occur. In *Marchantia polymorpha* gemma cup (Figure 71) production ceases while it is producing sexual reproductive structures (Terui 1981).

Recently, Pereira *et al.* (2016) noted in Amazonian **Calymperaceae** that gemmae-bearing shoots produced fewer gametangia than shoots without gemmae, although both sexual and asexual reproduction were positively related to monthly precipitation amounts. Likewise, in his assessment of life cycle strategies, During (2007) concluded that there is a negative correlation between processes and structures (such as propagules and sexual structures) that serve the same functions in the life of the bryophyte.

Figure 71. *Marchantia polymorpha* with gemmae cups. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Stieha *et al.* (2014) confirmed that in *Marchantia inflexa* (Figure 9), male plants produce gemmae more quickly and prolifically than do females. Nevertheless, this is not necessarily an indication of a greater role for asexual reproduction in males. Once gemma cups are produced, male plants of this species increase production of gemmae to week 4 and stop at about week 9. Female plants, on the other hand, have stable production of gemmae during the first three weeks of cup existence, increasing sharply in week 4, then declining in subsequent weeks. On the other hand, male gemmae suffer greater desiccation effects, resulting in greater gemmae mortality than that of female plants. But once gemmae are dispersed (about 20 cm per minute in light rain), they have a high survival rate if they remain moist and are critical for maintaining both sexes.

Differential survival may account for the observed sex imbalance (see above in Germination Patterns and Spore Mortality; Environmental and Geographic Differences). And it appears this could diminish the role of males in asexual reproduction. Newton (1972) demonstrated the loss of young males from leaf regeneration in *Mnium hornum* (Figure 72) and *Plagiomnium undulatum* (Figure 73-Figure 74) where none of these survived desiccation, but 77% of the leaf regenerates from females did survive.

When Males Are Dominant

But we must remember that females are not always the dominant sex. In her 1972 study Newton showed that isolated spores of *Plagiomnium undulatum* (Figure 73-Figure 74) had a sex ratio of 4.1♀:1♂, changing little to 3.5♀:1♂ in the first protonemal buds, but in the same family *Mnium hornum* (Figure 72) had a ratio of 0.89♀:1♂, becoming more skewed in favor of males (0.45♀:1♂) in the first protonemal buds. Other examples exist of expressed male dominance in some populations within a species. This could be an advantage in species where differences in stress tolerance favor males. And

having more males increases the chances for some of the sperm reaching eggs.

Laaka-Lindberg (2005) found that only 8% of the females were sex-expressing whereas 17% of the males were sex expressing in the leafy liverwort *Lophozia ventricosa* var. *silvicola* (Figure 75), with a female to male sexual ratio of 0.61:1. Furthermore, the timing of gametangia production and conditions needed for development differed between the males and females. This timing in females varied among years, suggesting that the environmental signals differed between the sexes. Such timing differences could cause a mismatch between male and female maturation that could reduce fertilization.

Figure 75. *Lophozia ventricosa* from Europe. Photo by Michael Lüth, with permission.

Alvarenga Pereira *et al.* (2013) found a highly male-biased condition ($0.43 \text{ ♀} : 1 \text{ ♂}$ at ramet level, $n=604$) in the epiphyllous moss *Crossomitrium patrisiae* (Figure 76) in the Brazilian Atlantic rainforest. In this study of 797 ramets, a high rate of 76% were expressing sexual structures. This species had an extremely high rate of sporophyte production, with 40% of all female ramets, and 74% of female ramets occurring in mixed colonies bearing sporophytes. For this species, arriving and establishing on a new leaf, a short-lived habitat, is a necessity for the species to continue, and this is best achieved by spores that can more easily become airborne than many larger vegetative propagules. Low levels of abortion and high investment in sporophyte maturation provide this species with the dispersal units to survive in this ephemeral habitat.

Figure 76. *Crossomitrium patrisiae* habit in Costa Rica. Photo by Michaela Sonnleitner, with permission.

Also the aquatic liverwort *Scapania undulata* (Figure 77) exhibits a clearly male-skewed expressed sex ratio (Holá *et al.* 2014). The authors suggest that the high production of males is a strategy to overcome sperm dilution and ensure fertilization over longer distances in water.

Figure 77. *Scapania undulata* with capsules, a species with more males than females. Photo by Michael Lüth, with permission.

Maintaining Sexual Dimorphism in a Population

What factors might maintain the balance of males to females to retain the dioicous character in a bryophyte species? We have seen many cases of male suppression, some so strong that they could lead to male extinction in some populations, at least when we look at sex-expressing plants. Maintenance of both sexes is important for fitness and evolution. We find that the same factors that separate the environments of males and females might contribute to the continuation of both sexes. That is, some years and conditions may favor one sex, whereas other years and modified conditions may favor the other. For the slow-growing bryophytes, this slows competition between the sexes and prevents rapid extinctions.

Marchantia inflexa (Figure 9) demonstrates the complex way in which sexual expression might occur. In this as in many other bryophyte species, it is common for males to be rare. Single-sex populations, especially of females, are common (Garcia-Ramos *et al.* 2002). In the USA, only single-sex populations are known, but in tropical sites, populations with both sexes occur. Spread of both sexes by clonal growth and vegetative propagules is common. Garcia-Ramos and coworkers found that in *Marchantia inflexa* seasonal disturbances (desiccation) delay the elimination of males within the patch, whereas large scale disturbances permit re-establishment by spores. It is these large-scale disturbances that permit both sexes to coexist at a **metapopulation** level (*i.e.* group of partially isolated local populations of same species, but connected by migration). In this species, isolated clonal populations seem independent of sexual reproduction, but at the landscape scale, sexual reproduction is crucial for re-establishment by spores.

Fuselier and McLetchie (2002) explored the question of what maintains sexual dimorphism, using *Marchantia inflexa* (Figure 9) as a model system. They suggested that there is sex-specific selection, as already seen for *Syntrichia caninervis* (Figure 15) (Stark *et al.* 2005) and discussed above for this species (Environmental and Geographic Differences), causing one sex to be favored over the other under certain stressful conditions. When the habitats of the sexes do not overlap, the sex with the higher cost of sexual reproduction should experience higher mortality in the more stressful habitats (Lloyd & Webb 1977; Charnov 1982; Bierzychudek & Eckhart 1988; Fuselier & McLetchie 2002). Whereas habitat specialization can lead to difficulty in obtaining mating success, it leads to a wider habitat range for the species, albeit by separating males and females. In this case, the species must be maintained by asexual reproduction. Fuselier and McLetchie (2002) reasoned that such a strategy would favor males with a high degree of asexual reproduction, but females with a low asexual reproduction.

In *Marchantia chenopoda* (Figure 78), Moyá (1992) found that there was a large female bias, even when the population seemed to be relying on its abundant sporophytes. The **selective forces** acting on asexual vs sexual fitness can act in opposition and may help to explain the persistence of sexual dimorphism and the smaller number of males.

Figure 78. *Marchantia chenopoda* in Puerto Rico, a dioicous species. **Upper:** male population; **Lower:** female population. Photos by Janice Glime.

Sexual dimorphism may occur at the clump level while seemingly absent at the shoot level. Moore *et al.* (2014) found that when 25 male and 25 female shoots of *Bryum argenteum* were cultured, no differences in water-holding

capacity could be ascertained between the sexes. However, when 1 cm² samples were saturated with water and then centrifuged to remove external water, the female clumps retained more water per unit of clump area. The researchers suggested that this water retention ability could favor greater growth of females and contribute to a female bias in expressed sex ratio.

Season and Sex Expression

Those of us in the temperate and arctic climates expect bryophytes to be dormant in the winter and that many species will take advantage of rainy or melting periods in spring for fertilization. But not all species conform to those expectations (Arnell 1878, 1905). In the majority of species in temperate regions, phenology of fertilization and sporophyte formation are clearly seasonal, and differ among families and habitats.

Capsules take varying periods to mature, some taking more than a year, so those can be found almost year-round, albeit on different species (Milne 2001). In the tropics, a seasonal cold period is absent, but precipitation may cause seasonality. Maciel-Silva and Marques Vlio (2011) examined the effects of season on bryophyte sexual expression in Brazilian tropical rainforests. They found that many of the species exhibited sexual expression continuously over the 15-month study in both the sea level and montane sites.

Seasons did, however, affect the length of time required for gametangia to mature in the tropics (Maciel-Silva & Marques Vlio 2011). Male gametangia typically matured by the end of the dry season, providing sperm when the rains were present, presumably facilitating their dispersal during the following rainy season. Female gametangia, on the other hand, were receptive over the entire period, even having many mature before the start of the rainy season. This strategy would assure that females were ready at any time the rains came, allowing for year-to-year differences. It is interesting that the male gametangia took longer to develop and that many aborted. This scheme also maximizes the dispersal of spores, permitting them to mature near the end of the dry season when conditions are best for dispersal; rains will soon follow to induce germination.

If seasons are indeed important, then there should be differences between sea level and montane reproductive cycles at the same latitude, in this case the Brazilian Atlantic rainforest. Maciel-Silva *et al.* (2012) found that species at sea level produced more sexual branches and had a more strongly female-biased sex ratio than did the montane populations. There were more frequent fertilizations among the montane populations, but ultimately, the number of successful sporophytes was about the same at the two elevations. Fertilization occurred mostly during the rainy season of October to December. Moreover, monoicous species exhibited a higher reproductive performance in terms of number of sexual branches, fertilization, and sporophyte formation. The authors concluded that both the breeding system and the

environment influenced the sexual expression and mating strategies.

But even when sex is expressed in plants within proximal distance suitable for fertilization, that sporophyte production might not occur (Bisang & Hedenäs 2008). This is the case in *Pseudocalliergon trifarium*, based on transplantation experiments. Even when the archegonium was present, it was never swollen, and no sporophytes became evident. Instead, the archegonia withered. Although *Rhytidiadelphus triquetrus* had sporophytes in 100% of the transplant plots that made both sexes available, *Abietinella abietina* produced them in only 41% of the plots, and *Pseudocalliergon trifarium* in none! Although we can postulate potential causes for the lack of sporophyte development, we lack the kind of evidence needed to support such hypotheses.

Role of Asexual Reproduction in Dioicy

By now it should be clear that dioicous bryophytes suffer from lack of sexual reproduction in many populations. On the other hand, asexual reproduction can maintain the population and help it spread. But is specialized asexual reproduction more common among dioicous taxa?

It appears that among British mosses, asexual propagules are common among dioicous colonists (Longton 1992), but this relationship does not exist among the liverworts (Longton 1997). Rather, among the British liverworts the production of asexual propagules is not related to sexuality (monoicous vs dioicous).

In examining the Japanese flora, Une (1986) found support for the concept of vegetative success in the relationships of specialized vegetative reproduction. Of the 111 moss taxa that produced **asexual diaspores** (any structures that become detached and are dispersed) (Figure 79), 86 were dioicous (77.5%), whereas only 11 (9.9%) were monoicous. A further phenomenon in this story is the presence of more asexual propagules in the erect-growing dioicous mosses than in the prostrate (creeping) taxa. Could it be that these rarely sporulating but upright taxa take advantage of vegetative propagules to facilitate movement "in search" of the opposite sex?

Figure 79. *Calymperes erosum* with gemmae on the leaf tip. Photo by Li Zhang, with permission.

Similarly, During (2007) was able to show that among bryophytes in Belgium and The Netherlands, dioicous taxa more commonly had vegetative propagules than did monoicous ones. But among the mosses, this relationship only held true for acrocarpous species; the pleurocarpous taxa were able to achieve significant expansion by clonal growth, thus negating much of the advantage of vegetative propagules. During suggested that the tradeoff between propagules and vegetative growth seen in the liverwort *Marchantia inflexa* (Figure 80) might be a common phenomenon among bryophytes. He found that negative correlations generally occur between processes and structures that serve the same functions in the life of the bryophyte, suggesting that vegetative diaspores and sexual organs compete for the same energy reserves. A more detailed discussion of asexual reproduction follows.

Gemma-bearing Dioicous Taxa

We have previously mentioned (Chapter 3-1, Or the Dioicous Advantage?) the importance of asexual propagules in dioicous taxa. To the examples cited above, we can add that of 715 species of mosses examined in eastern North America, 13% have some obvious means of specialized asexual reproduction (Crum 2001). Of these, 76% are dioicous, 19% monoicous, 5% of unknown sexuality. Old data from Germany (Correns 1899) indicated that of 915 species, 12% had true gemmae, with 86% of these dioicous and 14% monoicous.

Longton (1992) indicated that producing asexual propagules in many dioicous moss taxa provided them with a safety net, permitting reproduction under conditions when sexual reproduction was not possible. Such a strategy permitted them to survive in marginal habitats and in years when the weather was unfavorable to fertilization due to drought or frost (Longton 1990). Furthermore, it appeared that a greater number of rare taxa relied on asexual reproduction – not surprising due to the greater ease of dispersal of spores (Schuster 1988; Miles & Longton 1990; Söderström & Herben 1997; Bolker & Pacala 1999).

Figure 80. *Marchantia inflexa*. Photo by Scott Zona, through Wikimedia Commons.

The moss genus *Aulacomnium* is known for special brood bodies (Figure 81-Figure 82). In most species, these are comprised of reduced and thickened leaves in a cluster on stalks at the tips of plants (Figure 81-Figure 82). However, in *Aulacomnium heterostichum* (Figure 83), sporophytes are common and these brood bodies were overlooked until 1991 when Imura *et al.* reported them from Japan. In this species, brood bodies are on a terminal stalk, but the individual propagules are not thickened as in other *Aulacomnium* species and only slightly modified from the leaves (Figure 84). It is likely that brood bodies have been overlooked in other bryophyte taxa as well, particularly rhizoidal tubers and protonemal gemmae.

Protonemal gemmae predominate among the **Pottiaceae**, even when the plants are expressing gametangia. *Dicranella heteromalla* produces chloronemal gemmae with well defined tetra cells (Duckett & Matcham 1995). The tiny *Ephemeropsis* produces protonemal gemmae on its leaf substrate (Pressel & Duckett 2009). Duckett *et al.* (2004) found propagules on protonemata in species where they were previously unknown, including *Ditrichum cornubicum*, *Saelania glaucescens*, *Seligeria carniolica*, and *Zygodon gracilis*. And the aquatic moss *Fontinalis antipyretica* produces protonemal gemmae (Ares *et al.* 2014).

Spores, Asexual Propagula, and Rarity

There seems to be a distinct correlation between spore size and asexual propagules, with plants having small spores being more likely to have propagula (Longton & Schuster 1983; During 2007). If having small spores means having more of them, such a species would seem to have the best of all worlds, with a good chance for long-distance dispersal through spores, and colony expansion through readily sprouting propagula. Its price would be in lower viability of small spores compared to large ones.

The possibility to self-fertilize would suggest that sexual reproduction should be more frequent in the monoicous condition, with the possibility of cross fertilization with sister plants in the same clone, if not on the same plant. Longton (1997, 1998) agrees. He predicts that at least among the colonists, fugitives, and annual shuttle species (all inhabiting newly available substrata; Figure 47), the trend toward monoicy will be accompanied by an increased reproductive effort, decrease in life span, and decrease in the age of first reproduction. To facilitate such a strategy, he predicts that the life cycle will have substantial **phenological** (timing of events) flexibility and that the success of establishment from spores will increase. He suggests that the specialized asexual propagules that are common among dioicous colonists compensate for their more limited sexual reproduction.

To sum up what we know now, it appears that species that rarely produce capsules are more likely themselves to be rare (Miles & Longton 1990; Söderström 1992; Laaka-Lindberg 2000). Monoicous species produce capsules much more frequently than do dioicous species, with the

distance between archegonia and antheridia being a limiting factor (Longton & Schuster 1983; Wyatt & Anderson 1984; Longton 1990; Laaka-Lindberg 2000; Bisang *et al.* 2004). Even monoicous species may become rarer in severe habitats where weather conditions may prevent even short-range dispersal of sperm to egg (Laaka-Lindberg 2000). Asexual propagules are more common among dioicous moss species. (See Chapter 4-7, Adaptive Strategies: Vegetative vs Sexual Diaspores, for more information on asexual vs sexual reproduction.)

Why Are Liverworts Different?

Laaka-Lindberg (2000) found that the relationship between rarity and presence of asexual vs sexual strategy differs markedly between British mosses (Longton 1992) and liverworts. Whereas only 18% of the mosses produce asexual propagules, 46% of the liverworts do (Longton 1992), a group that is 68% dioicous (Villarreal & Renner 2013). And, unlike the mosses, production of asexual propagules in liverworts is not linked to the dioicous condition, but is nearly equal to that in the monoicous condition. The researchers warn us, however, that the ephemeral nature of liverwort sporophytes could create a bias in herbarium data since liverworts are more likely to be collected in sterile condition than are non-sporophytic mosses with persistent capsules elsewhere in the population. This could also increase the collected representation of propaguliferous plants among liverworts compared to mosses. There also seems to be less evidence of fragmentation success in leafy liverworts (see, for example, Miller & Howe Ambrose 1976).

Nevertheless, the long-identified association between dioicy and the ability to produce vegetative propagules in mosses in different regions and at different scales has recently also been challenged by Laenen *et al.* (2015). The authors applied comparative phylogenetic methods with 303 out of 382 liverwort genera currently recognized globally. They were unable to find a correlation between dioicy and the formation of vegetative propagules. They did not compare 'rarity' with reproductive system, but used size of geographic ranges. Interestingly, the production of vegetative propagules was positively correlated with range size, but sexual system and spore size were not. This suggests that asexual reproduction may play a more important role than hitherto thought in long-range dispersal of liverworts, and calls for further investigation of the spatial genetic structure of bryophyte populations in relation to their mating systems.

Laaka-Lindberg *et al.* (2000) concluded that those British liverwort taxa that produce neither spores nor vegetative propagules tend to be rare (Figure 85). Rarity of capsule production does correlate with rarity of the species, with those failing to produce spores being three times as likely to be rare. Monoicous taxa have a higher proportion with sporophytes than do dioicous taxa, but among those species of both mating systems that do produce capsules, there is greater rarity among the monoicous taxa. This suggests that there is a fitness price for selfing or sibling crosses due to suppression of genetic variation that would be available through outcrossing. Data are needed to support this hypothesis.

The production of asexual propagules is not related to rarity in British liverworts, with propagules occurring as often in common species as in rare ones (Laaka-Lindberg *et al.* 2000). It is interesting that whereas there are few liverwort taxa in which sporophytes are unknown anywhere (Figure 85), there are many taxa in which vegetative propagules are unknown (Figure 86), and the frequency of those lacking such propagules is twice as great among dioicous liverworts as among monoicous liverworts, although the proportion is about the same in both (Figure 86) (Laaka-Lindberg *et al.* 2000). Spores are more likely to provide long-range dispersal, but among seeds Thompson *et al.* (1999) concluded that the best predictor of range among British plants was diversity of habitats used. It is likely that this is true for bryophytes as well.

Could it be that liverworts, rather than using specialized asexual means as a safety net, more frequently are opportunistic, having occasional sexual reproduction, but gaining the advantages of both means of reproduction (Green & Noakes 1995; McLellan *et al.* 1997)? Their horizontal growth habit, producing ramets, permits them to expand on their substrate without having to reproduce. Asexual reproduction, including ramification, is suggested to require less energy, particularly on the part of females, and therefore may be useful under stressful conditions (Longton & Schuster 1983; Newton & Mishler 1994). This concept is supported by greater occurrence of species with asexual propagation in arctic and alpine areas than in the tropics (Schuster 1988). In stable environments, maintenance will permit survival of the population, but in habitats subject to frequent disturbance, dispersal of progeny is essential (Schuster 1988; Söderström 1994) and may even depend on delay through dormancy (McPeck & Kalisz 1998).

Figure 86. Comparison of frequencies (six classes, rare and very rare combined) of asexual reproductive structures for liverworts in four sexuality groups within Britain. Modified from Laaka-Lindberg *et al.* 2000.

Are Epiphytes a Special Case?

For epiphytic species such as the presumed dioicous *Orthotrichum lyellii* (Figure 87), the same tree needs to be colonized by both sexes to facilitate sexual reproduction. Norris (see Sex Reversal above) finds that colonies frequently have both sexes. Fortunately, sperm can be washed downward considerable distances by rainfall, facilitating fertilization. The presence of numerous gemmae permits this species to spread vegetatively and the gemmae may help it to become established on its vertical substrate, increasing chances for both sexes to survive. But this begs the point Norris tried to make about sexual expression (see Sex Reversal above). We need to be cautious about generalizations and look closely for variability due to age relationships, habitat expressions, or hidden connections.

Figure 87. *Orthotrichum lyellii*, an epiphytic dioicous species. Note brown gemmae on leaves. Photo by Michael Lüth, with permission.

Smith (1982) reported that the proportion of monoicous taxa among those restricted to bark greatly exceeds that among mosses in general. Devos and coworkers (2011) found that the mostly epiphytic liverwort

genus *Radula* (Figure 88) exhibits evidence of shifts from dioicy to monoicy multiple times as new species arose, with some epiphytes having facultative shifts. It is interesting that they found no correlation between asexual gemmae and either dioicy or strict epiphytism in *Radula*. Rather, the obligate epiphytes tend to disperse by whole gametophyte fragments, avoiding the protonemal stage that is more susceptible to the ravages of rapid changes in moisture. The former is in line with findings of Laaka-Lindberg (2000) for British liverworts and by Laenen *et al.* (2015) for liverworts at the global scale (see above, "Why Are Liverworts Different?").

Figure 88. *Radula complanata* growing epiphytically and exhibiting gemmae. Photo by J. C. Schou, with permission.

As a result of their dispersal by fragments and often the absence of successful sexual reproduction, many epiphytes may have a special problem in maintaining the species due to lack of genetic variability. Because of the limited success of establishment on the vertical substrate of tree trunks and vertical rocks, these substrates often have only one clone and therefore only one sex in dioicous taxa. Hence, in the frequent absence of sexual reproduction, reproduction is accomplished by clonality or possibly selfing or among siblings. This may result in a lack of genetic diversity, as exemplified by *Leucodon sciurioides* (Figure 89) in Europe (Cronberg 2000). Glaciated areas had lower genetic diversity, as might be predicted for an area of lower age. Furthermore, the unglaciated populations from the Mediterranean region reproduce sexually, whereas the younger and more isolated populations from glaciated areas reproduce asexually, leading further to lack of genetic variability. This lack of variability may contribute to the disappearance of epiphytic populations under stress of air pollution and climate change.

Summary

Many species exhibit a strongly female-biased phenotypically expressed sex ratio that likewise is in some cases genetic and in others possibly due to varying responses of sex expression to environmental conditions. The "shy male" hypothesis lacks support in explaining most of this female bias. Examples of distinct male bias in expressed sex ratios also exist. Sex ratios based on genetic information on non-expressing plants is known for a very limited number of species.

Some species, perhaps more than we realize, have sexual plasticity. That is, they have different sex expressions in different years, possibly dependent on age or available energy resources. This can be due to hormonal expressions of the same or neighboring plants.

When sexual reproduction fails, asexual reproduction by specialized propagules can compensate, and this is especially true for dioicous mosses at the same scales. In addition, clonal growth and fragmentation can help the species spread. Because of the energy cost of producing sporophytes, males may exhibit higher vegetative performance. A modelling study suggests that disturbance level (weather, pollution, fire, etc) affects sexes differentially, hence maintaining both sexes in the long term. Epiphytes are frequently isolated on a tree with only one sex present. Although there seems to be no correlation between epiphytism and asexual propagules, there is a greater proportion of monoicous taxa among epiphytes than in general.

Acknowledgments

We greatly appreciate the numerous comments and suggestions of Lars Hedenäs who provided a critical review of an earlier draft of this chapter and gave us encouragement. Heinjo During asked probing questions, challenged me (Glime) to do more, and provided me with

references to do it. Linley Jesson provided us with unpublished data that helped demonstrate the transsexual possibilities for a bryophyte. Nicholas McLetchie and Llo Stark provided us with valuable references regarding effects on sex ratio. Catherine La Farge pointed me to Deguchi's publication. Bryonetters have been especially helpful in providing examples and observations to answer questions arising during the preparation of this chapter. As always, many people have contributed images, as noted in the captions.

CHAPTER 3-3

SEXUALITY: SIZE AND SEX DIFFERENCES

Figure 1. *Plagiommium* producing male splash cups as it grows amid *Thuidium delicatulum*. Photo by Janice Glime.

Sex-related Differences in Gametophores

For most bryophytes, secondary sexual characteristics are subtle and are noticed only by the most observant. Fuselier and Stark (2004) consider size, morphology, physiology, reproductive investment, and stress response all to be expressed among sexual differences in bryophytes. Une (1985 a, b) with the moss *Macromitrium* and Fuselier and McLetchie (2004) with the thallose liverwort *Marchantia inflexa* (Figure 3) have shown that males and females of the sex-expressing individuals of these species can respond differently to stress. Even at the spore stage, size and morphology are traditional characteristics used to determine **anisospory** (two spore sizes) and **anisogamy** (size, shape, or behavioral differences in gametes) in bryophytes as well as in algae. For bryophyte gametophytes, reproductive investment has been shown to

differ between antheridia and archegonia in some species (e.g. Stark *et al.* 2000; Horsley *et al.* 2011), but not in others (Bisang *et al.* 2006).

Shaw and Gaughan (1993) noted non-reproductive differences between the sexes in the moss *Ceratodon purpureus* (Figure 2). Among 160 single-spore isolates representing 40 sporophytes from one population, female gametophytes outnumbered males by a ratio of 3:2 at the time of germination. The resulting female gametophytic clones formed significantly more biomass, and individual female shoots were more robust than in male clones. On the other hand, male clones produced more numerous stems. Shaw and Gaughan suggest that this strategy may permit the females to provide more nutritional support for the sporophytic generation.

Figure 2. *Ceratodon purpureus* with young sporophytes. Photo by Jiří Kameníček, with permission.

Even in *Ceratodon purpureus* (Figure 2) that lacks **dwarf males** (see below under Dwarf Males) and where sex is chromosomally determined, sexes differ in size and in maturation rate, a character that Shaw and Beer (1999) suggest may prove to be widespread among bryophytes.

Even factors related to photosynthesis can differ between sexes. In their study Groen *et al.* (2010) found that females of *Marchantia inflexa* (Figure 3) had higher chlorophyll *a:b* ratios. And in the same study they found that females had a negative relationship between thallus thickness and gross photosynthesis whereas males did not, but they were unable to explain that negative relationship. Finally, differences between sexes in physiological traits may also occur at the clump level, as recently demonstrated in *Bryum argenteum* (Moore *et al.* 2016). Female clumps held more water and included more robust shoots than male clumps.

Figure 3. *Marchantia inflexa*, a species in which photosynthetic factors differ between males and females. Photo by Scott Zona, with permission.

Size and Sex Differences

"Why is the world full of large females?" (Lewin 1988). Particularly among insects, fish, amphibians, and reptiles, females are larger than males (Lewin 1988). Darwin explained this as the need of the species to produce a large number of eggs, a concept known as the fecundity-advantage model. Shine (1988) feels the concept is flawed in that evolution should maximize lifetime reproductive

success, not instantaneous reproductive success. He suggests that the fecundity-advantage model implies one large reproductive effort late in life, thus subjecting the female to great energy costs, and would only be of benefit when energy resources are non-limiting. With that in mind, it is interesting that mammals that must carry their young within do not generally have larger females than males. It is also the case in seed plants that are dioecious; only the female must bear the fruits. Yet it is not typical among seed plants for the female plant to be larger.

Bryophytes present an interesting contrast here. No other group of plants or algae is characterized by the need for the gametophyte to persist through the entire development of the sporophyte (there are individual exceptions, such as the fern *Botrychium*). In bryophytes, the female must supply the energy to support the developing sporophyte. Indeed, some bryophytes do have larger females than males [e.g. the liverworts *Cryptothallus* (Figure 4), *Pallavicinia* (Figure 5), *Pellia* (Figure 6-Figure 8), *Riccia* (Figure 9), and *Sphaerocarpos* (Figure 10)]. There are also a number of mosses with **dwarf males** [male plants that are considerably reduced in size relative to female plants, usually occurring on leaves (Figure 14) or in the tomentum of female plants, e.g. *Micromitrium* (Figure 11)] – about 60 genera already identified by Fleischer (1900-23, 1920). Females smaller than males are rare, with the non-sexual part of *Diphyscium foliosum* (Figure 12) being a notable exception.

Dwarf Males

Dwarf males are a notable exception to the observation that there is little, if any, size difference between males and females among most bryophytes. Even early publications on bryophytes recognized examples of sharp size distinctions (Bruch *et al.* 1851-1855; Limpricht 1895-1904; Fleischer 1920). Dwarf males occur in approximately 60 genera and 22 families (Rosengren & Cronberg 2015); estimations suggest that they occur in 10-20% of all moss species (Hedenäs *et al.* 2011). Where spores germinate on the leaves (**phylloidioicy**; Figure 13-Figure 18) or other parts of the female, some species produce **dwarf males (nannandrous males)** whose primary function is to produce sperm (Crum 1976). This production of dwarf males is unique to bryophytes among land plants [but is present in some species of the green alga *Oedogonium* (Figure 19) in Oedogoniaceae (Maier & Müller 1986)].

Figure 13. *Ptychomnion aciculare*, a species that produces dwarf males. Photo by David Tng, with permission.

Although dwarf males have been known for many decades in some genera, their widespread occurrence among many more genera has been overlooked (Hedenäs & Bisang 2011). This is especially true for facultative dwarf males. Hedenäs and Bisang (2011, 2012) estimate that 25-44% of the dioicous pleurocarpous moss species exhibit dwarf males, with about 75% of these producing them **facultatively**, *i.e.*, the species has the ability to form both normal-sized and dwarf males. The underlying mechanisms (discussed below under How Do Facultative Males Develop) are currently unresolved in most cases, although at least some seem to produce normal males on a non-moss substrate and dwarf males on a moss substrate. Nearly 60% of the 1737 species in the total data set investigated by Hedenäs and Bisang are dioicous. Of the 178 species reported to produce dwarf males, 113 are considered to form obligate dwarf males. When they examined in detail a subset of 162 species, 72 produced observable dwarf males, but only 18 of these had obligate dwarf males. Hedenäs and Bisang (2011) reason that these dwarf males are likely to be overlooked when counting male presence.

This **phyllodioicous** strategy has been repeated in at least 27 separate families of mosses (Fuselier & Stark 2004), including both acrocarpous (Schellenberg 1920; Ramsay 1979; Yamaguchi 1993; Une & Yamaguchi 2001; Hedenäs & Bisang 2004) and pleurocarpous species (Une 1985a; Goffinet 1993; Hedenäs & Bisang 2011). Hedenäs and Bisang (2011) found dwarf males in 22 pleurocarpous families.

Even when we find dwarf males, we can't be certain of the sex unless they have gametangia. For example, Fleischer (1900-23) suggested a strategy for *Trismegistia brauniana*, wherein spores that germinate on leaves of normal females all develop into dwarfs – both male and female. But these were non-expressing dwarfs, so there was no way for Fleischer to determine if there were really females (Lars Hedenäs, pers. comm. 4 April 2013).

The dwarf male strategy may increase fitness for the species by saving space and conserving resources. A sexually reproducing female bryophyte needs to nurture the developing sporophyte. Fitness of the reproductive output may be increased if the female individual is large, permitting that female to occupy more space and obtain more light, and possibly more water and nutrients. Males,

on the other hand, need only produce sperm and do not sacrifice nutrients and energy to a developing embryo.

Vollrath (1998) referred to the condition of dwarf males associated with females as being short of true parasitism. Although the females provide a kind of room and board for the males, the males provide sperm to the females. But we are unaware of any evidence that the females provide nutrition. Rather, they provide a safe habitat that offers protection from desiccation and a short route to the egg.

Revisiting the Sex Ratio

Realization that 10-20% of the pleurocarpous moss species worldwide produce functional dwarf males requires re-examination of our data on sex ratios (Hedenäs & Bisang 2011) (discussed in Chapter 3-2). Using herbarium specimens of five Macaronesian species as models, Hedenäs and Bisang (2012) examined the effect of adding these newly recognized dwarf males to the calculation of sex ratio. If dwarf males were not counted, male availability was reduced by 51-61%, with that reduction increasing to 74-76% for sporophyte-producing plants. As one might expect, presence of sporophytes was positively correlated with presence of dwarf males. Hence, in those species with dwarf males, the sex ratio at the specimen level was balanced if dwarf males were counted, but strongly female biased if they were not.

Dwarf males in *Homalothecium lutescens*

Rosengren and co-workers (2014) examined the nanandrous sexual system in the pleurocarpous moss *Homalothecium lutescens* (Figure 20) in grassland habitats in southern Sweden and on the Baltic island Öland. These detailed studies, covering both ecological and genetic aspects, greatly advanced our knowledge on the conditions for and consequences of male dwarfism in mosses. *Homalothecium lutescens* has facultative dwarf males, but large males are extremely rare in this species (Wallace 1970; Rosengren *et al.* 2014 and references therein). In one of the study sites, dwarf males were almost exclusively found on sporophytic shoots (Rosengren *et al.* 2014). Investigating 90 colonies from three localities, Rosengren and Cronberg (2014) found that dwarf male density was positively related to colony moisture (two localities).

Figure 20. *Homalothecium lutescens*, a species with facultative dwarf males. Photo by Michael Lüth, with permission.

In addition, fertilization frequency was positively affected by dwarf male density, but also by canopy cover in one locality (Rosengren & Cronberg 2014). Their findings suggest that nannandry reduces the problem of short fertilization distances in bryophytes, but that the presence of water is still critical. In terms of genetic affinity, dwarf males are most closely related to their host shoot, then to neighbors within their colony of 0.5m², and finally, to plants in the remaining population (Figure 21) (Rosengren *et al.* 2015). This means that spores giving rise to the dwarf males are at most commonly produced by the mother shoot or by a shoot in the close vicinity. Occasionally, however, dwarf males seemed even to originate from outside the host population, *i.e.* from another of the four study populations within a radius of 60 m². The researchers conclude that although dwarf males have in general local origin, sporadic dispersal to greater distances happens. These events contribute to the gene flow across populations and to the accumulation of genetic diversity within a population. Overall, the levels of genetic diversity were comparable between dwarf males and females within each population (Rosengren *et al.* 2015).

Figure 21. Inbreeding vs outcrossing in *Homalothecium lutescens* from four populations in Sweden. Each box represents the lower and upper quartile of 4-6 sporophytes on a single female shoot. The thick horizontal lines within boxes represent the median and whiskers denote the total range of data (minimum and maximum values outside the quartiles). Horizontal lines across each population section represent the mean H_{exp} (mean expected sporophyte heterozygosity over all loci, based on male and female allele frequencies). Sporophytes falling below that line could be considered inbred, with a few exceptions. Numbers below the y=0 line represent the number of sporophytes on the shoot that are homozygous in all loci, *i.e.* probably self-fertilized or inbred. Modified from Rosengren *et al.* 2016.

Rosengren *et al.* (2016) also genotyped sporophytes, female host shoots, and dwarf male plants in these populations. The high proportion of entirely homozygous sporophytes confirms frequent mother-son mating. Nevertheless, 23% of sporophytes exhibited a higher heterozygosity level than the expected population mean, which gives evidence of occasional fertilizations by non-host males (Figure 21). Further, almost 60% of the sporophytes were sired by distinct fathers (Rosengren *et al.* 2016). The extent of **polyandry** (multiple male parents) in bryophytes is poorly understood, but Szövényi *et al.* (2009)

also reported prevalent multiple paternity (polyandry) among sporophytes in *Sphagnum lescurii* (Figure 22).

Figure 22. *Sphagnum lescurii*, a species that has multiple paternity of its sporophytes. Photo by Bob Klips, with permission.

In an *in vitro* experimental approach by sowing spores from three species [*Homalothecium lutescens* (Figure 20), *H. sericeum* (Figure 23), *Isoetium alopecuroides* (Figure 16-Figure 17) on shoots of *H. lutescens*, Rosengren and Cronberg (2015) noted distinct differences in germinability of the sown spores among the three species (Figure 24). While no dwarf males were formed from spores of the distantly related *I. alopecuroides*, both *H. lutescens* and *H. sericeum* spores developed into dwarf males (Figure 25). The latter points to a possible pathway for hybridization between the two species (Rosengren & Cronberg 2015).

Figure 25. Number of fertile dwarf male-expressing plants of *Homalothecium lutescens* and *H. sericeum* that germinated from spores placed on *Homalothecium lutescens*. Redrawn from Rosengren & Cronberg 2015.

What Is the Role of Vegetative Propagules?

As noted above, some species of the alga *Oedogonium* (Figure 19) (Chlorophyta) have a similar dimorphism in the size of the filaments, whereupon a male spore produces a dwarf male when it germinates upon a female (Rawitscher-Kunkel & Machlis 1962). However, if a male spore develops away from a female, it will grow into a larger filament and produce asexual spores that again have the opportunity to locate a female and form a dwarf male, a possible strategy that has apparently received no consideration among bryophytes.

I (Glime) became curious as to a similar relationship between vegetative propagules (since asexual spores do not

exist in bryophytes) and facultative dwarf males in bryophytes. That is, do vegetative propagules develop into normal-sized male plants when establishing on "ordinary" substrate away from a female, but form minute males on a female individual, as has been observed for spores in some species (see below). Would the non-dwarfed males then produce vegetative propagules that might develop dwarf males if they were to land on a female? Bryonettors brought me several examples, predominantly in the genus *Dicranoloma* (Figure 26-Figure 27). But species bearing both dwarf males and gemmae in Asia and Australia [*D. bartramianum*, *D. dicarpum* (Figure 26), *D. platycaulon*, *D. leichhardtii* (Figure 27)] do not produce gemmae in New Zealand (Milne 2000; Pina Milne and Allan Fife, pers. comm. 9 January 2014). In southeastern Asia, Malaysia, and Oceania, *D. braunii* has the most frequent and conspicuous gemmae and produces dwarf males (Niels Klazenga, pers. comm. 8 January 2014). But this still begs the question, do gemmae that land on females produce dwarf males, and do those that land on soil continue to produce gemmae-producing non-sex-expressing plants?

Figure 26. *Dicranoloma dicarpum*, a moss with both dwarf males and gemmae. Photo by Tom Thekathiyil, with permission.

Figure 27. *Dicranoloma leichhardtii*, a moss with both dwarf males and gemmae. Photo by Niels Klazenga, with permission.

Several other examples exist. *Platygyrium repens* (Figure 28) produces brood branches and sometimes produces facultative dwarf males (Lars Hedenäs, pers. comm. 8 January 2014). Many species of *Garovaglia* (*Ptychomniaceae*) have both dwarf males and produce filamentous gemmae, with *G. elegans* (Figure 29)

producing gemmae rather frequently (Neil Bell, Bryonet 8 January 2014). But despite these examples, Pedersen and Newton (2007) found no correlation between the evolution of dwarf males and the filamentous gemmae in the order **Ptychomniales**.

Figure 28. *Platygryium repens* with bulbils clustered at the branch tips. Photo by Dick Haaksma, with permission.

The problem with trying to interpret these observations is that if a non-expressing individual has propagules, we have been unable to tell if it is a male or a female. Hence, it is difficult to assess the importance of vegetative propagation in males that developed away from a female. Do bryophyte male propagules in any species behave as do nannandrous species of *Oedogonium*, reproducing asexually until they land on a female? Do the gemmae of asexual (sterile) male plants of some species develop into dwarf males if they land on a female substrate? Fortunately, we now have genetic means to identify sex of non-sex-expressing plants using DNA markers. As markers become available in more species, we may be able to answer these questions more easily.

Figure 29. *Garovaglia elegans* with capsules. Photo by Li Zhang, with permission.

For my *Oedogonium* comparison to work for bryophytes, we need evidence that asexual propagules, e.g. gemmae or bulbils, produced by male plants, are able to germinate on females and produce dwarf males. Tamás

Pócs (pers. comm. 14 January 2014) kindly pointed me to his publication (Pócs 1980) on the liverwort *Cololejeunea borhidiana* (Figure 30) as a new species. He illustrates a dwarf male, complete with antheridia, developing from a gemma from this species (Figure 30), a much smaller version than a male that develops into a normal-sized plant (Figure 31). This is the only evidence that dwarf males exist among liverworts, and is the only evidence we know of a dwarf male developing from an asexual propagule. The complete story for this species is not known and we have no evidence that the spores ever form dwarf males. However, it suggests the possibility that an asexual strategy for males that fail to land on a female might exist among some bryophytes. *Cololejeunea borhidiana* is **epiphyllous** (growing on leaves of other plants), and the ability to produce vegetative plants until a gemma reaches a female to induce formation of a dwarf male could be very advantageous for a species that occupies a somewhat short-lived substrate that is difficult to reach and colonize. But was it a female that stimulated this gemma to become a dwarf male, or was it the current environmental conditions? And is this an isolated occurrence, with dwarf males otherwise unknown in liverworts? Knowledge of gemmae of any bryophyte developing into dwarf males seems to be otherwise lacking, so we cannot measure its importance among the bryophytes. In the case of *Cololejeunea borhidiana*, we don't know if the gemma came from a male or a female plant. If the nannandrous *Oedogonium* strategy does exist among some bryophytes, it presents an interesting adaptation that could be quite beneficial in difficult habitats.

How Do Facultative Males Develop?

Dicranum has a well-established record of dwarf males. Based on a literature review, Pichonet and Gradstein (2012) estimate that such dwarf males occur in about 20% of the *Dicranum* species, with most species being obligately nanandrous. However, in at least two species, *D. bonjeanii* (Figure 32) and *D. scoparium* (Figure 38), both normal-sized and dwarfed males occur. In this genus, the environment seems important to control male plant size.

Figure 32. *Dicranum bonjeanii* showing the dense tomentum that provides a habitat for dwarf males. Photo from Frullania Data Portal, through Creative Commons.

One must ask how a spore can become a full-sized male on soil or other substrate, but when it lands on a female of its own species, it develops into a dwarf. This facultative behavior may support the suggestion of Loveland (1956) that the dwarfism on leaves of the same species was the result of some chemical interaction with the substrate leaf. For example, in *Trachybryum megaptilum* (Figure 33) normal-sized males never have dwarf males on them (Wallace 1970), suggesting that the female has some sort of chemical, most likely hormonal, control over expression of the dwarf male – or could it be that the male plant prohibits germination of the male spore.

Figure 33. *Trachybryum megaptilum*, a moss that may have several hundred dwarf males growing on the female. Photo by Martin Hutten, with permission.

Hormones – Hormonal suppression seems to account for the development of males in a number of taxa (Loveland 1956; Wallace 1969, 1970). In fact, some species prevent growth of males among females, but those spores fortunate enough to germinate away from a female become males (Crum 2001). This would seem to be maladaptive for purposes of fertilization but reduces competition for resources between the sexes.

In the moss genus *Dicranum* (Loveland 1956), *D. drummondii* (Figure 34), *D. sabuletorum* (Figure 35), *D. polysetum* (Figure 36-Figure 37), and *D. scoparium* (Figure 38) (Preston & Mishler 1997) and in other dimorphic bryophyte species, spores cultured on agar produce normal-sized males, suggesting hormonal control of plant size that is determined by the female. Briggs (1965) provides further evidence in this genus, with those species that have a variety of sizes of males only producing dwarf males in culture when they are grown near females.

Figure 37. *Dicranum polysetum* dwarf males on the tomentum of a female. Photo courtesy of Lars Hedenäs.

In *Leucobryum*, *L. glaucum* (Figure 39) and *L. juniperoideum* (Figure 40) males can be dwarf to full size (Blackstock 1987). Dwarf males form on the tomentum of *L. boweringii* and *L. juniperoideum* (Figure 40), but normal males also form on non-*Leucobryum* substrates (Une & Yamaguchi 2001). Furthermore, Une and Yamaguchi

found that dwarf *Leucobryum* males removed from the female and grown on a different substrate grew into tall male plants. Suggesting physiological differences between the sexes, males of these *Leucobryum* species, particularly normal males, are restricted to lower altitudes and latitudes in Japan, but females are not. This is also the case in some *Macromitrium* species (Figure 41) (Ramsay 1979; Une 1985c).

There seem to be a number of possible hypotheses to explain ways that hormones from the female could influence the sizes of males.

1. The spore must land and probably germinate before the female produces the "hormone" that determines the size, with the spore or germling serving as a stimulant. Hence, the "hormone" would act on the protonema. This would be like a response to a fungus or herbivory that stimulates production of a secondary compound in seed plants and similar to the response of the alga *Oedogonium* that produces its oogonium after the spore lands on the filament (Rawitscher-Kunkel & Machlis 1962).
2. The "hormone" from the female is highly volatile and thus only works when the spore/protonema/young plant is in direct contact with the plant that provides it. Ethylene could do this.
3. The "hormone" is rendered inactive by contact with soil (binding by soil). That, however, would not explain the epiphytic *Macromitrium*, assuming bark does not have the binding properties known for soils.
4. The level of "hormone" is too weak anywhere but on the female plant.
5. Similar to 4, but the "hormone" is water soluble and is soon washed away elsewhere, but is continually produced on the female.
6. Similar to 1; there is some sort of complementation between male and female plant – both must be present for the female to produce the "hormone."

Heinjo During (Bryonet 27 February 2009) suggested that the variation in sizes of males may in some cases relate to the **distance from females** (possibly related to hypotheses 2, 4, & 5). He has observed this size variation in *Leucobryum* (Figure 39-Figure 40). A possible explanation for this observation is that a hormone gradient exists, but it is also possible there is a male size gradient due to an environmental gradient away from the female colony in this cushion-former. The colony could create this gradient through such factors as moisture retention, nutrient usage, or pH alteration.

During (Bryonet 27 February 2009) reports that *Garovaglia* (Figure 29) seems to lack those intermediates, with males being either full size (similar to the size of females) on a non-leaf substrate, or dwarf when sitting on a female leaf. During suggests that a lack of intermediates, as in *Garovaglia*, indicates that dwarfing is genetically fixed and not dependent on effects of female neighbors. One possible explanation is that the large *Garovaglia* males are mutants in which the dwarfing is inactivated. We can also consider that if a certain level of hormones is required for dwarf males to develop in a species, a hormonal gradient away from the female could reach a threshold at a certain distance from the female, with those farther away and beyond the threshold becoming full-sized males.

Inhibitors – Absence of dwarf males on older parts of mosses suggests that emission of some inhibitor, perhaps the gaseous hormone **ethylene**, may suppress germination, thus being adaptive by avoiding the waste of energy and resources on a part of the plant too far from apical female reproductive organs for fertilization success. Alternative explanations might be that the stimulant hormone has been leached out of older parts and is not being replaced, or that growth conditions, especially with respect to light, are unfavorable.

Nutrient Considerations – Rod Seppelt (Bryonet 1 March 2009) suggested another possibility – a nutritional limitation. He suggested that when the spore germinates on a moss leaf, it could be at first rain after a dry period. At this time, the moss would leak nutrients due to membrane damage during desiccation. This would provide the nutrients needed for the male plant to start growing, but once the membranes were repaired in the substrate leaf, the nutritional source would be gone, hence limiting the further growth of the male, causing it to be a dwarf. Those spores on soil would obtain nutrients from the soil and the male gametophyte plant could grow to a full size. I have observed this in flowering plants. In one of my early attempts at gardening I grew poppies in very poor soil. Instead of growing to 60 cm tall, they were only 3-4 cm tall, but nevertheless produced miniature flowers. However, Hedenäs and Bisang (2012) could find no support for this nutrient limitation hypothesis in the pleurocarpous mosses they examined. Rather, they observed that dwarf males are most common shortly after spore release, the dwarfs being dead and more difficult to detect during the period before spore maturation.

Genetically Obligatory Dwarfs – In Japanese *Macromitrium* (Figure 41), eight species are dimorphic, producing dwarf males (Une 1985a; 2009). In these **anisosporous** (anisospory – having 2 spore sizes in the same tetrad following meiosis, see also the section on Anisospory below) species the dwarf males are genetically determined, whereas in **isosporous** (one spore size) species the dwarfness is apparently regulated by hormones from the female plants, with the potential to develop into normal plants in absence of the hormones. In his experiments, Une found that the hormone **2,4-d** (an auxin – growth hormone) caused dwarf males to develop in the **isosporous** species, supporting the hypothesis that hormones produced by the substrate leaf are the factor determining the development into a dwarf male.

Andréa Pereira Luiz-Ponzo (Bryonet 2 March 2009) and her students examined dwarf male biology in *Orthotrichum* (Figure 42-Figure 45). They found that in all species that have dwarf males, there are two spore sizes (**anisospory**). In those that exhibit full-sized males, the spores are **isomorphic** (all the same in form and size; Figure 45). So far they have found no species with both dwarf males and full-size males that also exhibit anisospory.

Hedenäs and Bisang (2011) present evidence that the presence of male dwarfism is related to family membership, and that it does not correlate with geographic area. Such examples of dwarf male relatedness occur in the currently configured family **Miyabeaceae**: *Homaliadelphus*, *Miyabea*, *Bissetia* (Olsson *et al.* 2009). Olsson *et al.* have placed these three genera in the same family, **Miyabeaceae**, based on a molecular phylogenetic analysis. *Homaliadelphus* (formerly in **Neckeraceae**; Figure 46) produces normal-sized males or facultatively produces dwarf males, whereas *Miyabea* (formerly in **Thuidiaceae**) and *Bissetia* (formerly in **Neckeraceae**; Figure 47) produce obligatory dwarf males. *Homaliadelphus* has all the spores the same size, but those of the obligatory dwarf male genera *Miyabea* and *Bissetia* are of two distinct sizes.

Neoteny vs Progenesis

These two conditions are easy to confuse because they have similar results. **Neoteny** is the condition of slowing down developmental growth (**somatic** or body cell), resulting in sexual reproduction that happens in what was ancestrally a juvenile morphologic stage. **Progenesis** is the condition of developmental growth at a normal rate, but the production of gametangia occurs at a faster rate, resulting in **paedomorphosis** (retention by organism of juvenile traits into later life), *i.e.*, reproduction also happens in what was ancestrally a juvenile morphologic stage. Mishler and DeLuna (1991) consider the development of dwarf males to be **progenesis**.

Dwarf males typically attach to the female by rhizoids (Johannes Enroth, pers. comm 29 December 2020) and at least in *Garovaglia* and *Euptychium* also protonemata (Heinjo During, Bryonet, 29 December 2020).

Neoteny and progenesis should not be confused with **sexual dimorphism** such as that found in *Sphaerocarpus* (Irene Bisang, pers. comm., 28 December 2020).

The Dwarf Male Advantage

So, we repeat the question here, what is the advantage to having a larger female? Lewin (1988) suggests that bigger females may produce more fit offspring; smaller males may have increased mobility (an animal bias but could be applied to small spores); females may survive longer after reaching sexual maturity and continue growing. Do these explanations apply to bryophytes?

For those species with small male spores and large female spores, the greater dispersal distance that correlates with small spore size could be an advantage, especially in species where asexual diaspores are produced by the males. This could eventually increase reproductive success by providing males with greater possibilities to reach females.

Among *Dicranum majus* (Figure 48) female plants with dwarf males, there was an 84% success rate in fertilization compared to 75% when including those identifiable females without dwarf males (Sagmo Solli *et al.* 1998). In the northern part of Lower Michigan, monoicous species of mosses achieve the same rate (75%; Rohrer 1982). Also in *Homalothecium lutescens* (Figure 20), fertilization rate was positively associated with dwarf male density (Rosengren *et al.* 2014, see above). The dwarf male mechanism seems to ensure fertilization success while wasting little on production of male plant

tissue, thus avoiding competition with female plants for resources. Nevertheless, it appears that in some cases males must be reborn each year, as Sagmo Solli *et al.* (1998) were unable to find any males on female *Dicranum majus* parts more than one year old.

Figure 48. *Dicranum majus*, a species with dwarf males from Bretagne. Photo by Michael L  th, with permission.

So it appears that one strategy of energy conservation and assurance of having males nearby females that works for a number of genera is to dwarf any male that develops on a female plant (Wallace 1970) (see also below, evolutionary drivers). Wallace found that in *Trachybryum* (= *Homalothecium*) *megaptilum* (Figure 33) only one plant in 200 is a normal-sized male, whereas a single female may have several hundred dwarf male plants growing on her.

Some bryophytes make certain that sperm dispersal distance is absolutely minimal. *Leucobryum martianum* (Figure 49) produces rhizoidal heads (Salazar Allen 1989). Yamaguchi (1993) later reported that the characteristic rhizoid formation in *Leucobryum* occurs at the lower abaxial side of the inner perichaetial leaves. Young plants develop on this rhizoidal tomentum and this was originally considered a means of asexual reproduction. Further examination revealed that these young plants were actually dwarf males developed from spores, located conveniently close to the archegonia.

Figure 49. *Leucobryum martianum*, a species with rhizoidal tufts on the inner perichaetial leaves where dwarf males grow. Photo by Jan-Peter Frahm, with permission.

Hedenäs and Bisang (2011) suggest that **evolutionary drivers** toward dwarf males in bryophytes may have included (1) competing selective pressures on cytoplasmic and nuclear genomes, (2) selection for reduced mate competition, in particular when resources are limited, and (3) selection for reduced fertilization distances. In many cases it is likely that combinations of these drivers existed. Furthermore, the associated niche shift of the males may provide them with a habitat that is both humid and nutrient-rich (but see above - nutrient considerations under How Do Facultative Males Develop? by Seppelt).

Dwarf males seem to be sensitive to microclimate, living shorter lives than the females of the species. This results in variation of male frequencies among years (Sagmo Solli *et al.* 2000; Rosengren & Cronberg 2014; Lang *et al.* 2021).

Lang *et al.* (2021) investigated the facultative dwarf males in *Dicranum scoparium* (Figure 38). They found that numbers of dwarf males differed greatly between sites. When present, the dwarf males usually outnumbered both females and normal males. Genetic variation was low within a locality. It was strongest between cushions for both females and normal males and within cushions of dwarf males. They found indications that inbreeding occurs some of the time.

Species Interactions

If females can inhibit the development of males of their own species through nutrition or hormonal control, can they likewise do this to other species?

Mishler and Newton (1988; Newton & Mishler 1994) experimented with interaction effects of moss leaves and leaf extracts on spore germination. They determined the effect of *Dicranum scoparium* (Figure 38) and four species of *Syntrichia* (previously in *Tortula*) on *Syntrichia* spore germination. Spores planted on agar or sand had normal germination and growth, but spores (either sex) of *S. ruralis* (Figure 50) and *S. laevipila* (Figure 51) that were planted on *Dicranum scoparium* or *Syntrichia* leaves either didn't germinate or germinated very slowly. *Syntrichia princeps* (Figure 52) germination was inhibited by extracts from leaves of its own species. Even a water extract of *D. scoparium* caused a significantly slower spore germination or resulted in significantly smaller plants than those grown with no extracts. At least in this case, it appears that when the inhibition of other species exists, it is to a degree that sexual maturity is not reached. What is puzzling is that in three of the species germination was inhibited by leaf extracts of their own species.

In contrast, spores of *Homalothecium lutescens* (Figure 22) and *H. sericeum* (Figure 23) both germinated on shoots of the former, but spores of the more distantly related *Isoetium alopecurioides* (Figure 16-Figure 17) did not (Rosengren & Cronberg 2015; see above). This suggests that the regulation of spore germination on host shoots is associated with the degree of relatedness between species. In contrast, spores of *Homalothecium lutescens* and *H. sericeum* both germinated on shoots of the former, but spores of the more distantly related *Isoetium alopecurioides* did not (Rosengren & Cronberg 2015; see above). This suggests that the regulation of spore

germination on host shoots is associated with the degree of relatedness between species.

Spore Differences

Spore differences can account for male-female differences. Mogensen (1981) elaborated on the types of spores in bryophytes; note that these definitions refer to the species, not to individuals, and are based on spore size frequencies (SSF) and mean spore size frequencies (MSSF) across populations:

isospory – one SSF and MSSF; spore mortality none or only a few percent

ex.: *Fissidens limbatus* (Figure 53), *Funaria hygrometrica* (Figure 54-Figure 55), *Mnium hornum* (Figure 56); probably the most common type in bryophytes

[heterospory – large female and small male spores present [microspores produced in microsporangia and mega(macro)spores produced in megasporangia] – bryophytes have only one type of sporangium

ex.: not known in bryophytes]

pleurispority – 2 or more SSF grouped around 1-2 MSSF

ex.: *Ditrichum difficile*

anisospory – SSF and MSSF grouped around 2 mean sizes in 1:1 ratio; probably in 2-3% of mosses

ex.: some *Orthotrichum* (Figure 42-Figure 43) & *Macromitrium* spp (Figure 41)

pseudoanisospory (= false anisospory) – SSF & MSSF grouped around 2 mean sizes, usually in 1:1 ratio; small spore fraction is aborted

ex.: *Cinclidium* spp. (Figure 64), *Ceratodon purpureus* (Figure 69), *Rhizomnium magnifolium* (Figure 66), *Fissidens* spp. (Figure 67), *Macromitrium* spp. (Figure 41)

amphispority – SSF & MSSF grouped around 2 mean sizes in varying ratios; small spore fraction is aborted

ex.: *Pleurozium schreberi* (Figure 57)

combispority – SSF & MSSF grouped around 3 or more mean sizes; may have aborted spores but also living spores in at least 2 sizes

ex.: *Macromitrium* spp. (Figure 41)

Anisospory

The "big female" concept has been based on animals, but like so many other evolutionary concepts, the broader concept is applicable throughout living organisms. Haig and Westoby (1988) have applied this concept to the origin of heterospory in plants. But bryophytes are not quite there yet. Instead, they have evolved (in relatively few species) only to **anisospory** with some related variants.

Spores in bryophytes are always **homosporous** and generally **isosporous** (all the same size). **Heterospory** can be defined as bearing spores of distinctly different types; it is the condition when **microspores** are produced in microsporangia and **mega(macro)spores** in megasporangia. Micro- and megaspores differ in size and sex. Heterospory has evolved independently several times in vascular plants, but does not occur in bryophytes. Early diverging ferns are homosporous; several families of aquatic ferns are heterosporous. All bryophytes are homosporous in this sense, all seed plants are heterosporous, and in ferns both conditions exist.

Anisospory in bryophytes refers to a bimodal size difference between spores produced in the same sporangium (Magill 1990). In this case, meiosis results in a tetrad of two small spores that generally produce male gametophytes and two larger spores that produce female gametophytes (Ramsay 1979; Magill 1990).

Anisospory has been reported in a variety of mosses, not just in connection with male dwarfism as described above, with several explanations for their occurrence. But the usage of the term may not always be precise. Pant and Singh (1989) reported several possible cases of anisospory in liverworts: *Targionia indica*, *Targionia hypophylla* (Figure 58), *Cyathodium aureonitens*, and *Cyathodium barodae*. They based this conclusion on the wide variations in size of spores, similar to those in the moss family **Orthotrichaceae**. They did not determine sex or viability, hence we cannot eliminate the possibility of **false anisospory**. Multiple spore sizes can occur in bryophytes

as a result of unequal growth of the spores, or in some cases abortion of spores (Ramsay 1979). These cases do not have any known relationship to sex.

Figure 58. *Targionia hypophylla* with marsupium (black), a structure that houses the archegonia and sporophyte. Photo by Des Callaghan, with permission.

Support for the anisospory concept comes from some species with dwarf males (see paragraphs above). In several dioicous taxa [*Lorentziella*, some *Macromitrium* (Figure 41), including the former *Schlotheimia* (Figure 59)], small, yellow spores produce males and larger, green spores produce females (Ernst-Schwarzenbach 1938, 1939, 1944). But this differentiation in spore size seems to be rare among the bryophytes.

Alfayate *et al.* (2013) have recently provided irrefutable evidence of anisospory in two more genera – irrefutable because both sizes of spores germinated. In *Leucodon canariensis* (Figure 60) viable spores were of two classes - uni- or multicellular, medium-sized (26-48 μm) spores and multicellular, large (50-94 μm) spores. In *Cryptoleptodon longisetus*, viable spores are likewise of two kinds in the same capsule, unicellular, small spores (11-24 μm) and medium-sized (26-35 μm) spores. Furthermore, in both species, germination was present within the capsules. Somewhat similar anisospory occurs in *Brachythecium velutinum*, with both sizes germinating (Herguido & Ron 1990).

False Anisospory – Spore Abortion

Mogensen (1978a) described **false anisospory** (appearing to have two sizes, one chlorophyllous and one not), later (1981) referring to it as **pseudoanisospory**; false anisospory seems to be the terminology most used. Mogensen does not include any sex relationship for this condition.

In several species that exhibit **dimorphic** (having two forms) spores, one can find on closer examination that the small ones are dead (thus not implying a difference in sex) and satisfying the condition Mogensen (1978a) termed false anisospory. (Dimorphic does not imply that the size difference is genetically based.) He first reported aborted spores in *Cinclidium* (Figure 61-Figure 64) (Mogensen 1978a) and later in *Macromitrium japonicum* (=M.

incurvum; Figure 65), *Rhizomnium magnifolium* (Figure 66), and *Fissidens cristatus* (Figure 67) (Mogensen 1978b). In *Cinclidium arcticum* (Figure 61-Figure 62) and *C. stygium* (Figure 63) 50% of the spores abort, whereas in *C. subrotundum* (Figure 64) only 11% abort. It is also known in *Lorentziella imbricata* (Figure 68) (Crum 2001). The result is that large, green, live spores cohabit the capsule with small, brown, dead ones.

Mogensen (1978a, 1981) tracked the spore sizes of *Cinclidium arcticum* (Figure 61) as the capsule dried. He concluded that the columella serves as a reservoir of water (Mogensen 1978a). He demonstrated a range of spore sizes in a single capsule and that as the columella dries and shrinks, the smaller spores die first. A similar loss of smaller spores during maturation was present in *Ceratodon purpureus* (Figure 69) (Mogensen 1981). Premature drying can cause the operculum to be released before the spores reach their potential size, stopping their development (Mogensen 1981).

Glime and Knoop (1986) observed a similar phenomenon in the dioicous aquatic moss *Fontinalis squamosa* (Figure 70-Figure 75). Because its capsules are constantly wet in nature (Figure 70), it was possible to simulate their maturation conditions in the laboratory and examine the spores at various times during development (Figure 71). In that species, death did not occur to all spores simultaneously. At any point in time during development, large and small spores were present (Figure 72-Figure 75). However, small spores at later points in time were larger than small spores at earlier points in time. It was not clear whether the first degenerate spores disintegrated before larger ones appeared, or if different spores accomplished abortion at different developmental stages. Some already were abortive in their tetrads following meiosis (Figure 75). Glime and Knoop suggest that at least in *Fontinalis squamosa*, spore abortion is a gradual and continual process as the capsule matures, and that it is determined either randomly or by location of developing spores in the capsule, rather than by genetic predetermination. This species is not known to have dwarf males. The smaller spores had a much lower germination rate.

Figure 72. Spores of *Fontinalis squamosa* showing large, healthy green spores, smaller white dying or dead spores, and small brown spores that may be dead. These are not anisospores because they are not of two sizes at the end of meiosis. Photo by Janice Glime.

Figure 73. Normal and aborting spores of *Fontinalis squamosa* in white light (left) and the same spores fluorescing under ultraviolet light (right), showing red healthy spores and yellow or green dying spores. Note the lack of fluorescence in the small, deflated spores and the yellow edges of some that are beginning to abort. Smaller spores with no remaining chlorophyll are not visible in this image through fluorescence. Photo by Janice Glime.

Figure 74. Normal (left) and smaller aborted (right) spores of *Fontinalis squamosa*. Photo by Janice Glime.

Figure 75. Tetrad of spores from *Fontinalis squamosa*. Note one abortive spore. Photo by Janice Glime.

Zander (1972) reported a similar situation for *Leptodontium viticulosoides* var. *viticulosoides* (Figure 76). In this case, the seeming anisospory was actually a large, chlorophyllous spore and a small, non-

chlorophyllous spore, *i.e.* false anisospory. The small spores were, as in most for *Fontinalis squamosa* (Figure 74), not viable. So I would add another possibility, although with absolutely no proof for *Fontinalis* or any other species. If the smaller spores in some species are indeed viable, they could produce a smaller gametophyte due to reduced starting nutrition. In this case, a leaf producing inhibitory substances would not be needed. However, such a function for small spores is not known for *Fontinalis* or any other bryophyte.

Figure 76. *Leptodontium viticulosoides*. Photo by Li Zhang, with permission.

Rhizomnium punctatum (Figure 77), a species closely related to *Rhizomnium magnifolium* (Figure 66), provides further support for the hypothesis that false anisospory can result from the progressive abortion of spores during the stages leading up to spore maturity. This species exhibits false anisospory during early capsule development but in the mature capsule the spores are isosporous (Mogensen 1978b). Mogensen further points out that there is no correlation of spore size with the monoicous or dioicous condition, at least in his small sample of taxa.

Figure 77. *Rhizomnium punctatum* with capsules in Europe, a species in which mature spores are isosporous. Photo by Michael Lüth, with permission.

But not all capsules have the progressive abortion we have been describing. In *Bryowijkia ambigua*, abortion

occurs in the tetrad stage, with two spores aborting and two presumably remaining viable (De Luna 1990). This brings to mind the image a spore tetrad from *Fontinalis squamosa* above (Figure 75) where one visible spore is likewise aborted in the tetrad stage. In the case of *F. squamosa*, spore abortion may begin as early as the tetrad and continue throughout development, or it might be that I have misinterpreted the continual abortion throughout development. Nevertheless, as seen in Figure 78, three spores can abort in one tetrad, suggesting that the number of abortions is not a programmed event in the tetrad stage.

Figure 78. *Fontinalis squamosa* showing what to be three aborted spores in one tetrad. Photo by Janice Glime.

Figure 79. *Bryowijkia ambigua*, a species in which spore abortion occurs in the tetrad stage. Photo by Li Zhang, with permission.

It is likely that abortion of some spores is the rule among bryophytes, and it would be interesting to investigate how widespread the process is. It might be that in seasons of low water or nutrient availability the abortion is more common. This would be an interesting topic to explore for both its control and its adaptive value. The number of studies of changes in spore size during sporogenesis are insufficient to make accurate generalizations. Mogensen (1981) suggests that the abortion is a selection against certain genotypes, and he (1978a) interpreted this phenomenon to be a genetic factor that is lethal to a fraction of the spores prior to vegetative growth of the spore. Without further detailed study we

cannot rule out random abortion between the sexes or resource-related abortion, perhaps based on crowding, water availability, or nutrient availability.

Evolution of Spore Differences

In studying the evolution of heterospory in ferns, Haig and Westoby (1988) predicted that sporophytes would produce spores of a size that would maximize return in gametophyte fitness per unit investment. He postulated that the evolution of heterospory would occur in three steps:

1. a gradual increase of spore size in a homosporous population
2. the sudden introduction of smaller microspores
3. subsequent divergence in size and specialization of the two spore types.

This implies that larger spores would occur in those taxa that depend on stored reserves of the spore for successful reproduction. No surprises there. Their model predicts that because there are only minimal costs for male reproduction compared to that of female reproduction, larger food reserves would therefore evolve for female reproduction. Following this model, above some critical spore size, the population can be invaded by smaller spores that are predominately males (assuming that small spores travel farther?).

If one continues with this logic, it would then imply that the population would have few large females and more small males. A larger number of small males would increase chances of some of these males being near a female and strategically placed so that sperm can reach and fertilize the egg. Whenever male reproductive cells must travel by themselves to the female, many will be lost, literally unable to find the female, or perishing before the distance is accomplished. Hence, such a system will necessarily require many male gametes. In bryophytes, by having many small gametophytes, it would be possible for more gametophytes to occupy available small spaces near the female and offer more opportunities for successful fertilization.

The theory presented by Haig and Westoby (1988) would seem to make sense for the heterosporous ferns where the gametophyte is contained within the spore wall. And it makes sense for the seed plants where male gametophytes can travel reasonably long distances. But does this concept really work for evolution of anisporous bryophytes where the sporophyte and sporangia have no sex distinction and the gametophyte is **exosporic** (develops outside the spore wall)? The number of male and female spores produced in the bryophyte case should be equal, dividing in a 1:1 ratio at meiosis, at least in the absence of sex ratio distorters. The model would only seem to be applied in bryophytes if size differentiation occurred after meiosis, during spore development. Then, it would require that being a small spore caused differentiation into a male while larger spores containing more stored nutrients became female. But unlike heterosporous ferns such as *Marsilea*, the bryophytes do not have gametophyte development and fertilization within the spore wall and the spore is not used to nourish the developing embryo. And to satisfy the Haig and Westoby model, the distinction in

spore size would have to favor few large spores and many small spores. This possibility cannot be ruled out, and there may be some support for it in *Fontinalis* (Figure 70-Figure 75), where a distinction between small and large spores occurs throughout spore development (Glime & Knoop 1986), but linkage of size, number, and sex has not been established.

Advantages of Anisospory and False Anisospory in Bryophytes

One must wonder if the progressive death of spores is a waste of energy, or a way of saving or even providing resources. Dead spores may serve a useful function by reducing the rate and extent of desiccation, and by reducing the drain of nutrients, until the remaining spores are larger and crowded, thus protecting each other. Finally, they could be a reservoir of nutrients readily available as they abort. It would be interesting to explore whether seasons of low water or nutrient availability increase the percent abortion.

Whereas the anisoporous condition seems to be favorable for dioicous taxa, the false anisoporous condition can occur in monoicous taxa (Mogensen 1981), but is not restricted to them. This leads us to consider the space-nutrient need as a possible selection factor for false anisospory.

New Methods

Our understanding of bryophyte sexuality should become increasingly easier with the development of molecular techniques. Pedersen *et al.* (2006) amplified DNA from nine mosses and one liverwort. This technique permitted them to obtain sufficient DNA from a single dwarf male of *Dicranum scoparium* (Figure 38). This will permit us to study genetic variation even in such small plants as dwarf males.

Summary

Males and females can differ in non-sexual ways, including size, biomass, branching, maturation rate, chlorophyll content, and photosynthetic rate and other physiological traits. Large female and small male plants (**dwarf males**) are known among bryophytes, but not the converse, except in non-sporophytic *Diphyscium*. Most dwarf males develop on the leaves or tomentum of females of the species. Dwarf males are often missed in surveys and this omission can cause misleading results in sex ratio determination. Spores of some species develop dwarf males on females of the species but normal males on other substrates. Dwarfism can increase the success of fertilization while decreasing the competition for resources with the females.

Bryophytes are **isoporous**, but some species exhibit **anisospory**; some exhibit **false anisospory** due to abortion of spores. The anisoporous condition seems to present a potential advantage for fertilization when it is correlated with the presence of dwarf males. On the other hand, this strategy reduces the dispersal of

the larger female spores compared to that of the smaller male spores. This is less of a problem if nearly all females get fertilized. Many **anisoporous** and **false anisoporous** conditions occur in species with no dwarf males (Mogensen 1981). This causes us to seek other explanations for their presence, including abortion related to water, space, and nutrient limitations within the capsule. The abortions can provide room for remaining developing spores while maintaining protection and resources for them.

Acknowledgments

We greatly appreciate the numerous comments and suggestions of Lars Hedenäs who provided a critical review of an earlier draft of the paper and gave us encouragement. Linley Jesson provided us with unpublished data that helped demonstrate the sex possibilities for a bryophyte. Bryonettors have been especially helpful in providing examples and observations to answer questions arising during the preparation of this chapter.

CHAPTER 3-4

SEXUALITY: REPRODUCTIVE BARRIERS AND TRADEOFFS

Figure 1. *Funaria hygrometrica*, a monoicous species showing numerous capsules. Photo by Michael Lüth, with permission.

Reproductive Barriers: Selfing and Hybrids

Bryophytes are fundamentally different from tracheophytes by having a dominant haploid generation. Since many bryophytes can produce both antheridia and archegonia on the same plant (Figure 1), self fertilization (**selfing**) is likely to occur. Reproductive barriers to prevent selfing are important components of speciation. As long as genes are able to mix and appear in new offspring, the populations involved will be unable to become distinct species (Anderson & Snider 1982). When two species reside within centimeters of each other, they may receive sperm from the other species. We might expect some of the same mechanisms to prevent both selfing and hybridization.

Linley Jesson (pers. comm. 25 January 2014) used allozyme markers and successive innovations to measure selfing rates between individuals expressing one sex (in one year) and individuals expressing both sexes. Her (unpublished) work has shown extensive hybridization in the *Atrichum* (Figure 2-Figure 3) complex.

Selfing and Inbreeding Depression

Selfing in bryophytes can happen in two ways: intragametophytic and intergametophytic. **Intragametophytic selfing** is self-explanatory, where the crossing occurs between antheridia and archegonia on the same ramet (branch/gametophore), and can thus occur only

in unisexual bryophytes. Being **gametophyte** (haploid) and **monoicous** (having male and female reproductive organs on same gametophyte plant) means that all gametes are produced by mitosis, hence are identical. Therefore, any result of intragametophytic self-fertilization (sometimes also referred to as 'true self fertilization' or **autogamy**) results in a sporophyte that is homozygous for every trait!

Figure 2. Female *Atrichum undulatum* showing perichaetial leaves. Photo by Janice Glime.

Figure 3. Male *Atrichum undulatum* showing male splash cups. Photo by Janice Glime.

Intergametophytic selfing, therefore, is a specific type of inbreeding where mating occurs between separate gametophytes produced by the same sporophyte (Klekowski 1969; Krueger-Hadfield 2013). This is the only form of selfing that is possible in **dioicous** (male and female reproductive organs on separate gametophyte plants) bryophytes, where the two sexes are, by definition, on different plants. It is genetically comparable to selfing as the term is applied in heterosporous seed plants (see, e.g., Shaw 2000). When meiosis occurs in a dioicous bryophyte sporophyte, some spores will give rise to female plants and some to male plants. Those will not be identical, due to independent assortment during meiosis, but will be siblings. When those siblings mate (**inbreeding**), those events in bryophytes are considered to be **selfing**. If one considers the event in flowering plants, meiosis occurs in separate male and female sporangia, and makes separate gametophytes, so the gametes, even from the same plant, are not identical and are no more closely related than bryophyte gametophytes developed from separate spores. Hence, whether spores develop enclosed within the sporophyte (flowering plants) or on the substrate

(bryophytes), if they came from the same sporophyte and they cross, it is selfing.

Since **inbreeding** results from fertilization by close relatives such as siblings or in bryophytes between ramets of the same gametophyte, this may imply duplicating deficient genes or inheriting absence of genes. In tracheophytes, this typically results in decreased fitness. Some organisms are protected from this wasted energy and decreased fitness by having mechanisms to suppress inbreeding, such as different maturation times of male and female parts on the same individual. Others express the inbreeding depression in the offspring, typically by reduced fitness. But based on tracheophytes, we are accustomed to evaluating the effects of inbreeding in diploid organisms, not haploid generations such as the leafy bryophyte gametophyte. Nevertheless, inbreeding is an expected consequence of monoicous bryophytes with limited capacity for sperm dispersal.

Fortunately, at least some bryophytes have mechanisms to prevent self-fertilization (Ashton & Cove 1976), but Crum (2001) assumed that most were self-fertilized because the sperm and eggs mature at the same time on the same plant (but see Chapter 3-2 on Protogyny and Protandry in this volume). Ashton and Cove (1976) showed experimentally that among six strains of *Physcomitrella patens* all were self-sterile, but certain combinations were cross-fertile. In this case, the self-sterility resulted from mutations to the nicotinic acid and p-aminobenzoic acid genes. Hence, incompatibility can result from missing but necessary genes, and these are supplied by having an outside partner. Does this mean the incompatibility affects the embryo? But abortion later in sporophyte development is also possible. Nevertheless, Maciel-Silva and Válio (2011), examining bryophyte sexual expression in Brazilian tropical rainforests, found that monoicous species used strategies that increased their chances for out-crossing. For example, they produce unisexual branches as well as bisexual ones. It is further possible that self-infertility is widespread; we simply have not gathered the data needed to understand the extent of its distribution, as proposed by Stark and Brinda (2013). These authors suggest incompatibility after self-fertilization in a clonal line of the monoicous *Aloina bifrons* (Figure 4). They also refer to reports of self-incompatibility in *Desmatodon cernuus* and mutants of *Physcomitrella patens* (Figure 5). Modern DNA techniques should make it relatively easy to determine this.

Figure 4. *Aloina bifrons*, a monoicous species that seems to be self-incompatible. Photo by Martin Hutten, with permission.

Figure 5. *Physcomitrella patens* on soil. Photo by Michael Lüth, with permission.

Although truly self-fertilizing monoicous taxa pass on the full complement of genes to all their offspring, each sporophyte is in fact a separate **genet** (group of genetically identical individuals) that results from a single fertilization (Eppley *et al.* 2007). The sporophyte has no normal means of spreading vegetatively, so that genet cannot spread. Hedrick (1987) suggested that the complete homozygosity that results from intragametophytic selfing in monoicous bryophytes should select for extremely high inbreeding depression, but Eppley *et al.* (2007) considered that elimination of those (spores?) with deleterious alleles resulting from the inbreeding would remove those genotypes from the population and remove the inbreeding depression in future generations, hence favoring selfing. But dioicous species predominate, so we must examine the situation further.

Eppley *et al.* (2007) suggest that it is the level of intergametophytic selfing that maintains dioicy. If the level of selfing is low in dioicous bryophytes, accumulating deleterious alleles in the diploid stage would create a high cost for selfing through such effects as sporophyte abortion. Hence, the cost of selfing may maintain separate sexes. On the other hand, if selfing is high in both mating systems, deleterious genes would cause selection against both sexual strategies and select for monoicy due to higher fertilization rates. Eppley and coworkers found low or non-existent selfing in a mean of 41% of the sampled five dioicous species. If their reasoning is correct, this could explain the high level of dioicy in bryophytes when compared to flowering plants.

Selfing in bisexual bryophytes is evidenced by high F_{is} values (*i.e.*, a measure of heterozygote deficiency) observed in the sporophytic phase of all bisexual species investigated so far (Eppley *et al.* 2007; Hutsemekers *et al.* 2013; Johnson & Shaw 2015; Klips 2015; Rosengren *et al.* 2016). Using allozyme electrophoresis to estimate the deviations from expected heterozygosity, *i.e.* to estimate inbreeding, Eppley *et al.* (2007) estimated **selfing rates** for 10 species of New Zealand mosses. As one might expect, monoicous species had significantly higher levels of heterozygote deficiency (more selfing) than did dioicous species (inbreeding coefficient = 0.89 ± 0.12 and 0.41 ± 0.11 , respectively). An unexpected result, however, was to find that in two dioicous species [*Polytrichadelphus*

magellanicus (Figure 6-Figure 7) and *Breutelia pendula* (Figure 8)], there were significant indications of mixed mating or biparental inbreeding in a handful of populations.

Figure 8. *Breutelia pendula*. Photo by Tom Thekathyl, with permission.

The classical explanation for the success of dioicous plants, based on tracheophyte literature, is that inbreeding, a product of having both sexes on the same plant, decreases fitness. In that case, one might assume that bryophytes, like other plants, have some mechanism of inbreeding depression (Beatriz Itten, Bryonet 26 May 2005). That is, they have some lethal or deleterious allele that gets expressed, leading to death or greatly reduced success. If such a gene is expressed in the haploid gametophyte, it is eliminated, rather than depressed, due to death of the individual.

In an attempt to remedy the absence of experimental data, Taylor *et al.* (2007) tested inbreeding depression in a monoicous and a dioicous moss species. Somewhat contrary to expectations, inbreeding depression occurred in the dioicous *Ceratodon purpureus* (Figure 9); crossing between siblings of the opposite sex significantly reduced fitness in both seta length and capsule length out of the four traits they examined. By contrast, the monoicous *Funaria hygrometrica* (Figure 10) exhibited no evidence of inbreeding depression in seta length, spore number, capsule mass, or capsule length. Jesson *et al.* (2011) found that hermaphroditism (monoicy) increased selfing rates rather than depressing them in *Atrichum undulatum* (Figure 2-Figure 3). Furthermore, they failed to demonstrate significant inbreeding depression in monoicous individuals of this species.

Figure 9. *Ceratodon purpureus* with sporophytes in a mixed population of males and females. Photo by Christian Hummert through Creative Commons.

Szöveni *et al.* (2009) noted in dioicous *Sphagnum lescurii* (Figure 11) that sporophyte size was correlated with the level of heterozygosity, in line with the prediction of inbreeding depression. This species experienced multiple paternity among sporophytes of a single female, enabling preferential maternal support of the more heterozygous embryos, which suggested active inbreeding avoidance and a possible post-fertilization selection. In contrast, inbreeding depression did not appear to be common in either dioicous or monoicous species in a multi-population study of 14 *Sphagnum* species (Johnson &

Shaw 2015), despite that monoicous species exhibited higher levels of inbreeding than dioicous ones.

Figure 10. *Funaria hygrometrica* in southern Europe. Photo by Michael Lüth, with permission.

Figure 11. *Sphagnum lescurii* with *Thuidium delicatulum*. Photo by Bob Klips, with permission.

Although further research on inbreeding depression in bryophytes is necessary, the evidence above suggests that the effects of bryophyte inbreeding are mitigated by the rapid purge of deleterious mutations during the gametophytic stage (Taylor *et al.* 2007; Jesson *et al.* 2011; Johnson & Shaw 2015). In particular, bisexual species are thought to rapidly purge recessive deleterious mutations through intra-gametophytic selfing (*i.e.* merging of gametes produced by shoots from the same protonema and hence, originating from the same spore. (See also below, Hybrid Success.)

Flowering plants frequently have mechanisms to prevent selfing. Could it be that monoicy in bryophytes is so recent that bryophytes have not yet evolved mechanisms to discourage it, or is it that they don't need to depress selfing, as implied by some of the above-cited studies? The former seems unlikely in view of evidence of many reversals indicated above (see also Chapter 3-1 in this volume).

We can suggest possible mechanisms to prevent selfing. As mentioned above and in Chapter 3-2, these might include timing (antheridia and archegonia mature at different times), as well as mechanisms of self incompatibility during fertilization or development. Hypotheses for possible mechanisms include:

1. rejection of sperm with same genotype (reminiscent of autoimmune diseases)
2. need for gene complementation to develop
3. embryo abortion
4. failure at meiosis

However, it would seem that any post-fertilization mechanism (2-4) would be wasteful (but see Szövényi *et al.* 2009, above), so selection should be greater for those species that can reject their own sperm, hence still allowing for subsequent outcrossing.

Could it be, then, that bryophytes are different from other major plant groups? Patiño *et al.* (2013) consider that **Baker's law** – as the loss of dispersal power and the bias toward self-compatibility after immigration to islands – applies to bryophytes. To defend this assertion, they cite evidence that the proportion of monoicous taxa was significantly higher on islands, and that a significant proportion of continental species that are monoicous or dioicous are represented on oceanic islands only by monoicous populations. This argument assumes a Founder Principle in which few colonists arrived and contact with the opposite sex was impossible. But it is also true that monoicous populations from the continent would have a greater chance of arriving on the island due to the greater ease of fertilization and spore production on the mainland. The shifts in life history traits toward a greater proportion of species producing asexual propagules and smaller proportion of species producing spores point to the loss of long-distance dispersal ability of bryophytes on oceanic islands.

Reduced Fitness

One consequence of selfing can be reduced fitness. This is illustrated in *Atrichum undulatum*. Populations in the *Atrichum undulatum* complex (Figure 2-Figure 3) contain females, males, and hermaphrodites, and hermaphrodites can have sex organs in close proximity or spatially separated across branches. In their experiments Jesson *et al.* (2012) found that there was significant selfing within gametophytes, whereas there was no significant selfing between siblings, supporting the importance of proximity for fertilization. But what is the price for this selfing? They found that sporophyte size did not differ between sibling (**intergametophytic**) and **intragametophytic** selfing, but other factors suggest reduced fitness for products of selfing. Sporophytes from females contained 29% more spores than those from monoicous (~30% selfed on same branch) individuals. When the cultures were stressed by supplying only tap water instead of a nutrient medium, only the progeny from females (*i.e.* non-selfed) survived on tap water after 6 months (Figure 12). Progeny of females transplanted onto tap water media had a greater photosynthetic capacity but higher non-photochemical quenching than did the

monoicous individuals, causing these females to have photosynthetic rates similar to those of the monoicous progeny. These are weak effects of partial selfing, but under certain stressful conditions may result in lower survival among progeny that are the product of selfing.

Figure 12. Proportion of culture plates with spores from females ($n=39$) compared to progeny of monoicous individuals ($n=30$) of *Atrichum undulatum* s.l. (Figure 2-Figure 3) germinating after 6 months on nutrient medium (Bold's basic media) vs tap water (stressful condition). Modified from Jesson *et al.* 2012.

Hybridization

Hybridization is the opposite of reproductive isolation. In the past, bryologists tended to consider hybridization in bryophytes to be unimportant (Andrews 1942; Vitt 1971; Smith 1978, 1979; Anderson 1980). But in fact, it seems to be widespread among bryophytes (Ruthe 1891; Nyholm 1958; Andrews & Hermann 1959; Crundwell & Nyholm 1964; Proskauer 1967; Ochi 1971; Delgadillo 1989; Schuster 1991; Ros *et al.* 1994; Natcheva & Cronberg 2004), often confounding attempts at cladistics when hybrids are among the data sets (Xu 2000).

It is interesting that among the bryophytes gametophyte hybrids seem only to exist in mosses, at least based on genetic information (Natcheva & Cronberg 2004). A number of hybrid liverwort species have been suggested, based on morphology, but so far few have been supported by genetic/molecular data – see, for example *Targionia hypophylla* (Figure 13) (Boisselier-Dubayle & Bischler 1999). Summarizing data, Natcheva and Cronberg concluded that moss hybrids usually occur among the "weedy" species with life history strategies of fugitive, annual, and short-lived shuttle or colonist, *i.e.*, species with life spans of only a few years.

Figure 13. *Targionia hypophylla*. Photo by Ken-Ichi Ueda through Creative Commons.

Intergeneric Hybrids

Intergeneric Hybrids – It is even more interesting that within the **Polytrichaceae** there are apparent **intergeneric hybrids**. *Polytrichastrum pallidisetum* (Figure 14-Figure 15) and *Polytrichastrum ohioense* (Figure 16) both appear to have had one progenitor in *Polytrichastrum* and one in *Polytrichum* (Figure 43) (Derda & Wyatt 2000). *Polytrichastrum sexangulare* (Figure 17) appears to have had a species of *Pogonatum* (Figure 18) as one of its progenitors (but then, the mosses may classify themselves differently from the way we currently do and place themselves all in *Polytrichum*).

Hybrid Success

Sphagnum (Figure 19-Figure 21) is a genus where polyploids are common (see also 3.1., Genome Doubling). Ricca *et al.* (2011) point out that we might expect all occurrences of polyploidization to result in instant sympatric speciation. But they cite several cases, *e.g.* *S. lescurii* (Figure 11), in which the resulting hybrid produces triploid sporophytes that are larger than those of the parents, but most of the spores are not viable. Furthermore, the spores that do germinate develop their sporelings more slowly. But such species are able to persist because of the pervasive vegetative reproduction. And some day in the future, some genetic error might enable successful spore reproduction.

Shaw *et al.* (2012) demonstrated **homoploid hybridization** (no change in chromosome number) and allopolyploidy in multiple species of *Sphagnum*. In the *S. fimbriatum* (Figure 19) complex they found one species with diploid gametophytes. Based on plastid DNA sequences, all samples of the polyploid *S. tescorum* (Figure 20) share an identical haplotype with most samples of *S. girgensohnii* (Figure 21). Fixed or nearly fixed heterozygosity at ten microsatellite loci show that *S. tescorum* is an allopolyploid. Many other examples indicating the role of hybridization in creating species differences are known in this genus.

Figure 20. *Sphagnum tescorum* in Alaska. Photo by Vita Plasek, with permission.

Figure 21. *Sphagnum girgensohnii* with open capsules. Photo by Janice Glime.

Flatberg *et al.* (2006) studied natural hybrids between haploid female *Sphagnum girgensohnii* (Figure 21) and diploid male *S. russowii* (Figure 22). These hybrids were discovered because when *S. girgensohnii* was in the presence of *S. russowii*, large capsules formed. The spores from these crosses yielded viable spores that produced triploid protonemata and juvenile gametophores in culture. *Sphagnum russowii* is itself a hybrid of *Sphagnum girgensohnii* and *S. rubellum* (Figure 23). Not only were the capsules larger in the *S. girgensohnii* x *S. russowii* cross, but spores were larger as well. Nevertheless, spore germination from this hybrid was less than 5%, which is much less than when *S. girgensohnii* is crossed with others of its own species. Hence, while these hybrids may make a few super plants, the numbers of offspring are greatly reduced. Even so, through vegetative reproduction such a population could expand and grow.

Figure 22. *Sphagnum russowii*. Photo by Blanka Shaw, with permission.

Figure 23. *Sphagnum rubellum*. Photo by Jan-Peter Frahm, with permission.

It is fitting, then, to conclude that barriers to cross breeding among species are incomplete in the bryophytes and that evolution of new species through hybridization may occur somewhat frequently in this group. This suggestion is supported by the apparent lack of external barriers to cross fertilization and the nearly total absence of sperm vectors to help enforce same species selection.

When Barriers Are Needed – or Not

Eppley *et al.* (2007) conclude that for taxa that are colonizers and must be able to self-fertilize in repeated colonization events, being self-compatible is an evolutionary advantage. This permits them to establish and spread rapidly in a new location. This is also suggested by Baker's law, which was recently found to apply for bryophytes (Patiño *et al.* 2013; see above).

In seed plants, elaborate modifications help to ensure that the male gametophyte (pollen grain) will disperse and reach the appropriate female gametophyte, where it will release sperm and effect fertilization. Specialized behaviors of pollinators also ensure that self-pollination is minimal. Such specialized facilitators (**external isolating mechanisms**) are rare in bryophytes, but other environmental mechanisms exist. As in seed plants, reproductive isolation that prevents hybrids in bryophytes may also result from various **internal isolating mechanisms** or a combination of internal and external isolating mechanisms (Natcheva & Cronberg 2004).

In bryophytes, the spore is needed for dispersal, and being small permits a greater distance for that dispersal

than that of many seed plant pollen grains. On the other hand, dispersal of the sperm of the bryophyte to the female reproductive organ lacks the protection and carrier capability of a pollen grain in tracheophytes and must get there by other means. As already discussed (Cross Fertilization in Chapter 3-1 of this volume), these gametes are motile and most of them must be transported in water or swim through a film of water. Thus, gene flow in bryophytes is affected by both gamete flow distances and spore dispersal distances. Anderson and Snider (1982) further contend that bryophyte establishment is more hazardous than that of seed and seedling establishment (see also Wiklund & Rydin 2004; Cleavitt 2005; Söderström & During 2005). These limitations make it advantageous to be bet-hedgers (having more than one strategy; see below) and permit at least some self-fertilization.

Effects of different reproductive barriers might be seen in the lack or scarcity of sporophyte formation. Bisang and Hedenäs (2008) transplanted males of the dioicous fen moss *Drepanocladus trifarius* (Figure 24) into the center of female patches. They could not observe any sporophytes in archegonia in the 'swollen venter stage.' Rather, the archegonia were withered or dehiscent. Using a similar experimentation in forest habitats, the dioicous *Rhytidiadelphus triquetrus* (Figure 25) produced capsules freely, with 100% of the plots exhibiting sporophytes (Bisang *et al.* 2004). *Abietinella abietina* (Figure 26), on the other hand, had sporophytes in only 41% of the plots. Furthermore, these *A. abietina* sporophytes maintained their calyptrae and did not dehisce when they should have; 36% of the capsules aborted. These examples demonstrate that not only lack of one sex or spatial segregation of the sexes are responsible for lack of capsules in dioicous bryophytes, but multiple factors may have an influence and probably interact. *Hamatocaulis vernicosus* (Figure 27) fails to produce capsules in France; only embryonic sporophytes were observed in more than 12,000 studied archegonia from 45 localities (Pépin *et al.* 2013). A combination of factors related to sexual phenology and environment is required for sporophytes to be produced: sex expression of mixed-sex colonies, short distance between sexes, light grazing, and high water table.

Anderson and Snider (1982) summarized these differences and presented the reproductive barriers "used" by bryophytes. Bryophyte reproductive barriers can, as in seed plants, be divided into external and internal barriers (Anderson & Snider 1982).

External Barriers

Spatial or Geographic Isolation

For spatial or geographic isolation to occur, the distance between biotypes must be greater than the spore dispersal distance. That is more a theoretical limit than a practical one because spores can occasionally travel great distances through the atmosphere. Nevertheless, the greater the distance, the smaller the chance for genetically compatible biotypes to join. This same external barrier applies to sperm, which rarely travel more than a meter. However, as Anderson and Snider (1982) and much earlier Gayet (1897) suggested, it has by now been demonstrated that **mites**, **springtails**, and other small invertebrates can not only carry the sperm from male **perigonia** to female **perichaetia**, but in some cases facilitate much greater fertilization than in their absence (Cronberg *et al.* 2006; Rosenstiel *et al.* 2012; Bisang *et al.* 2016). Furthermore, we now know that some small portion of sperm are likely to survive even desiccation (Shortlidge *et al.* 2012), permitting survival during a much greater dispersal distance. Nevertheless, short-distance spatial separation is much more effective as an isolating mechanism among bryophytes than among tracheophytes.

Bryophytes, like tracheophytes, often exhibit incomplete isolation (Natcheva & Cronberg 2004). For example, some geographic races of the liverwort *Sphaerocarpos texanus* (Figure 28-Figure 29) are partly reproductively isolated whereas others are fully interfertile (Allen 1937). The hornwort *Phaeoceros* (Figure 30) has good reproductive isolation among species, but under some circumstances geographic races of *Phaeoceros laevis* (Figure 30) are able to interbreed (Proskauer 1969).

Figure 29. *Sphaerocarpos texanus* female. Photo by Martin Hutten, with permission.

Figure 30. *Phaeoceros laevis* with sporophytes. Photo by Bob Klips, with permission.

Ecological Isolation

A second external barrier is ecological isolation. In this case, the biotypes are confined to different habitats, making crossing unlikely. These differences were difficult to identify until recently because one had to do common garden or transplant studies to determine if perceived morphological differences were environmentally induced or genetically based. Such environmental plasticity differences have been especially noticeable for species that occur both in and out of water. And often transplanted populations did not succeed or looked different from any established field population. Now advances in the use of genetic markers permit us to identify different variants of a species. These may eventually be expressed as races, cryptic species, or microspecies, and if isolated long enough may evolve into separate species.

Ecological isolation in bryophytes is closely tied with spatial isolation because of the typical short distance of sperm dispersal. If they are close enough for the sperm to reach the archegonium, the microhabitat is not likely to differ much.

Seasonal Isolation – Gametangial Timing

In some locations, timing or climate can make one gender unable to complete its task. Seasonal isolation, as in pollination, can cause male and female gametangia to mature at different times (see Protogyny and Protandry in Chapter 3-2). Species that arrive by long distance travel may lack the necessary environmental triggers at the appropriate time to ensure that gametangia are coordinated. New arrivals may not be coordinated with established populations. Hence, if male and female propagules arrive at different times or from different places, they may be seasonally incompatible, a factor that can also isolate wind-pollinated members of the same genus among seed plants. This mechanism may be incomplete, working as an isolating mechanism in some years but not in others, depending on the weather.

We seem to have little verification of seasonal isolation in bryophytes. We do know that timing of male and female gametangial maturation can differ in monoicous bryophytes (Anderson & Lemmon 1973, 1974; Longton & Miles 1982; Shaw 1991). This mechanism can successfully isolate the eggs from being fertilized by sperm from the same plant (See Protogyny and Protandry in Chapter 3-2).

Speculation suggests that seasonal isolation is effective among several species of *Sphagnum* (Natcheva & Cronberg 2004). Other speculations include *Weissia* (Khanna 1960; Williams 1966), and the geographic races of *Anthoceros* (Proskauer 1969). A combination of phenology studies and genetic information revealing closely related **sympatric taxa** (having overlapping distributions) should reveal some examples.

Internal Barriers

In addition to external barriers, internal barriers may exist. Natcheva and Cronberg (2004) referred to these as reproductive isolation.

Gametic Isolation

Gametic isolation is a mechanism known from algae, animals, and tracheophytes, but it appears to be lacking, or perhaps simply unknown, in bryophytes. Wiese and Wiese (1977) define it in the green alga *Chlamydomonas* as nonoccurrence of initial contact between non-compatible gamete types. In other words, the opposite gene types such as sperm and egg cannot find or attract each other. In *Chlamydomonas*, gamete contact depends on molecular complementarity between **glycoproteinaceous** components. Parihar (1970) suggested that in bryophytes attractive substances such as sugars or proteins might help to guide the sperm to the archegonium and hence to the egg, but the importance and exact identity of such substances remains to be studied. (See Sperm Dispersal by the Bryophyte in Chapter 3-1.)

Natcheva and Cronberg (2004) found no studies to support the hypothesis that bryophytes produce substances to hamper or prohibit foreign sperm from entering the neck of an archegonium or to prevent penetration of the egg. In fact, Showalter (1926) showed that both moss and liverwort sperm [*Aneura* (Figure 31), *Sphaerocarpos* (Figure 29-

Figure 28), *Asterella* (Figure 80), and *Funaria* (Figure 38-Figure 39)] were able to penetrate the egg cells of the liverwort *Fossombronia* (Figure 81). Duckett (1979; Duckett *et al.* 1983) even reported that sperm of *Mnium hornum* (Figure 32) were able to penetrate the egg cells of the tracheophyte *Equisetum* (Figure 33).

Figure 31. *Aneura pinguis*, a possible sperm donor for the liverwort *Fossombronia*. Photo by Li Zhang, with permission.

Figure 33. *Equisetum* prothallus with archegonium (arrow). Note the neck projecting from the gametophyte. Eggs of this species can be penetrated by sperm of other phyla, including the moss *Mnium hornum*. Photo by Ross Koning, with permission.

Nevertheless, it does appear possible that the archegonium may attract and perhaps trap the sperm. In most cases, when the archegonium is mature and ready to receive the sperm, the neck canal cells and ventral canal cell disintegrate and exude a gelatinous matrix from the opening of the archegonial neck (Watson 1964). This has been considered the attracting substance, but others consider it a means of entrapment.

Since we know little about this entrapment in bryophytes, let's consider a well-known fern example. In the fern *Marsilea*, sperm reach the gelatinous matrix extruded by the archegonium when the neck canal opens. Once "entrapped" by the matrix, sperm are all directed toward the neck of the archegonium, which they enter, albeit slowly. Although Machlis and Rawitscher-Kunkel (1967) argue that these *Marsilea* sperm are trapped rather than attracted, it is significant that all sperm are clearly pointed toward the archegonial neck. Machlis and Rawitscher-Kunkel cite Strasburger (1869-1870) for a description of the massing of sperm at the opening of the neck canal in *Marchantia polymorpha* (Figure 34-Figure 35), suggesting that this likewise was entrapment in a gelatinous matrix surrounding the opening of the neck canal. Machlis and Rawitscher-Kunkel further cite Pfeffer (1884) as confirming observations of chemotactic responses of sperm to archegonia in the liverworts *Marchantia polymorpha* (Figure 34-Figure 35) and *Radula complanata* (Figure 36) and mosses *Brachythecium rivulare* (Figure 37), *Funaria hygrometrica* (Figure 38-Figure 39), and *Leptobryum pyriforme* (Figure 40). Alas, no substance he tested attracted the two liverwort sperm. Sperm of *Brachythecium rivulare*, *Funaria hygrometrica*, and *Leptobryum pyriforme* responded to sucrose, whereas the pteridophytes examined responded to malate. Parihar (1970) reported that sperm of the thallose liverwort *Riccia* (Figure 41) were attracted by proteins and inorganic sources of potassium.

Figure 41. *Riccia sorocarpa*, a thallose liverwort that attracts its sperm by proteins and inorganic sources of potassium. Photo by Michael Lüth, with permission.

These early observations were somewhat hit or miss and did not clarify what substances in the archegonia had attractive powers. Furthermore, Showalter (1928) reported that in the thallose liverwort *Riccardia* (Figure 42) the collapsed cells of the archegonial neck played no role in attraction.

Figure 42. *Riccardia latifrons* with emerging capsules. This species does not seem to produce a sperm attractant when the archegonial neck cells disintegrate. Photo by Michael Lüth, with permission.

More recent compendia ignore the topic completely (Chopra & Bhatla 1990; Crum 2001; Vanderpoorten & Goffinet 2009). We find it hard to believe that the archegonia of bryophytes lack such attractants. But are they able to attract only specific sperm? Perhaps it is the clonal nature of bryophytes that decreases the likelihood of a foreign sperm finding the egg. Nevertheless, specialization occurs, as demonstrated by studies where invertebrates carry the sperm to archegonia that attract those insects (Rosenstiel *et al.* 2012).

Genetic Incompatibility

Stenøien and Sæstad (2001) contend that bryophytes might experience inbreeding depression through genes that are silenced in the gametophyte phase but expressed in the sporophyte phase. Experimental evidence for this is beginning to emerge.

McLetchie (1996) found that in the dioicous liverwort *Sphaerocarpos texanus* (Figure 29-Figure 28), increasing inter-mate distance and decreasing male size reduced sporophyte production, thus suggesting sperm limitation. On the other hand, when three males and three females were mated in a factorial design resulting in nine unique crosses, sporophyte production was very low in some pairs of genotypes known to be fecund in other combinations. McLetchie suggested that genetic interactions may be responsible for some of the low levels of sexual reproduction in dioicous bryophytes. This would suggest that genes from a different population might be less compatible.

Genetic incompatibility was also suggested as one potential explanation for rare and incomplete sporophyte formation in dioicous *Abietinella abietina* (Figure 26) in a transplantation experiment (Bisang *et al.* 2004). But detailed data on the mechanisms in bryophytes are lacking. Natcheva and Cronberg (2004) could find no data indicating abortion of embryos in bryophytes and we are unaware of anything more recent. Nevertheless, Van Der Velde and Bijlsma (2004) found that up to 90% of the hybrid sporophytes from the crossing of *Polytrichum commune* (Figure 43) x *Polytrichum uliginosum* (= *Polytrichum commune* var. *uliginosum*; Figure 44) were aborted. Despite this poor reproductive performance, *P. uliginosum* has been considered to be a synonym of *P. commune* var. *commune* (Kew 2014), but Kew currently lists it as *Pogonatum uliginosum*.

Hybrid Sterility

Internal isolation among bryophytes is usually manifested by sterility of the hybrid sporophyte (Natcheva & Cronberg 2004). Nevertheless, hybrid sterility seems to be less important in bryophytes than in tracheophytes. There are numerous examples of presumed hybrids in mosses, in many cases being the mechanism of becoming monoicous. One consequence of fertilization from the wrong species is that the reproduction following that cross is unsuccessful. For example, sporophytes from these individuals typically produce many non-viable spores. But, since bryophytes are clonal, vegetative reproduction can lead to populations of ramets that are compatible with each other because all have the same number and type of chromosomes. There have also been a number of presumed interspecific hybrids noted in natural populations. Wettstein (1923) experimented with hybridization in the **Funariaceae** and was able to produce phenotypes that could also be observed in the field.

Bryophytes have two known types of **sterility barriers**: chromosomal sterility and developmental sterility. **Chromosomal (segregational) sterility** results from structural differences in chromosomes of the two parental species, causing disruption of pairing during meiosis and ultimately resulting in spores with incomplete chromosome sets or extra chromosomes. This type of sterility is known in pairing between *Ditrichum pallidum* males (Figure 45) and *Pleuridium acuminatum* (Figure 46, Figure 47), a case in which few spores formed and those that did aborted (Anderson & Snider 1982). The hybrid has intermediate characters of seta length, differentiated but indehiscent operculum, and spores of variable size (Andrews & Hermann 1959). Finally, Anderson and Snider (1982) reported almost a complete lack of chromosome pairing in hybrids between *Pleuridium subulatum* (Figure 48-Figure 49) ($n=26$) and *P. acuminatum* (Figure 47) ($n=13$).

Figure 45. *Ditrichum pallidum* with capsules, a species that hybridizes with *Pleuridium subulatum*, producing hybrid sporophytes with intermediate characters but that do not function normally. Photo by Michael Lüth, with permission.

Figure 49. *Pleuridium subulatum* with capsules, a species that hybridizes with *P. acuminatum* but hybrids subsequently exhibit failure of chromosome pairing. Photo by Kristian Peters, with permission.

Consider that of the numerous spores formed in some species, it seems likely that there will be the occasional spore that gets the right set of chromosomes during pairing of meiosis. But wait, spores normally are protected by other spores, and as we have seen, those other spores die slowly as some continue to enlarge and reach maturity. Those other spores help to maintain moisture and may even provide nutrients as needed in the maturing capsule, so this massive abortion could explain why those normal spores generally are not able to reach maturity in a capsule lacking protection by other spores due to abortion during or immediately following meiosis.

Developmental sterility occurs when hybridization successfully produces a new plant, but it is developmentally different from its parents. Typically, these plants are sterile, producing what appeared to be normal tetrads of meiospores, but lacking viability. Wettstein (1923) suggested that one explanation was that the paternal set of chromosomes was unable to function in the maternal cytoplasm. There are other possibilities of incompatibility between the two sets of chromosomes – chromosomes that led to production of incompatible or lethal substances or that interfered with timing mechanisms.

These hybridization phenomena occur in nature as well as in the lab, as in the well known examples of hybrids between *Astomum* (Figure 50) and *Weissia* (Figure 51) (Nicholson 1905; Andrews 1920, 1922; Reese & Lemmon 1965; Williams 1966; Anderson & Lemmon 1972). These hybrids between *Astomum* (Figure 50) and *Weissia* (Figure 51) resulted in sporophytes that were intermediate in seta length, capsule shape, operculum being present but non-dehiscent, and presence of a rudimentary peristome (Nicholson 1905; Andrews 1920, 1922; Reese & Lemmon 1965; Williams 1966; Anderson & Lemmon 1972).

Figure 50. *Astomum crispum* with capsules, member of a genus that is able to produce hybrids. Photo by Jan-Peter Frahm, with permission.

Figure 51. *Weissia muhlenbergianum* with capsules, a species with chromosome numbers of $n=13$ and $n=26$. Photo by Bob Klips, with permission.

But if one tracks chromosome numbers in bryophytes, it becomes clear that some of these hybrids have succeeded in making new species (see 3.1, Genome Doubling in Mosses). Hence, from the basic chromosome number of 10 in bryophytes, we find that *Weissia* (= *Astomum*) *muhlenbergianum* (Figure 51) has a basic number of $n=13$ and $n=26$ (Reese & Lemmon 1965; Anderson & Lemmon 1972). It is interesting that all hybrids in these two genera occur with *Astomum* as the gametophyte female parent. Is that merely a problem of human perception of what constitutes the two genera?

In the cross of *Weissia ludoviciana* with *W. controversa* (Figure 52) and of *W. muhlenbergiana* (formerly placed in *Astomum*) (Figure 51) with *W. controversa*, meiosis proceeded normally (Anderson & Lemmon 1972). But during the maturation and differentiation of the spores, abnormalities occurred, including spore abortion, failure to enlarge, retention in tetrads, and failure to develop chlorophyll.

Figure 52. *Weissia controversa* var. *densifolia* with capsules. Photo by Barry Stewart, with permission.

It is likely that many species experience both selfing and cross fertilization. These species necessarily either lack reproductive barriers or have barriers with incomplete effectiveness. For example, in the polyploid ($n=18$) monoicous liverwort *Plagiochasma rupestre* (Figure 53), both self fertilization and cross fertilization occur (Boisselier-Dubayle *et al.* 1996). Using two isozyme markers, Boisselier-Dubayle and coworkers determined that the two chromosome sets behave independently.

Apomixis?

Ozlem Yayintas asked me if mosses have apomixis. That stopped me short. I understand it in seed plants – seeds are produced without fertilization due to a failure in meiosis. Dandelions have apomixis. But do bryophytes? If so, what would define it?

Hans Winkler (1908) defined **apomixis** as replacement of the normal sexual reproduction by asexual reproduction, without fertilization. Bryophytes certainly have lots of forms of asexual reproduction that fit his original definition. But as time passed, the definition narrowed and is often restricted to production of seeds without fertilization, a definition that cannot fit bryophytes. If we stay with Winkler's original definition, bryophytes have exhibited chromosome doubling through autopolyploidy, but they also have created sporophytes from gametophytes,

fitting more closely with the seed definition (see Sporophytes from Fragments in Chapter 3-1 of this volume).

We turned to Google to see what others have said about apomixis in bryophytes. We found a 2013 study in which the researchers removed the KNOX2 gene and caused apomixis in a bryophyte (Elder 2013)! Sakakibara *et al.* (2013) deleted the KNOX2 gene in the moss *Physcomitrella patens*, the bryophyte version of a lab rat, and caused it to develop gametophyte bodies from diploid embryos without meiosis. It may sound easy, but it is a lengthy process. The next step for the food world is to knock out that gene in hybrid food plants, create apomictic offspring, and have reliable seeds with the hybrid characters they want, representing two sets from the mother.

Vegetative Apomixis?

Terminology evolves as our knowledge evolves, and we find that some bryologists use the broader definition of Winkler (1908). This confuses those familiar with the seed plant definition. As suggested by Katja Reichel (Bryonet 21 February 2014), perhaps it is best not to define it for bryophytes, i.e., don't use it. She cites the ambiguity of the earlier definition by Åke Gustafsson (1946) that includes every form of asexual reproduction in plants, compared to Gustafsson's later definition as **agamospermy**, which means seed formation without fertilization. But Täckholm (1922) had already clearly defined apomixis in higher plants as being divided into two groups of phenomena: agamospermy and vegetative multiplication. Richards (1997) removed the vegetative form of apomixis in the chapter Agamospermy in his 2nd edition of Plant Breeding Systems, arguing that it is not a breeding system. No matter how we choose to define it, the damage has been done and confusion will continue to reign.

Reichel refers us to Goffinet and Shaw (2009) for a discussion of apogamy and apospory: a life cycle without sex and meiosis, where the term is avoided in a discussion where its use would be appropriate with the broader definition. Similarly, information on apomixis can be found in the discussion of asexual reproduction in mosses by Newton and Mishler (1994).

"But who knows," Reichel continues, "perhaps we just do not have enough data to find sporophytes producing $2n$ spores after a failed attempt at meiosis (this would, I think, be equivalent to 'diplospory' in seed plants) etc!" We agree with Reichel: "Since the frequency and importance of all this in nature appears to be largely in the dark and/or controversial, perhaps it's still more important to describe what is seen than to try to find the right box and label."

Reproductive Tradeoffs

When conditions are constant, we can expect either sexual or asexual reproduction to dominate, ultimately to the loss of the other (Brzyski *et al.* 2014). But conditions are not constant, and year-to-year or habitat variations can favor one reproductive system in some years and the other system in other years (Bengtsson & Ceplitis 2000; Bowker *et al.* 2000). That is, the relative fitness varies among years and habitats. For example, in *Marchantia inflexa* (Figure

54), females invested more in asexual reproduction in man-made environments relative to females in natural habitats, and relative to males in similar habitats (Brzyski *et al.* 2014).

Figure 54. *Marchantia inflexa*. Photo by Scott Zona, with permission.

Cost of Sexual Reproduction

But what is the cost of producing a sporophyte, or more generally, of reproducing sexually? The basic assumption is that reproduction is costly, *i.e.* that a tradeoff exists between present reproduction and future performance (cost of reproduction) (Bell 1980; Williams 1996). Ehrlén *et al.* (2000) provided the first estimates of cost of sporophyte production, using the moss *Dicranum polysetum* (Figure 55) by experimentally manipulating sexual reproduction. They estimated that 74.8% of the total carbon allocation into top shoots during the study interval of about one year went to sexual structures in sporophyte-producing shoots. Shoots that aborted all sporophytes had significantly higher growth rates in the top shoots than did those with sporophytes. The difference in the mass of vegetative apical growth between control shoots and shoots in which sexual reproduction was manipulated was mainly because of different length increments. Mass per unit length was similar between groups.

In the same species, *Dicranum polysetum* (Figure 55), Bisang and Ehrlén (2002) found by examining patterns of growth and reproduction in shoots that females invest 16% of their productivity, as measured by photosynthetically active gametophyte biomass, into reproduction leading to sporophytes, but only 1.3% when eggs remain unfertilized, providing evidence of reproductive cost. Consequently, there is a negative correlation between development of mature sporophytes and annual shoot segment and innovation size. Sporophyte development further reduced the probability of future perichaetial development and mass of new perichaetia. It appears that the gametophyte and sporophyte must compete for limited resources within the plant.

Figure 55. *Dicranum polysetum*, one of the few bryophytes producing multiple sporophytes from one gametophyte apex. Photo by Janice Glime.

Laaka-Lindberg (2001) explored biomass allocation in the leafy liverwort *Lophozia ventricosa* var. *silvicola* (Figure 65). She found that females allocated an average of 24% of their biomass to sexual reproduction whereas males allocated only 2.3%. Gametangial shoots had shorter stem length and modified branching patterns.

Costs for sporophyte formation were also demonstrated in other species, measureable as lower shoot elongation in *Entodon cladorrhizans* (Figure 56) (Stark & Stephenson 1983), less favorable size development and branching patterns in *Hylocomium splendens* (Figure 57) (Rydgren & Økland 2002, 2003), and decreased regeneration capacities in *Pterygoneurum ovatum* (Figure 58), *Tortula inermis* (Figure 59) and *Microbryum starckeanum* (Figure 60) (McLetchie & Stark 2006; Stark *et al.* 2007, 2009, and references therein). Stark *et al.* (2009) induced sporophytic abortion in *Pterygoneurum ovatum*, and subjected plants to upper leaf removal and nutrition amendment treatments. The sexually reproducing plants were less likely or were slower to regenerate tissues or parts (protonemata or shoots). Nutrient amendment had no effect on ability or time of sexual reproduction or on the ability to regenerate clonally. Removal of leaves around the sporophyte base made the sporophytes slower to mature, less likely to mature, and smaller than those with their normal leaves remaining. Hence, there appears to be a cost in future development due to sexual reproduction.

Figure 58. *Pterygoneurum ovatum* with capsules. Photo by Hermann Schachner, through Creative Commons.

Figure 59. *Tortula inermis* with young sporophytes. Photo by Michael Lüth, with permission.

Stark *et al.* (2000) also found that males in *Syntrichia caninervis* (Figure 61) seem to invest more in antheridia than do females in archegonia. They made two assumptions and suggested that these may apply to other female-biased populations: 1) that male sex expression is more expensive than female; 2) that sexual reproduction is resource limited. This would give support to the "cost of sex" hypothesis, which predicts that the sex that is more expensive should be the rarer sex (Stark *et al.* 2000).

Figure 60. *Microbryum starckeanum* with sporophytes. Photo by Jonathan Sleath, with permission.

Figure 61. *Syntrichia caninervis*. Photo by Proyecto Musgo, through Creative Commons.

Using the dioicous moss *Drepanocladus trifarius* (Figure 62), Bisang *et al.* (2006) asked whether the formation of sexual structures indeed incurred a cost in terms of reduced growth or future sexual reproduction. This species is female dominant but rarely produces sporophytes. The annual vegetative segment mass was the same among male, female, and non-sexual individuals, suggesting there was no threshold size for sexual expression. On the other hand, sexual branches in females exhibited higher mean and annual mass than did those in males, while branch number per segment did not differ from that of males. Females thus had a higher prefertilization reproductive effort (11.2%) than did males (8.6%). Nevertheless, these investments had no effect on vegetative growth or on reproductive effort in consecutive years. Therefore, a higher realized reproductive cost in males, suggested to occur in the desert moss *Syntrichia caninervis* (Figure 61) (Stark *et al.* 2000), cannot explain the unbalanced sex ratio in *Drepanocladus trifarius* (Figure 62).

Figure 62. *Drepanocladus trifarius*. Photo by Andrew Hodgson, with permission.

Spore Size and Number

Spore size matters as well. During (1992) points out that when spores are small, bryophytes have the problem of juvenile mortality risk, but when they are large, the species has reduced dispersal potential. So it is not only a tradeoff in expenditure of parental energy vs providing offspring energy, or having many offspring vs few, but one of expanding the species to new areas vs staying put.

It would seem that having lots of large spores would overtax the female, whereas producing lots of small spores would provide ample opportunity to reach a suitable location for development of progeny. A compromise might be reached, but apparently has rarely been achieved by bryophytes, by having small male and large female spores. But is there further tradeoff to having lots of small spores? Noguchi and Miyata (1957) think there is. Their data indicate that mosses that produce abundant spores (implying mostly small ones) have a wide geographic range – the result of improved dispersal for tiny objects borne by wind, but the trade-off is reduced establishment success that restricts their habitats.

Where animals have had the evolutionary choice of producing many small offspring or few large ones and seed plants of producing many small seeds or few large ones, the bryophyte has a choice between producing spores of a small size in great numbers, larger spores but few in number, or producing no spores at all. For those taxa that produce no spores at all, we must assume that for most, either one sex is missing, or that they have spread beyond the range in which the proper signals and conditions permit them to produce spores. This usually means that fertilization cannot be accomplished. In these cases, vegetative means maintain the population and even permit it to spread to new localities, an option not available to most other groups of organisms.

Sexual vs Asexual Strategies

Sexual vs asexual strategies affect **metacommunity** (set of interacting communities which are linked or potentially linked by the dispersal of multiple, potentially interacting species) diversity (Löbel *et al.* 2009). In a study of Swedish obligate epiphytic bryophytes, forest patch size affected the species richness of monoicous species that reproduced sexually, whereas it did not affect the dioicous species that reproduced asexually. Löbel *et al.* found that it could take several decades for monoicous species to reach sexual maturity and produce spores. The researchers indicated that population connectivity in the past was more important for species richness in monoicous taxa than present connectivity. The difference in reproductive potential creates a tradeoff between dispersal distance and age of first reproduction. They suggested that this may explain the parallel evolution of asexual reproduction (primarily dioicous taxa) and monoicy for species that are able to live in patchy, transient habitats. Success in these conditions implies that relatively small changes in the habitat conditions could lead to distinct changes in the diversity of the metacommunity, wherein species using asexual reproduction may drastically decline as distances among patches increase, whereas those sexually reproducing species may decline as patch dynamics increase. (Sexual vs asexual strategies are discussed

further in Chapter 4-7, Adaptive Strategies: Vegetative vs Sexual Diaspores, in this volume.)

Bet Hedgers

Bet hedgers are those species that use multiple strategies, often making each of those strategies less successful than they might be if all energy were concentrated on one of them. They are beneficial in unpredictable environments where one strategy is best in some years and another in different years or where disturbance may occur.

Specialized asexual reproductive structures such as gemmae require energy and thus compete with productions of sexual structures. But it seems that at least some, perhaps most, of the bryophytes are bet hedgers by maintaining both vegetative and sexual reproduction. They may reduce this competition for energy by temporal separation of the programmed asexual and sexual reproductive stages. For example, in the thallose liverwort *Marchantia polymorpha* (Figure 34-Figure 35), in which large archegoniophores and antheridiophores require considerable tissue production, the production of gemma cups and their asexual gemmae is timed so it does not coincide with development leading to sexual activity (Une 1984). In the moss *Tetraphis pellucida* (Figure 63-Figure 64), the terminal position of the gemmae and their splash cups precludes the simultaneous production of the likewise terminal reproductive structures.

Figure 63. Top view of *Tetraphis pellucida* showing terminal gemma cups that prevent simultaneous development of reproductive structures. Photo by Janice Glime.

Figure 64. Side view of *Tetraphis pellucida* showing terminal gemma cups (and clusters that have lost their cup leaves) that prevent simultaneous development of reproductive structures. Photos by Michael Lüth, with permission.

Nevertheless, distinct tradeoffs between sexual and asexual reproduction have been detected. In studying biomass allocation of the leafy liverwort *Lophozia ventricosa* var. *silvicola* (Figure 65) Laaka-Lindberg (2001) found that sexual reproduction affected gemmae production. Female shoots averaged 800 gemmae, males 1360, and asexual shoots 2100, revealing a trade-off between sporophyte production (female sexual reproduction) and number of gemmae (asexual reproduction). In *Marchantia inflexa* (Figure 54), female sex expression was negatively associated with gemmae production under certain light conditions (Fuselier & McLetchie 2002). In agreement, *Marchantia polymorpha* ceases gemmae cup production during the period of producing sexual reproductive structures (Terui 1981). Pereira *et al.* (2016) reported a trade-off between pre-zygotic investment into gametangia and asexual reproduction, in terms of fewer gametangia in gemmae-producing shoots compared to barren shoots. Both the formation of gametangia and gemmae were in their turn positively associated with monthly precipitation. In contrast, Holá *et al.* (2014) suggested a minimal trade-off between sexual and asexual reproduction to occur in the aquatic liverwort *Scapania undulata* (Figure 66-Figure 67) as they found high gemmae production on male and female sex-expressing shoots.

Whereas tracheophytes may often reproduce by bulbs, rhizomes, stolons, or other specialized bulky organs, bryophytes have the advantage that most can reproduce by tiny fragments (Figure 68) from any part of the gametophyte, and under the right conditions, sometimes even sporophyte parts, all of which can travel more easily than the bulky organs of a tracheophyte. This strategy is an effective fallback even for many successive years of spore production failure.

The Japanese and others have taken advantage of fragmentation to propagate their moss gardens, pulverizing mosses, then broadcasting them like grass seed (Shaw 1986; Glime pers. obs.). For some mosses, like *Fontinalis* species (Figure 69) (Glime *et al.* 1979) or *Bryum argenteum* (Figure 70) (Clare & Terry 1960), fragmentation may be the dominant reproductive strategy, and for those dioicous taxa where only one sex arrived at a location, or one or the other sex is not expressed, or sexes are spatially segregated, it is the only means.

Growth vs Asexual Reproduction

Gemma cup number was negatively related to vegetative meristematic tips in *Marchantia inflexa* (Figure 54) (McLetchie & Puterbaugh 2000). Gemma production in *Anastrophyllum hellerianum* (Figure 71), on the other hand, did not affect shoot mortality (Pohjamo & Laaka-Lindberg 2004).

Figure 71. *Anastrophyllum hellerianum* with gemmae in Europe. Photo by Michael Lüth, with permission.

To test the tradeoffs in growth rate, asexual and sexual reproduction, and allocation to above and below-ground regenerative biomass, Horsley *et al.* (2011) cloned *Bryum argenteum* (Figure 70) for a growth period of 92 days, replicating each genotype 16 times, to remove environmental effects. There appeared to be three distinct ecotypes among the populations tested (representing 12 genotypes). It appears that the degree of sexual vs asexual reproductive investment is under genetic control. Furthermore, growth of the protonemata was positively correlated with both asexual and sexual reproduction. Asexual reproduction (Figure 72) was negatively correlated with shoot density, suggesting an energetic trade-off. None of these relationships appeared to be sex-specific. The sexes did not differ in growth traits, asexual traits, sexual induction times, or above- and below-ground biomass, but female sexual branches (Figure 73-Figure 75) were longer than those of males (Figure 76-Figure 77). Males produced many more perigonia (Figure 76) per unit area of culture media than the perichaetia produced by females, giving males 24 times the prezygotic investment. Horsley *et al.* considered that this strong sex bias in energy investment in male perigonia could account for the strongly female-biased sex ratio.

Significance of a Dominant Haploid Cycle

Longton (2006) provided evidence that dispersal of a spore is an extremely important aspect of bryophyte success in establishing new populations, whereas vegetative reproduction is more important for colony expansion and maintenance. Spores are $1n$ (**haploid**), and to be effective as a dispersal propagule, that body derived from the spore must have the characters needed for survival of the environment. This contrasts with those plants where it is a $2n$ (diploid) seed that gets dispersed. In the latter case, the $2n$ plant provides the needed environment for the development of the gametophyte, and the gametophyte is greatly reduced and resides mostly within the tissues of the

$2n$ plant. Hence, those plants (bryophytes and non-seed tracheophytes) that disperse largely by spores must find a suitable habitat for their gametophytes (See chapter on Dispersal).

In bryophytes, the diploid stage is forever attached to the haploid stage and dependent at least partially upon it. Haig and Wilczek (2006) point out that the diploid stage has one set of nuclear genes in common with its haploid mother, in addition to obtaining resources from that mother; the paternal haploid genes are not in common with those of the mother. They explain that all of the "offspring's maternal genome will be transmitted in its entirety to all other sexual and asexual offspring that the mother may produce," but not all will have the genes of the father. Haig and Wilczek suggest that this will favor genomic imprinting and predict that a "strong sexual conflict over allocation to sporophytes" will occur. Furthermore, chloroplast genes are inherited from the mother, but there has been little or no assessment of the effect this has on physiological behavior or environmental needs of bryophyte species as they relate to sexual bias.

Ricklefs (1990) reminds us that, just as in the algae, the haploid ($1n$) plant has the ability to express its alleles in the generation where they first occur, whereas the diploid ($2n$) plants have the ability to mask deleterious recessive alleles. The haploid ($1n$) generation possesses "immediate fitness" if a favorable change occurs among the alleles, but is immediately selected against if the change is unfavorable, unless, of course, the trait is one not expressed in the gametophyte. This immediate expression is a tradeoff with the ability to mask genes that may be retained and beneficial in a different location or different point in time.

Zeyl *et al.* (2003) used yeast, with both haploid and diploid generations, to test the question of whether there is any advantage to being haploid. Based on their experiments, they argued that being haploid permits an organism to accumulate beneficial mutations rather than to avoid the effects of those that are deleterious. This is founded on the premise that even beneficial genes are masked in diploid organisms and thus provide no immediate advantage, if ever. Rather, the rate at which a beneficial gene increases in frequency in a haploid organism is far greater than in a diploid organism (Greig & Travisano 2003). Of course it is never the case that all genes are expressed simultaneously, or even that all genes are expressed during the lifetime of an organism. They are there to be turned on when the physiological state of the organism calls for them.

Zeyl *et al.* (2003) hypothesized that in small populations, the haploid organisms would lose their advantage. They reasoned that by having twice as many of each gene, diploid organisms may have an increased rate at which adaptive mutations are produced. Hence the supply of adaptive mutations would be reduced, rather than any reduction in the time required to fix them. By doubling the adaptive mutation rates (diploidy) the adaptive mutations become more important in small populations. When adaptive mutations are rare the rate of adaptation by diploid populations approaches a doubling of that found in haploid populations. In small populations, having two sets of chromosomes is an advantage if the adaptive mutations are dominant because they will be expressed and gain

prominence through natural selection. But when the mutations are recessive, diploidy is a disadvantage because the mutations are not often expressed. In large populations, the extra genes (of the $2n$ state) would gain little advantage over the increased rate of expression of mutated genes.

Their experiments with haploid and diploid yeast (*Saccharomyces cerevisiae*) supported their hypothesis; in large populations, haploid populations adapted faster than diploid populations, but this was not the case when both populations were small (Figure 78) (Zeyl *et al.* 2003). They reasoned that a greater adaptation rate is not a general consequence of diploidy and does not, by itself, explain the prominence of diploidy in plants or animals. However, in their experiments they did not permit the yeast to mate, thus reducing the advantage of mixing in diploid organisms with chance mating of two beneficial or complementary mutations.

Figure 78. Rates of adaptation in large and small haploid and diploid populations of yeast. Bar length and 95% confidence interval was determined by slopes using linear regression of fitness on the generation number ($n=5$ pooled for 4 regressions). Ploidy was highly significant for large populations ($p<0.001$), but not for small populations ($p=0.35$). (2-tailed heteroscedastic t tests). Modified from Zeyl *et al.* 2003.

Would these experiments on one-celled yeast produce the same results if tried on multicellular bryophytes? There are genera, for example in the **Mniaceae**, in which some monocious taxa possess a double set of chromosomes, apparently derived from a dioicous taxon with a single set. These would seemingly make appropriate experimental organisms for such testing. Our current molecular methods should make such an evaluation possible.

Having a dominant gametophyte has its limits, however. Longton and Schuster (1983) remind us that, unlike tracheophytes, once having achieved fertilization, the bryophyte is able to produce only a single sporangium that subsequently produces spores all at one time (except in **Anthocerotophyta**). On the other hand, tracheophytes (polysporangiate plants) produce many branches, hence many sporangia, and these may be produced on the same plant year after year, all resulting from a single fertilization. The closest behavior to this among the bryophytes is in **Anthocerotophyta**, a dubious bryophyte as noted earlier, where meiosis occurs on the same sporophyte over a period of time, with older spores at the apex and new ones produced at the base of the sporophyte (Schofield 1985).

But bryophytes are more '**polysporangiate**' than they might seem. Whereas they cannot produce multiple sporophytes from a single fertilization, pleurocarpous species do have multiple sporangia produced on a single gametophyte plant (Figure 79), each potentially with a different combination of genes. And most bryophytes are **perennial** (persisting for multiple years), thus in most cases sequentially accomplishing multiple fertilizations under multiple conditions and selection pressures. Furthermore, the meiotic events in multiple cells of sporogenous tissue, even though all in one sporophyte, result in different sortings of chromosomes, thus different combinations among the many spores produced.

Figure 79. *Callicladium haldanianum* showing multiple capsules from one plant. Photo by Misha Ignatov, with permission.

In diploid plants, on the other hand, the number of recessive alleles continues to increase until the effect of their expression is the same in the **homozygous diploid state** (both alleles for a trait are the same) as it is in their haploid state (Ricklefs 1990). This provides the diploid organism with a short-term advantage of maintaining steady state while sequestering alleles that may at a later date become advantageous due to changing environmental conditions. A further advantage to diploid plants is that heterozygous organisms (those having two different alleles for the trait) frequently are the most fit, in some cases due to complementation (two traits that complement or help each other), in others due to having more possibilities of possessing fit alleles. On the other hand, presence of two alleles can mask somatic mutations (*i.e.*, mutations in non-reproductive cells) that ultimately could result in a lack of coordination between cells. Perhaps this lack of masked genes is only a disadvantage for a large (complex) organism that must keep all its parts working together, whereas in organisms where there are few cell types to coordinate, the condition is less likely to be problematic, particularly in an organism where vegetative reproduction is often the rule and little other specialization occurs.

Immediate fitness of haploid organisms permits the few individuals possessing a trait to exploit a new situation, whereas the delayed fitness of diploid organisms that require a like partner is unlikely to permit these species to respond quickly to environmental change.

One complication to this scenario of haploid and diploid is that often haploid organisms are not pure haploids. In fact, it appears that **autopolyploidy** (having more than 1 set of homologous chromosomes in the gametophyte) has been a significant factor in bryophyte evolution (Newton 1984). Many, probably most, genes are identical in the two sets, but some differ, and possibly in rarer cases, an entire chromosome may differ. These cases of autopolyploidy result in **functional haploidy** (Cove 1983), albeit with twice as many alleles as were present in the parent species. But does meiosis subsequently separate them into the same identical sets after fertilization has joined these with a new doubled set? Wouldn't this be an opportunity for new combinations of alleles to have different homozygosity and heterozygosity?

Do Bryophyte Sexual Systems Affect Genetic Diversity?

Where do these strategies leave bryophytes in their genetic variation? Bryonettors questioned the lack of diversity in bryophytes (see also Glime 2011). Do their mating systems, and in some cases lack of them, affect their genetic diversity?

Most people think of diversity in terms of morphology. But genetic diversity may not be expressed as morphological diversity. Rather, differences in biochemistry may occur without our recognition. Recent studies using molecular and phylogenetic methods support the conclusion that bryophytes in fact have greater diversity than we have supposed, as evidenced by the genetic differences between geographically different populations (Shaw *et al.* 2011).

Although differences in form among closely related species of small organisms such as bryophytes are limited because of their small number of cells and small size, we are beginning to find that physiological variety is great. Stenøien and Sæstad (2001) suggest that the mating system does not really matter in bryophytes in this respect. Rather, inbreeding can profoundly influence variation in the haploid generation. Furthermore, high levels of selfing are not a necessary consequence of being monoicous, as outbreeding is still possible, and even likely in some cases (see Reproductive Barriers above). Such mechanisms as different male and female gametangial maturation times would force outbreeding. Rather, the monoicous condition provides many other individuals nearby with whom genes can be exchanged, and it is possible that some of these have come from spores that represent a new combination of genes.

Whereas seed plants spend most of their lives with two sets of chromosomes ($2n$), they seldom express the mutations that arise because a second allele is present that still retains the old trait. For example, the absence of a gene to code for making a red pigment in the leaf might result in a green leaf in a species that would normally have a red leaf. Organisms with such hidden traits therefore have hidden changes that are retained in the population and that might at some future time be an advantage when conditions change. The ability to retain traits provides the plants with variability that might mean future success, but that do little for immediate fitness. In our pigment example, red pigment could protect the leaf against strong UV light, but if greenhouse gases and atmospheric exhaust

were to shield the Earth from UV light and reduce the light available for photosynthesis, being red might be less advantageous and a green leaf might then become beneficial for trapping more of the photosynthetically active portion of the spectrum.

Haploid bryophytes, on the other hand, cannot carry adaptive genes in a second set of chromosomes, but rather have immediate fitness or lack of fitness with the advent of a new gene. If these beneficial mutations occur in vegetative cells, they can be carried forward in clones or established in new colonies through fragmentation with no masking effects. Hence, if the bryophyte has a red pigment to protect it against strong UV light, it might not succeed in the shade, but those microspecies with no red pigments are immediately ready for the lower light levels. The individuals that do not have suitable genes may die, but those that have them are immediately fit.

Perhaps the answer to the paradox of genetic variation without cross fertilization does lie in asexual reproduction. It seems that asexual reproduction in bryophytes, unlike that of tracheophytes, may be a source of considerable variation (Mishler 1988, Newton & Mishler 1994). In addition to fragmentation, we know that bryophytes produce a variety of asexual propagules or gemmae (see Gemma-bearing Dioicous Taxa above and Chapter 4-10 of this volume) both above- and below-ground.

Clearly, producing gemmae or other propagules has served the dioicous taxa well. Growth by divisions of a single apical cell (instead of a meristematic region as in higher plants) can provide considerable genetic variation, with the fitness being determined almost immediately (Newton & Mishler 1994). Subsequent branches from this new growth, including gemmae and other propagules, and fragments that form new plants, would spread this new genetic variant. In some taxa, for example *Lophozia ventricosa* var. *silvicola* (Figure 65), the number of gemmae produced annually seems to outnumber the number of spores (Laaka-Lindberg 2000). Mishler (1988) suggested that sexuality is regressing in bryophytes with a concomitant increase in asexual reproduction, as later supported by During (2007) and others, particularly for dioicous bryophytes with high propagule production. Mishler feels that genetic variability is being maintained through somatic mutation, a suggestion by Shaw (1991) to explain variability in *Funaria hygrometrica* (Figure 10, Figure 38-Figure 39). The loss of sexuality is in sharp contrast to the suggestion of Longton (1997, 1998) that the monoicous condition will increase and with it the success of sexual reproduction.

If bryophytes can truly accomplish somatic mutations and make new plants, and they can derive new combinations from mating of autopolyploid plants, why then, are bryophytes still seemingly so primitive? Have they had a particularly slow evolution, with mutations providing little or no advantage? Some researchers have defended the position of slow evolution by referring to their small chromosome number (base = 9 or 10 in most, but 4 or 5 in some). Speculation suggests that their lack of structural support places severe limitations on the size bryophytes can support and the efficiency of water movement internally. This, in turn, limits the structural complexity they can support. However, recent biochemical evidence supports a genetic evolution as rapid as that of

lignified plants (Asakawa 1982, 1988, 2004; Asakawa *et al.* 1979a, b, c, 1980a, b, 1981, 1990, 1991, 2012; Mishler 1988; Stoneburner 1990; Newton & Mishler 1994). That is to say, the rate of allele change and the number of isozyme differences found among species is as great as in their more complicated lignified relatives.

So where have all these genetic changes been expressed? One explanation is that the bryophytes harbor a tremendous variety of secondary compounds (Asakawa 1982, 1988, 2004; Asakawa *et al.* 1979a, b, c, 1980a, b, 1981, 1990, 1991, 2012), *i.e.* compounds that do not seem to have any direct role in any metabolic pathway. Their apparent role in antiherbivory, antibiotics, and protection from desiccation and light damage may be the secret to the continuing success of the bryophytes.

With an understanding of the life cycle, we can begin to understand the conditions that are required for the survival of an individual species. Yet, few studies have examined the requirements and responses of individual species throughout all the stages of their lives. Their absence on a given site may relate to climatic events during their juvenile life when they must bridge the stage between spore and leafy plant, when they are a one-cell wide protonema and fully exposed with no protection from desiccation or blazing sun, or when they arrive as other forms of propagules (Cleavitt, 2000, 2002a, b). In the coming chapters we will examine their growth patterns, the effects of their habitats on their phenology, and their ability to adjust to habitat variability.

The Red Queen Hypothesis

Nothing in the life of a species plays a more important evolutionary role than reproduction. The ability to retain non-expressed genes that may later be expressed and be beneficial permits organisms to be pre-adapted to sudden or gradual changes in their environment.

The terminology **Red Queen** derives from Lewis Carroll's *Through the looking-Glass*. The Red Queen explained to Alice the nature of Looking-Glass Land: "Now, here, you see, it takes all the running you can do, to keep in the same place." Van Valen (1973) saw coevolution as running to keep in the same place.

The **Red Queen Hypothesis** was first proposed by Van Valen (1973) as an evolutionary hypothesis that proposes that organisms must "constantly adapt, evolve, and proliferate not merely to gain reproductive advantage, but also simply to survive while pitted against ever-evolving opposing organisms in an ever-changing environment." Van Valen devised the hypothesis to explain constant extinction rates exhibited in the palaeontological record as a result of competing species on the one hand and the advantage of sexual reproduction by individuals on the other. The theory was developed to explain predator-prey and host-parasite interactions in the evolution of animals. If the prey developed more skill in avoiding the predator, the predator subsequently developed more skill in catching the prey. If a host developed immunity to a parasite, the parasite that survived was a more virulent or aggressive one. The theory expanded to explain other evolutionary drivers. In our context here, it emphasizes the importance of sexual reproduction in maintaining protection against changes in the environment, including predators and parasites.

An example of the workings of this concept can be illustrated by the snail *Potamopyrgus antipodarum* (Jokela *et al.* 2009). When mixed asexual and sexual populations of this snail were cultured, the parasite population increased. The asexual snails were quickly reduced by the parasites, with some clones going extinct. Sexual populations, on the other hand, remained nearly stable over time, apparently adapting through genetic selection for the resistant genotypes that had been carried as a result of sexual mixing. Kerfoot and Weider (2004) supported the Red Queen Hypothesis by demonstrating a genetic relationship between changing predators and prey (*Daphnia*) through time using diapausing eggs of *Daphnia*, a parthenogenetic cladoceran. These eggs were derived from cores of sediment in Portage Lake from 1850-1997 and the eggs subsequently cultured to assess changes in characters. Clay and Kover (1996) tested the hypothesis in plant host-parasite interactions. They found that portions of the theory are supported, but not all.

At first this may not seem to apply to bryophytes, but consider the wide array of secondary compounds present among them. These compounds are known for their ability to protect the bryophytes from bacteria, fungi, and herbivores. This consideration can be considered as a parallel to the predator-prey or host-parasite relationships. As more herbivores evolved to attack the bryophytes, those bryophytes with the most protective array of secondary compounds were most likely to survive. But can it help to explain the persistence and re-introduction of the dioicous condition in bryophytes, as demonstrated for some animals (Morran *et al.* 2011)?

Sexual reproduction at the gene level permits sexually reproducing organisms to preserve genes that may be disadvantageous at present, but that may become advantageous under future conditions. This is somewhat complicated in bryophytes because of the dominance of the haploid gametophyte. But if the gene is not disadvantageous, or it is expressed only in the sporophyte, it could remain in the genetic line for centuries. If these genes code for secondary compounds that have been effective against predators, bacteria, fungi, or other dangers, they may be conserved in the genotype even if the danger is no longer present. And as new dangers arose, different secondary compounds would have been preserved in the genome, with the surviving bryophytes changing as the dangers changed. If the Red Queen Hypothesis applies, we should be able to see changes in the secondary compounds or the genome that relate to changes in the dangers. We can argue that the variability provided by the dioicous condition makes such changes possible to a greater extent than does the monoicous condition.

To our knowledge, there has been no test of the Red Queen hypothesis in bryophytes. Suitable fossils are scarce, but we should be able to test these ideas in ice cores that provide living organisms as much as 1500 years old (Roads *et al.* 2014)! By growing new organisms from fragments (see La Farge *et al.* 2013; Roads *et al.* 2014), we can compare the genes and also the potential responses to bacteria, fungi, or predators by looking at concentrations of secondary compounds using methods similar to those of Kerfoot and Weider (2004) for *Daphnia*.

Surviving in the Absence of Sexual Reproduction

Surviving unfavorable conditions is often a sexual function. In algae, **zygospores** (resting, resistant stage following fertilization) are the most common means of survival. In many invertebrate animals, including those living among bryophytes, the fertilized egg is likewise often the survival stage. Bryophytes do not use the fertilized egg to survive unfavorable conditions because that stage is dependent on the leafy haploid stage. Rather, many can produce sexual spores (meiospores) that survive during periods of drought and other unfavorable conditions. Spores are known to survive for long periods (See Chapter on Dispersal). Some species form persistent sporebanks that allow them to bridge unfavorable periods, then become active following disturbance. But bryophytes have many physiological means that permit them to survive without sexual reproduction.

As an alternative to spore survival, bud survival is important to some species. Haupt (1929) found that the thallose liverwort *Asterella californica* (Figure 80) survives hot, dry summers on banks and canyon sides in southern California as a leafy plant, but that only the ends of branches remain alive, starting new plants in autumn when sufficient moisture returns. In southern Illinois, *Fossombronina foveolata* (Figure 81) produces capsules in spring, but likewise survives the dry summer by means of its terminal bud, resuming growth in autumn and producing capsules a second time that year on the same plant (James Bray, pers. comm.).

These physiological mechanisms permit bryophytes to survive through vegetative reproduction for many years in the absence of sexual reproduction. And bryophyte species, unlike most tracheophytes, can survive for centuries without the intervening genetic mixing and resting stages afforded by sexual reproduction.

Bryophytes vs Seed Plants

The higher percentage of dioecy in bryophytes than in seed plants still begs explanation, and we have discussed possible explanations above and especially in Chapter 3.1. Could it in addition be that fragmentation, generally only available in poorly dispersed underground structures in seed plants, but available and easily dispersed from any part of the plant in bryophytes, might account for greater success of the dioicous condition among bryophytes?

Furthermore, since bryophytes are haploid-dominant, being dioicous provides immediate production of new genotypes as soon as sexual reproduction occurs, thus making selection for this strategy more rapid than in seed plants. Does this explain the high degree of dioecy among the early-diverging bryophyte group, where there has been considerable time to develop the best of the two strategies?

One answer may lie in short-distance dispersal of the male gametes, coupled with ease of vegetative reproduction in bryophytes. In seed plants, the male gametophyte (pollen grain) is more easily dispersed with less danger to its viability. There has been an enormous amount of evolution perfecting transfer by vectors, especially insects, among seed plants. While this would seem to improve dioecy fertilization success, it also provides for considerable outcrossing success for monoecy. It may also be the case that seed plants have more effective mechanisms for preventing successful self-fertilization. On the other hand, the vegetative ability to reach new locations is extremely limited in seed plants, although it can be quite effective over the short distance. For seed plants, long distance dispersal is almost entirely dependent on sexual reproduction. By contrast, many bryophytes can be dispersed considerable distances by both specialized vegetative diaspores and fragments (see for example Laenen *et al.* 2015), thus compensating for any lack of spores.

Summary

Monoecy (both sexes on same individual) frequently has arisen through **hybridization** and **polyploidy** (multiple sets of chromosomes). Barriers to hybridization and to **selfing** in bryophytes are poorly

known. These include **external barriers** such as **spatial/geographic isolation**, **ecological isolation**, and **seasonal isolation**. **Internal barriers** include **gametic isolation**, **genetic incompatibility**, **hybrid sterility**, and **reduced fitness**. Nevertheless, hybridization seems to have played a major role in the evolution of monoecy due to lack of these barriers in many species.

Formation of gametangia and especially sporophyte formation incur reproductive costs measurable in reduced future vegetative and reproductive performance. Overall investment in sexual reproduction may vary among species, in some cases being greater in males and in others greater in females, depending on if assessed at the pre- or postfertilization stage.

Tradeoffs occur between dispersal ability of small spores and success of establishment of large spores. Fragments and vegetative diaspores are most successful at colonizing over short distances and are more likely to succeed than spores. Asexual reproduction can keep the species going for many years in the absence of sexual reproduction. Tradeoffs occur also among asexual reproduction, sexual reproduction, and vegetative performance. These tradeoffs vary among species.

The dominant haploid state of bryophytes limits their ability to store **recessive alleles**, but **autopolyploidy**, **somatic mutations**, **vegetative reproduction**, and **independent assortment** at meiosis contribute to genetic diversity. Despite their clonal nature, bryophytes still exhibit considerable genetic variation. This may be explained in part by the **Red Queen hypothesis**, a hypothesis that also might explain the persistence of evolution to a dioicous condition despite the difficulty of accomplishing sexual reproduction. Inbreeding depression may occur in monoicous bryophytes, but limited data suggest that it may be to a lesser degree compared to that of tracheophytes.

Bryophytes may lack the morphological diversity expressed by sporophytes in higher plants, but there is evidence that haploid plants and their diaspores can contain as much diversity as tracheophytes, often expressed in their biochemistry as a variety of secondary compounds rather than in morphology. They have life strategies that have survived since the beginning of land plants.

Acknowledgments

We greatly appreciate the numerous comments and suggestions of Lars Hedenäs who provided a critical review of an earlier draft of the paper and gave us encouragement. I greatly appreciate the collaboration of my coauthor Irene Bisang, who offered an invaluable critique of this subchapter and asked probing questions that have greatly improved both organization and content. Aaron Garceau provided a student's perspective on the clarity of the Red Queen Hypothesis. Bryonettors have been especially helpful in providing examples and observations to answer questions arising during the preparation of this chapter.

CHAPTER 4-1

ADAPTIVE STRATEGIES: PHENOLOGY, WHAT DOES IT MEAN?

Figure 1. *Hylocomium splendens* emergent from the winter snow. Timing of reproduction must be such that sperm do not mature on a warm day in winter, only to be frozen by ensuing sub-freezing temperatures. Photo by Michael Lüth, with permission.

Phenology, defined by Stark (2002) as "the study of the timing of growth and reproductive events," is also used to refer to the series of events and includes changes of form and phenomena of an organism through time as they relate to climate and season. Classical studies in Europe have included branching architecture, timing of vegetative growth, gametangial initiation times, fertilization times, duration of sporophyte development, and time of spore liberation (Stark 2002). To these we can add nutritional status, population dynamics, fitness measures, spore dispersal patterns, interplay of sexual and asexual reproduction, **sexual dimorphism** (sexes look different), structural development, dormancy, and desiccation tolerance. Studying phenology permits us to understand interplay of plants with a constantly changing environment.

In the temperate forest, trees lose leaves in autumn, bloom and leaf out in spring, and store **photosynthate** (product of photosynthesis) in summer. These canopy phenological events have profound impact on smaller

plants growing beneath them. Spring flowers bloom before leaves emerge on trees, taking advantage of a nearly full complement of sunlight. A few shade-tolerant species grow more slowly and take advantage of the tree canopy to protect them from bright light of summer. Other species use fungal partners to connect them with trees, taking advantage of canopy photosynthate that permits them to survive in low light. As these ground cover taxa enlarge through summer, bryophytes are impacted by light-depriving leaves of larger neighbors.

Bryophytes also must cope not only with a changing light and moisture regime resulting from the direct effect of changing seasons, but also with microclimatic changes resulting from changes in the tracheophytes around them. Their C_3 photosynthetic pathway (CO_2 is immediately put into photosynthesis, forming 3-C compound) permits them to take advantage of early light and moisture at snowmelt (Figure 1) when low temperatures prevent even other C_3 plants from having effective photosynthesis.

Bryophytes are limited in their occupancy of deciduous forests by the phenological event of leaf fall that fully blocks the light essential for their photosynthesis. Most forest bryophytes are perennials, yet, unlike their tracheophyte counterparts, most are unable to avoid the changing seasons by storing energy underground and losing their photosynthetic parts. As C_3 plants, they are able to photosynthesize at low temperatures as soon as the snow is gone, but they are likely to find the hot temperatures of summer to be detrimental. Furthermore, they require water to transfer their swimming sperm, rarely having an animal vector to carry these for them. Based on these constraints, we should expect that bryophytic phenological responses differ somewhat from those of their lignified vascular companions as the bryophytes take advantage of or avoid the changes provided by these companions.

One need only examine a few bryophyte floras to recognize that phenological events for mosses are poorly documented. Almost any flowering plant flora will include flowering dates, but bryophyte floras from Japan (Noguchi 1987-1994), the Nordic (Nyholm 1986, 1988, 1993), Michigan (Crum 2004), and the tropics (Gradstein *et al.* 2001) all fail to mention any season for any life cycle event, even the season of spore dispersal. Crum and Anderson (1981) occasionally include the season of spore ripening for the Eastern United States, but never any information on seasons for other events. In treating the genus *Sphagnum*, for which both authors are world-renowned systematists, not a single species of the 42 described includes any phenological information. Conard (1947), in reporting the phenology of Iowa bryophytes, was able to find dates in the literature for presence of antheridia or archegonia for only 15 taxa out of 292. He was more successful in finding documentation of capsule production dates, locating it for all but 28 of the taxa that fruit in Iowa.

As the young field of bryophyte ecology began taking shape in the early 1970's, Longton (1974) suggested that the International Association of Bryologists and the British Bryological Society (Longton 1982) embark upon bryophyte phenology as a project. Perhaps because of British national pride, or because of the large number of good bryologists among the British society's mostly amateur membership, such a project had appeal to the BBS. It was a way for many people to contribute important information that could only be gained by such a wide undertaking. Through concerted efforts, they could define not only the phenology of a wide array of species, but could look at differences in patterns throughout the British Isles, comparing inland species with coastal, mountain and moor with valley and field.

Developing Consistency in Reporting

For comparisons among various studies and localities, a consistent way of examining and describing life cycle stages is necessary. Again, the British were the leaders, with a publication by Greene (1960) elucidating the stages. The British faithfully followed this nomenclature in making their reports. Slight modifications and refinements have made this system workable around the world.

Most researchers seem to recommend observing every two weeks to elucidate the phenology (Stark 1984). In general, the life cycle stages are arrested while the plants are dry, so it is possible to collect specimens periodically,

then examine them later at one's convenience. The ability of bryophytes to continue their life cycle upon rehydration makes it possible to identify the stages after rehydration and even to photograph them. Nevertheless, one should exercise caution if high resolution is needed in defining dates because the ability to retain water may permit the bryophytes to continue development for a period of time. Mosses kept in plastic bags may continue growth for a month, elongating abnormally in the lower light of their new location. Dry mosses may shed the operculum prematurely, since drying itself is needed in most taxa to constrict the capsule and force the operculum off, occurring sooner in the dry lab than it would in nature with nightly dew to re-supply moisture.

When reviewing a series of dry collections, Stark (1984) recommends soaking the stems for a few minutes and removing the leaves on the upper 10-15 mm of the main stem, but not from the branches. This can be done with microforceps by holding the tip and pulling the leaves downward toward the base, being careful not to injure the gametangia in the process. Once leaves are removed, one can carefully remove a group of gametangia near the apex and place it in a drop of water on a slide. In **pleurocarpous** mosses (Figure 1), gametangia occur on side shoots, rather than at the stem apex where they occur in **acrocarpous** mosses (Figure 5). You can shorten the process by pressing the gametangia off with the side of a probe. In either case, use a cover slip and examine them with the compound microscope. Data should be recorded using one of the published systems of naming stages.

System of Naming

Fortunately for the British, and for bryologists everywhere, systems for scoring the developmental stages already existed. Greene made the "most significant" contribution to phenology (Stark 2002) when he suggested 20 stages (Figure 2), centering on the reproductive phases only, and omitting any presentation of the spore and protonema. He even recommended a method for preparing figures to illustrate the monthly changes (Figure 3).

Figure 2. Maturation stages as represented by Greene (1960). J = juvenile, I = immature, M = mature, D = dehiscing, W = withered archegonia or antheridia, SV = swollen venter, ECP = early calyptra in perichaetium, LCP = late calyptra in perichaetium, ECI = early calyptra intact, LCI = late calyptra intact, EOI = early operculum intact, LOI = late operculum intact, OF = operculum fallen, EF = empty and fresh.

Figure 3. Sample figure given by Greene (1960) to illustrate the gametangial and capsular cycles of three species of moss. **Numbers in parentheses** indicate number of collections in which the majority state occurred. The **circled x** represents the state that was clearly the most abundant, **x** alone represents other stages that occurred as majority states in some collections, and a **solid circle** indicates present but never abundant. As in the previous figure, **SV** = swollen venter, **ECP** = early calyptra in perichaetium, **LCP** = late calyptra in perichaetium, **ECI** = early calyptra intact, **LCI** = late calyptra intact, **EOI** = early operculum intact, **LOI** = late operculum intact, **OF** = operculum fallen, **EF** = empty and fresh; **J** = juvenile, **I** = immature, **M** = mature, **D** = dehiscent, and **W** = withered archegonia or antheridia.

Shortly thereafter, Forman (1965) developed a somewhat easier system by which researchers could make consistent descriptions related to phenological events. He decided that no two stages should be named separately unless they were morphologically distinct. Furthermore, the stages should be relatively easy to recognize without the use of a microscope. He defined the life cycle in 12 stages (Figure 4) for the purpose of describing the phenology and other events more precisely and in a standard fashion.

Forman (1965) decided that stages need not be delimited if they did not require any change in environmental conditions. For example, early and late stages of seta elongation are not separated because they occur as a continuous process independent of any environmental trigger. On the other hand, growth of the

- A. **Embryonic calyptra.** (This corresponds with the development of the embryo following fertilization.) This stage commences with fertilization and terminates with the rupture of the gametophytic calyptra from the tissue beneath. The seta is not visible under the expanded neck cells of the archegonium.
- B. **Seta with calyptra.** (This corresponds with the growth of the sporophyte from the embryo.) This stage commences when the seta becomes visible and terminates at the beginning of capsule expansion at the tip of the seta. A few plants lose their calyptras during this stage, but it is doubtful that these can eventually produce spores.
- C. **Capsule green with calyptra.** (This corresponds with meiosis.) This stage ends either with the shedding of the calyptra or with the urn of the capsule beginning to turn brown. Meiotic divisions may occur from the latter portion of capsule expansion through the darkening of the operculum, depending upon the species.
- D. **Capsule operculate and post-meiotic.** (This corresponds with spore maturation.) Since species appear differently in this stage, both green capsules without a calyptra and capsules at least partly brown with or without a calyptra are included here. This stage terminates with the dehiscence of the operculum.
- E. **Capsule de-operculate.** (This corresponds with spore dispersal at the beginning.) This stage includes capsules containing spores, empty capsules in the year of maturation, and empty capsules from a previous year.
- F. **Spore wall bulging.** (This corresponds with spore germination.) This stage terminates with the appearance of the cross wall of the first cell division.
- G. **Protonema.** (This corresponds with growth of the protonema.) This stage begins with the two-celled structure as it emerges from the spore and terminates with the initiation of buds.
- H. **Bud on protonema.** (This corresponds with the initiation of the leafy shoot.) This stage terminates with the beginning of rapid stem elongation.
- I. **Juvenile stem.** (This corresponds with growth of the leafy shoot.) This stage terminates upon cessation of stem elongation and development. In practice two criteria have been used to identify this stage, namely, smaller leaves at the shoot tip plus a lighter green color in these leaves (indicating new growth). These two criteria may not be apparent in all species, in which case additional criteria should be found.
- J. **Juvenile gametangium.** (This corresponds with the initiation of a sex organ.) Antheridia and archegonia are indistinguishable from each other at this stage. This stage ends when the sex can be determined.
- K. **Antheridium.** (This corresponds with growth of the sex organ and differentiation of microgametes, *i.e.* sperm.)
- L. **Archegonium.** (This corresponds with growth of the sex organ and differentiation of megagametes, *i.e.* eggs.) The presence of differentiated perichaetial leaves in some species will identify this stage from k.

Figure 4. Life cycle stages based on Forman (1965).

embryo within the perichaetium is likely to differ from growth of the seta because the developmental environment changes substantially once the seta emerges from the protective leaves. Forman conveniently chose the embryonic calyptra as the first stage (of course there is no beginning or end to a cycle), placing the protonema to gametophore stages (including production of gametangia) last, perhaps because these "later" stages are the most difficult and least likely stages to be observed.

Figure 5. *Bryum pallescens* showing terminal seta and capsule of an acrocarpous moss. Note that the capsule is protruding from last year's gametophyte while the growth for the current year is tall. Photos by Michael Lüth, with permission.

Stark (1984), in encouraging North Americans to join in collecting phenological data, recommended a modification of the systems of Longton (1979) and Greene (1960) for describing gametangia. It adds clarity and distinguishes between young, mature, and ruptured gametangia, distinctions that are important in taxa that have gametangial development interrupted by winter or a dry season:

- 1 = unruptured and less than 1/2 full length
- 2 = unruptured and more than 1/2 their full length
- 3 = green or hyaline with apices ruptured
- 4 = brown with apices ruptured
- A = abortive; brown and unruptured

Stark later (2002) developed a system of fourteen events, but this system requires a 400x lens to distinguish the beginnings of gametangia before the gender is distinguishable, and while it provides more information, such requirements as determining that the theca contains fewer than half the spores makes the system rather impractical.

Imura (1994) reduced the number of stages to five in his study of *Pogonatum inflexum*, but provided us with a graphical way of representing the sequence of events that is easy to produce and useful in understanding phenological relationships across multiple years (Figure 6). The degree of detail needed depends on the purpose, and certainly the representation by Imura serves a useful purpose to see the progression and overlap of events between years.

While the stages of the life cycle are similar for all bryophytes, the timing differs. This chapter will examine the major events and factors that control their timing. As demonstrated by Imura (Figure 6), these events include gametophyte growth, production of gametangia, fertilization, production of sporophytes, and dispersal of spores, as well as events that are more difficult to examine in the field – spore germination and development of gametophore buds.

Figure 6. Annual sequence of events for *Pogonatum inflexum* on Miyajima Island, Japan. Redrawn from Imura (1994).

Summary

Phenology is defined by Stark (2002) as "the study of the timing of growth and reproductive events." The term is likewise used to refer to the series of events and includes changes of form and phenomena of an organism through time as they relate to climate and season.

The life cycle of a bryophyte can be described based on those stages that are **observably different**, are **discontinuous**, and require a **change in environmental conditions**. This definition presents us with the recognizable stages of **embryonic calyptra**, **seta with calyptra**, **green capsule with calyptra**, **operculate post-meiotic capsule**, **de-operculate capsule**, **spore with bulging wall**, **protonema**, **protonema with bud**, **juvenile stem**, **antheridium**, **archegonium**.

Acknowledgments

I appreciate the helpful comments of Heather Smith in giving me a student's perspective on this chapter. Linda Luster checked the literature citations, proofread, and checked for needed glossary entries.

CHAPTER 4-2

ADAPTIVE STRATEGIES: PHENOLOGY, IT'S ALL IN THE TIMING

Figure 1. *Atrichum undulatum*, emergent from the snow, has already formed capsules, but must time the release of spores for a time favorable for their dispersal and germination. Photo by Michael Lüth, with permission.

Timing the Stages – Environmental Cues

It's all in the timing! Life cycles are the acrobatics of the plant world, and failure to time things correctly is just as deadly as missing your partner when swinging on the high wires. Timing determines when to germinate, when to release sperm, when to develop the sporophyte, and when to release the spores. This timing must be closely attuned to the climate of the area where the organism is growing and is a major factor in limiting the distributions of many species. In 1984, Taylor and Hollensen contended that there is "rarely any attempt to correlate life changes with time of year." However, where this ecophysiological information is lacking, there is no shortage of studies on dates of phenological events, despite their absence in most bryological manuals. In fact, the sheer numbers of studies are daunting and have caused the delay of this chapter. I will attempt to provide some of the implications of cause

and effect through that available literature and examine how habitat and geography influence the timing.

Patterns

Stark (2002a) has compiled patterns of temperate zone phenology based on publications of a few bryophytes [*Pohlia* (Figure 2) in UK, *Ptychomitrium* (Figure 3) in Japan, *Grimmia laevigata* (Figure 4) in Spain, *Bryum argenteum* (Figure 88) in UK, *Polytrichum juniperinum* (as *P. alpestre*; Figure 5) in UK, *Forsstroemia producta* (Figure 6) in eastern USA]:

1. Antheridia initiate in autumn and winter, maturing the next spring and summer (duration several months)
2. Archegonia initiate and mature in the same spring and summer (duration several weeks)
3. Fertilization occurs in summer, lasting two weeks to several months.

Figure 2. *Pohlia nutans* with capsules, in a genus used to represent phenology of UK mosses. Photo by Bob Klips, with permission.

Figure 5. *Polytrichum juniperinum* with antheridial splash cups, a species used to represent phenology of UK mosses. Photo by Ian Sutton, through Creative Commons.

Figure 6. *Forsstroemia producta*, a species used to represent phenology of eastern USA mosses. Photo from Earth.com, with permission.

This pattern most likely works well for the many bryophytes that live in areas where they rely on spring rains for fertilization. But notable exceptions exist to these examples with their strongly temperate bias. For example, in Brazil the period of fertilization for *Sematophyllum subpinnatum* (Figure 7) extends throughout the entire year (de Oliveira & Pôrto 2001). In the desert, both gametangial initiation and fertilization in *Trichostomum sweetii* occur in the autumn and winter (Stark & Castetter 1995).

Figure 7. Epiphytic moss *Sematophyllum subpinnatum* in Brazil. Photo by Michael Lüth, with permission.

The sporophyte is dependent on moisture for its own development, but it fares best if it is dry for spore dispersal. Stark (2002a) considered that six generalized patterns prevail for sporophyte maturation:

1. Fertilization in spring and summer with continuous development; spore dispersal anywhere from early summer to the following spring; suitable for a mild climate.
2. Fertilization in summer; embryos overwinter & sporophyte matures the following spring or summer; spore dispersal over extended period; typical of areas with harsh winter; two cohorts may be developing at the same time.
3. Fertilization in summer (or spring) with continuous development to or just past meiosis; overwintering in meiotic/postmeiotic phase; spore dispersal winter-spring; known in south temperate of Northern Hemisphere.
4. Fertilization in winter/spring with embryos forming first winter; dormancy in summer; sporophyte maturation second winter; known in several desert species.
5. Annual species, sporophyte development within two months; fertilization at various times of year – flexible.
6. No pattern; events throughout the year

Zander (1979) reported patterns with taxonomic affinities. He examined spore maturation times in the **Pottiaceae** and showed that differences tended to group by suprageneric taxa. The **Trichostomoideae** mature primarily in spring, **Pleuroseisidae** in midyear, **Barbuleae** are bimodal, **Pottidae** primarily spring, but also summer and winter, **Cinclidotoideae** spring and summer, and **Leptodontieae** poorly known but mainly spring. He attributed the patterns to regional climate and the stress-tolerant nature of these taxa. He further considered that their **ruderal** (waste areas) habitat subjected them to competition from annual tracheophytes that forced them to take advantage of snowmelt water. He further concluded that spores of nearly all mid-latitude Pottiaceae taxa of variable, dry, lowland habitats mature in winter, spring, or early summer. Yet these taxa typically take 9 to 12 months for their sporophytes to mature. Perhaps this strategy permits the spores to germinate immediately while there is still available water, space, and light. Those species that occur in seepage areas or near waterfalls have summer or autumn maturation times instead, again suggesting that water is a driving force in sporophyte maturation times for the other taxa. Zander also found that non-endemic

dioicous taxa in the Pottiaceae retain mature capsules slightly longer (mean 6.77 months) than do monoicous taxa (mean 5.55 months).

Growth

Growth is generally controlled by a combination of factors (light, temperature, nutrients, water), but in bryophytes, available water generally is the most important (Zehr 1979). Once moisture is available, the temperature must be sufficiently warm for the water to be in liquid form. Since bryophytes are C_3 plants, most function best at temperatures less than 25°C, so growth may cease during summer.

In temperate climates, growth generally seems to occur in spring and autumn, ceasing or at least diminishing in summer (Al-Mufti *et al.* 1977). For example, *Atrichum undulatum* (Figure 1) exhibits this type of growth in South Wales (Figure 27; Benson-Evans & Brough 1966). For other species, growth is predominately in spring, and autumn seems to be a time for elongation without biomass production (Rincon & Grime 1989; Figure 8). Other taxa, adapted to full sun, may be more productive in summer. This is the case in *Polytrichum juniperinum* (as *P. alpestre*; Figure 9), which grows in June and July (Longton 1979). Interestingly, dry weight continues to increase until September, despite the greater increase in photorespiration with rising temperature, a topic that will be discussed in more detail in the chapters on photosynthesis and productivity.

Figure 8. Comparison of relative growth rates in length and dry matter production in five bryophytes from calcareous grasslands. Redrawn from Rincon & Grime (1989).

Where winters are mild, growth may occur throughout the winter. In Japan Imura and Iwatsuki (1989) found that male plants of *Trachycystis microphylla* (Figure 10) elongate most rapidly from October until January, but interestingly, the female plants begin their rapid elongation in January and continue until June. In cases where this makes male plants taller than females during sperm dispersal stages, this could be an advantage for facilitating splash of sperm onto an archegonial inflorescence.

Epiphytes may take advantage of decreased desiccation and temperature in winter. Pitkin (1975) found the greatest growth of *Hypnum cupressiforme* (Figure 11), *Platygyrium repens* (Figure 12), *Neckera pumila* (Figure 13), *Isoetecium myosuroides* (Figure 14), and *Homalothecium sericeum* (Figure 15) in November to January in Oxfordshire, UK, corresponding to highest rainfall and mean temperatures below 10°C at 15:00 hours. Trynoski and Glime (1982) suggested that the appearance of more bryophytes on the south side of trees at breast height in the Keweenaw Peninsula of Michigan, USA, could indicate ability to grow in winter when protection and moisture were available in the space between snow and tree trunk.

Furness and Grime (1982) show strong seasonal effects of temperature that help to explain the phenology of some bryophytes (Figure 16). These results are consistent with peaks of growth in spring and autumn in British tall herb communities. But they also show that different parts of the bryophyte can grow at different times and be favored by different temperatures. In *Brachythecium rutabulum* (Figure 17) growth of rhizoids peaks at 12°C, branches at 15°C, and stems at 20°C.

Figure 16. Effects of lab temperature on growth of branches, stems, and rhizoids of *Brachythecium rutabulum* (Figure 17) and relative growth rate among 9 growth temperatures under conditions of constant humidity. Redrawn from Furness & Grime 1982.

This difference in temperature, and thus timing of life processes, is consistent with observations on *Fontinalis* organs (Glime 1980, 1982, 1987b) and suggests that the bryophyte apportions its limited photosynthate to different activities at different times. This conserves energy and permits directing that energy into the needed structures. In *Fontinalis*, we can presume that the timing is advantageous because the rhizoids (Figure 18) develop best at temperatures that coincide with the season when the moss is most likely to be stranded above water during low water (summer) and is therefore not likely to be dislodged by the

motion of the water. The plants are typically "glued" to the rocks by their covering of sticky algae at this time. Furthermore, in *Fontinalis* (Figure 19) branching and growth follow the season of maximum runoff when fragments have been delivered to new substrata in the stream. Intact but damaged plants can also be replenished then (Glime *et al.* 1979; Glime 1980; Figure 20). Timing of gametangial production must permit the gametes to be splashed from plant to plant without having these structures submersed where they will be carried away by the moving water in streams.

Many bryophytes, such as *Eurhynchium praelongum* (Figure 21), are relatively dormant in winter, resuming growth in spring (April) and continuing through August, with the main peaks in May and September (Benson-Evans & Brough 1966). The common boreal forest feather moss *Pleurozium schreberi* (Figure 22) grows little in winter, with growth from April to November (Longton & Greene 1969), but then one can't expect it to grow in the dim or absent light under snow.

Figure 21. *Eurhynchium praelongum* Bicton Common England. Photo by Janice Glime.

Figure 22. *Pleurozium schreberi*, a moss that spends its winter under snow and resumes growth when the snow melts. Photo by Janice Glime.

In contrast, Mishler and Oliver (1991) found that **innovations** (new shoots; in acrocarpous mosses, a new branch) in the drought-tolerant *Syntrichia ruralis* (in the mountains of southern New Mexico, USA; Figure 23) appeared in midwinter, lengthening slowly throughout spring, but growing rapidly in late summer and completing growth by winter. Likewise, the chlorophyll concentration was higher in late summer and winter than it was in early summer, but there was no regular pattern of chlorophyll *a/b* ratios.

Figure 23. *Syntrichia ruralis* benefitting from the rain. Photo courtesy of Peggy Edwards.

Other species in these temperate climates lack seasonal growth peaks. Benson-Evans and Brough (1966) found that *Funaria hygrometrica* (Figure 54) initiated new leafy shoots continuously throughout the year in South Wales, reaching their maximum height of about 5 mm in 10 weeks (Figure 27). This results in numerous shoots that can quickly colonize bare ground.

Sphagnum most likely is controlled primarily by water availability, not by temperature. Lindholm (1990) demonstrated that the hummock species *S. fuscum* (Figure 24) could grow at most normal temperatures above 0°C, but that moisture was the primary determinant in that range. Li (1991) found that 30-35°C was optimum for growth of the hummock-dwelling *Sphagnum papillosum* (Figure 25) and *S. divinum* (Figure 26) when adequate water was available.

In South Wales, *Atrichum undulatum* (Figure 1) becomes dormant in late summer and begins growth again in January (Figure 27). Benson-Evans & Brough 1966). Different clones of this species can have different growth periods. In *Funaria hygrometrica* (Figure 54), growth can begin from new plants in any month of the year and is relatively continuous (Figure 27).

Figure 27. Contrast in vegetative growth periods for two bryophyte species in South Wales. *Atrichum undulatum* (Figure 1) becomes dormant in late summer and begins growth again in January. The three curves follow three different sets of plants. In *Funaria hygrometrica*, growth can begin from new plants in any month of the year and is relatively continuous. Redrawn from Benson-Evans and Brough (1966).

The leafy liverwort *Lophozia silvicola* (Figure 28) seemed to exhibit no change in shoot density during the growing season (Laaka-Lindberg 1999). Measurements on liverworts are rare, and for the many very small species, very difficult.

Figure 28. *Lophozia silvicola* with gemmae, a species that does not seem to change shoot density during the growing season. Photo by Štěpán Koval, with permission.

One factor that may play a role in seasonal changes in growth is chlorophyll concentration. Valanne (1984) felt chlorophyll concentrations did not change seasonally. On the other hand, Raeymaekers and Glime (1986) found that

chlorophyll concentrations in *Pleurozium schreberi* (Figure 22) were slightly higher in summer than in early spring or late autumn. This is not surprising as the plants are shielded from light by snow in winter, thus being unable to replace chlorophyll. The heat and drought of summer can likewise reduce the ability to replace damaged chlorophyll. Habitats can affect the seasonal changes in chlorophyll content of bryophytes. For example, the forest species *Brachythecium rutabulum* (Figure 17) has seasonal chlorophyll changes (Kershaw & Webber 1986), increasing as the summer progresses and the light penetration decreases. Epiphytic bryophytes likewise respond to the decreasing light penetration through the canopy (Miyata & Hosokawa 1961). For the aquatic moss *Fontinalis* (Figure 29), both light intensity and temperature may play a role in the observed seasonality of chlorophyll content (Bastardo 1980).

Figure 29. *Fontinalis antipyretica*, a moss that grows in cooler weather. Photo by Andrew Spink, with permission.

Growth in most bryophytes is limited by water availability, with light, nutrients, and temperature playing lesser roles. Most grow best at temperatures below 25°C and go dormant above that. This puts most of their growth in temperate zones in spring and autumn, while permitting winter growth in warmer climates and summer growth in Polar Regions. Growth in mass can precede growth in length, and this may even be a general rule. Chlorophyll concentrations respond to changes in light intensity – a seasonal phenomenon.

Asexual Reproduction

The large number of propagule possibilities has already been discussed in the chapter on development. But what controls this production? In some species, these are so ever-present that they are used as taxonomic characters [*Plagiothecium* (Figure 30-Figure 31), *Pohlia* spp. (Figure 32)]. In fact, they may be more common than we supposed, as noted by researchers on *Orthotrichum* (BFNA 2007; Figure 33). But such propagula require energy to produce and thus we should expect some seasonal differences that avoid other large-energy-requiring events. It is well known that *Marchantia polymorpha* (Figure 34) does not produce gemma cups while it is producing sexual reproductive structures. This is

demonstrated by the suppression of gemma cup development during long-day conditions when archegoniophore development is occurring, but the addition of high sucrose concentrations can permit their development (Terui 1981). *Tetraphis pellucida* likewise does not have gemmae (Figure 35) and female gametangia or sporophytes (Figure 36) at the same time. Thus, we can in many cases surmise their phenology as those seasons when sexual reproduction is not occurring.

In liverworts, it appears that many taxa lack any seasonal absence of gemmae (Schuster 1988; Duckett & Renzaglia 1993), especially in the tropics (Schuster 1988). *Lophozia silvicola* (Figure 28) had gemmae throughout the sampling period of May to October in southern Finland, but their peak months were July through September (Figure 37; Laaka-Lindberg 1999; Laaka-Lindberg & Heino 2001).

Figure 37. Model predictions (pred.) and observed behavior of gemmae from five colonies of *Lophozia silvicola* in southern Finland in 1997-1999. Redrawn from Laaka-Lindberg & Heino (2001).

Laaka-Lindberg (1999) found that gemmae of *Lophozia silvicola* (Figure 28) was highest in early spring, declining rapidly as the end of the growing season approached. Laaka-Lindberg and Heino (2001) suggested that there is a seasonal dormancy in gemmae of *L. silvicola*. They modelled the effects of having two types of gemmae, dormant and non-dormant. Only the dormant gemmae could be expected to survive winter. This model fit well with data for southern Finland for this species and provided a mechanism for replacement of shoots lost to winter mortality. Success would be greatest if more dormant gemmae were produced at the end of the growing season.

Response to light intensity in some taxa suggests that at least some liverwort gemma production should be seasonal. Kumra and Chopra (1989) found that maximum

gemma cup production in *Marchantia emarginata* (Figure 38) occurred at continuous light at 4500 lux. However, this is an unlikely combination in nature, with full sun at ~70,000 lux and 24-hour light occurring only in Polar Regions.

Figure 38. *Marchantia emarginata* with gemmae. Photo by 楊玉鳳, through Creative Commons.

Laaka-Lindberg (2000) considered that gemmae most likely follow the same seasonal trends as vegetative growth. She reasoned that since gemmae are produced by mitotic cell divisions, albeit in specialized cells, they would be susceptible to the same environmental regulation of growth as normal gametophytic tissue. Since growth often is arrested during sexual reproduction, this is a reasonable possibility.

In west tropical Africa, two species of the moss genus *Calymperes* (Figure 39) exhibit distinct seasonal production of gemmae (Odu & Owotomo 1982). Reese (1984) found a striking seasonality in *Syrrhopodon texanus* (Figure 40), another member of the same family, with gemmae production increasing in August and peaking in September in the Gulf coastal plain. This follows the high rainfall season in July, which could be favorable to gemma production and establishment.

Aside from balancing the energy needs of sexual reproduction, the asexual structures generally do not have to wait for the right season, thus providing the plant with a more reliable means of reproduction.

Gametangia

Timing of gametangial production might well be the most important timing function a **cryptogam** (any plant with an independent gametophyte) could have. With only one cell layer of protection during development, gametes begin their existence in peril. Once released, the sperm have virtually no protection and must reach the egg in a film of water before effects of sun and winds render their required watery milieu non-existent. Furthermore, it is likely that they are susceptible to UV damage, lacking even a cell wall for protection. Gamete availability itself typically lasts only 1-2 weeks (Crum 2001), and even less in some species. Hence, mechanisms that position this development at a time most likely for success are essential for this step to reach fruition.

The timing mechanisms available to bryophytes have been studied extensively in, of course, the lab rat moss, *Physcomitrella patens* (Figure 41). Hohe *et al.* (2002) have determined that temperature, light intensity, and day length all impact the number of sporophytes produced, and thus by inference we must conclude also impact the success of the gametes. In this moss, the highest number of sporophytes resulted when the mosses were cultured at 15°C, 8:16 light:dark cycle at 20 $\mu\text{mol}/\text{m}^2/\text{s}$. Culture at 25°C or at 16-hour days drastically reduced the number of sporophytes, indicating that this species is adapted to reproducing under the conditions of spring in the temperate zone. As might be expected, growth diminished under conditions that favored reproduction. Hohe and coworkers even identified a MADS-box gene, PpMADS-S, that produced 2-3 times as much RNA under conditions that favored sporophyte development, suggesting its role in that development.

Figure 41. *Physcomitrella patens* with capsules; growth diminishes while capsules are maturing. Photo by Michael Lüth, with permission.

Laboratory experiments do not necessarily represent the real world. Day-night temperature differences may be critical, and certainly water is important. Maturation of reproduction must be timed to coincide with a season suitable for sperm transfer. For example, Odu (1981) showed that in four tropical African mosses, gametangia develop at the beginning of the rainy season. Sporophytes mature to coincide with the dry season.

Signals for timing of gametangial production are most likely a mix of direct responses to rainfall and other moisture sources and other cues, such as day length, that are generally good predictors of later environmental conditions. For example, we see in *Sphagnum* (Figure 42) that success of sporophyte production was positively related to the precipitation the previous summer and that summer droughts had a negative influence on gametangial formation (Sundberg 2002). Even after fertilization, however, drought has a negative effect on the sporophyte by drying it too soon before the spores are mature.

Figure 42. *Sphagnum palustre* with capsules. Photo by Andrew Hodgson, with permission.

In Scandinavia, this favorable season for gamete release appears to be spring (Arnell 1875), most likely taking advantage of "spring showers." Arnell (in Crum 2001) found that 15% of the taxa released gametes in January-March, 52% April-June (20% in May), 25% July-September, and 8% October-December. However, some taxa do not have a "season." Leitgeb (1868) found that *Fontinalis antipyretica* (Figure 29) formed antheridia from

spring until autumn [although I found that archegonia matured in autumn and that numbers were greatest under short (6-hour) photoperiods (Glime 1984)].

In milder climates, such as California, USA, late autumn or winter months can provide the best season for successful fertilization. *Fossombronia longiseta* (Figure 43) has mature archegonia and antheridia there in November and December (Haupt 1929b).

Figure 43. *Fossombronia longiseta*, a species that has successful fertilization in November and December in California, USA. Photo by D. L. Bowls, through Creative Commons.

In Japan, Deguchi and Yananose (1989) found that *Pogonatum neesii* (Figure 44) initiated its antheridia in early November, with maturity occurring in mid April. By late July they were all dead. Archegonia, on the other hand, matured only in early May.

Figure 44. *Pogonatum neesii* with capsules, a species that initiates antheridia in early November in Japan, with them maturing in mid April. Photo by Siddarth Machado, through Creative Commons.

Then there are bet hedgers. *Dicranum majus* (Figure 45) in central Norway can form gametangia in late autumn

or early spring, permitting fertilization in June and July (Sagmo Solli *et al.* 1998). It appears that this species has not fine-tuned its gametangial timing; mature antheridia are present all summer and autumn, but archegonia are available only in June and July.

Figure 45. Immature sporophytes of *Dicranum majus*. Photo by Michael Lüth, with permission.

The initiation and maturation of sex organs of one sex before those of the other in a population may be a common phenomenon. Longton and Schuster (1983) contend that initiation of antheridia several months before archegonia in dioicous taxa results in their maturation at the same time. In the cases of *Atrichum rhystophyllum* and *Pogonatum inflexum* (Figure 46) in Japan, Imura (1994) found that shoot production of male plants preceded that of females by about four months (Figure 47). Likewise, antheridia production preceded that of archegonia, but antheridia took longer to develop. Similar differences occur in *Atrichum androgynum* (Figure 46), with antheridia beginning development in spring after the sporophytes reach maturity (Biggs and Gibson 2006). Archegonia begin development one month later. Development of the sporophyte takes 12 months, with spores being released in the spring. In four species of *Ptychomitrium* (Figure 3) in Japan, Deguchi and Takeda (1986) found that antheridia typically required 9 months whereas archegonia required only 1 month to develop, with both maturing in the June rainy season.

Figure 46. *Pogonatum inflexum*, a species in which production of male shoots precedes that of female shoots by four months in Japan. Photo by Harum Koh, through Creative Commons.

Figure 47. Maturation dates of antheridia and archegonia of *Atrichum rhystophyllum* at Miyajima Island, Japan, during 1987-1988. Samples included 1-10 individuals. Based on table by Imura (1994).

In the functionally dioicous *Pleurozium schreberi* (Figure 22) in Great Britain, perigonia (♂) begin development in August whereas perichaetia (♀) first occur in October (Longton & Greene 1969). Both overwinter and fertilization occurs in April-May. This results in maturation of the sporophyte by October with spores being shed January-April. Fertilization is delayed in more northern areas such as Scandinavia. On the other hand, Greene (1960) found that in *Mnium hornum* (Figure 48) antheridia mature about one month before the archegonia, perhaps insuring that sperm will be available when proper conditions for fertilization occur.

Figure 48. *Mnium hornum* from Europe. Photo by Michael Lüth, with permission.

When differences in initiation time occur, we can presume that different stimuli are needed to initiate the development. This is discussed briefly in the development chapter on gametogenesis, but it appears we know little about the signals for initiation when they differ for the two

gametangial types. One such signal is light intensity. In *Riccia discolor* (Figure 49), female clones developed gametangia maximally at 3500 lux continuous light at pH 5.5 (Gupta *et al.* 1991). However, male plants failed to produce antheridia at pH 3.5 or 5.5 at any light intensity in the experiment.

Figure 49, *Riccia discolor*, a species in which light intensity signals time to develop female clones. Photo by Jan Ševčík, through Creative Commons.

The longer development time for antheridia is common. For example, in Australia *Dicranoloma menziesii* (Figure 50) and *D. platycaulon* (Figure 51) initiate their antheridia during winter and archegonia in the spring (Milne 2001). However, the archegonia mature in two months, whereas antheridia require 5-6 months. By contrast, a third species, *D. billardierei* (Figure 52), that is **sympatric** (occurring in the same geographic area) with these two, initiates its antheridia during late spring-summer and its archegonia in autumn. The result is that *D. menziesii* has fertilization in late summer, *D. platycaulon* in mid autumn, and *D. billardierei* in early winter. This separation of fertilization time permits these sympatric species to co-exist without the danger of interbreeding that could soon diminish the species distinctions. The sporophyte development is slow, requiring 18-24 months in *D. billardierei* and *D. platycaulon*, but only 12 months in *D. menziesii*.

Figure 52. *Dicranoloma billardierei*, a species that initiates its antheridia during late spring-summer and its archegonia in autumn. Photo by Michael Lüth, with permission.

Initiation of antheridia before archegonia may extend to monoicous taxa as well. Van der Wijk (1960) reported that 14 out of 18 mosses from the Netherlands initiated antheridia before archegonia; three of these 14 taxa were monoicous. The remaining 4 initiated archegonia in the same month as antheridia; one of these was monoicous. In his study, it was typical for antheridia to be initiated in the autumn with archegonia initiated the following spring. In *Entodon cladorrhizans* (Figure 56), a monoicous perennial, antheridia likewise initiate well before archegonia (Stark 1983).

Antheridia generally require longer to develop than archegonia. Therefore, male and female gametangia must time their development so that they both mature at the same time, and that maturity occurs at a time when water is available for fertilization. That fertilization period typically is less than one month. For many parts of the temperate zone, this means spring is the best season, with autumn being a second possibility, provided early frost is not a danger to the gametes or the embryo. In dry climates and the tropics, winter is usually the best season because of greater moisture.

Protandry and Protogyny

With the advent of the monoicous condition, bryophytes faced the problem of inbreeding. The solution to this is to have a mechanism to prevent that event. When there is no carrier organism involved, this can be accomplished in two ways. There can be some self-incompatibility mechanism involved, or the two types of gametangia can mature at different times.

Towle (1905) found protogynous timing in *Atrichum undulatum* (Figure 53), Egunyomi (1979) in *Octoblepharum albidum* (Figure 102). Longton and Schuster (1983) summarize several studies that indicate that **protandry** (maturation of antheridia before archegonia on same plant) and **protogyny** (maturation of archegonia before antheridia on same plant) are common among monoicous bryophytes, as in *Funaria hygrometrica* (Figure 54) and *Atrichum undulatum* (Figure 53). [*Atrichum undulatum* is functionally dioicous, at least in Michigan, USA, *i.e.*, it does not produce male and female gametangia on the same plant at the same time, but it can, at least in some populations, produce antheridia the first year and archegonia the next (Crum 1976)]. This is similar to the sequential hermaphroditism seen in some animals such as the blue-headed wrasse. Interestingly, Crum (1976) reports that in North America *F. hygrometrica* produces **perigonia** first (housing antheridia), then **perichaetia** (housing archegonia), making them **protandrous**, but Benson-Evans and Brough (1966) report the same species in Great Britain as **protogynous** (having females mature first).

Figure 53. Male plants with splash cups on *Atrichum undulatum*. Photo by Janice Glime.

Figure 54. *Funaria hygrometrica* with young sporophytes in Europe. Photo by Michael Lüth, with permission.

Even in the dioicous perennial moss *Forsstroemia trichomitria* (Figure 55), gametangial maturation is protogynous (Stark 1985). On the other hand, Greene (1960) was surprised to find that in perennial moss *Brachythecium rutabulum* (Figure 17) the intermixed archegonia and antheridia also had intermixed developmental stages for both gametangia, and that they both appeared to be produced year-round. But in *Bryum argenteum* (Figure 88), although archegonia and antheridia are produced at the same time in Reading, England, in north Wales antheridia typically begin development in November and archegonia in the following April (Miles *et al.* 1989).

Figure 55. *Forsstroemia trichomitria* with capsules, a species that develops female organs first. Photo by Jennifer Doubt, through Creative Commons.

Some monoicous mosses may benefit, or at least survive, with self-fertilization. In the Chihuahuan Desert, on *Trichostomum planifolium* each branch produces an average of 2 archegonia and 3 perigonia containing 6 antheridia, being at first protogynous, but then synchronous, and finally only male. Stark and Castetter (1995) found that fertilization among the gametangia on a single stem in this species appeared to be common.

Sporophyte Maturation

Degree of maturity of sporophytes may be reported in various ways, and the system of Greene (1960; see previous subchapter on phenology) seeks to straighten out these ambiguities. Some authors report the season for spores, which we may assume is the OF (operculum fallen) stage of Greene. Conard (1947), in his phenological study on Iowa herbarium specimens, considered the "perfect capsule" stage to include some opercula shed and others in place. The spike stage of Conard corresponds to the ECI (early calyptra intact) stage of Greene.

Energy Needs

Sporophytes require tremendous energy to mature. Stark and Stephenson (1983) have demonstrated the compensation for insufficient energy in the pleurocarpous *Entodon cladorrhizans* (Figure 56) through abortion of sporophytes, much like the abortion of fruits in *Asclepias* (milkweed). But it would seem that the best way to

provide sufficient energy would be to optimize time of development of the sporophyte. To this end, we will examine the timing of capsule production in several examples.

Figure 56. Gametophytes of the monoicous perennial *Entodon cladorrhizans*. Photo by Janice Glime.

A common way to optimize energy is to avoid having two means of propagation at the same time. Thus, *Tetraphis pellucida* (Figure 35-Figure 36) produces capsules in spring (Figure 36), whereas gemmae with gemma cups (Figure 35) are produced after spores are shed. In *Atrichum undulatum* (Figure 1), spores are shed in March in Vermont (Figure 1), and new archegonia are present by early May (Towle 1905). As already noted, the antheridia were present earlier (mid April), but they do not compete for sporophyte energy in this dioicous species.

Optimizing Dispersal Time

Often, maturation of capsules is timed to take advantage of dry weather for dispersal. For example, in Nigerian populations of *Octoblepharum albidum* (Figure 102), capsules develop quickly from August to early December, when spore liberation begins, coinciding with the dry season (Egunyomi 1979). But natural phenomena are rarely so predictable. The difficulty in drawing generalizations about behavior based on either habitat or climate is exemplified by comparing *Pylaisia polyantha* (Figure 57) to *Hypnum cupressiforme* var. *resupinatum* (Figure 58) (Greene 1960), two species that have somewhat similar gross vegetative morphologies. Although both taxa are found on the bark of deciduous trees in the same areas in the British Isles, *H. c.* var. *resupinatum* begins its sexual cycle like *P. polyantha*, with a swollen venter in July-August, but instead of the sporophyte requiring a year (or more), as in *P. polyantha*, it soon completes its capsule development and loses its spores beginning in January. Although *P. polyantha* is monoicous and *H. c.* var. *resupinatum* is dioicous, it is difficult to imagine how this could affect development of the sporophyte. Similar differences occur in *Ulota* in Great Britain (Jones 1946). *Ulota intermedia* (Figure 59) capsules mature in July-August, *U. crispa* (Figure 60) in spring, and *U. bruchii* (Figure 61) in winter, suggesting that season of dehiscence may not be critical for these taxa in this particular location.

One pattern that seems to emerge is that in many terrestrial bryophytes spore dispersal may be timed for alternating moist and dry conditions. If moss spores do indeed depend on flexes of peristome teeth, then a season in which moisture conditions change from wet to dry frequently would be advantageous. Liverworts seem to be largely timed for the same benefit (Schuster 1966). On the other hand, perhaps the important timing is not dispersal as much as it is germination. Spore germination requires water, and if spores are to germinate immediately before being consumed or losing viability, a season of alternating wet and dry could be an advantage. While this latter explanation may have merit for some taxa, it seems that many bryophyte spores are viable for long periods in quite adverse conditions (van Zanten & Pocs 1981; During and ter Horst 1983; During 1986; van Zanten & Gradstein 1988; van Zanten 1992; During 1997; Frahm 2002).

In *Sphagnum* (Figure 42), if the capsule dries too soon, the spores are not mature and are forced out of the capsule before they are mature (Sundberg 2002). It appeared to be an advantage for these taxa to mature and have early spore dispersal in the drought-sensitive lawn species to avoid the risk of premature drying of the sporophyte during the summer droughts.

In *Marchantia polymorpha* (Figure 62), we have already seen that long days are important for development of the archegoniophore, causing it to reach its maximum height by mid summer when sporangia are mature and warm, dry conditions most likely optimize dispersal of the mature spores (Terui 1981). Thus, this liverwort has to time its gametophyte to carry out the function known for

the sporophyte stalk of a moss, necessitating the expression of the trait in the gametophyte instead of the sporophyte generation. In its more tropical relative, *Marchantia chenopoda* (Figure 63), sporophytes mature earlier, in late spring to early summer (Moyá 1992), suggesting that temperature may be a signal.

Spring and Autumn Dispersal

The best overall picture of temperate zone sporophyte phenology seems to be that of Conard (1947) for Iowa, USA, bryophytes. He used herbarium specimens from the State University of Iowa and Grinnell College to determine the number of collections with sporophytes each month. Like gametangia, sporophytes exhibited two seasons of abundance. "Spikes," or setae with no capsule development, were present mostly in March - May and October - November (Figure 64). Capsules matured mostly May - June or October - November (Figure 64). However, these data lack details of timing, and as noted already, could possibly represent development that continued after the collecting date, and could have contained considerable collecting bias.

in spring (February - April). Previous work by Arnell (1875), as presented by Lackner (1939), on the beginning of capsule appearances for two locations in Europe are shown in Figure 65 and indicate that capsules began to form primarily from April to August in those locations. In these same areas and in Germany, Lackner shows spores ripening mostly in May through July, with other peaks (for East Prussia) in February and October (Figure 65).

Figure 65. **Top:** Months of capsule appearance in two locations in Europe. **Bottom:** Months of spore ripening in three countries in Europe. Redrawn from Lackner (1939).

As in mosses, Conard (1947) found that the months with the greatest number of mature liverwort capsules were April - June and September - October (Figure 66). Bray (pers. comm.) found that *Fossombronia foveolata* (Figure 67) produces capsules in both spring and autumn on the same individuals, drying out in the summer and surviving by producing a dense terminal bud that seems to be protected by its dark, red-brown color. *Fossombronia* typically lives in places where it gets submerged part of the year and dried out another part, so it is not surprising that it has a life cycle much like some of the moss ephemerals.

Figure 67. *Fossombronia foveolata* with capsules, a species that produces capsules in both spring and fall. Photo by Sharon Pilkington, with permission.

In the mild climate of California, USA, the thallose liverwort *Asterella californica* (Figure 68) occurs on moist banks and canyon walls, where its growth occurs autumn to spring and its capsules mature in April (Haupt 1929a). It dries out in summer and survives from tips of branches.

Development Time

Sporophyte maturation can be a slow process, thus crossing multiple seasons. Grimme (1903) reported that in Germany he found the minimum time for sporophyte development to be that of *Atrichum tenellum* (4 months; Figure 69-Figure 70) and the maximum to be for *Grimmia ovalis* (24 months; Figure 71). Crum (2001) reports *Polytrichum* (Figure 72) to require 13 months and *Dicranum* (Figure 45) 17 months. These times differ with geographic location and may depend on such factors as length of growing season, temperature, and water availability. Many other variations occur, attesting to the fact that these sporophytes must withstand a wide range of conditions during their development, yet maintain a timing that is suitable for spore dispersal.

In addition to defining developmental stages, Greene (1960) suggested a scheme based on time required for development (Figure 74).

Figure 71. *Grimmia ovalis* with both immature and spent capsules that take 24 months to develop. Photo from Earth.com, with permission.

At least in the temperate zone, the spring and autumn maturation times may follow a long development, as found in *Polytrichum* (Figure 9, Figure 72) – 7-16 months in Scandinavia, 9-20 months in Sweden (Arnell 1905), and *Forsstroemia trichomitria* (Figure 55) – 17 months (Stark 1984), or 15 months for *P. juniperinum* (Figure 9, Figure 72) in the Antarctic (Longton 1972). In others, such as

Mnium hornum (Figure 48, Figure 73), the seta emerges (Figure 73) in the autumn, remaining in that state throughout the winter, and continues development in early spring (Greene 1960). In Great Britain, this species has lost its opercula by early May.

Figure 72. *Polytrichum juniperinum* capsules with calyptra, a species in which capsules take 15 months to develop in the Antarctic; maturation time depends on location. Photo by Felipe Osorio-Zúñiga, with permission.

categories of sporophyte development

6 months	– no resting stage (ex. <i>Atrichum undulatum</i>)
10 months	– short winter resting stage (ex. <i>Mnium hornum</i> , <i>Eurhynchium praelongum</i>)
14-18 months	– resting stage in winter, often persisting partly into next growing season (ex. <i>Funaria hygrometrica</i>)

Figure 74. Scheme for representing sporophyte development. Based on Greene 1960; examples from Benson-Evans & Brough 1966.

The capsule cycle of the epiphytic *Pylaisia polyantha* (Figure 57) requires so much time for development that two generations of capsules are present at the same time, not only in Great Britain, but in many locations in both Europe and North America (Greene 1960). The venter is swollen in July to August, and the calyptra is retained for an entire year, falling in the next July. Capsule development continues, with the operculum falling early in the following year. In Great Britain, this species has lost its opercula by early May.

Winter Dispersal

Winter is a good time for capsule maturation to occur in mild climates where that is the moist season. In Great Britain, *Brachythecium rutabulum* (Figure 17) has lost its opercula by early May (Greene 1960). It continues development from its early calyptra stage in September on to an intact operculum with the operculum falling December to February. By March the capsules are empty. If it were to follow that timing in the Keweenaw Peninsula of Michigan, USA, its capsules would be imbedded in snow at the time of dispersal. In Japan, the thallose liverwort *Mannia fragrans* (Figure 75-Figure 76) has mature spores in early winter (Furuki 1992).

Figure 75. *Mannia fragrans* with emerging sporophytes. Photo by Samuel Brinker, through Creative Commons.

Figure 76. *Mannia fragrans* with nearly mature sporophytes, with mature spores in Japan occurring in winter. Photo by Botanical Wanderer, through Creative Commons.

Lackner (1939) found that *Orthotrichum* (Figure 86) species were notable exceptions to the spring and summer dispersals of bryophytes in his study. This epiphytic/saxicolous genus typically produced capsules in the winter months. Perhaps winter is good for mosses if they can avoid being covered by snow, although early frost causes mortality in young capsules of the soil-dwelling *Buxbaumia aphylla* (Figure 77-Figure 78) (Hancock & Brassard 1974). The result is that survival depends on the rapid maturation of the sporophyte in the autumn, permitting the capsules to be dormant during the winter.

Figure 77. Immature sporophytes of *Buxbaumia aphylla* in Michigan, USA. Photo by Janice Glime.

Figure 78. *Buxbaumia aphylla* mature capsules with one that has been damaged. Photo by Bernd Haynold, through Creative Commons.

Winter may also favor aquatic bryophytes, but for somewhat different reasons because the problems are quite different. Dispersal by air would seem to be nearly impossible when the environment is continuously moist or submersed. And, in fact, we have no direct evidence of the success of the spores of such submersed taxa as *Fontinalis*.

Nevertheless, *F. dalecarlica* (Figure 79-Figure 80) and *F. novae-angliae* (Figure 81) produce capsules in autumn and mature them in winter, at least in New Hampshire, USA, with abrasion apparently serving as the primary means of opening the capsule (pers. obs.). The subsequent dispersal of the spores is pure conjecture, but since the peristome teeth are generally not exposed to air, one might suppose that water is the only available agent. It is interesting that the aquatic liverwort *Scapania undulata* (Figure 82-Figure 83) likewise produces its capsules in winter (Grainger 1947).

Elevation Effects

For those bryophytes not adapted for development during winter conditions, elevation provides evidence of the importance of temperature. For thirteen taxa growing at four elevations in the Eastern Pyrenees, Girona, Spain, those living at higher elevations have dormant sporophytes in the winter, completing their development early in the summer (Lloret 1987). Those that live at lower elevations have continuous development. Only one species among these, *Schistidium confertum* (Figure 84), is able to continue development at locations above 1800 meters.

Figure 84. *Schistidium confertum* with capsules, a species that is able to continue its development at elevations above 1800 m. Photo by Gordon Rothero, with permission.

One of the factors that can affect success of a sporophyte is the weather during development of pre-winter stages, as shown by the high mortality due to early frost in young sporophytes of *Buxbaumia aphylla* (Figure 77-Figure 78) in Newfoundland (Hancock & Brassard 1974). In this species, young capsules are formed in the autumn and remain green over the winter, maturing the following spring. By summer, little evidence of the capsule remains, although their thick setae are sometimes still present.

Fortunately, mosses are adaptable in their physiological responses, often resulting in physiological races in different parts of the world. Longton (1979), in comparing *Polytrichum juniperinum* (as *P. alpestre*; Figure 9, Figure 72) populations at the more northern Churchill, Manitoba, Canada, site to those at Pinawa, Manitoba, found that the initiation of the LCP (late calyptra in perichaetium) stage began earlier in the autumn and that shift to the OI (operculum intact) stage occurred later in the spring at Churchill (Figure 85). However, the sporophyte development proceeded more quickly at Churchill during the growing season, surpassing that of the mosses at the Pinawa site, and compensating for the longer dormancy.

Figure 85. Comparison of sporophyte development of *Polytrichum juniperinum* in Pinawa and Churchill, Manitoba, Canada. Points represent the maturity indices with vertical bars indicating the range of stages present. Based on Longton (1979).

Spores and Protonemata

Spore dispersal is most advantageous if the air is dry and breezy, permitting the spores to travel long distances before becoming lodged within the minute crevices of the soil or other substrate. In fact, dryness usually initiates the shedding of the operculum, as illustrated by Johnsen (1969) for *Orthotrichum anomalum* (Figure 86). On the other hand, to mature, the capsule must have energy available, so these two factors must be included in the dispersal strategy to determine the season of dispersal. It may be this need for energy, then a dry season, followed by a suitable moist season, that some mosses disperse their spores in winter, e.g. *Anomobryum julaceum* (Figure 87) and *Bryum argenteum* (Figure 88) (Pedersen & Hedenäs 2002) and the liverwort *Mannia fragrans* (Figure 75-Figure 76) in Japan (Furuki 1992). In the seasonally dry interior of North America, *Syrrophodon texanus* (Figure 40) has optimal spore release in October to March, followed by rain that peaks in July, then decreases rapidly to a low in November (Reese 1984). As we have already seen, one way to accommodate these needs for energy and the right moisture conditions is for the capsule to persist in a mature state, operculum intact, for months to years before initiating dispersal.

Figure 87. *Anomobryum julaceum* with dry capsules that disperse spores in winter. Photo by David T. Holyoak, with permission.

Figure 88. Capsules on *Bryum argenteum*. Photo by Michael Lüth, with permission.

Using herbarium specimens, Nishimura (1993) determined the dates of dispersal for mosses from the Hiruzen Highlands on the island of Honshu, Japan (Figure 90). He found 34 species that disperse spores in late autumn to early spring (late November to early April), 12 in late spring to summer (May to August), and 5 in autumn (September to November). *Bryum argenteum* (Figure 88) dispersed in both spring and autumn. *Sematophyllum subhumile* (Figure 89) was the only species that had no definite season of dispersal. Although herbarium specimens can introduce error because opercula tend to come off more easily under the dry conditions of the herbarium, the 551 specimens used in this study give us a general picture of events.

Figure 89. *Sematophyllum subhumile* with capsules, a species for which dispersal is not seasonal. Photo by Geoff Bryne, through Creative Commons.

Egunyomi (1979) found that capsules of *Octoblepharum albidum* (Figure 102) in Nigeria matured just in time for spores to be liberated during the dry season. Stark (2001a.) finds that most desert bryophytes release spores year-round, an advantage in a dry climate where rainfall is rare and not seasonal. On the other hand, spores in *Pleurozium schreberi* (Figure 22) in Britain are shed January-April when it is cool and relatively moist (Longton & Greene 1969). In a later study in Great Britain, Longton and Miles (1982) found that five mosses had fertilization in

the period of April to July, but that sporophyte maturation time varied considerably. Spore liberation took place from six to twelve months later, spanning a variety of climatic conditions.

Figure 90. Seasons of dispersal in 51 species of mosses from the Hiruzen Highlands, Honshu, Japan. From data of Nishimura (1993).

To determine the availability of spores, Fenton and Bergeron (2006) studied the spore dispersal of *Sphagnum* (Figure 91) species in a black spruce (*Picea mariana*) forest (Figure 92) in Québec, Canada. Using spore traps, they determined the phenology of spore dispersal (Figure 93) for two years. Dispersal at these locations began in July, rose in mid August, and ended mid to late September, with peak dispersal near the beginning of September. The earlier dispersal than that of the study in Japan (Nishimura 1993) may be the result of the higher latitude.

Figure 91. *Sphagnum fallax* with capsules that disperse spores in July-August in Québec, Canada. Photo by James K. Lindsey, with permission.

Figure 93. Number of spores collected in 20 spore traps at each of three sites in Québec, Canada. Vertical bars represent standard error. Different letters indicate those values that are significantly different within a site. Redrawn from Fenton & Bergeron (2006).

Although the time of spore dispersal is fairly well known, or at least available in herbaria, virtually nothing is known about the time of spore germination. Longton and Schuster (1983) comment that little is known about spore dormancy in liverworts and virtually nothing about the effect of day length on germination. This is due largely to the difficulty of locating this stage and, even if located, to identify even the genus, much less the species.

We can speculate on the importance of timing for spore establishment. Proctor (2000) pointed out that the need for water would limit the successful establishment of spores and their protonema on rocks and bark to the lengthy wet season of autumn and winter in western Europe and whatever wet season elsewhere.

Even in taxa with persistent protonemata, *e.g.* *Buxbaumia*, where sexual organs are produced directly on the protonema, field knowledge is lacking. After extensive study of *Buxbaumia aphylla* (Figure 77-Figure 78) spanning three years, Hancock and Brassard (1974) were unable to determine if the protonema persisted for more than one season or if the gametangia were produced the same season.

In most taxa, it is probably not necessary to couple suitable germination and protonema development conditions with those of dispersal. Spore viability can last from less than an hour in some epiphyllous and epiphytic liverwort taxa (Longton & Schuster 1983) to 50 years in other bryophytes (Sussman 1965), and probably longer in some taxa. Most spores probably have considerable longevity, as seen in several diaspore bank studies in the Netherlands (*e.g.* During 1986, 1990, During & ter Horst 1983, During *et al.* 1987). They even survive temperatures near absolute zero when dried and placed in vacuum tubes (Becquerel 1932). Van Zanten (1976) has shown that most taxa can survive desiccation for one year, with wet-frozen spores surviving better than dry-frozen ones. But for spores that fall near their parents and do not effect long-distance dispersal, immediate germination success will provide a better chance of establishing the next generation, particularly in overwintering annual taxa, by giving them an early start and a higher percentage of survival.

Protonemata can likewise survive considerable drying (Lipman 1936) and in some taxa such as *Grimmia* (Figure 4, Figure 71) may even require a drought period before advancing to the next stage (During, pers. comm.). In fact, Johnsen (1969) found that in *Orthotrichum anomalum* (Figure 86) watering during the dormant period (hot and dry) was detrimental. Thus it appears that germination should require more than just the right seasonal event, but rather a seasonal event coupled with the right environmental conditions to take things to the next stage. There seems to be no hope at present of generalizing about phenological events related to the protonemata based on any foundation in data.

Duration of Stages

Longton (1997, 1998) found that those bryophytes that have shorter life spans become reproductively active at a younger age and tend to have greater phenological flexibility. This strategy necessarily implies that each stage is short. This is especially true for the colonists, fugitives, and annual shuttle species to be discussed later in the life strategies chapter. For those taxa that stay longer, the stages may be longer, often depending on habitat characteristics, particularly availability of water.

Gametangia

One of the factors that is important in maintaining distinct species when more than one member of a genus cohabit a region is that their reproductive periods do not

overlap or that their means of dispersing gametes are mutually exclusive. Among three Australian species of *Dicranoloma* (Figure 50-Figure 52), all three species studied required 5-6 months for antheridia to mature, but only 2 for archegonia (Milne 2001), the longer time for antheridial development being typical for most mosses. Yet the timing for these three taxa was such that their periods of fertilization were mutually exclusive.

For *Entodon cladorrhizans* (Figure 56) growing in Pennsylvania, USA, the fertilization period lasts five weeks (Stark 1983). In the desert moss *Syntrichia inermis* (Figure 94), maturation of the antheridia takes one to several years due to the intervening dry periods that cause dormancy (Stark 1997).

Table 2 provides additional examples of maturation times, ranging from less than one month for some archegonia and three months for some antheridia to nearly one year for others.

Sporophytes

Ephemeral species have short-lived capsules that may last only a few weeks. Liverworts do likewise, with their deliquescent stalk soon withering away. Furthermore, the valvate capsules of liverworts shed all the spores at one time, whereas in mosses peristome teeth operate to extend dispersal over a longer period, providing the mosses with more opportunities to disperse under conditions favorable for greater dispersal or germination success. *Sphagnum* likewise has short-lived stalks, in this case a deliquescent pseudopodium (Figure 91) that develops from the gametophyte to extend the capsule away from the plant. It

lacks teeth and disperses most of its spores in one explosive burst when the operculum is shed due to capsule drying and at least some of the time, internal gas expansion due to high temperatures.

Figure 94. *Syntrichia inermis* in its dry state beneath shrubs. Photo courtesy of Lloyd Stark.

But other mosses may have quite extensive periods of sporophyte development. In *Dicranoloma*, *D. billardierei* (Figure 52) and *D. platycaulon* (Figure 51) required 18-24 months whereas those of *D. menziesii* (Figure 50) required only 12 (Milne 2001). *Atrichum androgynum* (Figure 46) likewise requires 12 months for sporophyte maturation (Biggs & Gibson 2006).

Mosses that depend on rainy periods may have very short periods for maturation of the sporophyte, attuned to dispersal at the end of the rainy season, as in *Racomitrium africanum* (Figure 95), *Fissidens weirii*, *Thuidium gratum*, and *Stereophyllum* sp. (Figure 101) from SW Nigeria (Odu 1981). These mosses required 12 months from onset of gametangia to capsule maturity and dispersal, but sporophyte development itself is complete at the end of the rainy season (October-December), following gametangial development at the onset of the rainy season (March/April). Spore dispersal occurs during the dry season (November-April). The entire process requires 12 months. Other desert mosses can have very long

maturation periods spanning several years with long dormancy periods intervening.

The soil-dwelling *Syntrichia inermis* (Figure 94), in the Mojave Desert, USA, requires about 21 months for sporophyte development, while being dormant for 18 of those months (Stark 1997). Span of operculum detachment may last up to 2.5 years, and capsules of the same cohort may disperse spores over a period of three years (Stark 2001a). In the same desert, the rock-dwelling *Grimmia orbicularis* (Figure 97-Figure 98) required only 3 months for its capsule to mature following meiosis, and its operculum dehiscence spanned only three weeks; spore release of the cohort lasted about six months (Stark 2001a).

Zander (1979) did an exhaustive study in the Pottiaceae of the north temperate zone of Europe, Asia, and North America, comparing dioicous and monoicous taxa. The **Pottiaceae** typically require 12-13 months for sporophyte development (Krieger 1915), but Zander found that the phenology of the two sexual conditions differed, with dioicous taxa having mature capsules over a slightly longer period of time than did monoicous taxa. Non-endemic dioicous taxa have a mean span of mature capsules of 6.77 months, whereas the non-endemic monoicous ones have only a 5.55-month mean. Among the 86 dioicous taxa studied, 12 have mature capsules spanning nine or more months, whereas only 5 of the 82 monoicous taxa exhibit this duration. He reasoned that this afforded dioicous taxa a better chance for dispersal, perhaps in part compensating for the smaller likelihood of fertilization. This compensation concept was further supported by finding that the monoicous taxa did not have a significantly wider distribution. Since the ratio of monoicous to dioicous taxa in **Pottiaceae** is similar to that of bryophytes as a whole, this study might be a model of mature capsule duration in monoicous vs. dioicous taxa. It would be interesting to determine if capsule duration can indeed compensate for the reputedly greater percent of species producing capsules among the monoicous taxa than among the dioicous ones (Gemmell 1950, Longton & Schuster 1983).

Winter Effects

In bryophytes, unlike the tracheophytes, embryos and gametangia are capable of surviving prolonged freezing of winter (Stark 1984). Continuous melt of snow during parts of the winter could facilitate fertilization of some bryophytes under the snow, but no broad-scale studies have examined this in areas where the phenomenon is likely, and while the gametangia might survive, one must question whether the sperm can swim and locate a female at near-freezing temperatures. Furthermore, while sperm can swim at speeds of 100-200 μm per second (Richards 1978), they require a chemical attractant to find the archegonium (Muggoch & Walton 1942), and cold temperatures might reduce the effectiveness of such an attractant. Even so, we know that the aquatic liverwort *Scapania undulata* (Figure

82-Figure 83) produces gametangia and accomplishes fertilization in winter (Grainger 1947).

On the other hand, Imura and Iwatsuki (1989) found that in *Trachycystis microphylla* (Figure 99) in Japan, antheridia production begins in January with sperm being released March to May. Archegonia production is delayed until March, but they are ready to accept sperm from April to July. The partitioning of energy among life cycle stages would appear to be complex in this species, with overlapping life cycle stages, since spores are released near the time of fertilization of the next generation. (Imagine sending one kid off to college while you are pregnant with the next!) Development of the sporophyte begins in May, and rapid sporophyte elongation occurs in October to November and again in February. Spores are released in April – apparently near the time sperm are released. One would think this delicate timing would require competing environmental conditions, wet for sperm and dry for spores. Since spring is a time of alternating sunshine and rain, these contrasting conditions are probably available.

Figure 99. *Trachycystis microphylla*. Photo by Li Zhang, with permission.

One explanation for the success of overwintering antheridia as a strategy is that it may spread out the energy requirements over a longer period and give antheridia a chance to grow rapidly in spring, thus insuring that they precede the archegonia in maturity. Benson-Evans and Brough (1966) found that a cold period followed by warmer temperatures can induce more rapid maturation of sex organs if sufficient moisture is available, whereas low temperatures and drought retard development. In this case, the antheridia would receive the stimulation, but the archegonia, by delaying initiation until spring, would not. This advantage is consistent with the 10 out of 18 taxa examined by van der Wijk (1960) in which male gametangia overwintered; female gametangia in these were generally initiated in early spring. One must ask why it is the males that seem to overwinter, whereas females of the same species often delay initiating gametangia until spring. Is it because winter is in fact destructive, but male gametes are much more abundant than are female gametes and can therefore afford to sacrifice some in order to mature earlier? Is there some developmental reason why antheridia require a longer time to develop than do archegonia? Or is it a mechanism to increase protandry, thus ensuring at least some cross fertilization?

Despite the ability of gametangia to survive over winter, Arnell (1905) reported that most of the 33 German

and Swedish taxa he studied had gametangial dehiscence in the summer, which suggests that fertilization must have occurred then as well. However, many parts of the world lack sufficient moisture in summer to ensure fertilization.

Huneck *et al.* (1984) determined that essential oils in the temperate leafy liverwort *Bazzania trilobata* (Figure 100) were highest in September and lowest in January, suggesting that perhaps these oils might be used for energy reserves during autumn and early winter. It is also possible that they offer a protective function to the cells during the period of freezing and thawing in autumn.

Geographical Differences within Species

Earlier studies by Richards (1959) indicate that seasonal behavior of bryophytes may vary in different climatic regions. The basic developmental pattern of gametangia and sporophytes may differ. Furthermore, lack of proper environmental signals, such as not reaching the necessary temperature at the necessary photoperiod, or inability of the plant to interpret the signals, can result in failure to produce gametangia or in failure of females to produce mature archegonia at a time when sperm are ready for release (Newton 1971, 1972, Longton 1972).

Even within a small geographic range, signals can come at a different time. For example, in North Wales, *Bryum argenteum* (Figure 88) begins development of antheridia before winter, in November, whereas archegonia develop in April (Miles & Longton 1987). In Reading, UK, both gametangia develop at the same time.

Some taxa have adopted different physiological responses in different parts of the world, as, for example, *Lunularia cruciata* (Figure 101), which seems to function as a long-day plant in Wales and a short-day plant in Israel (Longton 1974), but in much of the British Isles it is the climate that prevents this liverwort from producing an archegoniophore and capsules (Benson-Evans & Hughes 1955).

Figure 101. *Lunularia cruciata*, a long-day plant in Wales but a short-day plant in Israel. Photo by David Holyoak, with permission.

Elevation has a strong effect on timing of the life cycle in the Eastern Pyrenees. Bryophytes at high elevations have arrested sporophyte development in the winter, with maturation occurring in the summer concurrent with the next fertilization. However, at lower elevations, there is a continuous progression of stages with no dormant period. *Schistidium confertum* (Figure 84), however, lives at elevations above 1800 m but, like lowland taxa, has no dormant period in winter.

The example of *Funaria hygrometrica* (Figure 54), as studied by Hoffman (1966), exemplifies the sorts of controls that determine the selection pressures affecting the maturation cycle. In that moss, Hoffman found that gametophytes appeared in early spring, with sporophytes maturing in June, but that maturation dates were progressively later at higher elevations. High light intensities contributed to more rapid gametophyte development, while a longer photoperiod resulted in larger stems and leaves. Thus, physiological controls adapt the bryophytes to their particular conditions and may be important factors in selection as bryophytes spread around the world. Whereas morphological variation between species is limited by small size, it is possible that bryophytes may have greater physiological variability than do tracheophytes, enabling individual species to occupy wider ranges of conditions than those of their tracheophyte counterparts. These adaptations permit bryophytes to conserve energy and to optimize it across time.

Seasonal Differences among Habitats

It is the sum total of the timing of all the life cycle stages that can adapt a bryophyte for a better rate of survival. As the seasons change, so do the selection pressures. Hence, we find that sperm dispersal is timed to coincide with a rainy season and spore dispersal with dry air. But these timing events differ considerably among habitats because the advantages of seasons vary among habitats.

Temperature, length of growing season, available moisture, and photoperiod all have effects on phenology. Studies on elevation can give us clues as to the effects of temperature, although gradients of these other variables exist as well. As already discussed, at low elevations of the Eastern Pyrenees, Spain, the life cycles follow a continuous progression of events with no dormant season (Lloret Maya

1987). By contrast, those living at higher elevations exhibit mature gametangia and accomplish fertilization in the first months of summer, with the sporophyte overwintering in a dormant state and maturing rapidly in early summer. If such differences exist in response to altitude, we might expect even greater differences among habitats of highly contrasting conditions. We shall examine the contrasts among the tropics, deserts, disturbed habitats, and wetlands as representatives of this spectrum.

Tropics

The rainy season is the primary governing factor in the phenology of many tropical mosses (Odu 1981). In four very different taxa of mosses [*Racomitrium africanum* (Figure 95), *Fissidens glauculus*, *Thuidium gratum*, and *Stereophyllum* sp. (Figure 96)], Odu found that gametangia develop at the onset of the rainy season (March/April), sporophytes develop later (October – December), and sporophyte maturation occurs at the end of the rainy season. In *F. glauculus* and *T. gratum*, sporophytes developed immediately after fertilization, and within one month in *R. africanum*, with all three producing mature capsules by the end of the rainy season (Odu 1982). Dispersal in these taxa begins at the end of the rainy season and continues into the dry season (November to April) (Odu 1981).

This same seasonal pattern existed in the herbarium specimens Odu examined (Odu 1982). The rainy season is likewise the best season for development of juveniles and gametangia for *Octoblepharum albidum* (Figure 102) (Pôrto & Oliveira 2002). The importance of humidity for *O. albidum* is underscored by its development of sporophytes one month earlier at sites in western Nigeria, with constantly high humidity, than at sites with lower humidity (Egunyomi 1979). Thus, gametangial timing must be set so that capsule maturation is completed in time to take advantage of dispersal in the dry season. Hence, archegonia mature during the rainy season and sporophytes begin developing while it is still rainy. It appears that these tropical bryophytes differ from temperate bryophytes in that their rapid cycle permits them to disperse spores during the next dry season and germinate when the rainy season returns.

Figure 102. *Octoblepharum albidum* on tree bark in Florida, USA. Photo by Janice Glime.

Initiation of archegonia and antheridia in some tropical taxa may occur throughout the year, as it does with *Sematophyllum subpinnatum* (Figure 103), nevertheless increasing in frequency during the rainy season (de Oliveira & Pôrto 2001). Although the most favorable season for fertilization is during the rainy season, it likewise can occur throughout the year in that species. Sporophyte development of *S. subpinnatum* usually begins later in the rainy season, reflecting the higher fertilization rates during that season.

Deserts and Dry Habitats

Growth in winter is most likely typical in the desert. Stark (2001a, 2002c) suggests that phenology of bryophytes of the Mojave Desert, USA (Figure 104), contrasts sharply with that of other climatic regions, such as Nigerian savannah mosses, with phenological events tied almost solely to local rainfall events, which are rare and unpredictable. One adaptation to this unpredictable environment is that spore dispersal occurs over a long period. *Grimmia orbicularis* (Figure 97-Figure 98), a rock-dwelling species, retains operculate capsules for three months before its 3-week dispersal period (Stark 2001a). The entire clone, however, may disperse spores over a period as long as six months and within the area may last more than one year. This long dispersal period may also partially compensate for the very high rate of sporophyte abortion in these mosses following a summer rainfall that apparently uses up too many resources in repairing the cells (Stark 2001b). *Syntrichia inermis* (Figure 94, Figure 105), a soil-dwelling species, retains operculate capsules for eleven months, then disperses spores for up to 2.5 years, the clone dispersal lasting up to 3 years! Stark (2001a) concluded that the steeply inclined rock surfaces, supporting short, broad, inclined capsules, account for the more rapid rate of operculum shedding in *Grimmia orbicularis* (Figure 98).

Figure 104. Mojave Desert where *Syntrichia inermis* survives under shrubs and may be dormant for long periods. Photo courtesy of Lloyd Stark.

But one can learn a lot about what makes things work by stressing them to their limits. Deserts provide a good model for such stressful conditions. Stark (2002b) found that in the Mojave Desert, one population of *Syntrichia inermis* (Figure 105) initiated sporophyte development in 1995, but that the cohort remained dormant until early 1998. By that time, approximately 66% of the sporophytes had aborted. The remaining viable sporophytes of this group were considerably shorter and had less biomass than the previous cohort. In the next two years, sexual reproduction failed completely, apparently due to reduced winter-spring rainfall. On the other hand, it appeared to be heavy summer rainfall in 1997 that caused the abortion of many of the 1995 sporophyte cohort, with sporophyte numbers increasing again following 1998 summer rains. Stark suggested that the abortion may have been the result of rapid drying and high temperatures while the sporophytes were hydrated, causing membrane damage.

In dry habitats such as the desert, it is often easier to eke out a tiny bit of water in the winter than in the summer when the little rain that does fall evaporates almost before it lands. Hence, we should expect the phenology of desert bryophytes to be different from that of bryophytes in most other habitats. Mojave Desert populations of *Syntrichia inermis* (Figure 105) took an incredibly long time for antheridia to mature (Stark 2001a). Whereas the archegonia matured and became receptive in the same year, antheridia took one to several years to develop! Despite this long maturation time in which desiccation was a common state, the abortion rate was only 3-4% for either gametangium type. Not surprisingly, more than 90% of the plants were morphologically bisexual. And unlike their temperate and northern counterparts, their growth was in the winter, albeit only 1.4 mm per year. To take advantage of this cooler and more moist season, fertilization occurred in winter, and despite the frequent desiccation, 50% of the perichaetia bore embryos. These embryos remained dormant from spring until fall, resuming their growth once more in the cooler days of winter when the seta and capsule developed (Stark 2001a); sporophytes endure 18 or more months of dormancy during their development (Stark 1997). Spore dispersal, however, was delayed until late summer and early fall.

Figure 105. *Syntrichia inermis* with capsules in various stages of dispersal. Photo by Michael Lüth, with permission.

Syntrichia inermis (Figure 105) sets several bryophyte records through its phenological strategies to survive in the desert (Stark 1997). Considering the importance of reproductive development during the unpredictable and rare rainy periods, it is not surprising that it has the lowest known rates of stem elongation. It also has the longest known period required for antheridial maturation. Growth is greatly sacrificed to complete reproduction, presumably permitting the spores to remain dormant for long periods of time and to disperse over a wide range.

Syntrichia caninervis (Figure 107) also a resident of the Mojave desert, exhibits a sex ratio of roughly 7.9 female to 1 male to 3.1 non-expressing individuals (Stark *et al.* 2001). This large ratio of female to male may help to compensate for the 63% loss of developing sporophytes observed during three years of study. However, there is also partial, if not complete, compensation of sexes by the greater number of reproductive units on males than on females.

Herrnstadt and Kidron (2005) examined reproduction in *Bryum dunense* (Figure 106) in three different habitats in the Negev Desert, southern Israel. Despite differences in exposure, including exposed site, under shrub canopy, and partially shaded at foot of north-facing dune slope, all three populations initiated their gametangial development prior to the first winter precipitation. This suggests that the species are attuned to their environment by a signal such as declining day length or temperature. This prepared them for dispersal of both bulbils and sperm as soon as water was available.

Figure 107. *Syntrichia caninervis*. Photo from Proyecto Musgo, through Creative Commons.

In the dry mountains of southern New Mexico, USA, a close relative of several desert species, *Syntrichia ruralis* (Figure 108) grew, in this case by **innovations** (new shoots), in midwinter (Mishler & Oliver 1991). Female gametangia likewise were initiated in midwinter, causing cessation of growth in that innovation – a definite tradeoff. These female gametangia remained on the plants 6-9 months (December to June or even until August), during which no male gametangia were evident, and, of course, no sporophytes. But growth and structural development do not tell the whole story. In this species, the chlorophyll to dry weight ratio was higher in the late summer and winter than it was in early summer. One must pause to wonder what circumstance permitted the higher late summer values.

Figure 108. *Syntrichia ruralis* var. *ruraliformis* (Sand-hill Screw-moss). Photo by Barry Stewart, with permission.

When maturation of gametangia is an autumn event, it forces the young embryo to survive the winter. Haupt (1929b) found that the liverwort *Fossombronia longiseta* (Figure 43) in California, USA, had gametangia in the "best" condition in November and December, perhaps relating to the wetter weather in winter. The overriding importance of water is evidenced by *Octoblepharum albidum* (Figure 102) in Nigeria, where immature antheridia and archegonia are most abundant during July, the wettest month (Egunyomi 1979).

Moisture obviously is important in the regulation of season of growth. In the mountains of southern California, *Asterella californica* (Figure 109) grows on canyon sides and moist banks that become dry in summer. The liverwort dries out in summer (cf. Figure 110), surviving by terminal buds (Haupt 1929a). Bray (pers. comm.) found a similar survival mechanism in *Fossombronia* (Figure 111) in southern Illinois, permitting it to grow in fall through spring.

Figure 109. *Asterella californica*, a liverwort that dries out in summer and survives by terminal buds. Photo by Peter J. Bryant, University of California, Irvine, with permission.

Figure 110. *Asterella tenella* with drying thallus and mature archegoniophore with open capsules. Photo by Janice Glime.

Figure 111. *Fossombronia incurva*. Photo by Des Callaghan, with permission.

Trichostomum planifolium, a tiny **protogynous** (producing female organs before male organs) desert moss, has populations 20-50 years old (Stark & Castetter 1995). It solves the capsule drying problem by having fertilization

in late fall with sporophytes maturing continuously until spring, when it disperses its spores. Completion of its entire sexual cycle during cooler months, coupled with extensive intra-stem fertilization, permits it to survive its desert habitat.

Bryophytes in deserts are very dependent on the annual moisture cycle for their life cycle. In the Nigerian desert, sexual cycles are short, occurring completely within the rainy season. In the Mojave Desert in southwestern USA, there is no rainy season, and rainfall events are unpredictable. In that regime, bryophytes have very long sexual cycles, sometimes taking several years to develop antheridia, several years for capsules to mature, and six months to disperse all the spores. Growth is mostly in winter, fertilization is in winter, and dispersal of spores occurs in late summer and early autumn. Some dry habitat thallose liverworts become dormant in summer, surviving as terminal buds while the remaining thallus dies.

Epiphytes

Epiphytes live in a habitat that is frequently dry, but unlike the desert, water is also frequently available. This alternate wet-dry microclimate brings its own set of problems. There can be relatively long periods of time when it is unsuitable for sperm transfer. The epiphyte *Forsstroemia trichomitria* (Figure 112) produces five sets of reproductive structures per year. This may be an adaptation to increase the chances of having the right weather (rain) to accomplish fertilization. Fertilization occurs in late summer through autumn, about four months duration. Both types of gametangia are produced at the same time. The sporophytes require 17 months for maturation, enduring two winters.

Figure 112. *Forsstroemia trichomitria*, an epiphytic moss that produces five sets of gametangia each growing season. Photo by Misha Ignatov, with permission.

Savannah

Contrasting with mosses controlled by the rainy season, as in the tropics, or those of dry periods that can last years, mosses of the dry habitat of Nigerian savannah have much shorter sexual cycles than those of the desert, as noted by Makinde and Odu (1994) for four mosses, *Archidium ohioense* (Figure 113), *Bryum coronatum* (Figure 114), *Fissidens minutifolius* (Figure 115), and

Trachycarpidium tisserantii. Their entire sexual cycle, from production of gametangia to dehiscence of capsules, occurs during the rainy season. Protonemata and gametophytes develop in March-April; capsules mature and spores are dispersed in September-October. Nevertheless, spore discharge is somewhat difficult in the **cleistocarpous** *A. ohioense* and *T. tisserantii* compared to the other two species. (Cleistocarpous capsules have no operculum and must break apart without aid of lines of dehiscence to expel their spores.) Makinde and Odu suggest that this short maturation period may be advantageous in their savannah habitat.

Polar and Alpine

Ayukawa *et al.* (2002) investigated *Polytrichastrum ohioense* (Figure 116-Figure 117) in the Yatsugatake Mountains of Japan. They found mature antheridia from late May to early August and mature archegonia from late June to mid July, permitting fertilization to occur from late June to mid July. This timing of gametangial maturity avoided the occasional temperatures below 0°C in May. The longer period of sperm maturity permits variability in time of egg maturation and suggests that the two types of gametangia respond to different triggers. Sporophytes began showing at the end of June, became dormant for the winter, and began growth again in May. Spores were dispersed from mid July to mid August. Hence the 13-month sporophyte maturation included a 6-month resting period in winter.

Figure 116. *Polytrichastrum ohioense*, sowing females with light green tops on left and males with unopened golden splash cups on right. Photo by Janice Glime.

Figure 117. *Polytrichastrum ohioense* with immature capsules. Photo by Li Zhang, with permission.

Antarctic populations of *Polytrichum juniperinum* (as *P. alpestre*; Figure 5, Figure 9, Figure 72) behave quite differently (Longton & Greene 1967). The antheridia begin development in March and overwinter (May-October) with no further development. Development resumes after

snowmelt and most of the antheridia mature in December–early January. Archegonia, on the other hand, do not begin development until the end of November, but still reach maturity at the same time as the antheridia. Sporophyte development was much longer, beginning with fertilization in December and January but not completing development until mid-March the following year.

Clarke and Greene (1970) found somewhat different timing adaptations in populations of *Pohlia* (Figure 2) in the Arctic and sub-Arctic. In these populations, maturation was somewhat faster than for the same species in Britain.

Disturbed Habitats – Ephemerals

The ephemerals, or short-lived taxa, face some of the same problems as desert bryophytes. They are very dependent on climatological events to coordinate their phenological events. They often grow in areas that experience flooding during part of the year. Although the sequence of most life cycle events is poorly known in ephemerals, Crum (1976) provides us with information on when to expect to see these plants (capsules) in Michigan. We can suppose that during the remainder of the year the moss exists either as spores or as dormant protonemata, but in some cases absence is really a measure of lack of collecting inconspicuous non-fruiting upright gametophyte plants. Because of their tiny stature and non-mossy look of their habitats, these taxa are often overlooked by visiting bryologists in a hurry to get as many taxa as possible, so their presence may be much greater than would appear from collection records, and their sporophytic stage is probably over-represented in collections. By targetting such habitats, Kucyniak (1946) found numerous new or rare species in Québec (Jean Faubert, pers. comm.)

Spring and autumn seem to favor ephemerals when more moisture is available than in summer in most habitats, with a number of species visible all winter (Crum 1976 for Michigan, USA): *Ephemerum crassinervium* (Figure 118) late summer to early spring; *Tortula acaulon* (Figure 119) November to May; *Microbryum floerkeanum* (Figure 120–Figure 121) October to April; *Acaulon* spores mature in late autumn to spring [*A. triquetrum* (Figure 122), *A. muticum* (Figure 123)]. Michigan spring ephemerals include *Pleuridium subulatum* (Figure 124), *Tortula truncata* (formerly in *Pottia*; Figure 125), and *Physcomitrium pyriforme* (Figure 126), whereas *Ephemerum cohaerens* (Figure 127) appears in both spring and autumn. *Pottia davalliana* (Figure 128) appears in the autumn, but sometimes can be found in summer.

Figure 127. *Ephemerum cohaerens* with perigonia, an ephemeral that appears in spring and again in autumn. Photo by Dick Haaksma, with permission.

It is not surprising that some ephemerals typically produce more than one generation of capsules in the same year. Gray (1935) found that *Aphanorrhegma serratum* (Figure 129) and *Micromitrium tenerum* (as *Nanomitrium austinii*; Figure 130) have life cycles as short as 62-65 days in Florida, producing two or more sets of capsules per year. Between these cycles the moss is often buried by floods and silt. Gray surmised that since he always found both mature and immature capsules, these mosses must continuously produce capsules when growing conditions are suitable. Younger plants seem to be produced at the edge of older clumps.

Figure 128. *Pottia davalliana*, an autumn ephemeral that sometimes also appears in summer. Photo by Michael Lüth, with permission.

Figure 129. *Aphanorrhegma serratum*, a species that in Florida has a short life cycle of about two months and that completes that life cycle two or more times a year. Photo by Bob Klips, with permission.

Figure 130. *Micromitrium tenerum*, a species that in Florida has a short life cycle of about two months and that completes that life cycle two or more times a year. Photo by Jan-Peter Frahm, with permission.

It appears that one strategy for these floodplain ephemerals is to produce some sort of survival structure. These may include very large spores, spores that remain in tetrads, and asexual structures that can remain in the mud for a prolonged period of time, then provide a good supply of energy to jumpstart the gametophyte plant when the mud

becomes exposed to the sun. Members of the Marchantiopsida, especially members of the genus *Riccia* (Figure 131-Figure 132), seem especially adapted for such strategies (Kürschner & Parolly 1999).

Wetlands

One might expect that bryophytes growing in wetlands face few problems in dispersing their gametes and might instead time events so that capsules are not submersed or too humid. But Sundberg (2002) found that even in this "wet" habitat, rainfall of the previous summer had a strong effect on the number of capsules produced, suggesting that gametangia formation was improved under wetter conditions. In wetter peat pits, the amount of precipitation in spring of the same year seemed more important,

suggesting that greater precipitation increased sperm dispersal and fertilization. Spore dispersal in *Sphagnum* (Figure 91) is indeed facilitated by dry air, but summer droughts can cause premature drying, which negatively affects spore dispersal. At least some *Sphagnum* species grow best at higher temperatures, around 35°C (Li 1991), but it seems that growth might need to compete with spore production. All the species in Sundberg's study release their spores from the beginning of July to the end of August (summer in the North Temperate Zone), with up to a month difference in release times among the species present. Even in this wet habitat, there are dry seasons and wet seasons.

Aquatic

In aquatic habitats, winter may be the best growth period. Glime (1987b), found that in the Keweenaw Peninsula of Michigan, USA, where snow covers the ground about five months of the year, the lake and stream moss *Fontinalis duriaei* (Figure 133) takes advantage of its C₃ metabolism and begins new growth in November, continuing through winter, then accelerating from February to June, with little subsequent growth until cooler weather returns. Laboratory data on temperature effects on growth of six *Fontinalis* species suggest this is a general trend in the genus (Glime 1984, 1987a, b, c).

Figure 133. *Fontinalis duriaei* in Japan, a moss that begins its growth season in November. Photo by Janice Glime.

For populations of *Fontinalis*, Glime (1984, 1987a) found that on Isle Royale and in the Keweenaw Peninsula of Michigan, USA, several species produced gametangia in September prior to resumption of growth. In this genus, autumn production of gametangia might be a means to facilitate movement of sperm in small puddles of water and on moist but not submerged mosses, reducing loss of sperm downstream due to strong currents. Once winter begins, these species of *Fontinalis* are completely submersed and this permits the development of the sporophyte in a fully hydrated state. *Fontinalis* species respond to photoperiod, having peak gametangia maturity in autumn and producing capsules in February. Temperatures soon become too warm in summer for aquatic bryophytes that generally remain hydrated, even when stranded above water. The easiest season for many of them to disperse sperm is autumn as water levels rise and dispersal is facilitated. Temperatures are cool enough for photosynthetic activity and the plant is almost guaranteed of remaining cool and hydrated following fertilization.

But the big surprise came when we found abundant capsules on *Fontinalis dalecarlica* (Figure 79-Figure 80) (Glime 1984) and *F. novae-angliae* (Figure 134) (Glime 1987c) in February in New Hampshire, USA. These capsules were abraded by spring runoff and had disappeared by the time the snow had melted. No wonder most bryologists think the genus almost never has capsules! No one is looking in midwinter. It appears that archegonia mature in the short days of September and the capsules are most likely the product of that fertilization season.

Summary

The life cycle of a moss can be described based on those stages that are observably different, are discontinuous, and require a change in environmental conditions. This definition presents us with the recognizable stages of embryonic calyptra, seta with calyptra, green capsule with calyptra, operculate post-meiotic capsule, de-operculate capsule, spore with bulging wall, protonema, protonema with bud, juvenile stem, antheridium, archegonium.

Growth requires sufficient moisture, nutrients, and light at a time when the temperature does not cause a high level of respiratory loss, below 25°C for most shade-adapted taxa. Growth usually ceases in hot summers when the temperature is too high and carbon loss would be greater than carbon gain, and in cold winters when there is no free water and bryophytes go dormant. Optimal temperatures for elongation, bud formation, and rhizoid production may differ. Furthermore, increase in biomass may occur without increase in height. There is a trade-off between growth and reproduction so that growth diminishes or ceases during reproduction. Chlorophyll concentrations generally increase in response to decreasing light intensity, thus responding to seasonal changes.

Gemmae are more likely than other life cycle events to lack seasonal behavior, but their production may cease during sexual reproduction due to competition for energy.

Antheridia generally initiate before **archegonia** and require longer for development. Many will begin development, then become dormant during winter, resuming in spring to mature when archegonia, initiated

in spring, are also mature. Reproduction may be coupled with photoperiod, light intensity, and temperature, and these will most likely be coordinated to provide the reproductive bryophyte with the greatest possibility of sufficient water for fertilization. Nutrients and pH may also play a role in signalling onset of sexual reproduction.

Cross-fertilization in monoicous bryophytes is supported by **protogyny** and **protandry** in many taxa. In dioicous taxa, the perigonia (housing antheridia) are typically initiated first and mature at about the same time as perichaetia (housing archegonia).

Desert bryophytes may have multiple periods of dormancy interrupting any of the developmental stages. Some take advantage of cooler temperatures and greater availability of water in winter to accomplish fertilization. Aquatic bryophytes such as *Fontinalis* may have fertilization in autumn when water levels are rising, ensuring water for development, then produce capsules in winter when spring runoff can aid dispersal.

Sporophyte maturation of most taxa is timed for dispersal during the dry season and may last from only a few days to several years. For most temperate zone bryophytes, spring and autumn seem to be the best time for dispersal. Elevation generally meant that events start later in the year, but higher light levels and in some cases longer days, along with innate adaptations, may cause stages to mature in less time than at lower elevations.

Acknowledgments

Thank you to Jean Faubert for his suggestions to alter the discussion of gemmae on *Orthotrichum*.

CHAPTER 4-3

ADAPTIVE STRATEGIES: PHENOLOGY, A *SPHAGNUM* CASE STUDY

Figure 1. *Sphagnum fimbriatum* with operculate capsules in midsummer. Photo by Janice Glime.

***Sphagnum*: A Case Study**

The easiest way to understand any phenomenon is to examine an example. The detailed phenological study by Pujos (1992) of *Sphagnum fimbriatum* in Haute-Normandie and *S. fuscum* in Québec provides us with this opportunity.

Most of us think of *Sphagnum* as living in wet places, but in fact, its growing tips are often under drought conditions. As the water level falls in the summer, the tops of hummocks are dry, and in winter, the water is frozen, thus creating desiccating conditions. Consequently, the apex of the moss often lacks sufficient water to carry on photosynthesis. This results in considerable variation within the genus regarding the months of photosynthetic activity and growth. Hulme and Blyth (1982) found that species that live in hollows, such as *S. cuspidatum* (Figure 2) and *S. auriculatum* var. *inundatum* (Figure 3), had a longer growing season (10-12 months) than did hummock species such as *S. papillosum* (Figure 4), *S. magellanicum* (Figure 5), and *S. capillifolium* (Figure 6) (5-7 months).

For *Sphagnum fimbriatum* (Figure 7) in Haute-Normandie and *S. fuscum* (Figure 8) in Québec, it appears that despite their ability to grow best at the warm

temperatures of summer, they become sexual in the cooler, probably wetter, conditions of fall (Pujos 1992).

Gametangia

In both species studied, antheridial branches (Figure 9) appear first at the end of summer, with the antheridial stalk forming before the antheridium. Although the antheridium develops rapidly, **spermatogenesis** (formation of sperm) spans two months. Like so many other perennial

bryophytes, archegonial development begins somewhat later in Haute-Normandie, in September, requiring about one month for development.

Figure 9. Antheridial branches displaying typical red color. Photo by Janice Glime.

Fertilization

Perichaetial leaves grow much larger than other leaves and protect not only the archegonia, but the developing capsule as well. However, fertilization is delayed until February, at least in Normandie, occurring as the temperature first begins to increase at the end of winter. Archegonial neck cells break down and form mucilage at about the same time the antheridia dehisce. Fertilization of *S. fimbriatum* (Figure 10) in Normandie in 1991 occurred in March.

Figure 10. *Sphagnum fimbriatum*. Photo by Dick Haaksma, with permission.

Embryogenesis (formation of embryo)

By early April, the embryo begins penetrating the branch beneath it and by the end of April mucilage completely surrounds the embryo. It is not until mid-May to June that **sporogenesis** (formation of spores, starting with meiosis) occurs and still another month passes before the pseudopodium (gametophyte extension that becomes a stalk to support the capsule) emerges with the capsule at its apical end (Figure 11).

Figure 11. Mature capsules of *Sphagnum palustre* with capsules still enveloped in perichaetial leaves before the pseudopodium elongates. Photo courtesy of Zen Iwatsuki.

Spore Release and Germination

Spores mature in July and changes in temperature and humidity cause the capsule to shrink, forcing the operculum off (Figure 12). Spores in both species germinate immediately after release (in the lab), producing a thalloid gametophyte and ultimately a single upright plant. But again, we know nothing of what happens in the field. Is there a dormancy, perhaps brought on by temperature or humidity, that delays the spore germination? How long does the protonema persist before the leafy plant develops? How long does it then take the leafy plant to reach sexual maturity?

Figure 12. Capsules after dehiscence and dispersal, with elongated pseudopodium, in *Sphagnum palustre*. Photo courtesy of Zen Iwatsuki.

Summary

In *Sphagnum fimbriatum* in Haute Normandy, as in most mosses, antheridia appear first, in this case late summer, developing over two months. Archegonia begin development in September and require only one month. Fertilization occurs in February or March at the end of winter. The capsule is mature in mid-May to June and sporogenesis occurs, but the pseudopodium requires another month before it elevates the capsule. Spores are released in July and can germinate immediately, but field behavior is unknown.

Acknowledgments

I appreciate the helpful comments of Heather Smith in giving me a student's perspective on this chapter and of Heinjo During in critiquing this case study. Linda Luster checked the literature citations, proofread, and checked for needed glossary entries.

CHAPTER 4-4

ADAPTIVE STRATEGIES: PHENOLOGY TRADEOFFS

Figure 1. *Hylocomium splendens* with sporophytes and young shoot showing new growth of an unexpanded branch to their right. Photo by Janice Glime.

Tradeoffs

Just when you think you have solved all the problems, you discover that the solution has created a new problem. So it is with life, and so it is with optimizing the events in the life of a plant. Large spores give the plant a better start, small ones travel farther. Lots of spores give more chances for landing at a suitable time on a suitable spot, but their survival chances are lower. But what sorts of numbers are we talking about?

Finding this information is not easy, as few papers are written expressly for the purpose of comparing these numbers. We need a concerted effort to put together a representative list. A few are shown in Table 1.

In an organism where the male gamete must disperse without a very specific carrier and the female is stationary, we assume that more males are needed to service the females because many males will be unsuccessful. Rydgren and Økland (2003) stated that we still do not know if bryophytes exhibit reproductive costs (energy costs). Meager evidence suggests they do.

Table 1. Comparison of numbers of reproductive parts of bryophytes. This table is in no way representative.	
<i>Octoblepharum albidum</i>	Pôrto & de Oliveira 2002
archegonia	6.7 per perichaetium
antheridia	13.4 per perigonium

archegonia	3-26 per perichaetium
antheridia	8-20 per perigonium
<i>Sphagnum</i>	Sundberg 2002
sporophytes	0.64-20 per dm ²
spores	16,000,000 per m ²
<i>Trichostomum perligulatum</i>	Stark & Castetter 1995
archegonia	2
antheridia	6
<i>Cyathodium bischlerianum</i>	Salazar Allen 2001
archegonia	1-2 per involucre
<i>Plagiochila adianthoides</i>	Johnson 1929
antheridia	22 per spike
sperm	25,000 per antheridium

Rydgren and Økland (2003) compared non-sporophyte-producing and sporophyte-producing sub-population of *Hylocomium splendens* (Figure 1) for five years. They found that indeed the plants with sporophytes had less size development of daughter segments, a lower branching frequency, and fewer new annual segments than those individuals with no sporophytes. This reduced development occurs primarily during the time when the capsule expands and spores are produced, suggesting that there is a significant cost for reproduction – a tradeoff.

However, if all the gametangia are accounted for, rather than individuals, this may not be the case. Stark and coworkers (2001), in examining the desert moss *Syntrichia caninervis* (Figure 2), found that when male and female expressing individuals were controlled for **inflorescence** (reproductive organ group) number, there were no significant differences in biomass between the sexes. Surprisingly, among those that were not expressing sexual traits, there was lower biomass, shorter total stem length, fewer branches, and shorter **ramets** (individual member of clone) than in sex-expressing males and females, and there were fewer ramets than there were sex-expressing female individuals. A threshold size seems to be necessary for sexual expression, accounting at least in part for size differences. In fact, for *Syntrichia caninervis* in this study, all individuals weighing more than 2.0 mg evidenced sexual expression. This biomass requirement supports the concept that more energy is needed for sexual expression, likewise supporting the expectation of a tradeoff between growth and reproduction.

Figure 2. *Syntrichia caninervis*. Photo by John Game, through Flickr Creative Commons.

Tradeoffs with Spore Production

To understand the seasons of sexual reproduction, one needs to understand the tradeoffs within the growth cycle as well. First, there needs to be a sufficient energy supply for either a sexual or an asexual event, and while the formation of sex organs does not seem to produce as much biomass, it is a developmental stage that is costly in energy. Second, the production of gametangia may interfere directly with further growth. In acrocarpous mosses, the gametangia are terminal on the main stem (Figure 3), and once they develop, they inhibit the further development of the stem, at least for that season (Figure 4). Thus,

vegetative growth, in acrocarpous taxa at least, may be strongly limited by time of gametangial production.

Figure 3. *Polytrichum piliferum* splash cups that effectively stop growth of the stem while they are functional. Photo by Janice Glime.

Figure 4. *Polytrichum ohioense* male stems with new growth extended from the splash cups. When the antheridia are developing, further growth of this apex is arrested. Photo by Janice Glime.

Pleurocarpous mosses, on the other hand, develop gametangia on lateral branches and these do not interfere with the growth of the main stems. This difference is further complicated by the fact that most (all?) pleurocarpous mosses are perennial, whereas many of the acrocarpous mosses are annual. Furthermore, one might suppose, the annuals are much more likely to produce capsules (and by implication, gametangia) to permit them to overwinter as spores, whereas many perennials persist by vegetative means only. But, we have very little direct field evidence to support or refute this supposition.

It might be interesting to compare seasons of vegetative growth vs gametangial season in acrocarpous vs pleurocarpous mosses and annuals vs perennials, but data on gametangia are scarce. Among the mosses in Conard's 1947 study, only 15 of the 232 taxa collected had gametangia.

Based on Conard's survey, it appears that peaks in gametangial production in liverworts occur during late spring and again in fall, at least among the 60 Iowa taxa (Figure 5). This is consistent with the report by Zehr (1979) that photoperiod is the dominant factor in gametangial formation in four of the five taxa he studied: *Lophocolea heterophylla* (Figure 6) is day neutral; *Diphyscium foliosum* (Figure 7), *Atrichum angustatum*

(Figure 8), *Trichocolea tomentella* (Figure 9), and *Nowellia curvifolia* (Figure 10) are long-day plants. However, Zehr's sample size is small and Conard's samples may have been biased, since they were subject to seasons favorable for collecting (and collectors), and collectors may be selective in what they collect and keep, favoring plants with capsules over those without.

Figure 5. Numbers of taxa with perianths (leafy enclosure of liverwort archegonia) per month among the 30 taxa having perianths out of 60 Iowa liverwort taxa (including Anthocerotopsida) in the herbaria at State University of Iowa and Grinnell College. Based on table from Conard (1947).

It seems that the co-occurrence of fertilization and spore release is relatively common among bryophytes, as seen in the studies of Grimme (1903), Arnell (1905), Lackner (1939), Jendralski (1955), Greene (1960), and van der Wijk (1960). Based on his British experience, Greene (1960) stated that even before a **cohort** (group of individuals with same starting point) of capsules has dehisced, new gametangia are developing. To him, it was "clear" that when sporophytes develop slowly, fertilization may be effected before the previous generation of spores has been released. Likewise, David Wagner (pers. comm.) finds spore and sperm dispersal during the same season in the Northwestern United States. Stark (2001) points out that we have few definitive studies on the duration of spore

dispersal and that in some cases this may last an entire year, as it does with most desert bryophytes.

Two determining factors must be kept in balance to maintain a life cycle: the energy requirements and the growing conditions. For dispersal of sperm, clearly water is needed, and energy must be available leading up to sperm maturation. Spore dispersal is most often favored by dry weather, which as already pointed out, can alternate effectively with wet weather in spring. Spore dispersal itself is a mechanical process and presumably requires no energy. Spore maturation does, but dispersal can wait, being effected in most cases when the capsule dries out, forcing the operculum off. This process likewise might be presumed to require no energy. Therefore, energy requirements may be sufficiently spread over time so that the processes of gametangial maturation and spore/capsule maturation do not compete enough to be detrimental. Once these demands are met, it is beneficial for spores that lack dormancy to be dispersed when good growing conditions are close at hand. The alternating wet and dry conditions of spring would seem to be ideal for this. It remains for us to demonstrate that in fact this is so, since we know virtually nothing about spore germination and protonema development in nature for most species.

Geographic Differences

Both latitude and altitude create different climatic conditions. Inland conditions can be quite different from coastal conditions. The wide range of temperature and moisture created by these geographic conditions imposes strong selection pressures on the genes controlling the phenology of the organisms living there.

Some bryophytes seem to ignore winter, as does *Schistidium apocarpum* var. *confertum* (Figure 11) in the eastern Pyrenees (Lloret Maya 1987). This species, despite living above 1800 meters elevation, is not affected by winter conditions. However, other taxa in these mountains have mature gametangia and fertilization early in the summer with dormant winter sporophyte development followed by rapid maturation of the sporophyte in the first months of summer. At the same time, species living at lower elevations exhibit a continuous progression of stages with no dormancy. Only *Schistidium apocarpum* var. *confertum* behaves this way at high altitudes.

Figure 11. *Schistidium apocarpum* var. *confertum* growing on rock and exhibiting its typical abundant capsules. Photo by Michael Lüth, with permission.

Longton and Greene (1969) demonstrated a latitudinal difference in *Pleurozium schreberi* (Figure 12). In Great

Britain, perigonal development begins in August. Antheridial development apparently is dormant in an immature stage through the winter. Archegonia are first evidenced by perichaetial development in October, but the archegonia likewise overwinter in an immature stage. In spring, both gametangia develop rapidly and fertilization ensues in April and May. The young sporophytes begin to emerge in May, but seta elongation is delayed until August. By October the operculum is in its mature stage, but spores are retained until January, with dispersal occurring January through April – a 9-12 month cycle. Thus, even in this maritime climate, winter is unsuitable for most developmental activities, although presumably winter growth is possible. In France, Finland, and North America, vegetative growth is arrested during the winter, resuming for the period of April to November.

Figure 12. The red-stemmed moss, *Pleurozium schreberi*. Photo by Michael Lüth, with permission.

Measuring winter growth under the snow is difficult. One cannot remove the snow to measure the growth because that would alter the conditions, affecting subsequent measurements. Ideally, one could measure length or biomass just before the first snowfall and just after spring melt, but that is not as easy as it may seem. The first snowfall may only provide temporary cover, followed by a warm period. One cannot be there every day to ensure measurement on the one day that lies just before the permanent winter cover. And spring is not as easy to determine as it might seem. In many habitats, bryophytes are covered with water for a short period of time during and just after snowmelt. Furthermore, the snow may leave, but the air remain cold, or temperatures might rapidly climb to a balmy spring day when there is no more change of state from solid ice to liquid or gas as the snow melts. Predicting and being there and knowing that the patch you measure has just come out from the snow would require being a psychic.

For many bryophytes, those early days following snowmelt are the best time all year for growing as they take advantage of the open canopy and warm but not hot temperatures. But we know next to nothing about the ability of bryophytes to grow under the snow. Could they get enough light through thin layers of snow and enough moisture from partial melt to photosynthesize at times in the winter? Is there a possibility they begin their spring productivity two weeks before they are uncovered? And what about the epiphytes that rest within that funnel of air between the snow and the bark? Are they warm enough

and humid enough to continue photosynthesis throughout most of the winter? Trynoski and Glime (1982) suggest they might, based on finding more bryophytes and bryophyte biomass on the south side of the tree at breast height in Keweenaw County, Michigan, USA.

Longevity Tradeoffs

In 2009, Bryonettters asked "How long do mosses live?" In 2014, Bryonetter Wang Zhe asked about the **longevity** (length of life span) of bryophytes. There is no satisfactory answer to this question. True, some have very short life cycles, emerging from spores as flood waters recede and completing an annual life cycle within a few months. Others, like *Sphagnum*, may live hundreds of years, dying at the bottom and growing at the top. Others challenge our definition of death, regaining photosynthesis after a long desiccation dormancy.

Thus, the first problem is to determine if the bryophyte is alive. In an organism that thrives on fragmentation, we are confounded by the possibility that a cell or cells remain alive and can under the appropriate conditions begin new growth, often to produce a new plant, a condition known as **totipotency**. In other cases, tissues may remain dormant for years, only to resume growth when getting the light and water they vitally need.

Guy Brassard responded to this query on Bryonet: "This is interesting in a rather odd way. Some years ago, when I was at Memorial University, I found a piece of *Hylocomium splendens* (Figure 1) that I had dried between the pages of a book some 20 years earlier. I put it on a damp paper in a Petri dish on a window ledge without hoping for anything to happen. But, much to my surprise, after about 2 or 3 weeks a NEW BUD appeared on the stem and proceeded to grow into a new branch. So there must have still been some live germ-plasm in the stem of that dried old specimen. If such a tiny piece could remain 'alive' for two decades inside the pages of a book (no water and essentially no light), this means that the time span for air-dried bryophytes retaining live tissue could be much longer (50? 100? years), and that most herbarium specimens are still 'alive' as well!"

This year I watched my moss garden emerge from under the snow after a long and especially cold winter. I was shocked to see that most of the mosses were brown and appeared to be dead. I resisted the temptation to replace them and watched. It took about a month, but green appeared, and most of the clumps now look fully green after a mild, bryophyte-favorable summer. How DO we recognize a dead bryophyte?

The second problem is to determine the age of the bryophyte. As already noted, some mosses have natural annual markers. *Hylocomium splendens* (Figure 1) is named stair-step moss because each year it produces a new primary branch. These stack up like stairs and can be used to determine the age of the moss. *Polytrichum* species have small sections of reduced leaves that mark the end of one year's growth and the beginning of the next (Figure 13). Male *Polytrichum* plants mark each year of growth with the antheridial splash cup (Figure 14-Figure 15). Petraglia (2007) reported *Polytrichastrum sexangulare* (Figure 16) in the Italian Alps as having shoots 9 years in age, with soil humidity apparently influencing longevity (Alessandro Petraglia, Bryonet 25 February 2009). On the

other hand, *Polytrichastrum formosum* (Figure 17) in a Dutch forest has an estimated age of 80-100 years, based on the size of the **genets** (free-living individuals that develop from original zygotes, parthenogenetic gametes, or spores and that produce branches vegetatively during growth) (van der Velde *et al.* 2001). Other genera [*e.g.* *Bryum s.l.* (Figure 18), *Schistidium* (Figure 19), *Zygodon* (Figure 20)] have indentations (Rod Seppelt, Bryonet 25 February 2009) similar to those of female *Polytrichum*. But does every plant produce sexual structures every year? How many years pass before the first sexual organs occur on the perennials? Do two rainy seasons cause two growth increments? Do drought interruptions cause growth increments?

Figure 13. *Polytrichum commune* showing growth interruptions (arrow). Photo by Michael Lüth, with permission.

Figure 19. *Schistidium rivularis* showing growth increment (arrow). Photo courtesy of Betsy St. Pierre.

Figure 20. *Zygodon dentatus* showing growth increments (arrows). Photo by Michael Lüth, with permission.

Although this also seemed like a simple question, the answer is often not so simple. As Heinjo During and Martha Nungesser (Bryonet 25 February 2009) pointed out, a single **ramet** (stem/branch) may behave as an **annual** (living only one year), but the **genet** may exist for decades. This seems to be the case for *Crossidium crassinerve* (Figure 21) in the Mojave Desert, USA (Stark & Delgadillo 2003). The problem of genets seems to be further complicated by more extensive sexual reproduction than we often imagine, with males and females arising from one clone and reproducing within a distance of centimeters to several meters, as in *Polytrichastrum formosum* (Figure 17) (van der Velde *et al.* 2001).

Figure 21. *Crossidium crassinerve*, a moss with annual ramets but perennial genets, from Europe. Photo by Michael Lüth, with permission.

As already noted, in *Sphagnum*, some plants may be 100's of years old, but these plants keep dying at the bottom and growing at the top, so one must determine what portion of the plant is still alive before answering any question about its longevity. Yet, Dick Andrus (Bryonet 25 February 2009) found *Sphagnum magellanicum* (Figure 22) measuring 80 cm in Tierra del Fuego and reminded us of Clymo's opinion that *Sphagnum* from a meter or so down could be a 1000 years old. Despite looking old, new plants could be grown from fragments down a meter or more from the surface.

Figure 22. *Sphagnum magellanicum*, a species that Clymo estimated could grow to be 1000 years old. Photo by Michael Lüth, with permission.

In the presumably annual *Crossidium crassinerve* (Figure 21), all is not what it seems to be. Stark and Delgadillo (2003) estimated that some of the stems were as much as 70 years old. Even the older portions were able to produce buds and protonemata in culture.

In the Antarctic, being frozen may suspend biological activity of bryophytes for even thousands of years (Miller 2014; Roads *et al.* 2014; Zimmer 2014). The moss *Chorisodontium aciphyllum* (Figure 23) was removed from a core sample of Antarctic permafrost (Roads *et al.* 2014). Samples from depths of 30, 110, 121, and 138 cm grew, suggesting that they had been preserved in permafrost that was subsequently overrun by a glacier. The stems removed from 110 cm showed evidence of growth *in situ* in ff days. Protonemata arose on rhizoids at the base of the core in 22 days. This older part of the core was estimated to be 1153-1697 years old.

Figure 23. *Chorisodontium aciphyllum* in Antarctica. Photo from Polar Institute, through Creative Commons.

LaFarge *et al.* (2013) found bryophytes emerging from the edge of the Arctic glacier on Ellesmere Island. The radiocarbon dating suggested they had been entombed by the ice during the Little Ice Age (1550-1850) AD. As these often blackened bryophytes emerged, some developed green stem tips or new lateral branches.

Tamás Pócs (Bryonet 18 September 2014) described longevity indicators in cushion-forming bryophytes like *Leucobryum* (Figure 24-Figure 26), *Dicranaceae* (Figure 27-Figure 29), and *Calymperaceae* (Figure 30) when living in seasonal climates. By examining the cushion in section, one can observe yearly layers, much like the annual rings of a tree trunk.

How do you determine the age of an individual *Sphagnum* (Figure 31) that can give rise to all populations on the Hawaiian Islands (see Karlin *et al.* 2012)? How do we deal with mosses like *Pleurozium schreberi* (Figure 12) that spread horizontally, dying (?) at the base while continuing growth at the tips? Do we start over in aging them when a branch breaks off, becoming an independent plant?

Figure 31. *Sphagnum fuscum* showing two heads that share a base. Photo by J. C. Schou, with permission.

Richard Zander (Bryonet 18 September 2014) suggested that perhaps it is the diploid (sporophyte) stage that we should measure because it is important in repairing gene damage. He referred to the gametophyte as mostly immortal but genetically degrading.

New methods are making more accurate age determinations possible. Robinson *et al.* (2007) has used ANSTO to make rapid and accurate age determinations from small amounts of material. This technique uses a radiocarbon analysis to determine growth rates based on samples from different portions (5 cm segments) of the plants. They have indicated changes in the growth rates of *Bryoerythrophyllum recurvirostre* (Figure 32) in the Antarctic.

Figure 32. *Bryoerythrophyllum recurvirostrum* from southern Europe, a species with documented changes in growth rate. Photo by Michael Lüth, with permission.

There surely are tradeoffs between longevity and new plants, but such tradeoffs have not really been investigated. We have evidence that spores of at least some bryophytes, for example *Dicranum scoparium* (Figure 33), are unable to germinate when subjected to water extracts of their parents or other members of the same species (Mishler & Newton 1988; Newton & Mishler 1994). Hence, there is a tradeoff between asexual reproduction by ramets and sexual reproduction producing new clones. But which is best for the species? For evolution, sexual reproduction is

usually best because it permits selection against plants with the weaker genomes. But the established genome is obviously adapted to that particular microenvironment.

Figure 33. *Dicranum scoparium* in Michigan, USA, showing what is most likely clonal growth because the adults inhibit the germination of spores. Photo by Janice Glime.

Control of Phenological Events

As implied by the above timing of life cycle stages, phenological events must have internal controls that are called into play by external phenomena. For example, *Funaria hygrometrica* (Figure 34) is under an intricate set of controls that determine where and when it germinates (Hoffman 1966). If it germinates where it is dark, it cannot complete its life cycle.

Figure 34. *Funaria hygrometrica* with developing sporophyte. Photo by Michael Lüth, with permission.

On the other hand, it does germinate over a wide range of both temperature and light intensities (Hoffman 1966). It fails to germinate without light, but can be stimulated to do so by supplying a source of carbon, particularly sugars, suggesting that the importance of light is to provide energy needed to power the process.

Funaria hygrometrica (Figure 34) produces its gametophytes in early spring, produces capsules in the early summer, and sheds its spores in July-September (Hoffman 1966). It fails to germinate on soil treated with nutrients, but succeeds on soil from burned areas. If it

germinates where nutrients are too rich, other plants will be able to grow more easily, so competing plants may shade it before it is able to reach maturity. Humic acids inhibit germination (Raeymaekers, unpub. data.), perhaps accounting for its short life after invasion of a new area.

While it grows well on soil previously heated to temperatures of 200-300°C (sufficient to destroy litter and associated humic acids), *Funaria hygrometrica* (Figure 34) fails to grow on soil previously heated to greater than 300°C. At these high temperatures, N and P are released; addition of these two nutrients to soil previously heated to 600°C permits the moss to grow. Since the moss grows in open areas, it does not benefit from nutrients leached from the canopy, so it is not surprising that addition of K, Ca, and Mg (important canopy leachates) failed to benefit it. The controls at other stages of the life cycle of *Funaria hygrometrica* are less well known, but we do know a considerable amount about the kinds of internal and external controls that are available to mosses, and thus an entire chapter will be devoted to that discussion.

Although we know little about field development of protonemata, we know much about their physiology from laboratory studies, as discussed in the chapter on development. From these, we can surmise the importance of certain environmental controls. Certainly water and light are needed for spore germination. Kinugawa and Nakao (1965) found that photoperiod was important for both germination and protonemal development in *Bryum pseudo-triquetrum* (Figure 35). Both processes required a minimum of 12 hours light, although they could be fooled into thinking they had sufficient light by interrupting a long dark period with only 2 minutes of light.

Figure 35. *Bryum pseudotriquetrum* with antheridia. Photo by David Holyoak, with permission.

Timing of phenological events that bring antheridia and archegonia in the population to maturity at the same time is crucial to reproductive success. Yet different controls seem to guide these two developmental pathways. Hence, as some taxa expand into new geographic areas with different timing of day length, uncoupling of appropriate temperature from appropriate day length, and changes in seasonal moisture regimes, it is not surprising that some fail to produce capsules despite the presence of both sexes. Clearly phenology is an area requiring further

study and may help us understand the success of bryophytes through the widespread areas where we find them. While their morphology has remained relatively unchanged, it appears that their ability to take advantage of seasonal events by a wide variety of phenological strategies, even within a species, may have been evolving rapidly.

Summary

There is a **trade-off** between growth and reproduction so that growth diminishes or ceases during reproduction. Growth also usually ceases in a cold winter when there is no free water and in summer when the temperature is too high and carbon loss would be greater than carbon gain. Optimal temperatures for elongation, bud formation, and rhizoid production may differ. Furthermore, increase in biomass may occur without increase in height. Reproduction may be coupled with photoperiod, light intensity, and temperature, and these will most likely be coordinated to provide the reproductive bryophyte with the greatest possibility of sufficient water. Nutrients and pH may also play a role in signalling onset of sexual reproduction.

Phenological events must not only coordinate with favorable climatic conditions, but they must coordinate with what is occurring among the other occupants of the ecosystem. For example, the non-competitive *Funaria hygrometrica* must grow in early spring, produce capsules in summer, and shed spores starting in July, permitting it to complete its life cycle before the arrival of other plants that compete for light and alter the nutrient regime. Following a fire, it takes advantage of the low nutrients before weathering, microbes, and other plants alter the soil and make it too nutrient-rich. Signals for initiation of life cycle stages often include photoperiod, and the required day length may differ between males and females of a species. Antheridia typically take longer to mature than do archegonia, thus requiring different signals to initiate in order to insure maturity at the same time.

Acknowledgments

I appreciate the helpful comments of Heather Smith in giving me a student's perspective on this chapter. Linda Luster checked the literature citations, proofread, and checked for needed glossary entries. KT McConnell suggested the mini-summaries of some sections and made suggestions to improve the clarity. Jean Faubert made several useful suggestions for this chapter. Jean Faubert helped me with the French reference by Kucyniak.

CHAPTER 4-5

ADAPTIVE STRATEGIES: GROWTH AND LIFE FORMS

Figure 1. *Hypnodendron menziesii* demonstrating the clonal growth and dendroid growth form that is possible in a humid climate such as that in New Zealand. Photo by Jan-Peter Frahm, with permission.

Growth Forms and Life Forms

Bates (1998) concluded that life form is a useful concept in bryophyte ecology because of the "exceptionally high dependence of bryophytes on transient external water supplies." He points out that for bryophytes it is not the individual that forms the ecological unit, but rather the clonal or colonial life form (Figure 1). The life form is so constructed as to minimize evaporative loss while maximizing photosynthetic light capture. For example, in the Taymyr Peninsula, Siberia, differences in life form can reduce evaporative rate by 5.3-46 times, depending on the species and site conditions (Vilde 1991).

Definitions

Meusel (1935) describes **growth form** as the overall character of a plant and explains it can only be determined by detailed morphological analysis. It is a purely morphological term, as opposed to **life form**, which is more encompassing and describes the result of life conditions, including growth form, influence of environment, and

assemblage of individuals (Warming 1896; Mägdefrau 1982). **Life form** embodies all the selection pressures that are brought to bear upon a species, or in the words of Mägdefrau (1969), "the organization of a plant in correspondence with its life conditions." Hence, life forms are genetically determined. Growth forms are influenced by the environment.

If these **life forms** persist genetically, we tend to assume they have adaptive significance. Gould and Lewontin (1979) and Mishler (1988) warn us of the trap of this type of thinking. We must recall that selection works against those things that are not beneficial, and that it is a slow process, even slower for those things that convey only a slight disadvantage. Furthermore, such characteristics as life forms may simply carry an occasional advantage, an occasional disadvantage, or little difference from another life form. Correlation of life form with habitat, however, can be used as supporting evidence for the adaptive value of a given life form.

Early classification of **life forms** had little relevance for bryophytes. Dansereau (1957, in Ricklefs 1990) classified plant life forms into trees, shrubs, herbs, epiphytes, lianas (vines), deciduous, evergreen, and bryoids. Raunkiaer (1934) relied primarily on winter characteristics and based his system on bud position:

phanerophytes (*phanero* = visible) – large shrubs and trees, buds at tips of branches; moist, warm environments

chamaephytes (*chamae* = dwarf) – shrubs and herbs, buds near soil; cool, dry climates

hemicryptophytes (*hemicypto* = half hidden) – die back to ground in winter; cold, moist

cryptophytes (*crypto* = hidden) – buds buried by soil; cold, moist

therophytes (*thero* = summer) – seeds; deserts, grassland

The classification of bryophytes into **acrocarpous** and **pleurocarpous** is somewhat analogous to Raunkiaer's system.

Mägdefrau (1969, 1982) considered that **life form** refers to the habit of the plant in harmony with its life conditions. Hence, life form includes growth form, the assemblage of individuals into formations, societies, or communities, and the influence of external factors. Life form is applied to communities, whereas growth form is applied to individuals. During (1979, 1992) stressed that life forms are linked to the life strategies of bryophytes.

Mishler (Bryonet 1996) takes a somewhat different approach by identifying three terms. He separates **architecture**, considering that to be the most fundamental expression of "internal" factors (genotype and development). This is determined by basic units of growth and their patterns of differentiation. **Growth form** is the middle condition, expressing a mixture of internal and external (environmental) factors and is expressed by the appearance of the stem in the habitat. **Life form** is likewise a mixture, but relies more heavily on external factors. It refers to the overall appearance of the whole colony. Mishler points out the importance of the hierarchical level we are examining – module, stem, or colony.

In response to the confusing array of definitions and uses of the terms life forms and growth forms in the literature, La Farge-England (1996) attempted to give a more precise definition, based on the early usage of the terms. She defined **life form** as "the structures and assemblage of individual shoots, branching pattern, and direction of growth, with modification by its habitat (*i.e.*, cushion, turf, dendroid, mat, pendant, *etc.*).". She emphasizes that the term **life form** applies to the **assemblage**. **Growth form**, by contrast, applies to the structures of the **individual shoot**, including direction of growth, combined with length, frequency, and position of branches. For example, a dense *Grimmia* (Figure 11) cushion is a life form that has responded to its xeric habitat and is a conglomerate of individuals. Its **growth form** would be erect stem, with variable numbers of branches, positioned along its stem (*i.e.* acrotonous or distally versus basitonous or proximally). Like Mishler, she asserts that **growth form** is really architecture of the individual shoot combined with the direction of growth.

Both Mishler and La Farge-England emphasize that the direction of growth does not necessarily imply

perichaetial position. Mishler suggested that *Hedwigia* (Figure 2) is a good example of this uncoupling. It is an acrocarpous moss with a prostrate growth form like that of most pleurocarpous mosses.

Figure 2. *Hedwigia ciliata* showing terminal (acrocarpous) capsules (**top**; photo by Robert Klips, with permission) and horizontal growth form (**bottom**; photo by Janice Glime)..

Jargon of Life History

First, perhaps it is necessary to distinguish between **life history** (or life cycle) traits and **life forms**. As During (1979) points out, **holomorphy** (total form, Hennig 1966; the German *Gestalt*) of plants resulting from their adaptations to their environments certainly relates to their **life strategies**. However, the **life strategy** refers to life cycle characteristics and their timing (treated in the next chapter), whereas **life form** refers to the morphological characters of individuals as well. La Farge-England (1996) points out the inconsistencies in the literature regarding the term **life form** and supports Barkman (1979) by defining it as "the overall organization of growth form, branching pattern, general assemblage of individuals, and modification of a population by the environment." **Growth form**, she reminds us, is "the structural architecture of the individual moss plant." But such architectures can be modified by the environment, hence merging life form and growth form (Tangney 1998). It would seem simpler to define one as the genetically programmed form and one as the environmentally modified form, but the muddle in the literature has crossed those lines with both terms. Thus,

even with the foregoing definitions, confusion in the use of terms will still be with us. I shall attempt to unravel their use in the literature presented here. Nevertheless, interpretation of their use should be done with caution.

Growth Forms

Since **growth form** is the simpler result of genetics, we should examine that first. Meusel (1935) applied the term growth form to individual shoots. It is therefore a purely morphological term expressing the architecture of the plant. As La Farge-England (1996) stated, the terminology of growth form, branching pattern, and position of perichaetia have been used inconsistently in the literature. This morass of literature makes it difficult to compare studies and to sort out the real meanings in nomenclature. After an extensive review of the literature and usage of the terminology, she recommended the following interpretations:

1. **Growth form** is distinct from **life form**.
2. Direction of growth does not necessarily imply perichaetial position; some **acrocarpous** mosses (having terminal perichaetia) grow horizontally, whereas some **pleurocarpous** ones (having perichaetia in lateral buds or on short side branches) grow erect.
3. **Cladocarpus** (Figure 3) is distinct from pleurocarpy, with perichaetia terminal on lateral branches and with juvenile leaf development similar to that on vegetative branches; perichaetial branches have lateral primordia that potentially develop subperichaetial branches. (It is defined in *Glossarium Polyglottum Bryologiae* as a type of pleurocarpy having sporophytes borne terminally on short lateral branches, as in *Fontinalis*).
4. **Pleurocarpy** is defined as having perichaetia terminal on lateral innovations that appear sessile and swollen along supporting axes. Juvenile leaves are morphologically different from those of vegetative branches. Perichaetial innovations lack lateral branch primordia and thus do not produce subperichaetial branches. Pleurocarpy is restricted to **Hypnales**, **Hookeriales**, and **Leucodontales** (Figure 6d), including **Spiridentaceae** and **Racopilaceae**.

Figure 3. Cladocarpous branches of *Macromitrium microstomum*. Photo by Janice Glime.

But traditionally, growth forms of mosses have been divided into those that are **acrocarpous** (Figure 4) and stand vertically (**orthotropic mosses**) and those that are **pleurocarpous** and lie horizontally relative to the substrate (**plagiotropic mosses**; Figure 6) (Meusel 1935). This of

course leaves a few out of the scheme, as noted by La Farge-England. The orthotropic mosses can be further divided into the **protonema mosses** (Figure 5), with short or non-existent shoots that wither after the sporophyte is produced, and **turf mosses**, with upright shoots that bear new shoots after the sporophyte forms and subsequently bear further archegonia and more sporophytes; these new growths are the **innovations**. The **plagiotropic** mosses (Figure 6) include **thread mosses** (e.g. **Leskeaceae**, some **Amblystegiaceae**), with little difference between the main stem and lateral branches, **comb mosses** (e.g. **Hypnaceae**, **Brachytheciaceae**, **Meteoriaceae**), with a strong main shoot with many simple or branched lateral branches, and the **creeping-shoot mosses** (e.g. **Leucodon**, **Antitrichia**, **Climaciaceae**, **Hypnodendraceae**), with rhizomatous main shoots that give rise to upright main shoots.

Figure 4. Acrocarpous growth form exhibited by *Oncophorus wahlenbergii*. Photo by Michael Lüth, with permission.

Figure 5. Protonema mosses. **Upper:** *Pogonatum aloides*. **Lower:** *Buxbaumia aphylla*. Photos by Michael Lüth, with permission.

The same species may exhibit more than one growth form. For example, in some populations *Hylocomium splendens* (Figure 7) exhibits **monopodial growth** (single central axis with apical growth) (Ross *et al.* 1998, 2001). However, some populations can continue by **sympodial growth** (growth produced by lateral buds just behind apex).

Figure 6. Plagiotropic, pleurocarpous, perennial mosses. **a & b.** creeping shoot mosses – *Antitrichia curtipendula*. **c.** creeping shoot moss – *Climacium dendroides*. **d.** creeping shoot moss – *Leucodon brachypus* var. *andrewsianus*. **e.** thread moss – *Amblystegium serpens*. **f.** thread moss – *Leskea polycarpa*. **g.** comb moss – *Brachythecium reflexum*. **h.** comb moss – *Hypnum sauteri*. **a, b, e-g** photos by Michael Lüth, with permission; **c, d** photos by Janice Glime.

In forest habitats of temperate to mid-arctic regions the growth of *Hylocomium splendens* (Figure 7) is primarily sympodial, creating the stair-step form that easily delineates annual growth (Ross *et al.* 2001). Higher nutrient availability promoted sympodial growth. In tundra and high arctic habitats, monopodial growth predominates and increments cannot easily be discerned. Transplant experiments demonstrated that these traits were plastic, but that natural variability was greater among those shoots in natural populations at transplant sites, indicating a genetic component as well as an environmental component to the differences, affecting both growth and life forms.

Figure 7. Weft life form of *Hylocomium splendens*, exhibiting well-defined annual branching. Photo by Michael Lüth, with permission.

Ross *et al.* (1998) found that the sympodial *Hylocomium splendens* (Figure 7) plants had increasing stiffness with stem segment age and flexibility decreased with age up through four years, then declined. However, monopodial plants showed neither of these age effects and no increase in stem diameter with age. The sympodial stems had significantly more cellulose than their monopodial counterparts, providing them with a higher stress yield. The predominance of these two forms differs with habitat, with more northern populations lacking the sympodial branching that defines the annual increments. Økland (2000) further determined that reproductive capacity differs with stem position and age. The apical tips are subject to greater exposure and are less likely to have successful reproduction. Reproductive failure is greatest for older segments buried within the weft (44%), lowest for intermediate vertical positions (12%), and relatively high for the emergent segments. The greatest annual increment is likewise at this intermediate level (2-10 mm below the bryophyte surface) where there is still sufficient light but the loss of water is minimized.

Økland (2000) pointed out the importance of "growth form" in the way that pleurocarpous and acrocarpous bryophytes interact in competition. In our study on Isle Royale (Raeymaekers, Zhang, & Glime unpubl), the interaction between the acrocarpous *Dicranum polysetum* (Figure 8) and the pleurocarpous *Pleurozium schreberi* (Figure 8) differed from year to year, most likely depending on the precipitation patterns. In some years, *D. polysetum* increased in area and overran *P. schreberi*, but in other years the reverse occurred. Økland suggested that the relationship of upper segments to lower ones represented **amensalism**, where the lower segments were

harmful. Small segments were more easily buried. This relationship can play an important role in both intraspecific and interspecific interactions among bryophytes.

Life Forms

Literature on life forms and growth forms is confusing because different authors have used the terms in different ways, sometimes in reverse of the descriptions above. Even in the long-studied tracheophytes, the terms have often been used as if they are interchangeable. In studying loblolly pine trees, Haney *et al.* (1993) illustrated effects of density on "growth form" of loblolly pine tree shape (Figure 9). They found that in low densities, trees were shorter and had more branches. At medium density, they were taller, but branches were few in number. At high densities, trees were tallest and branches were still few. These environmental influences on tree form fit the more encompassing definition of life form described above by La Farge-England (1996). As expected, allocation of biomass changes relative to density (Table 1), resulting in a different form. Such mosses as *Sphagnum* and *Climacium* (Figure 13c) would be interesting tests of a similar form change in bryophytes. *Climacium* is known to change form, but it appears to be under both environmental and genetic control; effect of crowding was not studied (Shaw 1987).

Figure 9. Illustration of forms in loblolly pine at different densities. Based on Haney *et al.* 1993.

Table 1. Allocation of biomass in trees of loblolly pine at three density levels. From Haney *et al.* 1993.

	low	medium	high
diameter (cm)	11.87	7.79	6.67
number of whorls	18	11	9
biomass (kg)	12	6.5	4.9
crown ratio	0.79	0.52	0.44
branches	50	27	21
branch length (m)	1.5	1.05	0.9

Bates (1998) raised the question "Is 'life-form' a useful concept in bryophyte ecology?" When he pointed out that most bryophytes are either clonal or colonial, he emphasized that it is these, not individual shoots, that are the functional units. The life form maximizes productivity and minimizes water loss, but it may also function to prevent photoinhibition or scavenge cloud water. Despite its usefulness in indicating moisture and light conditions, Bates considers life form to have limited use "as a framework in ecological studies." He also considers a major problem to be the inconsistent way the concept has been applied in the literature. Life forms also change, as pointed out by Warming (1896). Bates suggested that one interpretation of life form is to consider highly productive horizontal growth forms like that of *Brachythecium rutabulum* (Figure 10) to be an adaptation for **foraging** (horizontal growth that permits mosses to take wider advantage of nutrients and light; Bates 1998). Life forms do not evolve independently and are closely tied to the life cycle and reproductive traits. Nevertheless, Bates concluded that the concept was useful because of "the high dependence of bryophytes on external transient water supplies." However, the description of life form alone will provide insufficient understanding and will depend on knowledge of its relationship to other attributes of the life strategy.

Figure 10. Horizontal growth form of *Brachythecium rutabulum* that may be used for light-scavenging (foraging). Photo by Michael Lüth, with permission.

Age changes the life form and its effect on the physiology of *Grimmia pulvinata* (Figure 11) in a different way (Zotz *et al.* 2000). As discussed in the structural adaptations related to water, this moss forms cushions. As the cushion volume increases, so does the water volume. However, the surface area increases two-dimensionally as the volume increases three-dimensionally, causing a decrease in the surface area to volume ratio. This greatly enhances the water retention of the cushion as it enlarges. On the other hand, the CO₂ exchange decreased with size, again because of the reduced surface area. Lowered CO₂

exchange corresponded with lower rates of both net photosynthesis and dark respiration.

Figure 11. Cushion life form of *Grimmia pulvinata*. Photo by Des Callaghan, with permission.

Nevertheless, life forms are often indistinct from growth forms. A plant is predisposed to a certain growth form, and despite neighbors or environmental conditions, it retains that growth form as part of its life form. In this sense, Mägdefrau (1982) lists ten life forms for bryophytes (Figure 12, Figure 13), to which I (Glime 1968) have added **streamer**.

Mägdefrau Life Forms

- Annuals** – pioneers; no vegetative shoots remain to carry on a second year; *Buxbaumia* (Figure 5), *Diphyscium*, *Ephemerum* (Figure 13a), *Phascum*, *Riccia*
- Short turfs** – open mineral soils and rocks; regenerative shoots; form spreading turfs for only a few years; *Barbula* (Figure 13b), *Ceratodon*, *Didymodon*, *Marsupella*
- Tall Turfs** – forest floors in temperate zones; can conduct water internally; very tall; persist by regenerative shoots; *Bartramia* spp., *Dicranaceae*, *Polytrichaceae* (Figure 13c), *Drepanocladus*, *Herbertus*, *Sphagnum*, *Tomenthypnum*
- Cushions** – rocks, bark, Arctic, Antarctic, alpine; usually high light; grow upward and sideways; hemispherical; persistent for many years; *Andreaea*, *Grimmia*, *Leucobryum* (Figure 14), *Orthotrichum*, *Plagiopus*, no liverworts
- Mats** – rocks, bark, [on leaves (epiphyllous) in tropics]; plagiotropic and persistent for a number of years; *Lejeuneaceae*, most *Marchantiaceae*, *Homalothecium*, *Lophocolea*, *Plagiothecium* (Figure 13d), *Radula*
- Wefts** – forest floor of temperate zone; hold considerable capillary water; grow loosely and easy to remove from substrate; new layer grows each year; *Brachytheciaceae*, *Hylocomiaceae* (Figure 7), *Bazzania*, *Ptilidium*, *Thuidium*, *Trichocolea*
- Pendants** – epiphytes, especially in tropical cloud forests; long main stem with short side branches; *Meteoriaceae* (Figure 13e), *Phyllogoniaceae*, some tropical *Frullania* (also spelled pendent, but in English usage, this is the adjective form)
- Tails** – on trees and rocks, shade-loving; radially leafed, creeping, shoots stand away from substrate; *Cyathophorum*, *Leucodon* (Figure 6d), *Spidens*, some tropical *Plagiochila*
- Fans** – on vertical substrate, usually where there is lots of rain; creeping, with branches in one plane and leaves usually flat; *Neckeraceae* (Figure 13f), *Pterobryaceae*, *Thamnobryum*, some *Plagiochila*
- Dendroids** – on ground, usually moist; main stem with tuft of branches at top; *Climacium*, *Hypnodendron*, *Hypopterygium*, *Leucolepis*, *Pleuroziopsis* (Figure 13g), *Symphogyna hymenophyllum*
- Streamer** – long, floating stems in streams and lakes; *Fontinalis* (Figure 13h) (Glime 1968)

Environmental Influences on Life Form

These eleven forms may be further divided, as suggested by Horikawa and Ando (1952). As Mägdefrau (1982) points out, light and water are the predominant influences on life forms. Crowded shoots with dense foliage facilitate water movement and retention in areas with sufficient soil water, thus favoring **tall turfs**. **Mats**, **wefts**, **tails**, and **fans**, on the other hand, are unable to obtain water by capillary action, but depend on the capillary spaces to retain water and extend their periods of activity. **Pendants** (Figure 13e) are like laundry on the clothesline and are particularly susceptible to drying; hence they live in places with considerable rainfall or fog, assumedly directing the water to the growing tip. Mägdefrau (1982) cites his observations on mosses near waterfalls to support this assumption.

The **cushion** life form (Figure 14) is highly adapted for water conservation. Proctor (1980) found that the laminar flow patterns over moss cushions were consistent with the measured loss of water from surfaces of varying degrees of roughness. Water loss increased rapidly beyond a critical wind speed, at which the surface irregularities of the cushion could be related to boundary-layer thickness. The thickness of this boundary layer determines the rate of water loss, with thick layers reducing evaporation. Even cushions have turbulent flow as opposed to laminar flow (Rice *et al.* 2001), and the more deeply the air penetrates into the moss canopy, the more turbulent that flow and the greater the evaporation. Among the growth forms, we would expect cushions to have the least turbulence, with wefts and turfs creating more (Figure 15). Surface roughness increases conductance (Rice *et al.* 2001). However, Proctor (1980) found that hair-points of the leaves that project above the cushion surface reduce boundary layer conductance, for example, by about 20-35% in *Syntrichia intermedia* (Figure 16) and *Grimmia pulvinata* (Figure 11), hence serving as an adaptation to reduce water loss.

Figure 15. Diagram indicating turbulence and boundary layer as might be found above the irregular surface of a moss weft. Having all stems at the same height, as in a cushion, would reduce the turbulence. Drawing by Margaret Minahan.

Figure 16. *Syntrichia intermedia*, a species with hair points that reduce boundary layer conductance. Photo by Michael Lüth, with permission.

Rice *et al.* (2001) have used wind tunnel experiments to examine effects of architectural features on boundary layer thickness and subsequent water balance of bryophytes. Using evaporation rates of ethanol, they were able to assess differences among 11 taxa having a variety of canopy structures. They accounted for 91% of mass transfer of water loss using models based on surface structure. Even the seemingly smooth surface of cushions behaved as turbulent flow rather than laminar flow boundary layers. Conductance increased with surface roughness, causing those species with greater roughness to have higher conductance rates at all wind speeds.

Water-holding capacity is often more important than obtaining water. In the Antarctic, dense rhizoids contribute to high water-holding capacity in *Bryum algens* (Lewis Smith 1988). In *Schistidium antarcticum* (Figure 17), the **turf** form has a high water-holding capacity, whereas the densely packed **cushion** form has a lower water content relative to its dry weight. Nevertheless, the rate of water loss is much more rapid in the turf form (Lewis Smith 1988). I am puzzled, however, by the more rapid water loss in the more tomentose form of *Bryum algens* than in the form with fewer rhizoids. I would have to conclude that water was held loosely among the rhizoids, contributing to the magnitude of weight loss, and was lost more easily, giving a higher percentage loss. A similar phenomenon could explain the differences between the water loss of the turf and cushion. Lewis Smith found that the reverse relationship holds if the water loss is expressed

relative to the initial water content instead of the dry weight, supporting my interpretation.

Figure 17. Cushions of *Schistidium antarcticum* on Macquarie Island in the Antarctic. Photo courtesy of Rod Seppelt.

Physical factors of the environment also contribute to life form in other ways. Once the growing apex reaches the surface of the **cushion** or exceeds the protection of a rock, it would be exposed to air movement where it would dry out. However, the ethylene concentration around the growing tip would also diminish. Whenever the moss slowed its growth and fell below its fellow cushion members, the higher ethylene concentration trapped within the cushion could again accelerate its cell elongation. Results with *Fontinalis antipyretica* (Figure 13h) suggest that ethylene in mosses reduces cell division but permits and perhaps enhances cell elongation (Figure 18) (Glime & Rohwer 1983). If it indeed acts this way, such a mechanism could be a sensitive and effective control mechanism that would maintain the cushion growth form necessary for maximum moisture retention (Kellomaki *et al.* 1978) and surface light. If, however, ethylene retards elongation as it does in most tracheophytes (Abeles 1973), **IAA** (indole acetic acid, a growth hormone) is probably the controlling factor. IAA is destroyed by light (Goodwin & Mercer 1983), so those branches getting more light would grow less, not to mention being retarded by desiccation, whereas those within the mat would be shaded and grow more, as an etiolation response. Mosses kept humid in a plastic bag in a place where little light reaches them produce narrow, etiolated shoots. In a terrarium, *Dicranum scoparium* (Figure 19), *Pleurozium schreberi* (Figure 8), and *Brachythecium* (Figure 10) all produce etiolated tips, presumably in response to low light (pers. obs.).

Figure 18. *Fontinalis antipyretica* leaves showing uneven growth effects of ethylene produced by application of ACC. Photo by Janice Glime.

Figure 19. *Dicranum scoparium*, a species that becomes etiolated in very low light. Photo by Janice Glime.

Plants, including bryophytes, have specific mechanisms to combat light intensity changes. Species from open habitats respond to simulated shade with a large increase in stem elongation (Morgan & Smith 1981). This increase would carry the plant upward until it topped its competitors and could receive the needed sunlight. Lignified woodland species react much less or not at all; here the futile attempt to top the canopy would result in tremendous amounts of wasted energy. **Cushion** bryophytes, however, respond to shading by each other like species from open habitats. In nature we see rounded cushions of *Leucobryum* (Figure 14) and *Dicranum* (Figure 19), and we must wonder if the tall center plants and short border plants are merely a function of age. Yet when a clump is backed up against a rock, it is not as short on the rock side as it is on the other side, but rather it tapers down and away from the rock. Is it light intensity acting on IAA, exposure to desiccation, or ethylene concentration that maintains these cushions, or some combination of these?

In mangrove swamps, Yamaguchi and coworkers (1990) found that small, **appressed** liverworts, especially **Lejeuneaceae** and **Frullaniaceae** (Figure 20), predominated, whereas in more landward sites the larger **ascending** taxa such as *Plagiochila* (Figure 21) and pleurocarpous mosses were found. This distribution seems counter-intuitive unless the seaward sites were more subject to wind desiccation from buildup across the water, whereas the more landward ones were protected by the forest. Salt tolerance may enter the relationship as well, but this has not been explored.

Figure 21. *Plagiochila* sp. illustrating the loose growth form of this liverwort. Photo by Lin Kyan, with permission.

Birse (1957) showed that a normally monopodial dendroid *Climacium dendroides* (Figure 13c) can be induced to grow horizontally as a stolon when affixed to a substrate and supplied with ample moisture. It furthermore will reverse its direction of growth if turned upside down, yet, if placed in a moist pot, it will follow the substrate, growing down on the outside of the pot and ignoring gravity. If buried in sand, it will regenerate shoots that Birse *et al.* (1957) observed to grow up to the surface, then grow horizontally. She likewise observed that *Thamnobryum alopecurum* (Figure 22-Figure 23) exhibited growth forms ranging from simple branches in dripping water (Figure 22) to highly dendroid in very moist air (Figure 23).

Figure 22. Simple branching of *Thamnobryum alopecurum* in dripping water. Photo by David Holyoak, with permission.

Aquatic mosses such as *Fontinalis* (Figure 13h) do not fall easily into the above classification system. While most *Fontinalis* species hang in a pendent form similar to pendent epiphytes, their physiological relationship to their environment as a result of this growth form is quite different. The tip, instead of receiving water dripping down from the remainder of the plant, is immersed most of the year. This long form, which I have termed **streamer** (Glime 1968; Jenkins & Proctor 1985) is more likely a

result than an adaptation. The persistent growth of this moss permits it to grow farther and farther from its substrate, but many branches stack upon each other to make a thick weft, but one that is not easy to remove from the substrate. In *Fontinalis dalecarlica* (Figure 24), rhizoids are generally restricted to bases of stems, and the long, persistent stems are extremely strong (Glime 1980). In *F. novae-angliae* (Figure 25), rhizoids can originate throughout the stems, especially on the stolons, making a firmer attachment to the substrate. It would be interesting to examine competition in these two taxa since they can occupy the same streams and even the same rocks.

Although many studies describe dominant life forms, these descriptions are rarely based on quantitative data. Kürschner (1994) used mean cover values to describe life

forms on basic rocks in nine communities in southern Germany on the northern border of the Schwabische Alb. He found that communities subject to high light and temperature (photophytic and thermophytic) were dominated by cushions, short turfs, and perennial and short-lived colonists (life strategies discussed in the next chapter). As these graded into shady habitats, wefts and mats were more common, with perennial shuttle and perennial stayer life cycle strategies; reproduction was more "passive." Low light species (sciophytes) and aquatic species were perennial fan-formers with sexual reproduction.

Whereas growth form is important for water and light relations, we seldom speak of in relative to support. Nevertheless, with no lignin, bryophytes cannot grow very tall due to lack of support, utilizing cushion growth forms to provide support in some species, especially in *Polytrichum* and its close relatives. During *et al.* (2015) examined the relationship of support along an altitudinal gradient in northern Japan, using *Pleurozium schreberi* (Figure 8) and *Pogonatum japonicum* (Figure 26) as model organisms. *Pogonatum japonicum* had thicker stems, greater rigidity, and exhibited more effect with altitude than did *P. schreberi*. Both exhibited thinner stems and greater stem flexibility with increasing altitude. To me this was a surprising result, based on the knowledge that in tracheophytes wind causes stems to thicken due to greater production of ethylene (Biro *et al.* 1980). I would expect greater winds at higher altitudes. This is an interesting observation that needs to be replicated in other species on other altitudinal gradients.

Figure 26. *Pogonatum japonicum*, a species that exhibits thinner stems and greater stem flexibility with increasing altitude. Photo from Digital Museum, Hiroshima University, with permission.

Some stems can develop considerable stem stiffness and strength, as indicated by biomechanical tests (Frenzke *et al.* 2011). This is achieved by a dense hypodermal sterome "comparable with that of woody stems." With this strength, such mosses as *Dendroligotrichum dendroides* (Figure 27) are able to stand upright. Differences in stem strength are seen among the species of *Fontinalis*, with *F. dalecarlica* (Figure 24) exhibiting considerable stiffness and strength that permit it to live where there is rapid flow. *Fontinalis flaccida* (Figure 28), on the other hand, has a flaccid stem that cannot withstand the strong flow, forcing it to live in lakes and pools of streams. These differences can be observed as differences in the stems (Figure 29-Figure 30).

Physical Effects on Growth Form

Moss Balls

The strange phenomenon of moss balls was reported in 1912 by Dixon, who referred to them as "mosses growing unattached." Bryologists still remain fascinated by these strange organisms that grow in a ball and are mobile, so that at different times any part of the sphere may be exposed to sunlight or substrate. But bryologists are not the only ones fascinated by them. In Japan, a monument is dedicated to their preservation (Iwatsuki 1977).

In 1874, the United States sent an expedition to the Kerguelen Islands in the South Indian Ocean to observe the transit of Venus (Mägdefrau 1987). The surgeon of the expedition was also an amateur botanist and an avid collector. He brought back a "curious moss" that seemed "not to be rooted to another plant, but to be blown about by the wind indiscriminately," as described by the bryologist Th. P. James. Schimper later described these same mosses as having a size that varies between that of a cherry and a middle-sized potato. The smaller balls were *Blindia aschistodontoides*, and the larger ones were formed by stems of *Andreaea parallela* by radiating from a central core of soil or a small pebble. Since then similar wind-formed balls have been found in Alaska, Iceland, Norway, on Mount Ontaka in Japan, and even at the high elevation tropics of Mount Kenya, Mt. Elgon, and Mt. Kilimanjaro in Africa.

Such balls in Arctic and alpine areas could result from **solifluction**. **Solifluction** is a slow creeping of fragmented material down a slope over impermeable material, due to the viscous flow of water-saturated soil and other surficial materials, particularly in regions underlain by frozen ground (not necessarily permafrost) acting as a barrier to downward water percolation. Its drift typically occurs at a rate of 1-10 cm per year (White 2001) in relatively cold regions when the brief warmth of summer thaws only the upper meter or two of loose earth materials above solid rock, which becomes waterlogged because the underlying ground remains frozen and therefore the water cannot drain down into it. Mosses could travel and tumble with it (Figure 31).

Figure 31. This moss, probably *Grimmia ovalis*, has been termed a galloping moss due to its movement down its substrate. This behavior may be an example of solifluction. Photo by Wouter Bleeker, with permission.

Hedberg (1964) interpreted the African balls (*Grimmia ovalis*, Figure 31; Mägdefrau 1987) to form as a result of solifluction. Mägdefrau (1987) tested this hypothesis by experimenting with balls in Teleki Valley of Mount Kenya at 4200 m. The balls were marked and their locations sketched. When it was dry, there was no solifluction and the moss balls remained in place. However, when they experienced daily watering and frost at night, the balls rotated but held their positions. Rather, it appears that when ice crystals and ice needles form at night, they cause the mosses to be forced away from their substrate and broken off. These freed mosses are blown about continuously and thus grow in all directions, forming balls.

Mägdefrau (1987) observed that none of the mosses in balls had sporophytes, whereas those of the same species growing attached had plentiful sporophytes. He concluded that the growth of sporophytes is prevented by the rolling movement. It would seem likely that young setae and perhaps even archegonia at apices may be damaged by abrasion as they get beaten around over the rocky surface. When mosses lie for a longer period of time on one side, sporophytes develop on the edge of the disk.

On frozen Icelandic soil (Mägdefrau 1982) and Alaskan glaciers (Shacklette 1966; Heusser 1972; Iwatsuki 1976), dislodged mosses blow about across the surface, forming similar balls. During (1992) observes that this life form, which also includes lichen species, results in areas that have high winds and little vegetation.

Perez (1991) attributes the transport of *Grimmia longirostris* moss balls (Figure 32) in the Paramo de

Piedras Blancas of the Venezuelan Andes to needle ice activity. These balls had a high organic content (19%) and a collection of fine mineral grains (69%), a much higher fine grain than in the underlying mineral soils. This combination of organic content and fine grains affords the moss balls a much higher water retention capability than paramo soil, with water-holding capacity increasing with the size of the ball.

Figure 32. *Grimmia longirostris* solifluction moss balls in Ethiopia. Photo by Henk Greven, with permission.

At Tierra del Fuego, giant balls of *Racomitrium lanuginosum* form (Figure 33). Similar *Racomitrium* balls or hummocks form in Iceland (Figure 34). Examination of their interior revealed large clumps of grass. The *Racomitrium* had completely overtaken the grass.

Figure 33. These giant moss balls of *Racomitrium lanuginosum* have formed in the Tierra del Fuego. Could these be like the Iceland balls that form around clumps of grass, completely engulfing them? Photo by T. G. Allan Green.

Figure 34. *Racomitrium* hummocks in Iceland. Photo by Janice Glime

Wind and ice are not the only sources of creating moss balls. Action of waves can create similar assemblages (Figure 35-Figure 38). These strange assemblages of individuals have been reported from as distant places as Alaska (Iwatsuki 1976), Finland (Luther 1979), Japan (Iwatsuki 1956, 1977; Iwatsuki *et al.* 1983), and South America (Eyerdam 1967). Eyerdam found *Fontinalis* in balls up to 15 cm in diameter!

Figure 38. Side branch typical of many of the stems in these *Warnstorfia fluitans* var. *kutcharokensis* balls, creating the dense structure that makes the ball. Photo courtesy of Zen Iwatsuki.

In shallow water near lake shores in Hokkaido, Japan, *Warnstorfia fluitans* (Figure 39) attaches to small rocks (Iwatsuki 1956); once the rock is dislodged, wave action rolls the moss back and forth, causing it to lie first in one position, then another, with any protruding branches being broken off (Iwatsuki *et al.* 1983). These growths become extremely dense. As the mosses reach shallower water, wave action is even greater. Ultimately they may be deposited in great numbers along the beaches. Stress causes the production of ethylene, and ethylene can result in short, wide cells under stress conditions in higher plants (Abeles 1973). This could partly explain the short, but firm, branches in the moss balls.

Figure 39. *Warnstorfia fluitans* growing normally. Photo by Michael Lüth, with permission.

Even animals can create moss balls. In the Dutch wetland forest, it is foraging pheasants that turn the mosses upside down and initiate the upward growth that creates the ball (Wiegers 1983). Although *Dicranum scoparium* (Figure 19) and *Mnium hornum* (Figure 40) formed such balls, other upturned wetland taxa did not.

Adaptive Significance

Often the life form is a passive response to exposure; any protruding individual is more subject to desiccation and hence has a shorter period in which to be active for photosynthesis, thus reducing its growth rate below that of its shorter but hydrated neighbors. Although this is more commonly known in cushions, Perez (1991) found that the same phenomenon occurs in moss balls of *Grimmia longirostris* (Figure 32) in the Venezuelan Andes. This spherical life form holds more water than the soil, and

larger balls hold more than small ones. In some cases, the form may be modified to accommodate the capture of cloud water or to avoid photoinhibition.

Figure 40. *Mnium hornum* forming cushion that could become a ball. Photo by Stepan Koval, with permission.

Mägdefrau (1935) found a clear relationship between life form and type of conduction. Dense tufts increase conduction, but there is considerable humidity difference within the tuft that suggests an important role in water retention (Zacherl 1956). When the air humidity is only 50% a few cm above the tuft, it can be as much as 90% within the tuft. Larger volumes are able to store more water, and volume increases more rapidly than surface area. Larger cushions have a greater volume of water per unit of surface area, thus losing less to evaporation than small cushions with a thinner boundary layer and greater proportion of surface area (Proctor 2000). Zotz *et al.* (2000) used *Grimmia pulvinata* (Figure 41) to demonstrate that the greater the size of the cushion, the more resistance it had to water loss. This size increase had no effect on the water-holding capacity on a dry mass basis, and the combination of these two factors contributed significantly to the length of the hydration period.

Figure 41. *Grimmia pulvinata* from southern Europe. Photo by Michael Lüth, with permission.

The cushion growth form (Figure 42) is important in decreasing the loss of water by reducing the turbulence of airflow (Figure 15). At low and even moderate wind speeds, the evaporative water loss from the cushion mimics that of a flat or rounded surface of the same area (Proctor

1984). This form is reminiscent of the tundra formations, where the cushions of seed plants not only impart resistance to moisture loss, but facilitate warming and protect from wind damage. The cushion shape presents a boundary layer that resists loss of moisture and permits wind to cross the plants with a minimum of disruption. Proctor (1979, 1980, 1982) found that the resistance to water loss extends the period of active metabolism after the precipitation stops. Nobuhara (1979) showed that *Bryum argenteum* (Figure 43) increased its water-holding capacity as the volume increased, with more than 100 shoots reducing the water loss to something very small.

Figure 42. *Leucobryum glaucum* cushions. Photo by Janice Glime.

Figure 43. *Bryum argenteum* in a large clump that helps to conserve water. Photo by Janice Glime.

The wind also can play a role in the formation of the cushion. As a branch, whether moss or tracheophyte, grows above the cushion, drying and wind action slow its growth and may even damage the terminal bud. Proctor (1980) demonstrated that when such surface irregularities reach the thickness of the boundary layer, there is a rapid increase in water loss at higher wind speeds. Thus, when a branch extends beyond the cushion, the other branches can catch up with it in growth before it is able to regain hydration and resume its growth, and if the terminal bud has been damaged, that growth may never occur.

Lewis Smith (1988) described the ability of dense turfs of *Schistidium antarcticum* (Figure 44) to hold strongly to their water content, but that the less densely packed shoots of cushions in xeric conditions could not maintain as high a water content as the turfs. Longton (1979a, b) drew a similar conclusion, noting that in Antarctica the plant size

decreases as the shoot density increases; the shorter, more compact growth form could be adaptive to the cold, relatively dry habitats.

Birse (1957) found that in some cases the growth form of certain species of bryophytes is almost invariable, whereas in others variation occurs according to the conditions of the habitat. Birse (1958a), reported that as long as there was a constant ground water supply, a variety of growth forms could flourish, especially tall turf and dendroid forms. In the absence of ground-water supply, short turfs, round mats, and one dendroid species (*Climacium dendroides*, Figure 45) were the only forms to survive.

Figure 44. Growth of *Schistidium antarcticum* on Macquarie Island in the Antarctic. **Top:** The dense and well-hydrated turf surrounds *Ceratodon purpureus* growing in the crevices. **Bottom:** The uneven turf has exposed tops exhibiting dehydration. Photos courtesy of Rod Seppelt.

Figure 45. *Climacium dendroides*, showing dendroid growth form. Photo by Michael Lüth, with permission.

For endohydric mosses, growth form is important in water retention. Longton (1979a) found variations in the

seasonal growth patterns of *Hypnum cupressiforme*, and was able to relate these to water supply. Gimingham and Birse (1957) related growth form response to decreasing levels of moisture:

Relationship of Growth Form to Moisture

high moisture

dendroid & thalloid mats

rough mats

smooth mats

short turfs & cushions

low moisture

Dendroid mosses would seem to be particularly vulnerable to desiccation, with only a single stem in contact with the substrate and many exposed branches. Lorch (1931) found a correlation between the development of the central strand and the degree of branching, whereas the rhizome central strand became less developed, suggesting a greater importance for aerial water sources over soil sources as branching increased. Trachtenberg and Zamski (1979) supported these findings, re-affirming the importance of water absorption through the whole surface of the gametophyte and the utility of **apoplastic** transport.

Sollows and coworkers (2001) concluded that the colonial growth form of the leafy liverwort *Bazzania trilobata* (i.e. having branches lying on top of other branches; Figure 46) protected at least some inner shoots from the extreme exposures they experienced following clearcutting, avoiding the extinction of net photosynthesis observed in laboratory experiments following dehydration for 1-12 days. Likewise, it is likely that the overlapping leaves of this species afford additional water retention by creating capillary spaces.

Figure 46. *Bazzania trilobata*, illustrating the overlapping nature of the branches and leaves. Photo by Janice Glime.

Nakatsubo (1994) compared growth forms in the subalpine region in Japan and found that xeric species were indeed often **large cushions**, as well as **compact mats**. Mesophytic species, on the other hand, comprised **smooth mats**, **wefts**, and **tall turfs** on the coniferous forest floor. He demonstrated that the evaporative rate per dry mass was indeed much less in the xerophytic cushions and compact mats than in the mesophytic forms. While the evaporative rate and dry mass were closely correlated with the growth form, the evaporative rate per basal area was not necessarily smaller in xerophytic taxa.

Matteri and Schiavone (1988) demonstrated that some taxa, e.g. *Polytrichastrum longisetum* and to a lesser extent *Bryum macrophyllum*, conserve their growth form but exhibit different life forms under different ecological conditions. During (1979) likewise related the growth form to the habitat. He found that *Campylopus flexuosus*, *Orthodicranum montanum*, and several other taxa form large turfs with almost no vegetative reproduction when living in moist, undisturbed environments, but when found in dry forests they consist almost entirely of dense cushions of easily detached branchlets.

But what empirical evidence do we have that the various growth forms and life forms actually afford any moisture advantage? Hanslin and coworkers (2001) demonstrated that increased shoot density of *Dicranum majus* (Figure 47) and *Rhytidiadelphus loreus* (Figure 48) actually had a negative effect on relative growth rate and green biomass, but that these were optimal at intermediate shoot densities in conditions of low relative humidity. It is likely that these species suffered a trade-off between light availability and moisture advantage at higher densities. In contrast, Bates (1988) found that *Rhytidiadelphus triquetrus* (Figure 49-Figure 50), likewise a boreal moss, had optimal growth when the colonies were most dense (1000 shoots dm⁻²) (Figure 50). Apparently in this case the dense packing of the shoots gives the advantage of reduced water loss and outweighs the disadvantage of reduced irradiance.

Habitat Relationships

Certain growth forms seem to fare best in certain kinds of habitats (Proctor 1990). In the absence of direct physiological evidence, we can use the observed field relationships to form hypotheses concerning the best life form strategies.

Deciduous Woodlands

Proctor (1990) suggests that **large size** and **rapid growth** are important for woodland and grassland bryophytes to permit them to grow above the litter and surrounding vegetation. This life form permits them the competitive life strategy. Moist, shady habitats are more favorable for **smooth mats** and **small cushions**, but larger taxa occur as well, taking advantage of nutrients in throughfall and exposing more surface area for photosynthesis. In her study of British deciduous woodlands, Birse (1958b) found that **wefts** and **mats** predominated, responding primarily to light as a determinant of abundance.

In humid, montane **tropical** forests, **pendant** and **fan** forms provide the most surface area for interception of the limited light without sacrificing moisture in this humid climate (Proctor 1990). Furthermore, they are able to trap water from mist and clouds. However, the great exposure makes them vulnerable to air pollution.

Pine Woods

Using Proctor's principles as a guideline, then what should we expect in a pine forest where leaf litter is a minimal problem? Seim *et al.* (1955) examined a Jack pine forest (*Pinus banksiana*) in Itasca Park, Minnesota, USA, and found **wefts** and **mats** as the predominant growth forms, with **cushions** and **turfs** comprising most of the remaining taxa. Gimingham and Robertson (1950) likewise found predominately wefts in Northern Britain. However, in another study, Moul and Buell (1955) found the turf type to be predominant (84%) in a sandy coastal pine woods of New Jersey, as did Hamilton (1953) in the hills of central New Jersey, USA. In alpine regions of Japan, Nakatsubo (1994) found that mesophytic species consisted of **smooth mats**, **wefts**, and **tall turfs** on the coniferous forest floor.

Epiphytes

Horikawa and Nakanishi (1954) developed a key to the "growth" (actually life) forms of Japanese epiphytic bryophytes. In it they included **small cushion**, **large cushion**, **turf**, **fascicular & shrubby**, **dendroid**, **simple feather**, **branching feather**, **mat**, **carpet**, **hardly pressed mat**, **loosely pressed mat**, **epiphyllous**, **pendulous**. They pointed out that species will vary with growing conditions, causing the same species to be assigned to more than one type.

Peatlands

Some terrestrial and peatland bryophytes may solve the CO₂ problem by a cushion or other dense growth form (*e.g.* *Sphagnum*) that provides CO₂ mostly from their own transpiration stream. In fact, *Sphagnum* seems to take advantage of CO₂ rising from deep in the peat, bringing up carbon stored there 1000 or more years earlier. Perhaps there is some advantage to having your living parts sitting on top of your dead parts!

Aquatic

Aquatic mosses such as *Drepanocladus vernicosus* rely on a water medium when submersed but benefit from close contact when emergent (Frahm 1978). Aquatic bryophytes are most constrained by CO₂. The **mat** form of *Nardia compressa* (Figure 51) and *Scapania undulata* (Figure 52) is beneficial in water below 0.1 m s⁻¹ where its leaf-area index permits it to exploit the low boundary-layer resistance of high velocities without incurring a high drag. On the other hand, the **streamer** form of *Fontinalis* (Figure 13h) provides the most exposure (maximum surface area) in relatively quiet water of less than 0.01 m s⁻¹ where boundary-layer resistance is high. Nevertheless, *Fontinalis*, with the same streamer life form, occurs in very rapid and turbulent water of mountain streams. Perhaps the turbulence itself permits enough CO₂ to mix with the water for the moss to take advantage of its greater surface area.

In the Antarctic, aquatic mosses showed the greatest plasticity when submerged compared to being grown in the air (Priddle 1979). *Warnstorfia sarmentosa* (as *Calliergon sarmentosum*; Figure 53) grew longer stems (longer internodes) and larger leaves in the water, whereas *Sanionia uncinata* (Figure 54) varied little from its terrestrial form.

Deserts

It is significant that Frahm (1978) found only 9% of the bryophyte flora of the Sahara to be pleurocarpous. In the moist boreal forest, pleurocarpous is the dominant form. Pleurocarpous mosses expose much more surface area to the drying atmosphere; rather, in the dry desert, **small cushions** and **wefts** (loosely interwoven, ascending shoots capable of growing out of the sand are better adapted to the dry and shifting substrate.

Polar Regions

Longton (1979b, 1982) followed the life forms that Gimingham and Birse (1957) attributed to the polar regions in attempting to compare the Antarctic to other polar areas. He considered four Arctic bryophyte habitats: wetlands, mesic communities, polar deserts, and bryophyte-dominated habitats. He considered wetlands to be dominated by the **tall turf** life form, with lesser representation of **short turfs** such as *Seligeria polaris* (Figure 55) on small stones.

Figure 55. *Seligeria polaris*, small, short turf moss on a pebble. Photo by Dale Vitt, with permission.

Mesic communities had a wider range of life forms than the wetlands, but the **tall turf** was still a dominant, with **short turfs** and **mat-forming** species also among the dominants. Although Longton (1979b) recognized five

habitat types among the mesic communities, these forms were generally common among all five mesic communities. However, in Iceland, the **weft** community joined the **tall turf** in prominence, along with mats of leafy liverworts. Furthermore, the birch woods there had abundant weft mosses.

Gimingham and Smith (1971) showed that the *Polytrichum strictum* (Figure 56) and *Polytrichastrum alpinum* (Figure 57) turfs lost water more slowly than *Chorisodontium aciphyllum* (Figure 58-Figure 59) and *Sanionia uncinata* in the same habitats, attributing this to the waxy cuticle on the former two. That *P. alpinum* loses only about 10% of its water when centrifuged suggests that most of its water is held internally compared to the 20% lost from *Chorisodontium aciphyllum*.

Figure 59. *Chorisodontium aciphyllum* in the Antarctic, a species that loses water more rapidly than its waxy counterparts.. Photo by Zicheng Yu through Public Domain.

The dry polar desert fellfields have **cushions** of both mosses and flowering plants, but other open areas have compact forms such as **mats**, **carpets**, and **short turfs** (Longton 1979b).

The bryophyte-dominated communities are those unsuitable for most tracheophytes (Longton 1979b). These include boulders, cliffs, musk ox dung, and hollows where snowmelt is late. The latter supports **large cushions** and **tall turfs** with small flowering plants rooted among them. The liverwort *Anthelia juratzkana* (Figure 60) is common here. **Small cushions** form on boulders, cliffs, and other rocky habitats. Rock crevices harbor **small mats** and **turfs**. **Large cushions** form on stony and marshy ground near permanent rivers and streams, with few bryophytes in the streams themselves. Where bryophytes do occupy streams, they are mostly **streamers** and **mats**.

Figure 60. Leafy liverwort, *Anthelia juratzkana*, forming black mounds on the soil surface. Photo by Michael Lüth, with permission.

The most unique of the polar habitats are those enriched with nitrogen by animal dung that support dense communities of dung mosses (**Splachnaceae**). Bird perches and lemming burrows support short turfs of acrocarpous mosses (Longton 1979b). Soil fractures between the polygons (Figure 61) support short turfs of cosmopolitan taxa such as *Bryum argenteum* (Figure 43), *Ceratodon purpureus* (Figure 44), *Funaria hygrometrica* (Figure 62), and *Marchantia polymorpha* (Figure 63).

Figure 63. *Marchantia polymorpha*, a species that succeeds in the fractures between Arctic polygons. Image copyright by Stuart Dunlop <www.donegal-wildlife.blogspot.com>, with permission.

Racomitrium lanuginosum (Figure 33) forms extensive heaths resembling very large cushions in areas where it can gain water from the saturated atmosphere (Figure 34) (Longton 1979b). In areas with frequent precipitation as well as mist, *Sanionia uncinata* (Figure 54) forms moderately thick mats.

In the Antarctic, stones and gravel of nearly level ground support short turfs and cushions (Longton 1979b). In addition to these, calcareous substrata may have mats. Rock crevices have short turfs, small cushions, and mats.

Alpine

Alpine habitats seem to support mosses that resemble miniature tracheophyte growth forms. **Cushions** are common, but also **carpets** cover the dirt and provide protection from erosion. In studying the Ukrainian Carpathian Mountain alpine region, Ulychna (1970) included, in addition to these, bunches, dendroid, and interlacements, the latter two primarily in the transition into forest.

Studies Needed

While these growth and life form relationships to habitat seem to be well supported by field studies of species present, there has been little attempt to demonstrate that the proposed water relationships actually benefit the bryophytes. Transplant experiments need to be performed that compare the water loss of the various forms in a range of habitats, as well as their survival in this adult form without the need for surviving an establishment stage.

Summary

Growth forms are those genetically controlled characteristics of plants that determine their shape. These are manifest as **acrocarpous** with terminal perichaetia (including **protonema mosses** and **turf mosses**), **pleurocarpous** (**plagiotropic**, including **thread mosses**, **comb mosses**, and **creeping-shoot mosses**) with lateral perichaetia, **cladocarpous** with perichaetia terminal on lateral branches. **Life forms** encompass overall organization of growth form, branching pattern, general assemblage of individuals, and modification of a population by the environment.

The most widely used classification of **life forms** includes **annuals**, **short turfs**, **tall turfs**, **cushions**, **mats**, **wefts**, **pendants**, **tails**, **fans**, **dendroids**, and **streamers**. These can be subdivided, and a few others may exist in less well known habitats.

Growth forms and life forms of plants can aid in water retention by **reducing air resistance**, **increasing boundary layer thickness**, **providing capillary spaces**, and **protecting each other**. Thalloid forms protect one side of the plant at the expense of the other, but cuticular substances reduce the loss on the exposed side. Open growth forms (e.g. dendroid, rough mat, pendant) are more subject to water loss than compact, tight ones (e.g. smooth mat, short turf, cushion). The **cushion** form is able to provide the least surface exposure per unit of biomass and apparently has the lowest water loss rate. Conduction forms seem to

correlate with growth forms, with dense turfs increasing conduction as well as water retention.

Cushions and **moss balls** are formed as exposed shoots are broken off by force of wind, abrasion, and desiccation. Moss balls generally have a pebble at the center and arise in areas of wave action, wind on ice, solifluction (possibly), or other physical factors that tumble the moss.

Deciduous forests require large size and rapid growth such as wefts and mats to obtain enough light and avoid burial by litter. **Humid forests** support pendants and fans that can get moisture from fog and mist. **Pine forests** have wefts and mats, but also cushions, turfs, and smooth mats. **Epiphytes** include mostly appressed taxa such as smooth mats and small cushions, but a variety of other forms are possible in sufficient moisture. **Peatlands** take advantage of density to conserve moisture. **Aquatic** bryophytes are limited by availability of CO₂ and reduce the boundary layer resistance with **mats** or increase surface area with **streamers**. **Desert** mosses conserve water with small cushions and wefts. **Polar regions** support a variety of forms, depending on the habitat, with cushions predominating in habitats where tracheophytes also form cushions; turfs are common. **Alpine** bryophytes also benefit from the cushion form.

Acknowledgments

This chapter has benefitted from the help of Beth Scafone and Medora Burke-Scoll, who helped me explain things for beginning bryologists while at the same time not repeating myself. Linda Luster checked the literature citations, proofread, and made glossary suggestions from a layperson's perspective. Michael Lüth provided many of the images. Bryonettors contributed to the discussions of life and growth forms.

CHAPTER 4-6

ADAPTIVE STRATEGIES: LIFE CYCLES

Figure 1. Strap-shaped leaves of males and capsules with perichaetial leaves of females of the dioicous moss *Diphyscium foliosum*. Photo by Michael Lüth, with permission.

Life Strategies

By now it must be obvious to you that to understand the life strategies of bryophytes, one must first understand the life cycle (e.g. Figure 1). Frahm and Klaus (2001) state that bryophytes are able to react quickly to such events as climatic fluctuations because of their short life cycle and ease of dispersal by spores. It is likely that when all other plant life has perished from some Earth catastrophe, it will be the bryophytes that persist, surviving as spores or other propagules until conditions return to safety and once again surrounding the earth due to their ability to travel great distances as "dust."

By definition, the life cycle includes reproduction. However, even such a widely used term has ambiguities. In bryophytes, we shall use this term to refer not only to the sexual reproduction that results from union of sperm and egg (ultimately resulting in spores produced by meiosis), but also to the multitude of **asexual** (vegetative) means by which bryophytes are able to make more, physiologically independent plants (Mishler 1988). This definition separates reproduction, which can permit relocation, from

growth, which implies the increase in size of a physiological individual (Söderström 1994). On the other hand, growth can ultimately result in reproduction, as is the case when the plant branches and is physiologically connected, but later the branches separate and become physiologically independent. As you can see in Figure 2, the degree of reproduction by propagules depends on habitat. Among British habitats, short-lived habitats (wood, bark, farmland, dung) have the highest degree of propagular reproduction (that is, by vegetative means) (Herben 1994). On the other hand, the habitats with the greatest percent of the species are in the middle of the range of propagules.

Using the principle that extreme conditions might provide the best test of the limits of an organism, we learn that in the maritime Antarctic, bryophytes seem to have enhanced sexual reproduction (Lewis Smith & Convey 2002). This is contrary to the generally accepted belief that bryophyte fertility decreases toward the poles. Rather, 43% of the bryophytes (19 species) in Marguerite Bay and

47% of those on Alexander Island are known to produce capsules. But Lewis Smith and Convey attribute this to favorable microclimatic conditions. Nevertheless, in this extreme environment, the large majority of mosses with capsules were short, monoicous, acrocarpous taxa, suggesting that the predominance of dioicous taxa in more temperate climates may be possible because the environment is less stressful. In the more extreme environments of the Antarctic continent, the numbers of species producing capsules at similar latitudes (68-72°S) are much less (33%).

Figure 2. The percent of mosses that form spores or gemmae frequently or commonly in selected habitats of Great Britain. Asterisks indicate degree of significance (Chi-square test) when compared to the whole moss flora of Great Britain (* = $P < .05$, ** = $P < .01$, *** = $P < .001$). Redrawn from Herben (1994), based on data from Smith (1978).

Although life cycle strategies are obviously important, especially in extreme habitats, life forms and growth forms may be more important. During and Lloret (1996) found that within individual sites in Spain, species with the same life strategy exhibited similar patterns, and that between locations, growth forms differed more than life cycle strategies.

Clonal Growth

At the mature end of the gametophytic cycle, bryophytes can form masses of related individuals, or clones. **Clones** can be defined as groups of individual plants created by fragmentation, viviparous bulbils, or apomictic seeds (Callaghan *et al.* 1992), whereas if gene flow is present the groups of plants are called **populations** (Harper 1977). In other words, clones have the same genetic makeup as the plant from which they were derived. In addition to these tracheophytic means, bryophytes create clones through multiple buds on the protonemata. But, as already discussed, somatic mutations render even these "clonal" derivations to be variable in genetic makeup.

Callaghan, *et al.* (1992) attribute to clonal growth the ability to sequester space and increase fitness of the populations. Among the benefits are persistence; spread of development and reproduction over time and environmental conditions; risk-spreading between **ramets** (individual members of clone) of the same type, thus increasing chances for survival of the genotype; protection

of disadvantaged ramets that might later survive in the face of adversity; increased precision with the sequestering of space and dispersal of ramets; ability to monopolize resources for the benefit of the genotype. They furthermore include mobility, but I question whether this is much of a gain when compared to the alternative of wider distribution of propagules away from the parent.

One possibility that has barely been explored is the increase of genetic variability through production of these haploid genets. We had long assumed that the limited morphological development of the Bryophyta and Marchantiophyta reflected a limited genetic diversity, a case to be expected when the dominant generation is haploid and asexual reproduction is common. However, contrary to our expectations, moss populations are characterized by a high degree of isozyme variation, as shown for *Ceratodon purpureus* (Figure 3) (Shaw & Beer 1999). Cultivation of spores from one specimen of *Drepanocladus* (Warnstorfia) *trichophyllus* produced four distinguishably different morphologies (Sonesson 1966).

Figure 3. Color and leaf shapes of *Ceratodon purpureus*. **Top:** Green, broad leaf, hydrated form. **Middle:** Green, lanceolate leaf, hydrated form. **Lower:** Reddish dry form with capsules. Photos by Michael Lüth, with permission.

Velde and coworkers (2001) addressed this question of genetics of clonal relationships in *Polytrichastrum formosum*. They determined that identical genotypes between spatially separated shoots were almost never present, whereas identical genotypes among **genets** (branching of gametophytes resulting from clonal growth of rhizomes) was extensive. However, this view of the genet has some problems. Scrosati (2002) pointed out that somatic mutations are predictably common, giving rise to genetic mosaics within any connected genet. To deal with this lack of genetic homogeneity, Scrosati suggested that **genet** should be defined as a "free-living individual that develops from one original zygote, parthenogenetic gamete, or spore and that produces ramets vegetatively during growth." Nevertheless, it appears that even in adjacent populations of spore-producing plants, genetic variation is minor. In another example, populations of *Funaria hygrometrica* (Figure 4) growing in close proximity on contaminated tailings of a copper mine displayed very low levels of genetic variability, but had extensive morphological plasticity (Shaw & Bartow 1992).

Figure 4. Crowded *Funaria hygrometrica* with its abundant capsules. Photo by Michael Lüth, with permission.

During and van Tooren (1987) attempted to explain this paradox of genetic diversity in vegetatively reproducing taxa. Referring to earlier views of bryophytes as evolutionary failures, they contended that bryophytes in fact have high genetic variability, yet maintain their populations almost entirely by asexual means. They suggest that even though sexual reproduction, when it occurs, results in huge numbers of spores, establishment from spores in the field seems to be very difficult. Rather, they suggest that "remarkably rapid fine-scale dynamics" of many bryophyte populations may account for their ability to maintain a high degree of genetic variability.

Itouga and coworkers (1999) provide data on genetic variability in the liverwort *Conocephalum japonicum*. They consider both the species and populations to have low genetic diversity values of **Hes** (species genetic diversity) = 0.008 and mean **Hep** (population genetic diversity) = 0.008 ± 0.003 . Between populations diversity was likewise low with **Gst** (coefficient of genetic differentiation) = 0.062. They used this low diversity as an indication that reproduction by gemmae predominated over sexual reproduction by spores.

Velde and coworkers (2001) considered this strategy of producing clonal genets to be one that provided increased longevity for the genet that accompanies increased reproductive capacity. Nevertheless, they showed that male reproductive success in *Polytrichastrum*

formosum is determined primarily on spatial distance from females. In fact, these populations achieved their success primarily through sexual reproduction, facilitated by the ability of sperm to disperse to distances measured in meters rather than mm or cm.

Foraging and Sharing

The reproductive advantages of ramets may be enhanced by other advantages found more recently, at least in tracheophytes. In seed plants, the ability to relocate photosynthate from plant parts in the light to shaded parts has been demonstrated (Kemball *et al.* 1992), while other plants are able to translocate resources through rhizomes and roots (Landa *et al.* 1992). This permits the ramets to take advantage of flashes of sunlight called **sunflecks**, and horizontal growth that permits such advantages has been termed **foraging** (Bates 1998). Ramets furthermore may have seasonal advantages as different parts become exposed to light at different times of the year. Even nutrient and moisture advantages may accrue if part of the plant receives sunlight while another part extends into moister or more nutrient-rich soil. Even in simpler plants like lycopods (*Diphasiastrum flabelliforme*), Lau and Young (1988) demonstrated that ramets that had been severed from their connecting ramets experienced 50% more mortality than unsevered ramets. Those ramets connected to shaded ramets were able to maintain higher water potentials, giving them the ability to take advantage of the sun in one ramet while maintaining high water potential through that supplied by another ramet.

In bryophytes, as in tracheophytes, we can expect advantages to the clonal habit. Living where their parents have lived increases the probability that the habitat is suitable, thus reducing wastage of propagules. A greater area of soil and atmospheric water is contacted by a clone, in some cases permitting a greater nutrient capture and the opportunity to provide needed water and nutrients to the growing tip. However, the ability to transport hormones, nutrients, and photosynthate is known for so few examples of bryophytes that we cannot generalize these benefits. In some tracheophytes, leaves on different parts of the plant and within the clone differ in morphology, permitting different environmental conditions to favor them. Such differentiation may be possible on rhizomatous taxa such as *Climacium*, and some leafy liverworts exhibit different leaf morphologies on the same branch (e.g. *Lophocolea heterophylla*, Figure 5), but no systematic investigation has explored this as a possible clonal advantage.

Figure 5. Heteromorphic leaves of *Lophocolea heterophylla*. Compare the two leaves indicated by arrows. Photo by Janice Glime.

If indeed clonal transport such as that demonstrated in tracheophytes is possible in most bryophytes, nutrients could move internally from favorably placed ramets to those in less favorable positions in a patchy environment, benefitting the bryophytes in a competitive environment (Bates 1998). Bergamini and Peintinger (2002) likewise compared the bryophytes to tracheophytes, suggesting that their overall morphological responses to the differences in light levels approximated that of tracheophytes with stolons – a "spacer and branching strategy." But does this ability to share with less favorably placed ramets only work for bryophytes with internal conduction? Eckstein and Karlsson (1999) tested this hypothesis by comparing the movement of nitrogen in *Polytrichum commune*, with well-developed internal conduction, with that of *Hylocomium splendens*, with predominantly external conduction. Indeed, the labelled nitrogen pool in *Hylocomium splendens* moved from older segments to younger segments. In *Polytrichum commune*, it disappeared from younger segments in autumn, presumably going to underground storage organs. Both of these examples support the hypothesis that ramets can provide sources of translocatable substances from one part of the clone to another, but we have few studies to permit us to assess the extent of this phenomenon among bryophytes, nor does this explicitly demonstrate the transfer from one ramet to another less favorably positioned. And could gametophytes such as those in Figure 6 transfer substances from one gametophore to another through the protonema?

Figure 6. Circular growth pattern of gametophores developing from a single spore of *Funaria hygrometrica*. Photo by Janice Glime.

There need be no internal conduction to foster other types of advantages, however. For example, *Sphagnum magellanicum* is able to keep its neighbors moist through its efficient external conduction, and cushion mosses like *Leucobryum* (Figure 7) conserve moisture by growing in dense clones.

Implications for Reproduction

Perhaps there is a division of labor that provides a reproductive advantage among ramets of a clone that is independent of type of translocation. Stark *et al.* (2001) found that in the desert moss *Syntrichia caninervis* more mature ramets with larger size were more likely to reproduce than the smaller ramets, suggesting a division of labor that permitted smaller plants to conserve energy until they achieved a greater size. While this may be simply a

function of age, it would permit the colony to have multiple reproductive strategies simultaneously, with larger ones reproducing sexually and smaller ones using only fragments or vegetative propagules.

Figure 7. Cushion of *Leucobryum glaucum*. Photo by Janice Glime.

Many of the modes of reproduction of bryophytes result in clonal growth. Rarely does one see just a single bryophyte stem. Rather, clumps, cushions, tufts, mats, any number of growth forms, suggest that these are all siblings of an original single parent. In fact, even if only a single spore lands on the rock or soil, many plants arise, at least in mosses. The spore produces a protonema that branches, and in the case of the filamentous protonemata, the numerous branches can give rise to numerous upright gametophores. Knoop (1984) identifies two types of gametophore origin: *Funaria* type (Figure 6), developing gametophores on the caulonema only in a circular fashion around the spore; *Polytrichum* type, developing few gametophores near the germinated spore or even from the spore cell itself (Sood & Chopra 1973, Nehlsen 1979). Both result in several to many gametophores.

In *Sphagnum* a single spore produces a small thalloid protonema that gives rise to only one gametophore, thus resulting in populations when more than one spore germinates, and making one uncertain in any given clump of *Sphagnum* whether the clump is a clone derived from apical branching or a population derived from separate spores. However, if one considers that the branching of the **capitulum** contributes to a major portion of the mat growth, then, again, clonal behavior is at work. Furthermore, spores are likely to land on their own parents or siblings or cousins of the parent, and thus not be far removed from clonal relatedness.

Even gemmae can form circular arrangements of gametophores, as reported by Chopra and Rawat (1977) for *Bryum*, or other arrangements of numerous gametophores, as in *Physcomitrium sphaericum* (Figure 8; Yoshida & Yamamoto 1982). Since these have arisen from one parent, they likewise produce clones. In *Bryum bicolor*, numerous tubers and gemmae are produced early in the growth of the gametophore, permitting it to build up a large clone (Joenje & During 1977).

Density Effects

Colony density has varying effects on moss success. In ectohydric mosses, it is more likely that density will favor success and increase growth (During 1990; Økland & Økland 1996). But in *Sphagnum* (Clymo 1970) and *Rhytidiadelphus triquetrus* (Bates 1988) density is

detrimental to both branching and growth. Shoot mortality can increase, as in *Polytrichaceae* (Watson 1979), or decrease, as in *Tetraphis pellucida* (Kimmerer 1991), with density. Almost nothing is known of density effects on liverworts; Laaka-Lindberg (1999) showed that density had no effect on gemma production.

Figure 8. Clone of *Physcomitrium sphaericum*. Photo by Michael Lüth, with permission.

On the other hand, Kimmerer (1991), found that density was an important factor in asexual vs sexual expression in the acrocarpous *Tetraphis pellucida* (Figure 9). Gemmae were common in low-density colonies and the sex ratio was female-biased. High-density colonies, on the other hand, were more likely to have sexual reproduction and a greater proportion of males. She pointed out the advantage of this plastic strategy in unstable environments such as the rotting stump habitat of *Tetraphis pellucida*, permitting the plants to expand by gemmae when the colony was not dense.

Figure 9. *Tetraphis pellucida*. **Upper:** Uncrowded plants with gemmae on tips. **Lower:** Dense patch of plants with sporophytes. Photos by Michael Lüth, with permission.

Tradeoffs

Traditional life history theory holds that "maximizing reproductive value at each age is equivalent to maximizing fitness" (DeRidder & Dhondt 1992). However, in bryophytes, as in many species of seed plants, there is a negative correlation between sexual reproduction and asexual reproduction (Caswell 1985). On the other hand, in the clonal insectivorous flowering plant *Drosera intermedia*, DeRidder (1990) found only limited evidence of a tradeoff between the two types of reproduction. DeRidder and Dhondt (1992) suggest that traditional theory may apply to the clonal *D. intermedia*, whereas in many clonal species, it is an inappropriate theory because it was based on organisms (vertebrates) with only one mode of reproduction.

Ramets of one taxon, all from the same spore, seemingly competing for space and resources, seems like a maladaptive thing to do. However, the old safety in numbers adage may apply here. Multiple stems are less likely to dry out than a single plant. The colony can acquire a cushion shape as the middle members grow better due to moisture held by their neighbors. The edge members are slowed because if they too grow like the middle members, they are left with no protection from drought on the outer side. Hence, the adventurous stem that grows a bit taller is soon stopped by lack of moisture, and those on the edge are slowed the most because they lack a similar tall plant on the outside to protect them. For tracheophytes, Price and Hutchings (1992) also consider design constraints that limit vascular connections between some ramets, a consequence that should not be a problem for the ectohydric bryophytes. Could this, however, reduce the advantages for **endohydric** bryophytes, *i.e.* those relying significantly on internal conduction?

Perhaps one of the greatest benefits to ramets from a single spore of monoicous bryophyte taxa is availability of the opposite sex. Since in many cases, the male and female gametangia don't mature at exactly the same time on the same individual, gametangia of a neighbor are more likely to be receptive than other gametangia on the same plant. Such an opportunity is not so important to the tracheophytes because of their dependence on external pollinators that can readily visit nearby clumps of a different clone. Nevertheless, for the bryophytes, concomitant with the advantages of having nearby sexual partners are the tradeoffs in disadvantages of marrying your twin, in particular the loss of genetic diversity.

Like the tracheophytes, bryophytes must pay a price for the clonal habit. The advantage of being able to respond rapidly to environmental change is unlikely for the slow-growing bryophytes. Reduced recruitment from spores will make the clonal bryophytes vulnerable to permanent changes in the environment, and the connectedness makes the entire clone vulnerable to disturbance (*cf.* tracheophytes, Callaghan *et al.* 1992). The longevity of the clump in habitats like the Arctic make the probability of frost heave damage an eventuality in some habitats. Mosses seem less likely than tracheophytes to reap benefits from having only part of the clone disturbed. If part of a cushion is removed, the entire cushion is likely to dry out, whereas an intact cushion is able to keep its interior moist under most circumstances. In most cases, spread by spores in less clonal species may be a better

strategy, particularly for those that require fresh soil in open, disturbed areas. Thus, as their habitat changes, they have the means to move on to other suitable areas.

The trade-offs and benefits of clonal growth, contributing to increased bryophyte density, are hard to assess. The overwhelming presence of clonal growth suggests that it has its advantages for bryophytes, perhaps almost completely in the greater moisture retention.

r & K Strategies

Life cycles are basic to the survival of a species. Those that are annuals must usually survive the winter as spores. Those that are perennial must have other ways to survive the cold of winter. Still others may live where it is a dry season, not winter, that must be reckoned with. These differences in seasonal stresses are generally met by differences in life strategies.

Ramensky (1938) described three types of outcomes to the differences in life strategies as **violents** (aggressive species), **patients** (tolerant species), and **explerents** (non-competitive species that fill the spaces between others). Rabotnov (1975) added **pioneers** (species able to colonize substrata that are not yet suitable for other species). Meanwhile, MacArthur and Wilson (1967) introduced the concept of **r and K selection** as the extremes of a life cycle strategy continuum, and the western world seemingly ignored Ramensky and Rabotnov, generally only using the term "pioneer" among these. Although r and K strategies were largely described to fit animal concepts, many of the ideas can be applied as well to plants.

The **r-selected species** are characterized by a rapid growth rate, early reproduction, numerous, small offspring (spores or seeds in plants), and a high resource uptake; the **r** can be compared to the **r** (intrinsic growth rate) in the **logistic population model**. The **r strategist** is likely to be a short-stayer, adapted to disturbed or **ruderal** (field & wasteland) habitats where it is necessary to arrive quickly and mature before the habitat changes. By contrast, the **K-selected species** is characterized by slow growth rate, late reproduction, few, large offspring, and efficient use of resources; the **K strategist** optimizes for a high population density at the environment's carrying capacity (*cf.* the logistic model). The K strategist is likely to grow where the habitat is more stable, and it can be a long-stayer, eventually reaching considerable size (or cover). The K strategist is more likely to depend on asexual reproduction such as rhizomes and perennial habit whereas the r strategist is more likely to rely on seeds or spores and an annual habit with good dispersal.

Thus K strategists tend to be competitors; r strategists tend to be opportunists but not competitors. An r strategist is the more likely one to succeed on unstable, disturbed environments (sometimes a pioneer, sometimes an explerent), whereas the K strategist is the more likely one to succeed in more stable and predictable habitats (the patient or tolerant species and sometimes the violents or aggressive species).

Grime (1977) considered the **r strategist** to be **ruderal** (of field or wasteland) species that took advantage of disturbed habitats (Figure 10). The **K strategists** he considered to be the **stress tolerators** that were able to survive dry or cold periods as whole plants, the **perennial stayers**. Between those two he placed the competitors.

Figure 10. Frequency of ruderal (R), competitive (C), and stress-tolerant (S) species along an r-K continuum. Redrawn from Grime (1977).

Bet Hedgers

But between these two extremes are lots of possibilities for having some of the characteristics of each. Few species can meet all the criteria of either, and trade-offs abound to permit the organisms to meet the demands of their particular habitats. Plants that seem to have both good sexual reproduction and a means of vegetative reproduction are **bet hedgers**. Like the people to whom we refer as bet hedgers, these plants are "unwilling" to put "all their eggs in one basket." They use two strategies simultaneously so that they do not lose entirely. The price they pay is that they likewise never win entirely – at the ends of the spectrum, there is either an r strategist or a K strategist that is better adapted to the circumstances.

Production of gemmae among sexually capable species is one example of bet hedging. In the dry interior of North America, *Syrrophodon texanus* (Figure 11) exhibits seasonal production of gemmae, arising in August (33% of specimens) and climaxing in September (50% of specimens) (Reese 1984). In this species, rarity of males makes this bet hedging a desirable strategy, although sporophyte-bearing females invariably occur when males are present.

Figure 11. Gametophytes of *Syrrophodon texanus*. Arrow in lower picture indicates gemmae at leaf tip. Photo by Janice Glime.

Dedifferentiation Issues

It is somewhat difficult to consider bryophyte *r* and *K* strategists in the same way as that of seed plants. These two strategies rely heavily on three characteristics of the plant life cycle: arrival and persistence, establishment and growth to maturity in a developing community, and time taken for the species to reach critical life stages (During 1992). Bryophytes are problematic because they do not follow a consistent pathway from spore (propagule) → juvenile → immature individual → reproductive individual. They can revert, growing from a fragment into an adult, or growing from a broken tissue of a fragment into a protonema → juvenile → immature individual → reproductive individual. Bryophytes are able to **dedifferentiate** – return a cell to its embryonic (undifferentiated) state

Compared to most tracheophytes, most bryophytes would appear to be *r* strategists, utilizing many small progeny (spores) that travel great distances and having short life cycles, permitting them to move on to new locations easily. This may help to account for the widespread distribution of many bryophytes relative to that of seed plants. However, when compared to phanerogams, most bryophytes do not meet the requirement for rapid growth.

Since most species will fall between the two extremes of *r* and *K*, the first thing one must realize when trying to determine the *r* or *K* status of a species is that ascribing *r* or *K* must be done in the context of comparison. Thus, within bryophytes, both ends of the continuum exist, while most species have a mix of characters.

Although bryophytes typically produce large numbers of small spores, many taxa also can increase in numbers by stolons, rhizomes, and branching, qualifying them as *K* strategists, or long-term stayers. For example, Hedenäs and co-workers (1989) found that the invading moss *Orthodontium lineare* in Sweden had a high spore output, but that colonies had a clumped pattern that indicated strong neighborhood effects that permitted spread within a locality. Thus, within the bryophytes, as in tracheophytes, species can be divided into *r* and *K* strategists, but they are unlikely to meet all criteria of either, and many trade-offs exist (Stearns 1989). Instead, it appears that many of them are bet-hedgers, being prepared to take advantage of whatever comes along instead of being prepared with a single strategy.

To succeed, they must balance their energy expenditure between sexual reproduction and vegetative growth in a way that best permits them to survive. These strategies must of course be coordinated with their entire physiology and the methods by which each developmental stage is signalled.

The *r* Strategist

Like typical *r* strategists, bryophyte *r* strategists rely heavily on massive numbers, typically 50,000 per capsule, of small spores (10-15 µm) to get to a new location (Schofield 1985). For example, *Funaria hygrometrica* can arrive quickly on disturbed sites such as soil charred by fire or agricultural land. But should this be true in predictably disturbed sites such as flood plains? In flood plains one finds members of Archidiidae (Figure 12), a subclass of large-spored mosses, with spores usually 50-150 µm, large

enough to be seen without a lens (Schofield 1985). Here it would appear to be advantageous to stay put by producing large, long-lived spores (Söderström 1994). It is likely that this stay-put strategy is available to many mosses and liverworts through spore longevity in soil banks.

Figure 12. A floodplain moss, *Archidium alternifolium*. Photo by Michael Lüth, with permission.

The *K* Strategist

Our understanding of perennial stayers (*K* strategy) is limited by our ability to determine the age of an individual. To age a moss or liverwort is somewhat difficult because among the perennial ones, the bottoms typically die as the tops continue to grow. However, many mosses carry their own age markers (Hagerup 1935), as described in more detail in another chapter, much as trees can be aged by terminal bud scars while they are young. *Polytrichum* males can be aged by counting the number of splash cups along the stem, because a new year of growth will come from the cup in the following spring. Ulychna (1963) found *Polytrichum commune* with a mean age of 3-5 years, but dead parts in the hummocks ranged 15-17 years. Brunkman (1936) found *Hylocomium splendens* (Figure 13) up to 30 years old by counting the successive sets of branches that form like stair steps, each from a point near the apex of the old, but it is unlikely that the oldest parts were still live and functioning. Because most bryophytes do not require their lower parts to keep the upper parts of the plant alive, they could theoretically grow indefinitely in a location due to the growth of the tips. Such a phenomenon is approached in *Sphagnum*, which will continue to grow as long as the habitat remains suitable.

Figure 13. *Hylocomium splendens* showing stairstep branching used for aging the moss. Photo by Janice Glime.

Spores, however, are not the only stage in which *r* and *K* strategies might be applied. One could also expect that

there would exist a trade-off between numbers of male and female gametangia. Just as some trees, such as maples (*Acer*) can adjust the number of male and female flowers based on tree crowding, one might look for regulation of numbers of male and female gametangia. In their studies of tropical bryophytes, Cavalcanti Pôrto and Moto de Oliveira (Moto de Oliveira & Cavalcanti Pôrto 2001; Cavalcanti Pôrto & Moto de Oliveira 2002) found that development of gametangia was responsive to rainfall. In the moss *Sematophyllum subpinnatum*, the number of antheridia per perigonium was 8-20 while the number of archegonia per perichaetium was 3-26. For *Octoblepharum albidum* (Figure 14) mean number of antheridia per perigonium was 13.4 and of archegonia per perichaetium 6.7. Could moisture regime change these ratios?

Figure 14. *Octoblepharum albidum*. Photo by Michael Lüth, with permission.

Just how do the r and K strategies of bryophyte gametangia line up? Fuselier and McLetchie (2004) considered this problem in *Marchantia inflexa*. They found that females had a greater growth rate, but males had more asexual reproduction. Males were also more likely to be present in a high light regime (55% shade), where they began sexual development earlier; males in low light produced no sexual structures (McLetchie *et al.* 2002). Fuselier and McLetchie (2004) postulated that eventually, the greater female growth rate would result in a population of all females as they overgrew males. However, under a disturbance regime, more males would be successful. They found a female bias in sex expression, with many genetically male plants failing to express sexual traits.

The r and K strategies are at best a continuum. Individual species often do not meet the criteria completely. Evolution is imperfect and time is required to drive it toward perfection. Furthermore, the model predictions work only if the environment perfectly matches with the set of bryophyte characters predicted. In the Antarctic, extreme conditions would seem to test this r and K continuum to its limits. And there the imperfections of these predictions are evident. The disturbed nature of this volcanic habitat favors r-selected taxa that must arrive from considerable distances (Convey & Smith 1993). However, the difficulty of spreading during the short, cold growing season favors certain short-lived taxa with large spores. Five of the species that are widespread in the Antarctic have large numbers of small spores and are most likely long-distance colonists. Even the longer-lived taxa seem to defy the r & K model predictions, having a large investment in sexual reproduction.

Life Cycle Strategies

To combat all the insults of the environment that might be encountered in a global array of habitats and climates, a variety of strategies exist among both plants and animals. For bryophytes, the predominant controlling factor is available moisture, but we must consider that temperature is also a major contributor to the timing of life cycle events.

As we consider the life cycle strategies of bryophytes, we must keep in mind that they potentially expose all of their alleles to expression and selection through a considerable portion of their lives – as *1n* gametophytes. All the variety in strategies discussed above come into play in permitting these tiny organisms to occupy the widest array of conditions of any group of plants. For the greatest number of species to survive across the greatest number of habitats, some have adapted to be **opportunists**, constantly moving from place to place, while at the other extreme are **perennial stayers**, finding a suitable place and remaining there for a long time. But because an individual bryophyte must stay in one place, it must have a life cycle that permits it to survive the onslaught of environmental fluctuations during the entire time it develops from protonema to leafy plant to fertilization to sporophyte to dispersal of spores.

The environment thus provides the major selection pressure on the life cycle strategies. Recognizing the instability of the environment, Stearns (1976) classified the environment into three main types (examples are mine):

1. having **long cyclic fluctuations**, with a period much longer than that of the generation time of the organism (*e.g.* fires)
2. having **short cyclic fluctuations**, with a period that is as long as or shorter than the generation time of the organism (*e.g.* seasons)
 - a. cycle highly predictable
 - b. start of cycle unpredictable
 - c. start of cycle predictable, but conditions of growing season unknown
 - d. start of cycle predictable, but conditions only partly known
3. having **random fluctuations**, *i.e.* not predictable (*e.g.* flash floods)

To survive in a fluctuating environment, the life cycle must prepare the bryophyte for the fluctuations. This means that at times it is advantageous to "run for your life" to other locations (produce spores), whereas under other, more favorable conditions it is best to sit still and keep your family together (reproduce vegetatively).

During (1979) has examined in detail the life cycle strategies of bryophytes in dealing with environmental conditions. In finding that most tracheophyte life cycle strategy systems either did not apply or were incomplete for the bryophytes, he devised a system of six strategies. He considered that bryophytes utilize three major trade-offs: few large spores vs. many small spores, survival of stressful season as spores (**avoidance**) vs survival as a gametophyte (**tolerance**), and life span that is negatively correlated with reproductive effort (for tolerants only) (During 1992). In addition, there is a usually tradeoff between sexual and asexual reproduction (Schofield 1981, During 1992). These considerations resulted in his organization of strategies based on life span, spore number and size, and reproductive effort (Table 1 and figures from During 1992; table slightly modified):

Table 1. Spore and life span characteristics of the various life cycle strategies for bryophytes as defined by During (1979).

Potential life span (yrs)	Spores		Repro effort
	Numerous very light <20 µm	Few large >20 µm	
<1	Fugitives	Annual shuttle	High
Few	Colonists		Variable
	Ephemeral	Short-lived shuttle	
	Colonists	Long-lived shuttle	
	Pioneers		
Many	Perennial stayers	Dominants	Low
	Competitive		
	Stress-tolerant		

The system of During has attributes that work as well for higher plants, and Frey and Hensen (1995) have proposed a modified system based on this one to be used for all plants. (Now how often do you see those tracheophyte folks copying a bryophyte idea?! Kudos to During!) They have expanded upon the original six strategies proposed by During to include nine: annual shuttle species, fugitives, kryptophytes, short-lived shuttle species, colonists, perennial colonists, perennial shuttle species, perennial stayers, and perennial stayers with diaspore years. Hürschner and Frey (2012) included geophytes and perennial shuttle species to the bryophyte list.

Fugitives (Figure 15), **colonists** (Figure 16), **annual shuttle species** (Figure 17), and **short-lived shuttle species** (Figure 18) are **r strategists** and all succeed in disturbed environments. The fugitive strategy is relatively rare, with *Funaria hygrometrica* being one of the few examples (During 1992). That many species require disturbance and therefore are relatively rare in any specific locality is usually overlooked in trying to conserve rare taxa. The very disturbance they need to persist is often prevented in an effort to maintain them! Noble and Slatyer (1979) attribute success following disturbance to plant strategies related to three factors: method of arrival (fugitives, colonists, annual shuttle species) or persistence at disturbed site (short-lived shuttle species); ability to become established and reach maturity in disturbed site; time needed to reach critical life cycle stage. These criteria are not intended to include those of taxa adapted to continuously disturbed or catastrophically disturbed habitats, but rather to those recurring events such as fire, flood, or treefall. The **perennial** bryophytes are **K strategists** (Figure 19, Figure 20) of stable habitats.

During (1992) added the category of **dominant** to accommodate taxa with large spores and long life expectancy, such as some *Sphagnum* species. It is a rare combination among bryophytes, whereas it is relatively common among trees. Other categories will surely be added as we gain understanding of tropical ecology and the adaptive strategies of bryophytes there (During 1992). One such category could develop based on **neoteny**, where juvenile characters are retained in adults, a condition that occurs among some species of ephemeral habitats such as living on leaves in the tropics (During 1992). In some taxa, such as *Buxbaumia*, neoteny permits the species to avoid some life cycle stages, in this case the leafy gametophyte! La Farge-England (1996) has suggested the category of **protonema mosses** to encompass these few taxa (see chapter on life forms and growth forms). Others, such as

Dicranum and *Fissidens* species, have **dwarf males** that develop on leaves of female plants, facilitating the transfer of sperm to the egg, a kind of male neoteny. (See chapters on sexuality and on the development chapter on gametogenesis for further discussion of dwarf males.)

Diaspore Banks

Disturbed habitats, whether the product of predictable natural phenomena or unpredictable events such as human intervention or volcanic eruptions, benefit from the bank of spores and asexual **diaspores** (any structures that become detached from parent plant and give rise to new individuals) stored in the soil out of reach of sun and sometimes even water. Major disturbances can bring these propagules to the surface where they can break dormancy and become established. We need only look at a recently disturbed bank in a forest, sloping deforested hillside, or crumbling streambank to recognize the importance of bryophytes in colonizing and often maintaining the surface integrity. Yet, as Ross-Davis and Frego (2004) pointed out, while these regeneration processes "may be critical to conservation of severely disturbed communities..., they are poorly understood." In an attempt to quantify this importance they sampled two grids in managed Acadian forests of New Brunswick, Canada. They identified 51 taxa in the aerial diaspore rain and buried diaspore banks. Of these, 36 represented species in the existing community of the Acadian forest. The composition of aerial diaspores was more similar to the existing community than to that of buried ones.

Tradeoffs

For bryophytes, the system of success strategies is complicated by the ability to reproduce from fragments, and in many cases the production of asexual propagules on the protonemata as well as on the leafy plant, leading During to his 1992 revision. One must keep in mind that bryophytes may be among the best dispersers in the world. Therefore, large spore size, as opposed to small ones with worldwide dispersal potential, may be a tradeoff of great magnitude. While many of these small spores will not survive the long distance travel due to UV radiation and other atmospheric hazards (see dispersal chapter later), many will survive significant local travel, with a few travelling for hundreds of kilometers.

Once the spores arrive, different attributes become important. The spore must have sufficient energy to survive until favorable conditions arise, and it must get the new protonema off to a good start with enough energy to survive in some very harsh environments. This has resulted in a correlation of spore germination patterns with habitat (Nehira 1987). Epiphytic and saxicolous species of both mosses and liverworts tend to have **endosporic** germination (*i.e.*, early development of several mitotic divisions within the spore wall; Figure 21), permitting them to be multicellular when they emerge from the protection of the spore. This would suggest that these species carry sufficient nutrients with them to supply their initial developmental nutrient needs. On nutrient-poor, **xeric** (dry) substrates such as rock and bark, internal development could insure protection during early, critical stages of development. However, most mosses have **exosporic** germination (first mitotic division occurs outside spore after rupture of spore wall).

Life Cycle Strategies based on During (1979, 1992)

Fugitives

Fugitives – species that live in unpredictable environments

example: *Funaria hygrometrica*

short life span; ephemeral or annual

high sexual reproductive effort; large percent of plant devoted to spore production

low age of first reproduction (first year)

spores small (<20 μm), very persistent and long-lived

no asexual reproduction

innovations absent

open turfs

rare in phanerogams (mustards?) and bryophytes; found among bacteria, algae, fungi

Figure 15. **Fugitive** strategy. From During (1979).

Colonists

Colonists (sensu stricto) – species that live where habitat start is unpredictable, but lasts several years; secondary succession

bryophyte examples: *Bryum bicolor*, *Bryum argenteum*, *Ceratodon*, *Marchantia*

short life span; (annual-) pauciennial-pluriennial

sporophyte late, somewhat rare in many; first sexual reproduction at least after 1 and usually 2-3 years

high reproductive effort

spores < 20 μm , persistent

innovations present

asexual in early life; first asexual reproduction in a few months

usually short turf

old field species like *Solidago*

Figure 16. **Colonist (sensu stricto)** life cycle strategy. From During (1979).

Colonists

Colonists (ephemerals) – gap-dependent species

bryophyte example: *Bryum erythrocarpum*

short life span; (annual-) pauciennial-pluriennial

first sexual reproduction in a few months

sexual reproduction rare

spores < 20 μm , persistent, numerous

high asexual reproductive effort by subterranean tubers on rhizoids

river flood plains, low areas submerged in spring,

cultivated fields

usually short turf

Colonists (pioneers) – species that live where habitat start is unpredictable and habitat lasts at least several years after disturbance; make habitat suitable for perennial stayers (Rabotnov 1975)

bryophyte examples: *Grimmia*, *Schistidium*

long life span

slow growth

perennial

high reproductive effort

first sexual reproduction in a few years???

sexual reproduction low

asexual reproduction high

spores < 20 μm , persistent

river flood plains, low areas submerged in spring,

cultivated fields

usually short turf

Shuttles

Annual Shuttle – species that require small disturbances that last 1-2 years; survive severe stress periods

bryophyte examples: *Ephemerum*, *Physcomitrium*, *Fossombronia*

short life span; (ephemeral-) annual-pauciennial

sexual reproduction effort high and frequent

age of first reproduction < 1 year

spores large, 25-50 (-200) μm

survive by spores

capsules often immersed (short or no setae) (Longton 1988)

specialized asexual reproductive structures absent

innovations rare

open turf or thalloid mat

agricultural weeds, hoof prints, steep stream banks, dung

disturbed habitat species like *Brassica*

Figure 17. **Annual shuttle** life cycle strategy. From During (1979).

Short-lived Shuttle – species that don't avoid periods of severe stress; habitat lasts 2-3 years

bryophyte examples: *Hennediella heimii*, *Splachnum*, *Tetraplodon*

life span several years, pauci-pleuriennial

sexual reproductive effort high; sporophytes more or less frequent

overall reproductive effort medium

ages of first reproduction 2-3 years

spores large, 25-50 (-100) μm

asexual reproduction rare

innovations present

short turf or thalloid mat

Figure 18. **Short-lived shuttle** life cycle strategy. From During (1979).

Perennial (Long-lived) Shuttle – species that require stable environments, such as epiphytes, where end of habitat is predictable

bryophyte examples: *Orthotrichum*, *Marchantiales*

long life span; pluriennial, perennial

sexual reproduction effort moderate (During 1979) or low (During 1992)

age of first sexual reproduction high (>5yrs)

spores large (25-200 μm)

spore life span short

asexual reproduction effort moderate

innovations present

age of first asexual reproduction variable

cushion, rough mat, smooth mat, tuft

tracheophytes include bromeliads, *Betula*, *Populus*

Figure 19. **Perennial long-lived shuttle** life cycle strategy. From During (1979).

Perennial Stayers

Perennial stayers (competitive) – forest floor

bryophyte examples: *Brachythecium rutabulum*

long life span

perennials

rapid growth

sexual and asexual reproduction low or nearly absent

age of first reproduction several years

spores <20 μm

spore longevity variable

wefts, dendroids, mats, large cushions

Perennial stayers (stress-tolerant) – fens, bogs, desert

bryophyte examples: *Sphagnum*, *Syntrichia ruralis*

long life span; perennials

slow growth

sexual and asexual reproduction low or nearly absent

age of first reproduction several years

spores <20 μm

spore longevity variable

growth form plasticity

in deserts include acrocarpous taxa with long setae

tracheophytes include ericaceous shrubs

Figure 20. **Perennial stayer** life cycle strategy. From During (1979).

Dominants – bogs

bryophyte example: some *Sphagnum*

long life span; perennial

sexual reproduction effort low

spores large (>20 μm)

asexual reproduction effort low

turf

Figure 21. Endosporic development (arrow) in spores of the hornwort *Dendroceros tubercularis*. Photo courtesy of Karen Renzaglia.

But spores are not the only way to travel. Fragments and propagules can carry the species to a new location, although the generally much larger size would usually limit distance considerably. Moss balls (see chapter on life form) along lake shores and on glaciers and snow banks serve as means of dispersing large units, including multiple plants. Landslides, rock movement in streams, trampling, and vehicle tires can carry fragments for some distance. For those producing asexual propagules, sexual reproduction and asexual propagules are usually not produced at the same time. Thus, investment in specialized asexual structures is indeed a trade-off. Taxa with annual life cycles, surviving unfavorable conditions as spores, rarely produce such specialized structures, investing their energy instead in the production of spores (During 1992).

We know little about the energy costs of producing spores and other propagules, and in particular know nothing of the effect of spore production on mortality (During 1992). There is evidence, however, that development of sporophytes slows the growth of the gametophytic plant in *Scorpidium scorpioides* (A. M. Kooijman & H. J. During, unpubl. data) and *Plagiothecium undulatum* (Figure 22; Hofman 1991), as well as in *Dicranum polysetum* mentioned earlier (Bisang & Ehrlén 2002). This tradeoff may be a general rule, as discussed in the chapter on sporophyte development.

Figure 22. *Dicranum polysetum* exhibiting its multiple setae per stem. Photo by Janice Glime.

Some characteristics of the life strategies may be interrelated. For example, Hedderson (1995) found that in the Pottiales the probability of producing capsules decreased with increased life expectancy and was negatively associated with asexual propagules. As discussed in the chapter on asexual propagules (brood bodies), these compete for energy with the production of capsules and generally do not occur simultaneously. It therefore follows that dioicous taxa in this group have more asexual propagules, corresponding with their lower likelihood of having sexual reproduction. Unlike sporophytes, asexual propagules were positively associated with life expectancy. On the other hand, size accounts for only a small, but statistically significant, proportion of the variation in life history traits in the Funariales, Polytrichales, and Pottiales (Hedderson & Longton 1996). Rather, characteristics related to water relationships were most important, accounting for 40-50% of the variation. It is interesting that the ability to take in and retain water coincides with monoicous taxa that are short-lived and produce few large spores, whereas those at the opposite end of the endo-ectohydric gradient have opposite characters. Spore number and spore size are strongly related to family, with most of the variation occurring among genera. Variation among species is moderate. Hedderson and Longton suggested the possibility of coevolution of water relations and life history in these orders.

Longton (1997) used the concept of life history strategies to predict character relationships. Colonists, fugitives, and shuttle species exhibit an earlier age for first reproduction as the longevity decreases. These strategies are accompanied by greater monoicy and reproductive effort (Longton 1997, 1998). Such species tend to have more plastic phenotypes and experience greater success at establishment by spores. Dioicous moss colonists, on the other hand, are more likely to produce asexual propagules, whereas such propagules are widespread among liverworts.

Generation Time

Generation time is one of the contributors to life cycle strategy, but we have no comprehensive study by which to label this function for bryophyte species in general. In order to meet the IUCN red list criteria, bryophytes must be put into generation time categories. This is important because environmental changes may take longer to affect numbers of those species with a long life cycle than for those with a short one. Tomas Hallingbäck (Bryonet 9 January 2014) reports that in Sweden they have used templates of 10, 20, 50, and 100 years as the intervals for three generations. Since hard data are generally not available, the Swedes agreed upon approximate generation lengths and **life spans** and classified their species based on the potential life span of the gametophyte:

- 'short' (colonists s. str., fugitives) = 3 generations = 10 (e.g. *Microbryum* spp.)
- 'medium' (pioneer colonists, short-lived shuttle) = 3 generations = 20 years (e.g. a typical epiphyte like a *Syntrichia*)
- 'long' (long-lived shuttle – perennial stayers) = 3 generations = 50 years (e.g. *Hylocomium splendens*).
- For species rarely found with sporophytes, a generation time of 25 years was recommended

Habitat Studies

Occasionally a habitat study will describe the growth forms or life forms that dominate there. But quantitative studies to describe these are rare. However, a few examples from tropical habitats can serve to provide an understanding of their usefulness in giving a mental picture of the bryophyte cover in places we have never visited.

In the **Colombian cloud forest**, epiphytes are abundant due to the high moisture availability from the clouds and the infrequency of desiccation events. This type of climate supports growths of tall turfs and smooth mats as predominant growth forms on the trees (van Leeerdam *et al.* 1990). On the other hand, the life strategies of bryophytes on trees on the **eastern Andean slopes** of northern Peru reflect the drier habitat. Colonists form short turfs of acrocarpous mosses, primarily in secondary forests suffering disturbance. In the **lowland** and **submontane forests**, perennial shuttle species and perennial stayers exercise low sexual reproductive effort and take advantage of the high humidity to accomplish high vegetative reproduction through both propagules and clonal growth (Kürschner & Parolly 1998a). *Macromitrium* (Figure 23) and *Phyllogonium fulgens* (Figure 25) have dwarf males resulting from small male spores compared to large female spores. (Dwarf males are discussed more thoroughly in the chapters on sexuality and gametogenesis.) *Leptodontium viticulosoides* (Figure 24) exhibits functional heterospory in which small spores are dispersed long distances and large ones only short distances. On the other hand, at high elevations **near timberline**, the perennial shuttle and perennial stayer species instead exercise a high sexual reproduction and produce numerous sporophytes. Similar altitudinal differences occur in Southeast Asia and Central Africa.

Figure 23. *Macromitrium sulcatum*, member of a genus with small male spores and dwarf males. Photo by Manju Nair, through Creative Commons.

Bryophytes of the **tropical lowlands** have a very different character from these montane epiphytes, providing them with maximum water conservation in this much drier habitat. The mat life form encompasses species with water lobules, water sacs, and rhizoid discs (Kürschner & Parolly 1998b). This life form gives way to fans, wefts, dendroids, and pendants in the more humid

montane belt. These forms serve as collectors to condense water vapor from the frequent fog and mist (**fog-stripping**; Figure 26). Deeply fissured or ciliate leaves and rill-like arrangement provide the fine wire-like surfaces needed for this water capture. The **tropical oreale** (high altitude) and **subandean belt** contrasts with this foggy area by having strongly contrasting diurnal conditions and supporting short-turf, tall-turf, and tail life forms with central strands, rhizoids, and rill-like leaf arrangements.

Figure 26. "Fog-stripping" by thin leaves of *Campylopus holomitrius* in the mist from geothermal vents at Karapiti, New Zealand. Photo by Janice Glime.

Bryophytes of **arid habitats** are typically small and may include acrocarpous perennial stayers with small spores and long setae that aid in dispersal (Longton 1988). Annual shuttle species here are primarily ephemerals that avoid desiccation by going dormant as spores, develop rapidly to maturity following rain, and produce large spores in capsules that typically lack stalks and remain submersed among the perichaetial leaves; often these capsules lack peristomes and opercula and may be dispersed as whole capsules (see chapter on development of sporophytes). The perennial shuttle species are mostly thallose liverworts such as *Riccia* (Figure 27) that curl up and become dormant or survive as large spores. Fugitives may arrive, but generally are gone after 1-2 years, travelling to new sites as small spores.

Figure 27. *Riccia sorocarpa*, showing curling leaves that facilitate survival of dry conditions. Photo from Botany website, UBC, with permission.

González-Mancebo and Hernández-García (1996) related life strategies to habitats along an altitudinal gradient in the Canary Islands. They found the following trends for the most abundant strategies:

higher elevations: colonists
 rocks in driest forest: colonists, short-lived shuttle,
 long-lived shuttle

humid forest trees: long-lived shuttle, short-lived shuttle
 humid forest soil: perennials
 soil in shady, dry forest: perennials

These strategies seem to be determined by humidity conditions, substrate dynamics, and vegetation disturbance. Not surprisingly, the perennial life strategy had the lowest percentage of fertile species. The other strategies typically have approximately 70% fertility.

Summary

Bryophyte life strategies must be closely attuned to the water regime of their environment. They accomplish this fine tuning by using spores, fragments, and specialized asexual propagules during times when conditions are not suitable for the gametophyte. Furthermore, they attune their times of sexual reproduction to meet the availability of water. Secondary to the water schedule is the advent of disturbance for which some bryophytes are especially adapted (**opportunists**).

Bryophytes, especially mosses, are clonal organisms. All bryophytes are able to spread vegetatively through fragments and propagules. Perennial mosses also spread by branching (**ramets/genets**). Mosses, additionally, produce many upright gametophytes from the protonema developed from a single spore. Clones have the advantage of maintaining moisture, but have the disadvantage of being genetically identical. Bryophytes that grow horizontally have been considered **foragers** that are able to take advantage of a patchy environment to obtain nutrients, light from **sunflecks**, and even water in different parts of the plant. They are able, at least in some taxa, to transport these nutrients or the photosynthate to other parts of the plant. Sexual reproduction is favored when clones and clumps provide both sexes, and even in monoicous taxa the differences in maturation times among members of the clone become an advantage.

Density can work for and against bryophytes. At low densities, water loss is greater and sexual reproduction is less successful, favoring spread by spores at high densities. However, in some mosses, such as *Polytrichum*, shoot mortality can increase with density, but in other taxa it can decrease.

There is a tradeoff between sexual reproduction and asexual reproduction, including branching and growth, as these events compete for energy.

Compared to tracheophytes, bryophytes are **r strategists**, but within the bryophytes there is an entire range from **r strategist** to **K strategist**. The **r strategists** rely on large numbers of small spores and a short life cycle (**opportunists**). **K strategists** rely on their clonal, perennial growth (**perennial stayers**) and often have only limited sexual reproduction or are strictly vegetative. But most bryophytes lie somewhere on the **bet hedger** line, producing spores sexually, but using fragments and asexual propagules during seasons when energy is not needed for sexual reproduction or spore production. Because of their ability to

dedifferentiate, bryophytes often spread by fragments of ordinary tissue.

Availability of water is the most important determinant of life cycle strategy. Endosporic development is more common on low water, low nutrient substrates like rock and bark. Disturbance is actually required for some species.

Bryophytes utilize three major tradeoffs: few large spores vs. many small spores, survival of stressful season as spores (**avoidance**) vs survival as a gametophyte (**tolerance**), and life span that is negatively correlated with reproductive effort. **Diaspore banks** permit bryophytes to survive untenable periods of time in a dormant state and begin growth when suitable conditions return. **Endosporic development** permits some bryophytes to get a head start in particularly short-lived periods of adequate moisture, such as deserts, floodplains, and vertical substrates.

Acknowledgments

Jean Faubert caught some serious inconsistencies in the r-K selection text and made valuable suggestions to improve this subchapter.

CHAPTER 4-7

ADAPTIVE STRATEGIES: VEGETATIVE VS SEXUAL DIASPORES

Figure 1. *Marchantia polymorpha* showing both vegetative diaspores (gemmae in splash cups) and umbrella-like archegoniophores where sporangia and sexual spores are housed. Photo by Michael Lüth, with permission.

Importance of Dispersal

Boedeltje *et al.* (2019) considered the vegetative diaspores of bryophytes to be of pivotal importance in colonization of new areas. These, however, are dependent on life history traits and habitat.

Diaspores

Diaspores are everywhere and some are ready to grow. In bryophytes, **diaspores** are spores and other propagules, including fragments, that function in dispersal (see Figure 1). These may be airborne, drop within the parent colony, or become buried in a diaspore bank in the substrate. Some even are dispersed by animals or water. They serve both to increase colony size and to invade new places.

Nevertheless, spread of many species is dispersal limited. Sillett *et al.* (2000) found that nine species of bryophytes had colonized branches of Douglas fir (*Pseudotsuga menziesii*) from 1995 to 1999, with relatively rapid colonization in all age classes. Nevertheless, when bryophytes were transplanted to Douglas fir trees, they became more frequent on inoculated branches than on ones

not inoculated by the researchers. This suggests that these bryophytes were dispersal limited in colonizing the trees.

The importance diaspores is exemplified by the large number of bryophytes that occur on multiple continents. Of the 7567 accepted binomials for liverworts and hornworts, 2211 are found on more than one continent (Anders Hargborg, pers. comm. 23 February 2017). And of these, 20 are found on all 7 continents plus Oceania. Frey and Hensen (1995) considered dispersal of such importance that they proposed a life strategy system based on dispersal strategies. One strategy that differed from other systems was the **perennial stayers with diaspore years**. That is, some years have prolific reproduction, vegetative or sexual, whereas in other years these are more limited.

Sampling Methods

To fully understand the role of diaspores we must sample them. The methodology influences what we sample, so it is worthwhile to examine these first.

The most commonly used means of sampling spores and other diaspores in the atmosphere is to place open

Petri dishes with a common bryophyte nutrient agar in the field at various heights and distances from a known source for a species. For shorter distances, one can use **glass slides** coated with glycerine. The spores usually cannot be identified by themselves, unless one has considerable experience and a good set of pictures and/or samples for verification. Hence, they must be germinated and the developing protonemata must be coaxed to develop and produce gametophores. Even then, one cannot be certain that the ensuing growth form is representative, since the light is artificial, may be too low or too high, certain growth factors available in its environment may be missing, and nutrients may be at inappropriate levels.

Other traps can include filters or air funnels in strategic positions that catch microbiota carried by drafts and other wind patterns. Each of these methods has its drawbacks, in addition to the problems of culturing and identification. Contamination is certain, density is low, and local micropatterns in air movements may be more influential in what they record in some cases than major pathways.

Levetin *et al.* (2000) compared the **Tauber trap** (Figure 2-Figure 3) with the **Burkard volumetric spore trap** (Figure 4-Figure 5), the latter a trap used in Antarctica (Lewis Smith 1991). The Burkard volumetric spore trap is used primarily for collecting airborne pollen, whereas the Tauber trap is used primarily to analyze deposition. They found a strong correlation between the pollen trapping recorded by the Tauber traps and the cumulative sums of average daily airborne spores/pollen from collections with the Burkard spore trap. Peck (1972) used the Tauber trap to sample pollen in turbulent flow water and found that under those conditions the collection efficiencies for individual taxa vary with both size and weight of the grains and velocity of flow. Smaller grains were trapped less efficiently than larger ones. As the water speed increased, grain characteristics had less effect, but the trapping efficiency decreased.

Figure 2. Tauber trap. Drawing based on Pardoe *et al.* 2010.

Figure 3. Tauber's original design (a & c) compared to the modification used with the Pollen Monitoring Programme (PMP) (b & d). Images from Pardoe *et al.* 2010, through Creative Commons.

Figure 4. Burkard volumetric spore trap. Photo by Burkard at <<http://www.burkard.co.uk/7dayst.htm>>, with permission.

More sophisticated samplers collect, filter, and concentrate the spores. One that has been used in bryophyte studies is the Rotorod sampler (Rotorod® Sampler 2009). This is a programmable instrument with a

timer that spins the head, bringing the pollen-collecting rods out by gravity. Its standard sampling is a 10% duty cycle, meaning that it samples for one minute out of every ten. A 5% duty cycle would collect for 30 seconds out of every ten minutes. Spores are collected on polystyrene rods pre-greased with silicone grease. To count the spores, the rod is placed in one of the deep grooves of a microscope stage adapter and a few drops of Calberla's stain applied. The rod is covered with a standard coverslip at the distal end of the rod and the spores are counted under a compound microscope at 400X. I am concerned that this rod is apparently intended to be used again and could easily have remnants of spores from a previous sampling, despite careful cleaning. A reticule can be used to aid in counting and to calibrate. The company has found that 400 spores are sufficient to get an accurate estimate of what is there.

Figure 5. Burkard volumetric spore trap. Redrawn from Aerobiological Sampling, Universidad D Cordoba.

Nature provides her own traps that we can use, but these are varying pictures of time and not necessarily indicative of the present. In the Antarctic, snow provides an appropriate medium for analysis of deposition of diaspores (Lewis Smith 1991). And peatlands have been traditionally sampled for pollen as well as spores.

But not all evidence comes from trapping diaspores. Patterns of bryophyte distribution can help us to hypothesize the pathways and mechanisms. Lönnell (2011) summarizes indirect connections that can contribute to our understanding of dispersal:

1. genetic similarity between populations in different locations
2. successful colonization that can be connected through distribution patterns
3. diaspore longevity compared to species distribution
4. species composition with prevailing winds.

One problem with assessing the relative importance of asexual vs sexual reproduction is that we often misunderstand the mechanisms used by a species. Fritz (2009) demonstrated this for several pleurocarpous species. *Pseudoscleropodium purum* (Figure 6) and *Pleurozium schreberi* (Figure 7) are known for rarity of sporophytes, but Fritz found that genetic evidence of new gene combinations suggested that sexual reproduction followed by spore production was more common than suspected. This was further supported by finding frequent presence of both antheridia and archegonia.

Diaspore Banks or New Arrivals?

Leck and Simpson (1987) examined the spore bank in a Delaware River, USA, freshwater tidal wetland. Their samples came from rainwater, 0-2 cm, 4-6 cm, and 8-10 cm depth in high marsh, cattail, and shrub forest. These samples revealed 14 moss species and 2 liverwort species. The most common bryophyte was a species of *Bryum*. The 0-2 cm samples had more species and greater densities, but no cover. The sample spores required longer germination times in culture than what is typical for seed bank spores and may explain the lack of cover on the tidal surfaces.

In a forested floodplain in Ohio, USA, McFarland and Wistendhal (1976) found six species of mosses, with *Eurhynchium hians* (Figure 8) being dominant. In this case, they considered low light levels and occasional flooding to promote protonemal growth. Samples of soil with plants and fragments buried under 10 cm of alluvium had good regrowth and appear to be important to the establishment of terrestrial mosses on these flood plains.

Diaspores for colonizing an area can arrive from elsewhere or be exposed from propagules that have been buried and dormant. In areas experiencing recolonization,

propagule sources can arrive quickly from **diaspore banks**, those buried propagules that have survived for long periods until such time as they are once again returned to a position with sufficient light and moisture to grow. In this case, travelling the distance means travelling down to a depth where they can survive until they once again experience a favorable location. This may mean not travelling too far so that they never again surface; in other cases, deeper is safer.

Figure 8. *Eurhynchium hians* in Europe. Photo by Michael Lüth, with permission.

Heinken *et al.* (2004) found three recolonization mechanisms at work in pine forest gaps in Central Europe. These were 1) advance of shoots from the edge of the gaps through clonal growth; 2) dispersal of detached individual shoots and clumps; 3) regeneration of what appeared to be dead stems from a soil diaspore bank. Each of the regenerating species seemed to be best at one of the strategies. Disturbance temporarily increased diversity as colonists succeeded on newly available ground before the perennial stayers were able to completely occupy the gap.

Arrival can account for differences in species dominance. In a boreal forest, *Pleurozium schreberi* (Figure 7) didn't show any diaspore limitation (Lloret 1994). *Dicranum scoparium* (Figure 9) cover was not influenced by proximity of its neighbors, but it did increase its colonization when the species was introduced by planting. In these forest sites, *D. scoparium* seemed to depend on the diaspore bank for its establishment. *Hylocomium splendens* (Figure 194), on the other hand, did depend on the presence of neighbors.

Activation conditions usually mean reaching not only sufficient moisture, but being exposed to light. Continued metabolic activity without light is certain death, but most species seem to have mechanisms to prevent germination until light is available. For example, diaspore banks of the forest floor can be activated for germination by disturbance that brings propagules into sufficient light and available moisture (Korpelainen *et al.* 2011). Such diaspore banks may be the source of rapid colonizers after forest harvesting (Caners *et al.* 2009), mining of peatlands (Poschold 1995), or other soil/substrate disturbances.

Figure 9. *Dicranum scoparium*. Photo by Janice Glime.

Even within the same habitat, the diaspore bank can differ based on the medium. In the bushland of western Australia, Biggs and Wittkuhn (2006) found 11 bryophytes in the soil and 13 in the litter. *Tayloria octoblepharum* var. *octoblepharum* (Figure 10) and *Rosulabryum campylotheceum* (Figure 11) only occurred in soil diaspore bank samples and *Lunularia cruciata* (Figure 12), *Fissidens serratus* (Figure 13), *Racopilum cuspidigerum* var. *convolutaceum* (Figure 14), and *Tortula antarctica* (Figure 15) only occurred in litter samples. *Bryum argenteum* (Figure 16) and *Rosulabryum billardieri* (Figure 17) were present in soil samples from all nine floristic types (including various types of woodlands, shrublands, heath, and mobile dunes); *Gymnostomum aeruginosum* (Figure 18) occurred in litter from all nine floristic types. As in other studies discussed herein, the diaspore bank housed some species that rarely occurred above ground, e.g. *Riccia* (Figure 97) and *Physcomitrium* (Figure 20). Among the familiar taxa from studies in other parts of the world were *Funaria hygrometrica* (Figure 178) and *Pohlia nutans* (Figure 36) in these Australian diaspore banks.

During (2001) considers that species such as *Micromitrium tenerum* (Figure 19) and *Physcomitrium sphaericum* (Figure 20) that require "episodically suitable habitats" persist in the diaspore bank as spores. In Mediterranean habitats where conditions permit winter annuals to persist, a sporebank is likewise an important source. On the other hand, in temperate forests and grasslands, long-lived shoots (especially pleurocarpous mosses) are rare in the diaspore bank even if numerous on the surface, whereas the short-lived species are typically over-represented in the diaspore bank, often as asexual propagules, awaiting small-scale disturbance.

Figure 20. *Physcomitrium sphaericum* with protonemata, leaves, and capsules. Photo by Michael Lüth, with permission.

During (2001) considers that ruderal species often produce several types of propagules that are suitable for

different conditions. One such species is *Blasia pusilla* (Figure 21), which has stellate gemmae (Figure 22-Figure 23) that have two auricles with the nitrogen-fixing Cyanobacterium *Nostoc* (Figure 24) and large amylochloroplasts in the gemmae. Its second type of gemma is ellipsoid or ovoid (Figure 25) and produced in flask-shaped structures (Figure 21-Figure 26). They are filled with starch, proteins, and lipids but lack *Nostoc* (Duckett & Renzaglia 1993). The stellate gemmae are produced throughout the growing season, but do not survive the winter cold. The ellipsoid gemmae are not released until late summer or autumn and do survive winter, germinating in the spring. These latter gemmae are suitable for the diaspore bank, but their presence there does not seem to be documented (During 2001). It is likely that other taxa with multiple diaspore types likewise have a division of labor.

Species Differences

Not all diaspores enter the diaspore bank equally. Representation in diaspore banks is not necessarily a good

indication of what grows at the surface. During (1997) found that species that were short-lived above-ground were usually over-represented in the diaspore bank, but perennial species tended to be absent or rare. These diaspore bank species tend to have large spores, but many are only represented by vegetative diaspores.

Lönnell (2011) reviewed dispersal literature and concluded that diaspore banks have little representation by even dominant pleurocarpous mosses, whereas the short-lived species that one can easily miss in the flora are common in the diaspore banks. This may account for the observations of Vitt (2006), who summarized previous studies and concluded that diaspore banks usually lack good representation of the extant community. Instead, he found that the species dominating the current community are generally rare or absent in the diaspore bank; rather, spores present in the diaspore bank represent pioneer species that are not present in more mature stages. This latter statement supports the conclusion of Lönnell (2011) that the short-lived species are the most common. Lönnell also found that larger diaspores are better represented than smaller ones. This latter strategy is useful for species that must await an opening, then accomplish their life cycle quickly before the competition arrives. During *et al.* (1987) demonstrated that even in diverse habitats in Spain, this bias holds true. They found tubers, gemmae, leaf fragments, and viable cells on decaying stems in the diaspore banks. Despite the mix of bryophytes growing on the surface, the diaspore bank was dominated by species with a colonist life strategy. On the other hand, Poschlod (1995) concluded that for disturbed (mined) peatlands, recolonization is from the diaspore bank.

During and ter Horst (1983) found 37 species in the diaspore bank of a chalk grassland. Among these the **acrocarpous** (having archegonia terminal on upright stems; mostly growing vertically) colonists were likewise the most frequent, despite dominance of **pleurocarpous** (having archegonia on short side branches; mostly growing horizontally) mosses and perennial liverworts on the surface. During (1990) suggested that high species diversity in chalk grasslands might be maintained by intermediate disturbances that cause a high turnover of species originating from the diaspore bank.

During and Moyo (1999; During 2003) found that in a Zimbabwean savannah, fire did not seem to harm the diaspore bank. Following disturbance by burning, only *Exormotheca holstii* (Figure 27), 2 *Riccia* spp (Figure 97), 2 *Archidium* spp (Figure 109) and *Bruchia* (Figure 28) emerged from soil samples near the surface in the middle of the rainy season (During & Moyo 1999; During 2003). Nevertheless, in soil samples representing the diaspore bank 11 liverworts and hornworts and 21 moss species were present. As seen in a number of other studies, taxa often were absent in the surface flora and appeared only when the right disturbance conditions occurred (During 2007). During and Moyo (1999) found that some rare species and even some species previously unknown for that region were conserved in the diaspore bank (During & Moyo 1999; Zander & During 1999).

Some species always seem to be there when the landscape is scoured for a road cut or for making a ski trail. Such is the case for *Trematodon ambiguus* (Figure 29). In fact, this species had been considered to be extinct in

Belgium and the Netherlands, but following large-scale disturbance it reappeared, apparently from a long-lived spore bank in the soil (During *et al.* 2006). The spores are somewhat large (~30 μm), not especially numerous in the capsule (~14,000), and emerged from soil samples taken at 0-3 cm.

While not all bryophytes enter the diaspore bank equally, neither do they emerge equally. In a different road-cut study, Hassel and Söderström (1998) found that two species of *Pogonatum* behaved differently. *Pogonatum dentatum* (Figure 30) was most likely to occur on roads only 0-4 years old, whereas *P. urnigerum* (Figure 31) was more likely along roads more than 4 years old. At least for *P. dentatum*, frequency in the diaspore bank decreased with distance from parent colonies, suggesting that the diaspore bank is more important than diaspore rain.

Figure 31. *Pogonatum urnigerum* with capsules and young male splash cups (unopened). This species appeared along road cuts more than 4 years old. Photo by Michael Lüth, with permission.

Some tuber-bearing mosses (Figure 35) seem to be especially dependent on diaspore banks. They may be very common in the diaspore bank, but absent on the surface until the soil is disturbed (During 1995). Where they do occur on the surface, maintenance of that population seems to depend on occasional recruitment from the diaspore bank. Nevertheless, they can still exhibit clonal behavior because the tubers are deposited near the parent on relatively long rhizoids.

Arable Fields

In three cultivated fields of Switzerland, Bisang (1996) found *Anisothecium staphylina* (Figure 32), *Dicranella schreberiana* (Figure 33), *Bryum rubens* (Figure 34-Figure 35), *Pottia* sp (Figure 118), and *Phascum* sp (Figure 61) as common members of the soil diaspore banks. As is typical, some species were present in the diaspore bank but not

present among the flora of that field. Species of diaspores in these agricultural habitats varied most between localities.

Ponds and Lakes

One common bryophyte in the mud of ponds and lakes is *Physcomitrium sphaericum* (Figure 20). This species is not a regular member of the flora surrounding these water bodies because it requires conditions that are not present annually: exceptionally warm, dry summers (Furness & Hall 1981). In fact, the spores will germinate only in the range of 15-35°C. Its appearance under those suitable conditions is possible only because its spores remain viable in the mud for a long time.

Forests

The role of diaspore banks in various forested landscapes has been investigated through several studies. Caners *et al.* (2009) used mineral soil samples from mixed and coniferous stands of boreal mixed-wood forest in northern Alberta, Canada, to examine the role of these potential diaspore banks in reforestation after harvesting. Surprisingly perhaps, the composition of bryophyte species that were able to germinate related not to the forest types or harvesting intensity (measured by light regime), but to edaphic factors and, not surprisingly, to spatial proximity. Spatial proximity not only accounted for the species available, but also accounted for edaphic similarities. Nevertheless, light intensity had a significant influence on both the responses of individual species and on the species assemblages that arose.

In the boreal forest, Jonsson (1993) found 40 species, similar to the number found by During and ter Horst (1983) in chalk grasslands, of liverworts and mosses in the diaspore bank of an European *Picea abies* forest. The most abundant taxa were *Pohlia nutans* (Figure 36-Figure 37), *Sphagnum* spp. (Figure 47-Figure 52), and *Polytrichum commune* (Figure 88-Figure 89) / *Polytrichastrum longisetum* (Figure 38). In the boreal forest soil diaspore bank in southeastern Norway, Rydgren and Hestmark

(1997) found that *Plagiothecium laetum* agg. (Figure 39) and *Polytrichum* spp. (Figure 88-Figure 89) were the most frequent bryophytes germinating. Sean Robinson succeeded in growing new plants from a plant fragment of *Pohlia nutans* (Figure 37).

Forest gaps benefit from diaspore banks. Palisaar and Poschlod (2001) found that both forest and windthrow areas have a predominance of long-lived species, but the colonist strategist predominates in the diaspore bank, ready to take advantage of large, sunny gaps.

Tropical forest diaspore banks have rarely been studied, but it appears that their composition follows different patterns from those of other forests and periodically disturbed habitats. In lab cultures of diaspore banks from Brazil, bark (68) and decaying wood (55) species dominated, compared to soil species (22) (Maciel-Silva *et al.* 2012). Mosses were more numerous in both species and number of shoots than liverworts. Monoicous species were more common than dioicous species. Species that produced sporophytes and those producing gemmae were well represented in the diaspore banks. The biggest difference was that the diaspore banks represented the growing vegetation rather well.

When culturing samples from the diaspore bank of three Malaysian mountain rainforests, Bisang *et al.* (2003) found germination of more liverworts than mosses, especially from the lower altitudes, contrasting with the results of Maciel-Silva *et al.* (2012). These liverworts [*Cincinnulus* (as *Calypogeia*) *argutus* (Figure 40), *Mnioloma* (as *Calypogeia*) *fuscum*, *Lepidozia wallichiana* (Figure 41), and *Zoopsis liukuensis* (Figure 42)], were, as in the study of Maciel-Silva *et al.*, common taxa growing in the area. Stem fragments that had lost their chlorophyll seemed to be the diaspores that gave rise to *Isopterygium* sp. (see Figure 43) and cf. *Ectropothecium* sp. (Figure 44), but for other taxa they were unable to identify the type of diaspore.

Peatlands

In peatlands, recolonization is derived from diaspore banks and adjoining similar habitat. Sundberg and Rydin (2000) showed experimentally that 15-35% of *Sphagnum* spores could survive for 13 years when stored in humid conditions such as would be present in a peatland diaspore bank.

Campbell *et al.* (2003) found that in a regenerating Quebec, Canada, peatland, *Polytrichum strictum* (Figure 45) was widespread and its colonization showed no significant trends with distance from a living source. *Pleurozium schreberi* (Figure 46), *Sphagnum capillifolium* (Figure 47), and *Sphagnum fuscum* (Figure 48), on the other hand, only became frequent further from edges (> 20 m), suggesting that the right habitat conditions were absent at the edges. They explained the strong presence of *Polytrichum strictum* by the long fall times from capsule to substrate, coupled with its very small spores, facilitating its travel despite its low release height. Nevertheless, the diaphragm forces the spores out the sides, a position not conducive to aerial transport.

On the other hand, *Sphagnum angustifolium* (Figure 49), *S. papillosum* (Figure 50), *S. cuspidatum* (Figure 51), *S. subsecundum* (Figure 52), *Pleurozium schreberi* (Figure 46), *Leucobryum* sp. (Figure 53), and *Chiloscyphus profundus* (= *Lophocolea heterophylla*) (Figure 54) were present in the vegetation and absent in the measured diaspore rain of the regenerating peatland (Campbell *et al.* 2003).

Poschlod (1995) conducted extensive studies comparing milled peatlands to natural raised bogs in the Bavarian foothills of the Alps. He found for those peatlands that recolonization apparently came entirely from diaspore banks, especially for *Sphagnum* species. That

genus was entirely absent in the spore rain sampled. In particular, *Sphagnum magellanicum* (Figure 55), *S. capillifolium* (Figure 47), and *Polytrichum strictum* (Figure 45) occurred in the diaspore rain in at least one of the six sites studied.

Figure 55. *Sphagnum magellanicum* in Europe, a species that regenerates from diaspore banks. Photo by Michael Lüth, with permission.

Among the bryophytes in these peatland diaspore banks, Poschlod (1995) found six species of liverwort fragments. Of these, five of these are species that develop tubers. Furthermore, *Cephalozia connivens* (Figure 56) and *Kurzia pauciflora* (Figure 57) have subterranean shoot axes and *Calypogeia* (Figure 58) species have a shoot axis near the surface. Duckett and Clymo (1988) likewise found liverwort shoot axes in bogs in Great Britain and estimated that regeneration came from peat layers that were 25-60 years old. Based on studies by Clymo and MacKay (1987), they ruled out downwash into deeper layers.

Figure 58. *Calypogeia fissa*, a species that can persist in diaspore banks by its subterranean shoots. Photo by Hermann Schachner, through Wikimedia Commons.

Poschlod (1995) found all the *Sphagnum* species typical of raised bogs in the diaspore banks. Brown stems and branches of *S. capillifolium* (Figure 47) and *S. cuspidatum* (Figure 51) were able to regenerate from depths down to 15 cm. Peatland diaspore banks can be deep, with viable *Sphagnum* spores occurring as deep as 30 cm (Poschlod 1995). Poschlod (pers comm. 28 March 2013) concluded from this that the spores could survive more than two centuries!

Delayed Germination – Dormancy

Propagules may survive diaspore banks through dormancy (Hock *et al.* 2004). In two open grasslands in Hungary, gemmae of a species in the *Bryum atrovirens* complex (Figure 59) and *Weissia controversa* (Figure 60) exhibited dormancy. Likewise, dormancy seemed to be present in the spores of *Tortula acaulon* (= *Phascum cuspidatum*) (Figure 61). Hock *et al.* suggested that dormancy may be relatively common for diaspores of species living in habitats with short-term periods of unfavorable growing conditions.

Figure 60. *Weissia controversa* var. *controversa* with capsules. Photo by David Holyoak, with permission.

Figure 61. *Tortula acaulon* (= *Phascum cuspidatum*) with capsules. Photo by David Holyoak, with permission.

It is interesting that initially the highest number of species in the boreal forest diaspore bank arose from the mineral soil (9.9 per sample), but after four years the reverse was true (Jonsson 1993), with more arising from the humus, suggesting that some species have a delay mechanism that does not permit them to germinate right away. Watson (1981) suggested that *Polytrichum* species had the option of chemical inhibition to facilitate dormancy. Such delay mechanisms are known from flowering plants and include such factors as immature embryos (not applicable to bryophytes), chemical inhibitors

that must be washed away or removed by digestive enzymes of an animal (not yet shown for bryophytes but possible), or the need for hormones or vitamins from a fungal or bacterial partner [known for development of the gametophore in *Pylaisiella selwynii* (Figure 62) and several other moss species (Spiess 1977, 1979; Spiess & Lippincott 1978; Spiess *et al.* 1971, 1972, 1973, 1976, 1981a, b, 1982, 1984a, b, c, d, 1986, 1990)]. I have cultured *Fontinalis squamosa* (Figure 63) that produced protonemal gametophore buds in the presence of contamination while the cultures that remained sterile produced no buds. What other examples of bryophytes are out there in nature where a living partner is needed to provide some growth factor necessary for development to continue – or even start?

Figure 62. *Pylaisiella selwynii* on bark, a species that requires a bacterial partner to complete its development. Photo by Jan-Peter Frahm, with permission.

Figure 63. *Fontinalis squamosa* in Europe, a species that may require a bacterial partner to develop protonemal buds. Photo by Michael Lüth, with permission.

Other factors relating to delay of germination may be habitat condition or suitable weather. For example, in *Sphagnum* (Figure 47-Figure 52), dormancy may be conditional, depending on weather (Sundberg & Rydin 2000).

This leads us to ask what conditions are needed to break dormancy. Obviously, water is needed, and for continued success, light is needed. But water may be insufficient for continued development, so the spore needs a way to prevent germination when conditions are not likely to remain suitable. Mogenson (1981) suggested that spore surface sculpturing may serve to prevent small quantities of water from activating the spore by creating

surface tension that prevents the water from penetrating the spore. However, this hypothesis seems not to have been tested.

Blasia pusilla (Figure 22-Figure 26) is one liverwort whose gemmae do not germinate right away when brought to the surface from a diaspore bank (During 2001). Gemmae of *B. pusilla* do not germinate until the spring after their production (Duckett & Renzaglia 1993), a phenomenon well known for seeds. This delay could be related to its storage of food reserves as protein, which is slower to metabolize than the starch or oils of other spores (Crum 2001). It seems likely to me that there are other bryophytes that have this delayed germination mechanism in spores or other propagules, especially in the **Anthocerotophyta** with their protein food reserves (Crum 2001). The leafy liverwort *Lophozia ventricosa* var. *silvicola* (Figure 64) changes its dormancy based on the time of production, with those gemmae produced in the spring germinating readily, but those produced later seem to lose germinability with time of production (Laaka-Lindberg 1999). A similar seasonal relationship is known for the forest floor tracheophyte *Melampyrum lineare*. If a propagule begins to convert its food reserves, loss of water could stop the process and prevent germination. This could only happen a few times before the reserves are used up, and a small propagule would lose its reserves sooner than a large one.

Figure 64. *Lophozia ventricosa*. Photo by Hermann Schachner, through Creative Commons.

Asexual propagules likewise display dormancy. We have witnessed the effect of parents on inhibiting development of vegetative propagules, *e.g.* the absence of germination of *Marchantia polymorpha* gemmae (Figure 65) while they remain on the parent. There seem to be few species where either spores or vegetative propagules can germinate while still in contact with the parent, and many species, for example *Funaria hygrometrica* (Figure 178), are unable to germinate near their parents due to chemical inhibitors leached from the parent. Could there be biochemicals in the environment that must leach out before germination occurs in some species?

Even freshly produced spores may have dormancy (**innate dormancy**), as in *Archidium alternifolium* (Figure 66). This dormancy is broken slowly and the mechanisms for breaking it are unknown (Miles & Longton 1992). Germination was less than 65% and increased as the spores aged, up to 4 years. This delay suggests to me that there

may be a chemical inhibitor that is removed by leaching. In *Sphaerocarpos texanus* (Figure 67), spores are dormant when released, but dormancy is broken by fluctuating temperatures, typically 35/20°C and may even have dormancy/non-dormancy cycles resulting from temperature fluctuations (McLetchie 1999).

Figure 65. *Marchantia polymorpha* with gemmae. Photo by Michael Lüth, with permission.

Figure 66. *Archidium alternifolium*. Photo by Michael Lüth, with permission.

Figure 67. *Sphaerocarpos texanus* on disturbed soil. Photo by Adolf Ceska, with permission.

Dormancy relationships seem to be complex, making them difficult to predict. Kobayashi and Yamamura (2000) found that inbreeding caused an increase in dormancy, perhaps through complementation. But the spores have only one set of chromosomes, so this logic seems to fail. And under some conditions inbreeding leads to decreased dormancy – a combination of genes where dormancy is poor to start with? We also know examples where longevity of female spores is longer than that of male spores [McLetchie 1992 for *Sphaerocarpos texanus* (Figure 67)]. How does dormancy affect longevity?

The seed bank houses a set of seeds that represent a non-random set of genotypes. That is, at the seed bank level, there is selection. There is evidence that there are correlations among suites of characters such as temperature of response and seed longevity. Such relationships need to be explored for bryophytes. Furthermore, risk of predation by animals and attack by fungi are strong selection factors for seeds, but these likewise have received inadequate attention for bryophytes.

Does Depth Matter?

Bisang (1996) compared germination of diaspores from above and below 25 cm for diaspores that were disturbed by regular ploughing to a depth of about 10-25 cm. In general, protonemata of mosses were less vigorous in soil samples from below 25 cm. Furthermore, *Eurhynchium hians* (Figure 8) and *Riccia* sp. (Figure 97) were present only to a depth of 15 cm.

Benefits of Diaspore Banks

Diaspore banks that have a store of recent species are likely to provide the soil/substrate characteristics required for the successful re-establishment from diaspore growth, once they are in a position to obtain sufficient light and moisture. On the other hand, light conditions may differ from those when the diaspores were deposited, and the species represented are often different from those on the surface (During & ter Horst 1983; During 1997). Furthermore, the species richness of the bryophytes may be influenced by the species composition of tracheophytes that has developed while the diaspores lay dormant (Aude & Ejrnæs 2005). For the short-lived shuttle species of agricultural landscapes, even the soil characteristics may have changed due to agricultural practices of fertilizing, a condition that can be detrimental to many bryophytes adapted to low nutrient conditions.

Tradeoffs

Diaspores, like any other novel solution, have their tradeoffs, although our understanding of these is very limited. During (2001) suggests that the lack of perennial bryophytes in the diaspore bank represents a tradeoff between adult longevity and diaspore longevity. Spore size is another potential tradeoff. Species with small spores such as *Funaria hygrometrica* (Figure 178) tend to have short viabilities in the soil (During 1987). During (2001) suggests that a similar tradeoff between dispersability and soil longevity could account for the scarcity of such weedy species as *Marchantia polymorpha* (Figure 1), *Bryum argenteum* (Figure 16), *B. bicolor* (Figure 68), and *Ceratodon purpureus* (Figure 69) in soil diaspore banks.

Nevertheless, Biggs and Wittkuhn (2006) found *B. argenteum* in the soil diaspore banks in all nine habitats in their study in western Australia. Could it be that this is a different microspecies?

Figure 68. *Bryum bicolor* with capsules, a species with good dispersability and poor diaspore longevity. Photo by Jonathan Sleath, with permission.

Figure 69. *Ceratodon purpureus* in southern Europe, a species with good dispersability and poor diaspore longevity. Photo by Michael Lüth, with permission.

Rather than small spores and good dispersal, During (2001) finds that the overall trend in diaspore banks is just the opposite. Those species that persist in the soil diaspore bank tend to have large spores (Jonsson 1993). This is a reasonable expectation because it would make it possible for these species to grow rapidly when they do germinate, taking advantage of the absence of competition from tracheophytes. Furthermore, many of these species have cleistocarpous capsules and short setae, making dispersal to any distance an unlikely event.

This presence of large spores in the diaspore bank is in contrast to that of seeds, where small seeds predominate. During (2001) suggests that seed predation on larger seeds and ease of dispersability of small spores may account for the difference in relationships. Furthermore, asexual diaspores are much more common among bryophytes.

Spores vs Vegetative Dispersal

All bryophytes require dispersal in some form to continue the species as its current habitat changes or disappears. Spores may be especially important for colonizing epiphytic habitats and other vertical habitats

such as walls and cliffs, as well as being the primary source of propagules for forest clearings. Grime and coworkers (1990) contend that sporebanks are important in exploiting disturbed habitats, but even these sporebanks depend on aerial dispersal as well as local dispersal. These recolonization and new colonization events by spores are possible only because of the ease of dispersal of at least some of the spores.

Both spores and asexual diaspores provide the means by which bryophytes can reach new locations or spread in local ones. At some point, specialized asexual reproduction arose in photosynthetic organisms. Algae can make extensive use of fragmentation, and some algae have asexual spores. But bryophytes have developed specialized structures for their reproduction and never produce asexual spores, *i.e.*, they produce only meiospores.

We must ask then, what are the advantages of sexual vs asexual propagules, and under what circumstances? Newton and Mishler (1994) summarized our knowledge and pointed out that spores have a prerequisite of fertilization, and this process requires water. But spores usually disperse farther than vegetative propagules and germinate best in previously uncolonized substrates. Vegetative structures, on the other hand, can be produced even under stressful conditions, disperse well locally, and are more successful in germinating among existing colonies.

During (pers. comm. 5 January 2005), however, points out that in some cases, the role of spores in dispersal, particularly large spores, is very similar to that of asexual propagules, having short-range dispersal with greater chance of germination and establishment in a somewhat wider range of habitats. And if the species is **monoicous** (both sexes on same plant), it is likely that the spores resulted from selfing and thus have similar genetic makeup to that of any asexual diaspore that might be produced in the same species. Hence, there seems to be a trade-off in these species with large spores. There appears to be little advantage for them also to produce asexual structures for reproduction. This is especially true for annual shuttle species – these species may simply not have enough time to produce both, since many bryophytes typically do not have enough energy to produce sexual spores and vegetative diaspores at the same time, although they may ultimately be present at the same time.

Fritz (2009) tested the relative importance of asexual vs sexual reproduction in several species [*Pseudoscleropodium purum* (Figure 6), *Pleurozium schreberi* (Figure 7), and *Rhytidiadelphus squarrosus* (Figure 70)] where sporophytes are considered to be rare. First, he found that sporophytes were apparently not so rare, using molecular data to demonstrate that the level of genetic diversity was that to be expected from spore dispersal. In these small populations, the genetic structure showed positive correlations between genetic diversity of a population and sporophyte occurrence. It appears that there may be an energy tradeoff at work here, because Fritz found that in these three species, clonal plants were present primarily in small patches up to 6 m² and were restricted to populations where both antheridia and archegonia, as well as sporophytes, were absent, or where only one sex of gametangia was present. This would be a good contingency strategy – that of a **bet hedger**.

Figure 70. *Rhytidiadelphus squarrosus*. Photo by David Holyoak, with permission.

Pohjamo *et al.* (2006) compared spores and gemmae in the leafy liverwort *Anastrophyllum hellerianum* (Figure 71), where they are of equal size. Unlike the suggestion of During (pers. comm. 5 January 2005) that their dispersal distances would be equal, Pohjamo *et al.* found that dispersal distances differed, with gemmae travelling farther. Between 17.5 and 43.1% of the spores released and 0.64 and 4.8% of the gemmae available were deposited within 10 m of the central colonies. Rain had no effect on either dispersal pattern, but more gemmae were released on rainy days. This leaves us to wonder why gemmae travel farther. Perhaps their non-spherical shape causes them to be caught by the wind more easily, or to attach to animals more easily.

A number of species rarely produce capsules. If they likewise do not have any specialized reproductive structures, this presents a dispersal problem. But researchers continue to discover asexual means that were previously unknown or rarely described in floras. For example, despite the obvious presence of propagula in several species of *Aulacomnium*, these are seldom mentioned for *A. heterostichum* (Figure 72), but can be quite abundant in some populations (Imura *et al.* 1991; Figure 72). Such was the case for *Mnium stellare* (Figure 73), a species that rarely produces capsules in Europe. However, in 2012, Hugonnot and Celle discovered that it reproduces by leaf **fragmentation**. This is not just random fragmentation, but rather the result of both splitting (**schizogeny**) and breaking (**lysogeny**). In **lysogeny**, there is partial cell disintegration that facilitates the fragmentation. They suggested that **schizogeny** was probably the result of hydration of the middle lamella. In *Mnium stellare* the fragility of the leaves seems to be greater when the leaves are hydrated, rather than when they are dry. Hugonnot and Celle verified these fragments as legitimate dispersal units by showing that they readily germinated on wet peat. Other species are already known for their leaf fragmentation abilities, *e.g.* *Dicranum viride* (Figure 74), *D. fragilifolium* (Figure 75), *Tortella fragilis* (Figure 76).

Wang *et al.* (2012) used inter-sample sequence repeat markers and DNA sequences to investigate sexual vs asexual strategies in *Hypnum plumaeforme* (Figure 77) and *Pogonatum inflexum* (Figure 78). *Hypnum plumaeforme* reproduces primarily vegetatively. For this

species, the genetic diversity among island populations was significantly greater than that among lakeside populations where the habitat became available and isolated 50 years earlier, suggesting greater isolation among the island populations. *Pogonatum inflexum*, on the other hand, is frequently fertile, spreading primarily by spores. In this species there was no difference in genetic diversity between island and lakeside populations. Wang *et al.* (2012) considered this to be evidence that fragmentation of landscapes could increase genetic differentiation in species that have limited dispersal abilities, resulting in greater spatial differences in genetic structure.

Figure 78. *Pogonatum inflexum*, a species that reproduces primarily by spores. Photo from the University of Hiroshima Digital Museum, with permission.

Understanding dispersal of bryophytes is complicated by their ability to disperse by more than one means. Furthermore, some species are not known to produce spores and others don't produce spores in some locations where only one gender is present. As an example, Bremer and Ott (1990) reported that nearly 40% of mosses in the Netherlands never or rarely produce spores. Nevertheless, the first bryophytes to colonize forests there are those that produce spores frequently, with those rarely producing spores [*Orthodicranum montanum* (Figure 79), *Rhytidiadelphus squarrosus* (=R. *lozeus*; Figure 80), *Thuidium tamariscinum* (Figure 81)] arriving 20 years later. In these forests, experiments suggest establishment from spores is very rare for perennial stayers. It is only in older forests that one can find species with large spores.

Figure 79. *Orthodicranum montanum* showing dislodged bulbil (arrow). This species can form entire colonies of bulbils or form larger gametophyte stems accompanied by these bulbils. Photo by Janice Glime.

It is widely accepted that bryophyte spores are important for long distance dispersal to colonize newly available habitats (Newton & Mishler 1994). The time required, however, may be centuries or even millennia. Longton (1997, 2006) sums up the differences as one of spores being able to establish new populations more easily and asexual propagules being of major importance in colony expansion and maintenance.

Differences in Success

One question we might ask is why do some (actually many) bryophytes maintain both sexual and asexual reproductive propagules? Bengtsson and Ceplitis (2000) contend that for such a system to evolve and be maintained, the relative fitnesses of the sexual and asexual propagules must vary over the years. This would permit the most fit system to operate under the environmental conditions of that year. These conditions might be weather conditions, but they can also relate to competition, availability of bare soil, disturbance, herbivory, and other environmental factors. In this context, we might ask what hormonal changes occur in response to herbivory, or how does nutrient depletion affect asexual vs sexual reproduction? And if it is dry, will that stimulate asexual instead of sexual reproduction?

Frahm (2009) claims that there is no difference in effectiveness between sexual and vegetative propagation. He contends that the small size and weight of both spores and vegetative propagules would lead one to believe that both can be dispersed easily, thus supporting wide ranges for the species. Some species do have wide distribution, whereas others have very narrow ranges. And both of these categories include strictly vegetative reproducers and sexual (spore) reproducers. This disparity of ranges does not seem to relate to the abundance of propagules produced, with some species with high production of propagules demonstrating limited distribution and some sterile species having wide distribution (Frahm 2009).

But Callaghan and Ashton (2008) have arrived at a different conclusion for bryophytes in the British Isles. They found that among the 430 taxa there, range-size of both mosses and liverworts is significantly positively correlated with sporophyte production. But in seeming contradiction to this relationship, they found that **monoicous** (having both sexes on the same plant) moss species were rarer than **dioicous** (having the two sexes on different plants) species, suggesting that this rarity of monoicous taxa may be due to less fitness arising from self-fertilization.

Data on *Octoblepharum albidum* (Figure 82-Figure 83) demonstrate a different benefit than is typically attributed to gemmae. Their protonemata from gemmae grow faster than those from spores, most likely making their establishment more successful. On the other hand the spores produce more gametophytes. That is, one gemma produces one plant, but one spore produces many plants arising from multiple buds on a single protonema, at least for mosses.

It is not unusual for bryophytes to have more than one vegetative means of propagation. For example, *Rhytidium rugosum* (Figure 84-Figure 85) has three types of vegetative propagation: ramets (vegetative branches that separate by decay and disintegration when they are older; Figure 84); brood branches; and caducous branches (branches that easily break off as dispersal units; Figure 85). Pfeiffer *et al.* (2006) used AFLP fingerprinting to identify three clones from two plots, each having 2-15 samples with identical fingerprints. Presence of one clone in two plots indicates dispersal by vegetative diaspores. The close relationships between plots suggest that these plots were created through cloning, not spore dispersal.

Figure 85. *Rhytidium rugosum* demonstrating a dry branch that can easily be broken off (caducous) by a frisky squirrel. Photo by Michael Lüth, with permission.

Molecular data for *Pseudoscleropodium purum* (Figure 6) and *Pleurozium schreberi* (Figure 7) showed clonal reproduction [as in *Rhytidium rugosum* (Figure 84-Figure 85)] was an important part of their population dynamics (Fritz 2009). Fritz (2009) furthermore found possibilities for vegetative reproduction that had not yet been documented, including cloning, brood branches/branchlets, caducous shoot apices, and brood leaves (only in *P. schreberi*).

Löbel *et al.* (2009) compared mating systems and concluded that larger asexual diaspores enjoyed higher establishment rates at the cost of shorter dispersal distances, whereas the small sexual spores sacrificed establishment rate to achieve greater dispersal distances, a concept supported by the *Rhytidium rugosum* (Figure 84-Figure 85) study (Pfeiffer *et al.* 2006). This is an interesting contrast to that of Pohjamo *et al.* (2006) for the leafy liverwort *Anastrophyllum hellerianum* (Figure 71) where the vegetative gemmae travelled farther.

Limits to Success

These inconsistencies based on propagule size and abundance lead us to the conclusion that the propagules of different species have different abilities to arrive and colonize in new locations, using attributes independent of size. As Frahm (2009) points out, it suggests that the germinating propagule is limited by narrow ecological niches, age of taxon, local extinction, or historical events such as ice ages. Caners *et al.* (2009) also found that microhabitat conditions determine the success of species once they arrive or get exposed from soil banks. **Edaphic** (soil) factors are especially important, as well as habitable space. Although successful species composition did not relate to forest type or harvesting intensity, Caners and coworkers found that light intensity had a significant influence on the success of individual species and thus has important management implications in reforestation. To further their assertion of the importance of soil, we might consider the conclusions of Bischler and Jovet-Ast (1981) that in the **Marchantiales** (Figure 1) morphological characters may not be important to survival and dispersal, but rather their adaptations are primarily "linked to biochemical and biophysical properties of the cell content."

With respect to soil characters, I must caution about an area of research that has received little attention. In a new location, differences in soil chemistry could cause morphological differences that could cause even an astute systematist to assume a different species. This can of course be sorted out by DNA fingerprinting, but there is little experimental evidence to address this question. A few studies have, however, demonstrated the plasticity of species under different environmental conditions. For example, Zastrow (1934) cultured a variety of species and showed that responses to water culture include loss of central strand, papillae, alar cells, and leaf border, as well as showing reduction in costa and chlorophyll. Alkaline conditions caused stem elongation between nodes compared to that in neutral and acid conditions. Buryová and Shaw (2005) cultured six populations of *Philonotis fontana* (Figure 86-Figure 87) under two light and two water regimes and observed that both light and water affected growth, but cell dimensions seemed unaffected. Responses differed not only according to treatment, but also showed genetic differences in their responses. But others have shown changes in the number of cell layers in the stem of *Fontinalis* (Figure 63) species (Sée & Glime 1984). Such plasticity makes tracking species dispersal pathways more difficult and our understanding is likely to remain under constant revision for some time to come as molecular data refute our earlier hypotheses.

In recent years, genetic/molecular methods are facilitating our understanding of the relative roles of asexual vs sexual means of reproduction in bryophytes (Shaw *et al.* 2002). For example, Derda and Wyatt (1990) measured 38 multilocus genotypes in populations of *Polytrichum commune* (Figure 88-Figure 89). They found that 69% of these genotypes were distributed evenly across the range of the species, with a mean genotypic diversity of 0.546 ± 0.042 . This is a low value, coupled with potential for vegetative reproduction, and Derda and Wyatt used it to support the concept that spore-mediated gene dispersal in this species is limited. Van Zanten (1973) likewise asserted that dispersal of *Dawsonia* (Figure 90), another member of the *Polytrichaceae*, is limited due to the epiphragm that requires physical contact such as a raindrop to expel the spores.

Figure 88. *Polytrichum commune* with capsules. Photo by David Holyoak, with permission.

This chapter will consider each of these diaspore mechanisms and some examples of dispersal types among the bryophytes. Where possible (data are limited), we will examine what contributes to their success in getting established.

Which Strategy Accomplishes More?

In a model designed for Bryozoa, not bryophytes, Karlson and Taylor (1992) provided criteria for dispersal that would seem also to apply to bryophytes. Dispersal involves a tradeoff between energy spent on probable success of short distance dispersal and the energy lost to provide an expansion of the species through long-distance dispersal. "Using a procedure which minimizes the extinction probability for the lineage (hence maximizing survivorship of the genetic individual)," they predicted that "a high proportion of dispersed offspring should be associated with high numbers of asexual offspring, a low risk of mortality to offspring during dispersal, and high local survivorship of offspring."

One consequence of vegetative reproduction and dispersal might be a loss of genetic diversity. Van der Velde *et al.* (2001) used the genetic structure of *Polytrichastrum formosum* (Figure 91) to assess this genetic diversity in sexual vs asexual reproduction. They found that the levels of microsatellite variability were, on average, lower than those known for most other plant species. Nevertheless, genotypic diversity within the populations studied was high. They interpreted this as an indication that sexual reproduction is an important determinant of the within-population genetic structure of *P. formosum*. Furthermore, Van der Velde *et al.* found no significant differences among microsatellite markers between populations or between regions (450 km in Denmark vs the Netherlands). They likewise interpreted this as evidence of sexual reproduction with high effective spore dispersal between populations, despite the well known ability of this species to reproduce clonally, supporting the interpretations discussed above for *Pseudoscleropodium purum* (Figure 6), *Pleurozium schreberi* (Figure 7), and *Rhytidiadelphus squarrosus* (Figure 70) (Fritz 2009). Members of the *Polytrichaceae* do not produce specialized asexual reproductive structures, and reproduction by fragments exists but is poorly known for most of the *Polytrichum/Pogonatum/Polytrichastrum* group (Figure 91).

The leafy liverwort *Orthocaulis attenuatus* (= *Barbilophozia attenuata*; Figure 92) provides another example of the tradeoffs. Korpelainen *et al.* (2011) found that diaspores of this species in the diaspore bank of a forest floor can be activated by disturbance. A disturbance as small as ant trails can favor the establishment of large gemmae over small spores for establishment. They found that these gemmae are effective at short distances, but not at mid-distances. For longer distances, spores are an effective means of dispersal. This short-distance gemmae dispersal provides compatible genotypes already adapted to this environment, but the tradeoff is the lack of genetic diversity and other problems attached to inbreeding.

Lost Energy

Production of sporophytes is a cost in energy. First, it costs energy to produce antheridia and archegonia. Then it costs energy to nourish the sporophyte to maturity. Production of spores likewise costs energy. Therefore, this costly process needs to afford a significant advantage for the species to succeed and survive with this strategy through evolution.

Figure 92. *Orthocaulis attenuatus* (= *Barbilophozia attenuata*), showing gemmae at the tips of some branches. Photo by Michael Lüth, with permission.

Nevertheless, some species seem to produce sporophytes to no avail. Unfavorable conditions for development may make vegetative dispersal more important than dispersal of spores. In Nigeria, the widespread *Bryum coronatum* (Figure 93) produces abundant sporophytes, but it appears that they have a large failure rate (Egunyomi 1982). Among those in the study, 42% remained undehiscent even during the dry season when they normally discharge spores. Furthermore, 41% of the setae never developed capsules. Although the spore germination rate was 65-88%, protonemal growth was abnormal. The abundant production of axillary propagules is certainly important in those seasons, most likely frequent, when conditions during sporophyte development are less than ideal. This is a widespread species and sporophytes are most likely more important in other locations where conditions are more favorable for them.

Figure 93. *Bryum coronatum*, a moss with a large failure rate for sporophytes in Nigeria. Photo by Jan-Peter Frahm, with permission.

As already mentioned, for species that produce large numbers of spores that travel great distances, most of those spores will not reach a suitable substrate and microclimate, hence contributing to the loss of energy.

Liverworts vs Mosses

Longton (1997) pointed out that the production of specialized asexual propagules is more common among (leafy) liverworts than among mosses. Gemmae are so common among leafy liverworts that their species often are identified by the structure and location of their gemmae. In the British liverwort flora, Laaka-Lindberg *et al.* (2000) found no association between production of asexual propagules and rarity, or with the monoicous vs dioicous condition. But those species that produce neither spores nor special asexual propagules are typically rare.

Habitat Differences

Disturbed Habitats

Disturbance can play a selective role for species that may be mediated by tradeoffs between dispersal rate and establishment success. Kimmerer (1993) found that *Tetraphis pellucida* (Figure 94-Figure 95) benefitted from frequent disturbance, whereas suppressed disturbance caused it to become out-competed by other bryophytes. Its competitor, *Orthodicranum flagellare* (Figure 96), is

successful in colonizing gaps when there are other populations of the species nearby to contribute asexual brood branches. These germinate more rapidly than the gemmae of *Tetraphis pellucida* (Figure 94-Figure 95), making *O. flagellare* the better competitor.

Figure 94. *Tetraphis pellucida* gemmae in splash cups. Photo by Jan-Peter Frahm, with permission.

Flood plains, arable fields, and other regularly disturbed habitats are colonized by species that can lie dormant in diaspore banks during periods unsuitable for growth, or they must arrive quickly, colonize immediately, and complete their life cycles before the habitat is once again unfavorable. Such a habitat favors such species as thallose liverworts that can roll up their thalli, dry out, and resume growth from dormant terminal buds, as in *Riccia* (Figure 97). These are often invisible to the naked eye until those suitable growth conditions are provided, either in the field or in the lab. Kürschner and Parolly (1999) found that this community in Turkey consisted mostly of annual shuttle species and vegetative colonists that produced very large spores, retained spore tetrads, and/or produced asexual propagules, all of which survived in the diaspore bank during winter flooding and were able to re-establish the community quickly when the flood waters receded.

Figure 97. *Riccia bischoffii* var. *ciliifera* on drying mud. Photo by Jan-Peter Frahm, with permission.

Bijlsma *et al.* (2012) found *Ephemerum cohaerens* (Figure 98) and *E. serratum* var. *rutheanum* (Figure 99) in extensive beds where there was regular inundation and high flooding until May or early June, hence causing a setback to competing vegetation. They attributed the success of these species in these conditions to the flooding, life strategy, and soil characteristics. The large spores and tubers permitted these species to remain in the diaspore bank, whereas the rapid development of an extensive protonemal mat following the recession of flood waters gave them an establishment advantage. Their short life cycle permitted them to form plants in late summer and complete the life cycle to spore production in autumn.

Figure 98. *Ephemerum cohaerens* with perigonia. Photo by Dick Haaksma, with permission.

Figure 99. *Ephemerum serratum* with capsules. Photo by David T. Holyoak, with permission.

Arable fields are a man-made habitat that favors certain bryophyte species. This can be a suitable habitat for some members of the **Anthocerotophyta**, but changes in agricultural practices can make the habitat unsuitable. Following years of hornwort-unfriendly agricultural practices, new eco-friendly practices returned in some areas of Europe. Bisang *et al.* (2009) compared the presence of this hornwort group before and after the eco-friendly practices were established in the Swiss plateau and found the return of *Anthoceros agrestis* (Figure 100) and *Phaeoceros carolinianus* (Figure 101-Figure 102). The re-establishment of these two species apparently resulted from spores that remained persistent in diaspore banks through the many years of unfavorable conditions.

Other disturbed habitat colonizers, like *Marchantia* (Figure 103), are frequent in the diaspore rain (Gaur & Kala 1984; Ross-Davis & Frego 2004) and arrive almost continuously, ready to take advantage of the low competition. *Marchantia polymorpha* is one of the colonizers after a forest fire (Graff 1936). In their experiments on buried propagules in an old-growth forest, Ingersoll and Wilson (1990) found that most (88%) of the gametophores emerging were from vegetative sprouts. There were significantly more vegetative sprouts in the undisturbed treatments. The number of emergents responded inversely to an increase in disturbance, with exposure to sun causing a significant decline in the six most abundant species. Vegetative structures with shallow burial were lost in the fire treatment.

Unfortunately, our methods of determining what is in either diaspore banks or diaspore rain requires culturing, and this method is both time-consuming and incomplete, permitting us to identify the species if growth to a gametophore is successful, but often not permitting us to

identify the dispersal structure that produced it. And we might not provide the right conditions for its successful development.

Epiphytes

Löbel and Rydin (2009) found that in epiphytic bryophytes, the conditions in the habitat influenced the production of sporophytes, but not that of asexual propagules. Furthermore, development of sporophytes had a negative effect on growth, whereas presence of asexual propagules did not. Further detriments to the sexual strategy arise from the need to reach a certain colony size before reproduction is effective; there is no threshold for the asexual reproduction. Thus, two sets of trade-offs arise: dispersal distance vs reproductive age and dispersal distance vs sensitivity to habitat quality. They considered that habitat turnover and connectivity may be more important selection pressures than species interactions.

The genus *Radula* (Figure 104), a leafy liverwort in which both monoicous and dioicous taxa exist, demonstrates a specific case for the advantages of asexual reproduction. In this genus that lives in a frequently dry environment, there was no correlation with either dioicy or epiphytism (Devos *et al.* 2011). Rather, there seems to have been a shift from sexual systems (dioicy to monoicy) among the facultative epiphytic taxa several times. Both facultative and obligate epiphytes in this genus produce gemmae equally, as well as dispersing gametophyte fragments. These asexual propagules may provide a pre-adaptive mechanism that permits the facultative epiphyte taxa to live on trees where frequent wetting and drying out are detrimental to the development of protonemata into buds and gametophores. Fragments and asexual propagules can skip this stage or use it only briefly before developing into a leafy plant. Devos *et al.* suggest that the larger size of these diaspores imposes a tradeoff by limiting dispersal distance.

Figure 104. *Radula lindenberghiana* with gemmae. Photo by Jan-Peter Frahm, with permission.

Peatlands

Peatlands are unique habitats, and they seem to do lots of things differently. Poschlod (1995) examined the relative importance of spores and fragments in the recolonization of milled peatlands in the Bavarian foothills of the Alps. He found that spores were relatively unimportant in the diaspore rain, but that fragments did

appear in the spore traps. In particular, branches and leaves of *Sphagnum magellanicum* (Figure 55), *S. capillifolium* (Figure 47), and *Polytrichum strictum* (Figure 45) were captured in the traps in most of the study sites. Furthermore, diaspore bank samples were placed in pots and cultivated for more than one year. In these pots, only three species germinated and grew: *Betula* (birch tree), *Marchantia polymorpha* (Figure 103), and *Funaria hygrometrica* (Figure 178).

The Antarctic

Harsh environments impose different selection pressures from the ones at play in more friendly environments. Lewis Smith and Convey (2002) offered evidence to refute the long-held hypothesis that bryophyte fertility decreases as latitude (and climate severity) increases. Using the maritime Antarctic (68-72° S lat) as an example, they demonstrated that a relatively high proportion of the bryophytes there were capable of producing sporophytes. At Marguerite Bay, 43% of the species (17 species of mosses, 2 of liverworts) were known to produce sporophytes; at Alexander Island it was 47% (16 species of mosses, 1 of liverworts). In more arid parts of the Antarctic continent, the number was less (33%). This is still considerably smaller than that found by González-Mancebo and Hernández-García (1996) for an altitudinal gradient in the Canary Islands, where most life cycle strategies had 70% fertility, with that of the perennial stayers being lower.

Not surprisingly, Lewis Smith and Convey (2002) found that most of the Antarctic fertile mosses in their study areas were short, monoicous acrocarpous species. For dioicous species, the problem arises of having both genders arrive on the island in sufficient proximity and having both mature at the same time under a different set of temperatures, day length, and moisture regime than at their source.

In this harsh Antarctic environment, spores were more abundant than bryophyte fragments in the Rotorod® samplers of Signy Island (Marshall & Convey 1997). Spore size did not seem to matter, with all five taxa occurring in samples 0.5-1 km from their nearest known sources. Nevertheless, the presence of spores was small compared to their represented ground cover and in comparison to the lichen propagules in the same samples. This extensive ground cover most likely resulted from vegetative spread after spore arrival.

Plasticity of Spore Size

Habitat may matter as well in determination of successful spore size and means of reproduction within a species. Hassel and Söderström (2003) compared the spread of *Pogonatum dentatum* (Figure 105) in the mountains vs lowlands in Fennoscandia. The lowland plants seem to have a tendency to produce more but smaller spores (statistically non-significant) compared to the mountain plants. Nevertheless, establishment in the mountains seems rarely to occur from either spores or leaves whereas these two methods are frequent in the lowland. On the other hand, the diaspore bank is more important in the mountains because of the more regular and shorter disturbance intervals there. The diaspores of *P.*

dentatum are apparently too short-lived to survive the longer disturbance intervals in the lowlands.

Figure 105. *Pogonatum dentatum*. Photo by Jan-Peter Frahm, with permission.

Seasons

In a study of airborne pollen and spores in Buenos Aires, Noetinger *et al.* (1994) noted that while spores are scarce throughout the year, they are mainly represented by the bryophytes, with the greatest densities in May to June. For seed plants, pollen density was dependent on phenology of the species, and densities corresponded with blooming seasons of the various groups. Latorre *et al.* (2008), in Mar del Plata city, Argentina, found an increase in pollen with an increase in temperature, reaching a maximum in early spring. Data differed among the trap types, with a negative correlation with wind using the Burkard trap and negative correlation with humidity using the Tauber trap. Data supporting such correlations with phenology and weather for bryophytes are meager. And some bryophytes retain their capsules for more than one year.

Marshall and Convey (1997) were surprised to find that spores were captured over a long time period on Signy Island in the Antarctic, including captures in the winter months. With availability of bare substrate, it is possible that spores could be redistributed from non-trapping surfaces throughout the year. Just what is going on during the seasons when most of us are not looking?

For *Polytrichastrum ohioense* (Figure 106) in the subalpine zone of the Yatsugatake Mountains, Central Honshu, Japan, capsules endure the winter in an immature stage, taking 13 months to mature and dispersing their spores in the following mid-July to mid-August (Ayukawa *et al.* 2002). In *Racomitrium africanum* (Figure 107), *Fissidens weirii* (as *Fissidens glauculus*), *Thuidium gratum*, and *Stereophyllum* sp. (Figure 108) in southwest Nigeria, sporophytes develop and mature at the end of the same rainy season (Oct/Nov & Dec) as that for fertilization (beginning of rainy season) (Odu 1981). Spores from mature capsules of these species all dispersed during and after the dry season (Nov-Apr).

For *Archidium ohioense* (Figure 109), *Bryum coronatum* (Figure 93), *Fissidens minutifolius*, and *Trachycarpidium tisserantii*, also in southwest Nigeria, capsule dehiscence and spore dispersal occurred in September – October (Makinde & Odu 1994). But in this case, the stages of sporophyte development occurred during the rainy season, including capsule dehiscence and falling

of the capsules themselves. Not surprisingly, they found that the spores did not discharge easily from the cleistocarpous capsules of *A. ohioense* or *T. tisserantii*. In the Hiruzen Highlands of Japan, Nishimura (1993) found that dispersal dates for 34 species of mosses occurred in late autumn (late November) to early spring (early April); 12 occurred in late spring to summer (May to August) and 5 in autumn (September to November). One had no definite season and one had two dispersal seasons. In these examples, it appears that the season of dispersal is not random, but that conditions needed for one species may not be suitable for another. It is easy to understand that most small spores will benefit from dispersal when it is dry, permitting them to be carried by wind and air currents to new locations. For those with large spores that fall to the ground, a rainy season is beneficial for immediate germination and growth.

Figure 109. *Archidium ohioense* with capsules. Photo by Li Zhang, with permission.

Time of day matters and may help us to unravel the conditions favoring dispersal. For pollen, Pérez *et al.* (2003) found a maximum between 10:00 and 12:00 h, with a minimum at 18:00 h in Mar del Plata, Argentina. They suggested that optimal diurnal conditions for dispersal of arboreal pollen are high temperatures and low relative humidity. It is likely that this relationship could be applied on an annual scale and that it would also apply to bryophyte spores.

One seasonal advantage of asexual propagules is that they are generally produced throughout the growing season, whereas spores tend to be released during a limited time each year (During 2001).

Are These Adaptations?

Capsules and Setae

Setae develop first in **Bryophyta** and last in **Marchantiophyta** relative to the capsule. In either case, the elongated seta extends the spores farther above the plant (Figure 110), increasing the chances for them to be dispersed. Even in the **Anthocerotophyta**, where there are no setae, the elongate sporophyte matures from top down and dispels its spores from the top (Figure 100). Hence, we

might expect some differences in the length of the setae, with longer setae permitting spores to get farther from the parent bryophyte, and perhaps even hornwort sporophyte lengths, relative to dispersal needs. These may or may not correlate with characters of the capsule itself.

Figure 110. *Pohlia nutans* with nodding capsules and long setae. Photo by Michael Lüth, with permission.

We can list a number of differences among capsules that might contribute to their dispersal ability. Paramount among these is the means by which the capsule opens and dispels the spores. These will be discussed in some detail in the ensuing paragraphs, but one we might consider first is the drying of the capsule interior prior to spore expulsion. This process and its importance seem to lack experimentation except in *Sphagnum* (Figure 47-Figure 52), so some speculation is in order. Chater *et al.* (2011) have cited the regulation of stomatal behavior in photosynthetic organisms for 400 million years of evolution. Its role in leaves of tracheophytes is clear, but in bryophytes the sporophyte tissue is not in a leaf, and it is the sporophyte capsule that has the stomata (Renzaglia *et al.* 2000). However, it appears that as in the leaf, this tissue controls (perhaps permits is more appropriate) the loss of water. Recent evidence proposed by Duckett *et al.* (2010) suggest that we should consider the possible role of stomata in permitting the escape of moisture from the capsules of other mosses (Figure 111). Such drying leads to changes in capsule shapes and can contribute to the loss of the operculum, sometimes quite forcibly. This aspect of dispersal will be discussed in detail in another subchapter (4-9), but it may be helpful to keep this potential role in mind here as we examine dispersal strategies.

Habitat Differences

Spore capsules in mosses (but not in liverworts) seem to differ considerably among species, and many of these seem to fall into habitat categories. As Vitt (1981) points out, the function of the sporophyte is to produce and disperse the spores as efficiently as possible. In this role, selection pressures should shape the sporophyte into the most effective organ for its growing conditions. These selective pressures differ significantly among the major habitat classifications of hygrophytic, mesophytic, and xerophytic.

Figure 111. SEM of *Physcomitrella patens* stomata at base of capsule. Photo courtesy of Jeff Duckett and Silvia Pressel.

Xerophytes may be characterized by reduction of the sporophyte, including shorter seta length, broader and erect capsules, reduced or absent peristome including cleistocarpy, and large spores (Vitt 1981). These characters are often accompanied by a shortened life cycle that permits the xerophytes to avoid extended dry periods. As evidence, Vitt points out that this same group of adaptations has evolved in a number of unrelated mosses, including the acrocarpous genera *Bryobartramia*, *Viridivellus*, *Sporledera* (Figure 112), *Goniomitrium* (Figure 113), and pleurocarpous genus *Gigaspermum* (Figure 114). Others, including *Encalypta brevipes* (Figure 115), *Ditrichum* spp. (Figure 116), *Funaria* spp. (Figure 117), *Pottia* (Figure 118), *Stegonia* (Figure 119), *Trematodon* (Figure 120), and *Weissia* (Figure 121), lack the reduced life cycle but exhibit the other xerophytic adaptations.

Figure 121. *Weissia controversa* var. *densifolia* showing swollen urn. Photo by Barry Stewart, with permission.

Mesophytic taxa, on the other hand, can have amplified capsules, as in the entomophilous members of the **Splachnaceae** (Vitt 1981; Figure 199). Vitt lists other taxa exhibiting sporophytic amplification are some **Dicranaceae** (as polysety; Figure 122), **Mniaceae** (Figure 124), **Hypnodendraceae** (Figure 123), and **Dawsonia** [amplified peristome (Figure 126) compared to other **Polytrichaceae** (Figure 89)]. The mesophytic group, not faced with the extremes of habitat, has taken multiple routes that preclude a clear definition of adaptations. Vitt (1979, 1981) included elongate, straight setae; curved, horizontal to pendent capsules that are smooth, cylindric, and have well-developed peristomes as common characters of mesic forest floor mosses. Example taxa include *Plagiomnium cuspidatum* (Figure 124) and *Timmia megapolitana* (Figure 127).

Epiphytes usually have xerophytic adaptations, but these differ from those of the edaphic species because dispersal is a different problem for these elevated taxa. *Cladomnion ericoides* (Figure 125) provides a good example of epiphytic adaptations with its short, stout setae (permitting leaves and perichaetial leaves to protect the capsule from desiccation); erect, ribbed, ovate-oblong capsules; and sheathing perichaetial leaves (Vitt 1981).

Many epiphytic members of the **Isobryales** share similar features with other bryophytes of vertical surfaces: *Haplohymenium* (Figure 128), *Andreaea* (Figure 129), *Fabronia* (Figure 130), *Grimmia* (Figure 197), *Tortula* (Figure 131), *Hedwigia* (Figure 132), *Orthotrichum* (Figure 133-Figure 135), *Ptychomitrium* (Figure 136), *Racomitrium s.l.* spp. (Figure 137), and *Tortella* (Figure 76), presumably adapting them to vertical substrates where humidity alternates between dry and wet periods and light intensity is higher (Vitt 1981). These habitat characteristics seem to favor the short, erect, ribbed capsules; short, stout

setae; reduced peristomes; and sheathing perichaetial leaves. Epiphytic *Orthotrichum*, on the other hand, seems to have evolved from ribbed [e.g. mesophytic *O. lyellii* (Figure 133) or *O. vittii* (Figure 134)] to smooth [e.g. xerophytic *O. pusillum* (Figure 135)] capsules (Vitt 1981).

Vitt (1981) considers two groups of mosses with submerged or emergent habits. Those with aquatic gametophytes and terrestrial sporophytes, often produced at times of low water levels, include, for example, *Scorpidium* (Figure 138), *Hygrohypnum* (Figure 139), *Platylomella* (as *Sciaromium*; Figure 140), *Drepanocladus* s.l. (Figure 142), and *Platyhypnidium riparioides* (Figure 141). These taxa have sporophytes that align with mesophytic bryophytes from the forest floor. On the other hand, the aquatic mosses with aquatic sporophytes [e.g. *Blindia* (Figure 143), *Fontinalis* (Figure 144), *Wardia* (Figure 145), *Scouleria* (Figure 146)] tend to have reduced or absent peristomes; ovate or oblong, smooth, immersed capsules; enlarged perichaetial leaves; and thick or leathery **exothecial** (outer capsule wall) cells.

Anisospory

Mogensen (1981) points out that having **anisospory** (unequal spore sizes, in this case) creates different dispersal potential between males (small spores) and females (large spores). One would presume that small spores will disperse farther, hence making it more likely that males establish as single-sex populations in distant places. It also seems that there is an advantage in the production of dwarf males from these anisosporous male spores because some

of these will germinate on a female and thereby be close enough to accomplish fertilization. There is no equivalent advantage for the female spores to land on another member of the species because these are never known to produce dwarf plants that might somehow accomplish fertilization. Rather, in most cases, they will not germinate at all when landing on their own genotype.

Spores and Spore Walls

Liverworts and mosses differ in the number of layers in the spore wall (Mogensen 1981). Both have **intine** and **exine**. The **intine** (Figure 147) is the inner wall and possesses the aperture that is responsible for the breakup of the spore wall during germination. The **exine** is the outer wall and thus protects the spore from the environment. The **perine** is present only in moss spores and is laid down on the outer surface of the spore. It is not produced by the spore, but rather, the surrounding sporophyte deposits the perine (Figure 148) material on the spore walls. This perine is of taxonomic value and one might assume that it has environmental significance, but little information is available to provide us with such correlations.

Figure 147. *Andreeaea rothii* TEM of spore. Photo courtesy of Karen Renzaglia.

Figure 148. *Andreeaea rothii* spore SEM showing papillae (perine layer) laid down by the sporophyte. Photo courtesy of Karen Renzaglia.

Some speculation is in order so that we can develop hypotheses about this perine layer (Figure 148). This layer causes air to be trapped in spaces around the surface of the spore. So one hypothesis is that the spores trap air that makes them lighter in weight per unit volume, permitting them to float. What are the advantages gained by spaces so small that cohesion of water molecules prevents them from entering those spaces? Does this potential repellence of water prevent inappropriate germination? And what difference does the pattern make? Or could it be that this layer provides a food source for potential dispersal agents that pass the spore through the gut unharmed at some new location or simply carry the spores like ants do seeds with elaiosomes? Does the layer have any food value? Does it make adherence easier for both dispersal and attachment to substrate?

Liverworts

Bischler and Jovet-Ast (1981) contend that adaptations in liverworts are primarily those of biochemical and biophysical properties of the cell content, hence making them more difficult to assess. Both the gametophyte and sporophyte produce specific **flavonoids** that may protect the developing gametes and spores from UV light (Suire & Asakawa 1980). They likewise synthesize secondary compounds that seem to deter predators and parasites. SEM images provided by William T. Doyle seem to provide evidence that they are also adapted by differences in the sculpturing of the spore wall (Figure 149-Figure 154).

Although liverworts lack a perine layer, spores of many species are not without decoration (Figure 149-Figure 154). Some of the leafy liverworts, e.g. *Frullania chevalieri* (Figure 152), have quite intricate and interesting patterns of papillae; others have deep sculpturing, as in *Fossombronina* (Figure 154).

Figure 156. *Sphaerocarpos michelii* distal spore wall SEM. This species lives on damp soil of fallow fields, soils subject to seasonal flooding, and sandy soil of tall-grass prairies. Photo by William T. Doyle, with permission.

But what is the overall indication of these sculpturings? Van Zanten and Gradstein (1988) found no significant difference between the spore sculpturing of transoceanic and endemic Neotropical liverwort species, with both smooth (Figure 155) and finely **verrucose** (covered with warts or wart-like projections) spores (Figure 152) in both groups. On the other hand, they found that there were significantly more strongly verrucose spores among endemic species than among transoceanic species, regardless of size. Furthermore, species with strongly verrucose spores (Figure 156) are typically hygrophytic and terrestrial (a combination for species that live where they are submersed for short periods of time), suggesting to van Zanten and Gradstein that this sculpturing might aid in short-distance dispersal overland by water movements during heavy rainfall. Such a strategy could be useful for *Sphaerocarpos michelii* (Figure 156).

Bischler and Jovet-Ast (1981) attempted to assess reproductive adaptations for the **Marchantiales**. This group is characterized by large spores with an ornamented exine (e.g. *Asterella*; Figure 157). Few species of **Marchantiales** have specialized gemmae [e.g. *Marchantia* (Figure 1), *Lunularia* (Figure 158), *Blasia* (Figure 159) as exceptions], although these are common among leafy liverworts. The sporophyte is imbedded in or surrounded by gametophyte tissue, where it remains until the spores ripen. For many of the taxa, an archegoniophore is produced, hence raising the ensuing sporophyte above the thallus.

Figure 158. *Lunularia cruciata* showing gemmae. Photo by Martin Hutten, with permission.

Figure 159. *Blasia pusilla* gemmae on the thallus surface. Photo by Dick Haaksma, with permission.

Elaters occur among the spores of both **Jungermanniales** and **Marchantiales**. These elongate structures twist in response to moisture changes and help in the dispersal in many of the taxa – or do they hinder it by entangling the spores (Figure 160) and forcing them to be dispersed as a mass? Little is known about the role of these elaters in dispersal – perhaps their primary role is in maintaining moisture in the capsule during spore development.

Figure 160. Open capsule of *Jungermannia* sp. showing spores and entangling elaters. Photo by George Shepherd, through Creative Commons.

Monoicous vs Dioicous

One interesting result of the study by van Zanten and Gradstein (1988) is that among the Neotropical liverworts they considered, monoicy vs dioicy made a difference in dispersal. Gradstein (1985) found that 57% of the endemic **Lejeuneaceae** (Figure 161-Figure 162) are monoicous. In the **Jubulaceae** (Figure 163), only one transoceanic species is dioicous. Van Zanten and Gradstein (1988) concluded that if the species had spores larger than 35 μm, then dioicism may create a serious reduction in its long-distance dispersal ability. They reasoned that for small spores there were better chances for transport by air currents, hence providing a greater chance for dioicous species with small spores to arrive near a partner of the opposite sex. To achieve the same opportunity for a partnership in species with larger spores would take a longer time. It is also important to recognize that the only dioicous species to achieve transoceanic dispersal in the Jubulaceae was *Frullania ericoides* (Figure 163), a species that is also the only one with gemmae. On the other hand, all the species in Lejeuneaceae that have gemmae are endemic.

Ecological Adaptations

Not surprisingly, van Zanten and Gradstein (1988) found a positive correlation between Neotropical liverwort species range and xerophytic habitat. They found that correlation mainly related to large spore size. There was no similar relationship for species with small spores. Moreover, they found no relationship between spore drought tolerance and moisture level of the habitat. However, for sporelings there is a significant correlation with the average number of days for survival of desiccation, with 30 days for xerophytes, 25 for mesophytes, and 13 for hygrophytes. This suggestion that successful establishment may be more important than dispersal has appeared in other studies discussed herein.

Van Zanten and Gradstein (1988; Gradstein 2013) found that tropical lowlands have significantly more transoceanic species than at higher elevations. Most of these transoceanic species are members of the Lejeuneaceae and Jubulaceae, families with large, green spores. This requires some explanation since it is easier to get higher elevation species into the airstream, and large green spores suggest a need for immediate germination. But the lowland species are generally more widespread than are montane and alpine species, providing greater availability of these lowland species. Furthermore, this widespread habitat availability is in effect at the receiving

end as well, creating greater opportunity for a "stepping stone" effect in regions where there are oceanic islands with large areas of relatively low elevation.

Persistent Protonemata

Some bryophytes retain their protonemata even after the leafy gametophores are well developed. These include *Buxbaumia aphylla* (Figure 164), *Discelium nudum* (Figure 165), various *Ephemerum* species (Figure 166-Figure 167), *Fissidens exilis* (Figure 168), *Pogonatum pensilvanicum* (Figure 169), *Schistostega pennata* (Figure 170) (Bob Klips, Bryonet 22 December 2021), *Rhizomnium* (Figure 171), *Tetraphis* (Figure 172) (Wolfgang Hofbauer, Bryonet 22 December 2021), *Diphyscium* (Figure 173) (Rob Gradstein, Bryonet 22 December 2021), *Ephemeropsis* (Figure 174), *Cololejeunea metzgeriopsis*, *Protocephalozia ephemeroides*, *Radula aguirrei*, *R. yanoella*, and *Viridivellus pulchellum* (Gradstein & Wilson 2008). *Fissidens magnicellulatus* from a damp, vertical soil bank in Zambia likewise has persistent protonemata (Bruggeman-Nannenga 2013). *Mittenia* (Figure 175), like *Schistostega*, has persistent protonemata that reflect light when struck by it at right angles (Stone 1961).

When Furuki and Iwatsuki (1989) described the liverwort *Mizutania* as a new genus, they considered that the gametophyte thallus might actually be a persistent protonema.

Protocephaloza ephemeroides is a liverwort and consists of a mat of numerous branched filaments that give rise to very short, leafy sexual branches; it has been found only once – in 1854 in Venezuela (Gradstein & Wilson 2008). In *Pogonatum* (Figure 169), many species are represented by a mat of protonemata with only scattered leafy plants (Wyatt & Derda 1997). Protonemata in *Ephemerum* (Figure 166-Figure 167) produce long-lived tubers. Pressel *et al.* (2013) suggest that in their lake margin homes in the British Isles, these provide an alternative means of perennating that allows them to survive inundation when it occurs prior to sporophyte production.

In *Rhizomnium punctatum* (Figure 171), the protonemata are the dominant phase in the life cycle and remain persistent when leafy gametophores arise (Duckett & Ligrone 1994). Those produced by spores and those produced from excised leaf bases are the same. They produce gemmae on side branches and then secondary gemmae by proliferation. The gemmae germinate readily and the filaments are strongly adherent to solid objects. The protonemata are the dominant phase in the life cycle.

Stone (1985a) described an unusual persistent protonema in *Archidium thalliferum* in Australia. This protonema is cushion-shaped and thalloid, but composed of short-celled filaments. The thalloid structure has differentiated layers with functions of protection, photosynthesis, and possibly storage. The upper layer of filaments is greyish-white and protects the chlorophyllose tissue beneath it. The middle portion provides dense chlorophyll concentrations with large spaces among the protonemal filaments that would facilitate photosynthesis much like a mesopyll. The basal portion has colorless cells and is rich in oils, possibly serving as a storage organ. The filaments break off easily and could potentially serve as propagules, but their ability to regenerate remains to be demonstrated. The rhizoids produce gemmae and both the

rhizoids and the gemmae store oil. Stone suggested that these and the oil-filled spores might remain viable for years when rainfall was insufficient for successful germination. Upright gametophores may remain buried within the cushion. *Archidium minutissimum*, also in Australia, has persistent protonemata, but these do not form cushions and may be found on the ground or among the leaves (Stone 1985b).

Pursell and Allen (2017) found that the ephemeral *Fissidens exilis* (Figure 168), one of smallest species of *Fissidens* in eastern North America, grows from persistent protonemata on bare, usually disturbed soil. More recently, Kwon *et al.* (2019) found that *Fissidens protonemaecola* similarly produces a persistent protonema. The species occurs on shaded soil in Korea, where it produces small, bud-like shoots scattered on the protonemata. It is also known from China, Japan, and Taiwan.

Duckett and Pressel (2013) reported *Discelium nudum* (Figure 165) as a pioneer on unstable clay banks. It seems to persist or arrive as unicellular, colorless, starch-filled rhizoidal tubers (with up to 20 µm diameter starch grains) *ca* 1 cm below the surface. These diaspores are exposed on new clay surfaces when winter causes leaves of the vegetation to disintegrate. The diaspores are both abundant and germinate rapidly, a reproductive strategy that gives the *Discelium* a competitive advantage. The persistent chloronemata lack gemmae, but their spread is rapid.

The **Ephemeraceae** typically occur in sunny or partly shaded areas on disturbed soil where they face little competition from mosses or larger plants. They appear as patches of green protonematal filaments with occasional tiny leafy gametophores. Their asexual reproduction is mostly by protonemal fragments, but rare thick-walled elongate, swollen protonematal segments may detach and persist on or in the soil.

In *Bryum* (Figure 176) species with persistent protonemata, protonemal gemmae and tubers are in greatest production in winter when sporophytes are still immature (Pressel *et al.* 2007). Protonemal gemmae arise within only weeks, whereas sporophyte formation takes at least a year. The most rapid protonemal production is evident in species in arable fields in autumn, and in these species the gemma production is transient. The persistent protonemata grow in places where leafy gametophores are unable to flourish. Pressel *et al.* suggested that this persistence was due to low irradiance. This behavior is similar to that of *Dicranoweisia cirrata* (Figure 177), wherein the gemmiferous protonemata form in conditions with high nutrients. In *Bryum* species, the spores are packed with lipids and are long-lived, whereas the gemmae are filled with starch and presumed to be short-lived.

Thus it appears that persistent protonemata provide different advantages in different species. Their ability to produce vegetative propagules seems to be common, providing a means of reproduction in habitats where spores might not succeed due to their smaller size and therefore smaller amounts of stored nutrients. But their nutrient strategies seem to differ. In species like *Rhizomnium punctatum* (Figure 171) the rock substrate is low in nutrients, whereas in fallow fields some *Bryum* (Figure 176) species persist as protonemata on a soil substrate rich in nutrients. Some of the persistent protonemata are

present only in one or few species in a genus, whereas others characterize an entire order. Protonemal propagules have received insufficient attention in most bryophyte species, so overall statements as to the adaptive advantages of persistent protonemata with propagules would seem to be premature.

Who Is Travelling?

We seem to have a reasonable understanding of the algae that we are likely to encounter in diaspore rain, with genera like *Chlamydomonas* and *Chlorella* likely to show up in that translucent glass jar in which you are starting to root a plant. In fact, the water in most such glass jars will turn green before the plant has enough roots to put it in soil due to the arrival and successful colonization of *Chlorella*. But I was surprised to find we scarcely have similar information for bryophytes.

Ross-Davis and Frego (2004) examined the propagule rain in southeastern New Brunswick, Canada, forests that were managed for timber production. Using emergence, they identified 51 species in the aerial rain and soil propagule banks. Only 36 of these were extant species in the area sampled. The air-borne species were more similar to the extant vegetation than were the buried taxa, attesting to the readiness of the diaspore bank for changes in the conditions.

Anyone who has watched a disturbed area, peered at the cracks in the sidewalk, or investigated an area after a fire knows that one of the first bryophytes to arrive is often *Funaria hygrometrica* (Figure 178). To add to this list of habitats, this was the first moss to arrive and become established on the volcano Surtsey when it arose from the sea off the coast of Iceland (Schwabe 1974). This moss seemed to benefit from having its protonemata colonized by nitrogen-fixing Cyanobacteria, particularly members of the group *Schizothrix* (Figure 179)/*Plectonema* and members of the *Nostocaceae*, particularly *Anabaena* (Figure 180).

Figure 178. *Funaria hygrometrica* on rocky substrate in southern Europe. Photo by Michael Lüth, with permission.

Figure 179. *Schizothrix lenormandiana*. Photo from Cyanosite as freeware.

Figure 180. *Anabaena* sp., a common symbiont with some bryophytes. Photo by Janice Glime.

One test of the dispersal ability of bryophytes is to compare the spore rain with the extant species in the area. This will indicate those that are able to disperse there, but are unable to become established. This can be further tested by culturing the propagules to see if germination might be successful if different, and hopefully more appropriate, conditions are provided.

Certainly some species are more common in the diaspore rain than others. Leitaó *et al.* (1996) and Santos *et al.* (1996) used agar traps to identify cryptogamic organisms from the atmosphere in Coimbra, Portugal. These included many non-bryophytes, but 75% of those collected were spores <25 µm (Santos *et al.* 1996). In addition to non-bryophytes [Cyanobacteria, Chromophyta (Ochrophyta), Chlorophyta, and Pteridophyta], Santos and coworkers isolated the liverworts *Fossombronia angulosa* (Figure 181-Figure 183) and *Pellia epiphylla* (Figure 184) and the mosses *Leptodictyum riparium* (Figure 185), *Bryum dunense* (Figure 186), *Ditrichum* sp. (Figure 187), *Gymnostomum aeruginosum* (= *G. calcareum*; Figure 188), *Pottia* sp. (Figure 189), and *Trichostomum brachydontium* (Figure 190). *Bryum dunense* forms axillary bulbils and *Leptodictyum riparium* is monoicous and produces abundant capsules.

and identified spores of *Marchantia* (Figure 103), *Conocephalum* (Figure 191), *Pellia* (Figure 184), and *Metzgeria* (Figure 192) among the predominately fungal spores (65.5%) and flower pollen (23.9%). The liverworts in the spore rain were characteristic of the species growing in the area, so local dispersal could not be ruled out.

Gaur and Kala (1984) tested what is in the spore rain compared to what is growing in the Himalayan alpine zone of India. They used adhesive-coated slides at 3600 m asl

The most comprehensive study seems to be that of Ross-Davis and Frego (2004;

Table 1). They examined the propagule sources of forest floor bryophytes in two mature mixed-wood forests in southeastern New Brunswick, Canada. The bryophyte communities in the two forest locations they studied revealed 36 bryophyte taxa. They found 51 taxa in the diaspore rain and diaspore bank. They furthermore found seasonal differences in the diaspore rain. Of the extant species present, 36% were absent in both the spore rain and the diaspore bank. Both communities were dominated by the feather mosses *Pleurozium schreberi* (Figure 193) and *Hylocomium splendens* (Figure 194), and these two species were present in both the spore rain and the buried diaspore bank. But the dominant taxon in the diaspore bank was *Sphagnum* (Figure 195), which was not present among the extant flora in either location. Up to 22 species from the diaspore bank were able to germinate after a six-hour culture. The aerial diaspore composition was 62% similar between the two locations, whereas the diaspore bank had only 34% similarity.

But these studies are very local and tell us little about what species are most likely to be encountered in the

atmosphere. There are certainly not enough studies to assess the types of characters that seem to contribute to

their presence. May I suggest, then, that the most likely entrants into the aerial realm are those diaspores (mostly spores) that are small, light weight, perhaps have surface waxes or papillae that increase their surface area and buoyancy without adding proportional weight, and have some means of getting away from the capsule and into the air stream, such as the explosive expulsion of spores from a *Sphagnum* capsule (see Chapter 4-9). Research by Sundberg (2012) on *Sphagnum*, discussed in Chapter 4-8 under Everything is Everywhere, supports my last suggestion, but I have little support to offer for my other suggestions. They must also have a means to survive desiccation and protection against UV radiation. Testing these should provide for an interesting set of experiments. But first, we must find out what is in the spore rain around the world. This will be challenging because the concentrations are quite low. For example, Lewis Smith (1991) found no exotic bryophyte spores in the Antarctic air space, yet new volcanic land that was heated became colonized by species not known for more than 1000 km, suggesting that the diaspores are there in the diaspore rain but are too dilute to be sufficiently captured by our sampling methods.

Spore Dispersal Mechanisms

We might think of spore dispersal as having the same potential mechanisms as pollen dispersal, but some caveats exist. The flowers have carried the variety of dispersal agents to extremes, utilizing birds, bats, a variety of insects, water, gravity, and wind, and to a lesser extent, other mammals and invertebrate animals. To accomplish this great diversity, especially among the animal vectors, the flowers have spent tremendous energy in the production of attracting organs (the flowers themselves) that have colors, shapes, odors, and rewards that beguile their benefactors. Among the bryophytes, such extravagant expenditures of costly energy and biomass are rare, but some do exist (see subchapter 4-8).

For the seed plants, Hughes *et al.* (1994) concluded that plant growth form and stature can exclude certain dispersal modes. Since bryophytes generally are shorter in stature than their tracheophyte counterparts, we could expect all of them to exclude certain types of dispersal such as being eaten by large mammals. But some bryophytes could get around this problem by growing on trees, should any be suitable food for tall mammals. Their growth forms are such that they easily trap spores that pass by them, so the elevation of the capsule on a seta in most species seems necessary to reduce self-entrapment.

The third conclusion of Hughes *et al.* (1994) was that the availability of specific dispersal vectors seems to have no influence on dispersal mode. That conclusion needs some consideration, and dispersal vectors will be discussed in a later subchapter. But the wide range of dispersal vectors available to seed plants seems to have little similarity to the dispersal modes used by or even available to bryophytes in the same habitats, largely due to the small size of both the bryophyte plants and the propagules (Hughes *et al.* 1994).

Finally, Hughes *et al.* (1994) concluded that attributes of the physical environment rarely are important except

indirectly through influencing plant stature and seed size. We have discussed above the meager evidence to support the influence of the physical environment on spore size in bryophytes; for example, it does seem that ephemeral habitats may have placed a selection pressure for larger spores [e.g. Bijlsma *et al.* 2012 for *Ephemerum* spp. (Figure 98)]. Living among other vegetation that can trap the spores, including forest canopies, may prevent them from getting into the air stream. I do wonder if bryophytes that live high on vertical surfaces (Figure 196) may be influenced in their success by the greater opportunity for wind carriage due to greater wind velocity, as shown for seeds by Greene and Johnson (1996). Perhaps there is a relationship to spore size and in some cases to the plant overall structure in such habitats.

Figure 196. *Tortella fragilis* at Khibiny Mountains, Apatity, Murmansk, demonstrating a vertical substrate at a high elevation where it might more easily become windborne. Photo by Michael Lüth, with permission.

Sporophyte Adaptations for Dispersal

Hedenäs (2001) elevated the role of dispersal in evolution and considered spore dispersal to be one of the two functions causing differences in character state frequencies among various environments. He considered such spore dispersal to be related to **shape and orientation of capsules, annulus, appearance of exostome and endostome, spore size, spore maturation time, and seta length**. One might ask if aquatic mosses in general have short or absent setae, as in *Fontinalis* (Figure 144), thus reducing the chance of drag dislodging the capsule before maturity, and do epiphytes truly more commonly have erect capsules?

Stark (2001) compared capsule adaptations of two Mojave Desert species of mosses. They differed both in morphology and in period of distribution. The *Grimmia orbicularis* capsule (Figure 197) is inclined, short, and broad, releasing its spores over about 6 months; its position on nearly vertical rock surfaces permits it to drop the opercula and liberate spores quickly. The ground-dwelling *Syntrichia inermis* (Figure 198) releases its spores from a single cohort of capsules over a period of three years. Dispersal of the operculum and spores is less certain for this soil-dwelling species, and the operculum detachment period can last up to 2.5 years.

Figure 197. *Grimmia orbicularis* from southern Europe, showing the short, broad, inclined capsule and the vertical substrate. Photo by Michael Lüth, with permission.

Figure 198. *Syntrichia inermis* growing on soil. Photo by Jan-Peter Frahm, with permission.

Crawford *et al.* (2009) found an evolutionary relationship between separate sexes and small spores, although this might be backwards since it appears that evolution in mosses tends to go from the dioicous condition to the monoicous one through doubling of the chromosome number (often through the failure of meiosis) or addition of a sex chromosome. Hence, we might consider that large spores are more common in monoicous taxa, a phenomenon that might result from the doubling of chromosome number.

Most bryophyte spores are wind dispersed, carrying many, probably most, to unsuitable habitats, but usually assuring that at least some will not land among their parents. Nevertheless, some bryophytes have evolved ingenious dispersal mechanisms. The simple bryophytes lack the resources to create such large and elaborate structures as flowers, but have, even so, in some cases (*e.g.* *Splachnaceae*, Figure 199) created highly visible and odiferous attractions to their dispersal vectors, as described in Chapter 4-9 of this volume. Nevertheless, most bryophytes seem to rely on wind and gravity as their primary dispersal agents. To this end, **mosses** have developed elaborate **peristome** teeth (Figure 200) that move in response to moisture changes and that tend to facilitate spore dispersal in dry air when the greatest opportunity for wind dispersal prevails (Bonnot 1978). The teeth are covered by an **operculum** (Figure 201) that seals the capsule and that is usually shed in response to drying and shrinkage of the capsule. It appears that this mode is highly successful, and the exceptions to wind dispersal are few.

Figure 201. *Brachythecium populeum* capsules showing opercula. Photo by Des Callaghan, with permission.

One of the features of sporophytes that has fascinated my students is the twisting of the seta. When a dehydrated moss with sporophyte intact is hydrated, the seta of many species, *e.g.* *Dicranella heteromalla* (Figure 202), will gyrate in a spiral fashion, loosely coiling and uncoiling as its cells become hydrated, presumably unequally. Unfortunately, I have not observed that this has any effect on spore dispersal and must wonder if it is simply a consequence of the anatomy with no adaptive consequence at all. I am constantly reminded by the bryophytes that "all life has a twist in it."

Figure 202. *Dicranella heteromalla* with capsules and twisted setae that gyrate when the moisture changes. Photo by Biopix, through Creative Commons.

Sundberg (2005) examined capsule size in *Sphagnum* (Figure 203) to determine its possible role in dispersal distance. He tested four species of *Sphagnum* and found that the diameter of the capsule containing the spores was negatively correlated with the proportion of spores remaining in the capsule after dehiscence (5-16%), negatively correlated with those being deposited within the colony (2-14%), and negatively correlated with those being deposited between the colony edge and the outer sampled perimeter of 3.2 m (7-22%). These negative correlations imply that the larger diameter of the capsule somehow facilitates a greater dispersal distance.

Figure 203. *Sphagnum fimbriatum* with capsules that have lost their opercula. Photo by David T. Holyoak, with permission.

Thiers (1988) described morphological adaptations of the dispersal of liverwort propagules in the order **Jungermanniales** to their tropical habitat. These included **precociously** germinating spores (spores that germinate within the capsule; Figure 204-Figure 205), followed by a prolonged protonemal stage, and culminating in a **neotonic** life cycle (reproducing at an early developmental stage).

Role of Peristome

The peristome teeth have various patterns of movement, with some resting inward and others resting outward. The structure of the teeth often causes uneven shrinkage as they dry, causing them to pulsate or even twist. Patterson (1953) described three behavior types for peristome teeth:

1. teeth wherein outer teeth either exclusively or predominately bend inward [*Ceratodon* (Figure 206), *Barbula* (Figure 207), *Pylaisia* s.l. (Figure 208)]
2. teeth with outer teeth shrinking exclusively or predominately bending outward [*Grimmia* (Figure 209), *Orthotrichum* (Figure 210-Figure 211), *Dicranum* (Figure 212)]
3. teeth that oscillate strongly as they change from shrunken to swollen states [*Amblystegium* (Figure 213), *Hypnum* (Figure 214), *Neckera* (Figure 215), *Bryum* (Figure 216)]

Figure 216. *Bryum caespitium* peristome, with teeth that flex as they change moisture states. Photo by Michael Lüth, with permission.

Schnepf *et al.* (1978) described the movement of the outer peristome in the moss *Racopilum intermedium* (Figure 217). This movement arises from different swelling velocities of the outer plates and inner ridges of wall thickenings. These swelling differences arise from the suberin-like substances and wax lamellae enclosing the ridges. There is no suberin-like material in the plates.

Figure 217. *Racopilum intermedium* with capsules. Photo by Michael Lüth, with permission.

Estébanez *et al.* (2002) determined that strongly bound lipids, phenolics, and non-cellulosic polysaccharides were responsible for the movement of the teeth in *Arctoa fulvella* (Figure 218), *Grimmia decipiens* (Figure 219), *Grimmia pulvinata* (Figure 220), *Schistidium rivulare* (Figure 221), *Bucklandiella sudetica* (= *Racomitrium sudeticum*; Figure 222), *Ptychomitrium sinense* (Figure 223), *Glyphomitrium humillimum* (Figure 224), and *Venturiella sinensis* (Figure 225).

Takakia ceratophylla (Figure 226) has a dispersal mechanism that is unusual among mosses. The capsule has a spiral line of dehiscence. At maturity, when the capsule splits, this suture causes a spiral twisting that seems to help in spore dispersal (Higuchi & Zhang 1998). In many of the mosses, the annulus becomes modified as the capsule dries. For example, in *Ludorugbya springbokorum* the annulus rolls inwards, nearly covering the opening of the capsule (Hedderston & Zander 2007). Upon wetting, it rapidly everts, expanding the capsule opening. This exposes the two-sized spores within.

Figure 226. *Takakia ceratophylla* capsule showing spiral split. Photo by Ken McFarland, with permission.

Some bryophytes do not typically shed the operculum, but instead rely on disintegration of the capsule wall. *Buxbaumia aphylla* (Figure 227) seems rarely to shed the operculum (Glime & Liao, pers. obs.). Instead, the capsule cracks across its broad, flat upper face, peeling back to expose the spores (Figure 227). Eventually the tissue peels away, permitting the spores to escape. The protonema in this species produces sporophytes every year, and in Newfoundland, these sporophytes, which must overwinter to release the ripe spores in spring, can suffer high mortality from sudden frosts (Hancock 1973). *Diphyscium* (Figure 228) has a capsule with a similar small opening, but it does seem at least to shed the operculum. If it relies on the capsule splitting, I have not yet been able to observe it.

Figure 227. Capsules of *Buxbaumia aphylla* showing peeled away capsule wall on upper capsule. Photo by Janice Glime.

Figure 228. *Diphyscium foliosum* females with capsules showing shed operculum and teeth. Photo by Michael Lüth, with permission.

From my own observations, I concluded that *Fontinalis* (Figure 144) depends on abrasion for loss of the operculum. In spite of its beautiful lattice teeth, the operculum remains intact and winter-borne capsules become abraded by the silt load of melt waters. This abrasion removes sufficient tissue for spore dispersal to occur. In the absence of abrasion, the capsules seem to be so impregnated with phenolic compounds that the suture between the operculum and capsule body firmly glues them

together. But others have observed the beautiful teeth and spore dispersal, so my observations may only be of the unsuccessful capsules that remained after the others had dispersed their spores.

Cleistocarpy

In some mosses, the capsules have no peristome or operculum, a condition known as **cleistocarpy**. Such is the case for *Archidium ohioense* (Figure 109) and *Trachycarpidium tisserantii* (Makinde & Odu 1994). As already noted, these two species had poor spore release, compared to that of the two peristomate mosses, *Fissidens ovatifolius* (as *Fissidens minutulus*; Figure 229) and *Bryum coronatum* (Figure 93). All four species benefitted in their savannah habitat in Nigeria by having a rapid maturation cycle for their capsules.

Figure 229. *Fissidens ovatifolius*. Photo by Jan-Peter Frahm, with permission.

In *Archidium* (Figure 109), the cleistocarpous capsule hides on a short seta among the leaves. At maturity, the capsule wall ruptures by decomposition, permitting spores to escape (Lönnell 2011). Lönnell suggests that this method of spore exposure and the large size of the spores are not supportive of wind dispersal and that use of another agent, perhaps water, is more likely. *Riccia* species likewise have large spores (Figure 230). Their presence in flood plains and other habitats that periodically get reasonably inundated with running water suggests that the same may be true for them.

Herrnstadt and Heyn (1988) have pointed out to us that a similar elaborate, complex, **sexine** (outer, sculptured layer of exine) spore wall pattern is common to a large percentage of the species that have cleistocarpous capsules or lack a peristome. These cleistocarpous species typically are small mosses, annual, terrestrial, and living in open habitats, particularly in the Mediterranean and adjacent arid regions. They furthermore have capsules that are immersed in the perichaetial leaves and possess large spores [(25) 30-40 μm]. Does this mean that this spore wall pattern has an adaptive value in arid regions?

Figure 230. *Riccia sorocarpa* showing the large, highly pigmented spores. Photo by Des Callaghan, with permission.

Summary

Diaspores include both spores and other propagules that serve in dispersal. These are typically sampled by exposed agar plates, glass slides with glycerine, or traps, including Tauber and Burkard traps.

Spores are usually smaller than vegetative diaspores and are therefore the most successful agents of long-distance dispersal in bryophytes, whereas vegetative means help the population to become established and spread once having arrived. But spores require fertilization as a prerequisite and therefore nearness of males and females. Vegetative diaspores continue in production under stressful conditions, but spores do not. Fragmentation is common in many species and seems only to require dry conditions; animals can help both in fragmenting and in carrying these propagules.

The success of dispersal and range size seems to be related to the abundance of sporophyte production. On the other hand, genetic information, at least for some species (especially **Polytrichaceae**), suggests that vegetative dispersal may be more important, even in species that produce abundant spores, perhaps due to spore dispersal limitations.

Dispersal success requires a tradeoff between energy spent on short-distance but energy-rich diaspores and energy wasted for a few of many spores produced that succeed in long-distance dispersal. Vegetative reproduction requires a tradeoff between likely success and loss of genetic diversity. Liverworts, as a group, seem to spend more energy on asexual reproduction than do mosses.

Disturbance can create conditions for vegetative growth, bring buried diaspores to the surface where they can germinate, and disperse propagules for short or long distances. Some species are especially adapted to

disturbances such as fires, floods, cold events, and even ants.

Diaspore banks are important for species that live in disturbed habitats. The spores of species that are regularly disturbed, such as floodplains, are typically large and these species may have rhizoidal tubers or other forms of rhizoidal propagules. For those that grow in areas of unpredictable disturbances, taxa that are easily dispersed, such as *Funaria hygrometrica* and *Marchantia polymorpha*, are often important colonizers and can survive in spore banks as well as arriving through aerial dispersal. Representation in the diaspore banks often does not reflect the species at the surface, but rather has a strong bias toward acrocarpous species and species of early successional stages.

Peristome teeth in mosses, an **explosive capsule** in *Sphagnum*, and **elaters** in liverworts help in dislodging spores and dispersing them. Other factors influencing dispersal are capsule size, shape, and orientation, annulus, exostome, endostome, spore size, maturation time, and seta length. Some rely on splitting of the capsule, including **cleistocarp**. Strongly bound lipids, phenolics, and non-cellulosic polysaccharides contribute to peristome movement. Flood plain species tend to have large spores that permit a rapid life cycle. Dioicous species tend to have smaller spores, permitting them to travel farther on those occasions when sexual reproduction is successful. In some species, the spore size varies with altitude.

Maturation time can be important. For most spores, a dry atmosphere is favorable for longer distance dispersal. For vegetative propagules, some are favored by rain and others by dry wind.

It is likely that many species have spores that can survive years of dormancy, and some may survive hundreds of years while dry and in the dark. Those that start to germinate, then dry out again, will most likely die. Spores are also kept dormant by their parents, most likely due to chemicals from the parents.

Acknowledgments

This chapter has benefitted greatly from the wonderful discussion on Bryonet in March 2013. Thank you also to the helpful comments of a novice bryologist, Tatiany Oliveira da Silva, on places that needed to be clearer for international and novice readers. Karen Renzaglia provided images that I requested for specific purposes. William T. Doyle gave me permission to use any of his wonderful SEM images of liverworts and hornworts. Steve Trynoski offered several suggestions after a critical reading of this subchapter.

CHAPTER 4-8

ADAPTIVE STRATEGIES: TRAVELLING THE DISTANCE TO SUCCESS

Figure 1. *Conostomum tetragonum* with capsules in the mountains of Norway where its spores become windborne more easily than those of bryophytes in the forest. Photo by Michael Lüth, with permission.

Diaspore Travel Distances

Although bryophyte spores are typically wind-dispersed, it appears that few actually travel very far. Most never actually become airborne (Wyatt 1977; Stoneburner *et al.* 1992). More typically, most of the spores fall within a meter or less (Crum 2001) of the capsule. It is likely that the bryophytes themselves act as spore traps, particularly for the neighboring plants of their own species. Pardoe *et al.* (2010), using mosses to compare trapping efficiencies, demonstrated that mosses serve as traps for pollen, suggesting that they should be traps for bryophyte spores as well.

But trapping spores and quantifying atmospheric spore rain is difficult at best, and the worldwide distribution of a number of taxa attests to the fact that these diaspores must at least occasionally travel great distances. There are tests of survivability for spores, but even less is known about vegetative diaspores.

Failure to Leave Home

Most spores will fall near the parent. In *Tortula truncata* (= *Pottia truncata*; Figure 2), 67% of the spores released fell within the parent clump and 70% within 2 m (Roads & Longton 2003). Further evidence of lack of gene flow to new locations is that there was little or no genetic variation within the individual clumps, but no genotypes were in common between the populations, suggesting that genes (including those in spores) from one population clump had not reached the other one. Sundberg (2005) found that for six species of *Sphagnum* (Figure 3), 8-32% of the spores that dispersed beyond the colony did not travel beyond the active release area of 3.2 m. Stoneburner *et al.* (1992) demonstrated this stay-at-home behavior experimentally for *Atrichum angustatum* (Figure 5). In that species, 94% of the spores were collected within 2 m of the colony center; 1% were found 15 m from the center. On the other hand, Miles and Longton (1990, 1992b) found

that more than 80% of the spores of *Atrichum undulatum* (Figure 6) and *Bryum argenteum* (Figure 7) travelled beyond their 2-m trapping distance.

Figure 2. *Tortula truncata* (= *Pottia truncata*) with capsules; most of the spores fall within the parent clump. Photo by Des Callaghan, with permission.

Figure 3. *Sphagnum fimbriatum* with capsules. Photo by David Holyoak, with permission.

Figure 4. *Tortula acaulon* (= *Phascum cuspidatum*) with capsules. Photo by Jan-Peter Frahm, with permission.

In *Tortula acaulon* (= *Phascum cuspidatum*) (Figure 4), 98% of the spores remained within the colony in this annual shuttle species (Roads & Longton 2006). This resulted in three of the five permanent quadrats having this species in them again in the second year. Many of the

second-year colonies overlapped with the position of the first-year colonies, suggesting that spores fell close to home.

Figure 5. *Atrichum angustatum* with immature capsules; most spores apparently travel more than 2 m. Photo by Janice Glime.

Figure 7. *Bryum argenteum* with capsules in Europe. Most spores are apparently able to travel more than 2 m. Michael Lüth, with permission.

Polytrichaceae

Atrichum undulatum (Figure 6) may not be a good example of dispersal distance in bryophytes due to its

presence of an epiphragm. This membrane, a characteristic of the **Polytrichaceae**, connects the 32 teeth and prevents spores from leaving from the top of the capsule, forcing them to leave between the teeth (Figure 8-Figure 9; see also Figure 61). Such a mechanism precludes the upward thrust that might be seen in some capsules where spores can travel upward directly. Rather, it is likely that spore dispersal in this species is facilitated by raindrops on the epiphragm, as is known for *Dawsonia* (Figure 10), limiting its dispersal (van Zanten 1973) both by the wet atmosphere and the horizontal ejection because they are not ejected high enough to reach the wind turbulence.

Figure 8. *Atrichum undulatum* showing epiphragm membrane extended across opening and attached to teeth like a trampoline. Photo from UBC website, with permission from Wilf Schofield.

Figure 9. *Atrichum undulatum* with openings between peristome teeth showing spores. Photo from UBC website, with permission from Wilf Schofield.

Thus, based on limited data, it seems to be accepted that most bryophytes probably only disperse the majority of their spores within about 2 m (Table 1). But only a few spores need go farther to accomplish long-distance dispersal, and some species seem more able than others to accomplish this. Stoneburner *et al.* (1992) found that when air volume was increased, 4.5 million out of 25.8 million spores of *Atrichum angustatum* (Figure 5) from the colony reached the limits of their 15-m study area. Just think what would happen to spores caught in the updrafts of a forest fire or tornado!

Evidence from a Road Cut

Miller and McDaniel (2004) used a novel method to estimate the distance and rate of dispersal that delivered new species to a new substrate. Using a highway construction site on Whiteface Mountain, New York, USA (Figure 11), they examined the bryophytes on concrete mortar there and found that it had increased the bryophyte diversity by 50% above that found on local rock substrata. The local and mortar bryophyte floras differed considerably. Many of these new species were typical of lower elevation forests, at least 5 km distant, where they were not on concrete. The new diversity suggested that these colonizers had arrived and established at the rate of at least one species per year during the 65 years since the highway construction. Miller and McDaniel concluded that for at least some bryophytes, dispersal over 5 km or more are routine events.

Figure 11. Whiteface Mountain, NY, with new-fallen snow at the summit. Photo from Wikimedia Commons.

Epiphytes

For epiphytes, dispersal must necessarily be more than a few meters for the species to survive natural die-off of forest trees, not to mention the ravages of harvesting. Snäll *et al.* (2003) found that the occurrence of the epiphyte *Orthotrichum speciosum* (Figure 12) in a fragmented forest landscape was most affected by shading, but also by connectivity to nearby tree patches, aspen (*Populus*) tree diameter, and forest vitality, suggesting that age of forest was a contributing factor, perhaps in providing more time for colonization. Furthermore, once either *O. speciosum* or *O. obtusifolium* (Figure 13-Figure 14) became established on a tree, the species remained there until the tree died. Local extinctions were entirely a function of the life of the host tree. Hedenäs *et al.* (2003) found that environmental variables seemed to have little influence on the epiphytes (including *O. obtusifolium*) in a *Populus tremula* stand. Rather, asexually dispersing species were more common than sexually dispersing ones. Sexually dispersing species tended to be more aggregated than the tree species, whereas the asexually dispersing ones had a distribution similar to that of their host.

Figure 12. *Orthotrichum speciosum* with capsules. Photo by Michael Lüth, with permission.

Figure 13. *Orthotrichum obtusifolium* on bark, a species that remains with its host tree until the tree dies. Photo by Michael Lüth, with permission.

Figure 14. *Orthotrichum obtusifolium* with gemmae on leaves. Photo by Michael Lüth, with permission.

The occurrence of *O. obtusifolium* (Figure 13-Figure 14) in the fragmented landscape was controlled by similar variables but with different relative importance. Unlike *O. speciosum* (Figure 12), colonization of *O. obtusifolium* was not affected by connectivity. Snäll *et al.* (2004a) found that there was significant kinship between individuals of both *Orthotrichum speciosum* and *O. obtusifolium* up to 350 m apart. Snäll and coworkers suggested that this indicated they were dispersal limited and might be threatened by current silvicultural practices. Nevertheless, this distance is superior to that of the species listed in Table 1, although it probably represents **stepping stone** dispersal, discussed below.

For the epiphyte *Neckera pennata* (Figure 15-Figure 16) the past history of its occurrence accounted for much of its current distribution, emphasizing the importance of nearby sources of diaspores (Snäll *et al.* 2004b). Snäll and coworkers (2004b) suggested that its dependence on connectivity, tree age, and tree diameter (a surrogate for tree age) indicate a restricted dispersal range for *Neckera pennata*. Its primary distribution at heights of less than 1.6 m on the tree could also be a response to the restricted dispersal range.

Figure 15. *Neckera pennata* on bark of *Thuja occidentalis*. Photo by Janice Glime.

Figure 16. *Neckera pennata* branch with capsules, a species that seems to be dispersal limited. Photo by Jan-Peter Frahm, with permission.

Disturbed and Short-lived Substrata

One might assume that short-lived substrata would drive selection for species that have good dispersal capability. It appears that *Ptilidium pulcherrimum* (Figure 17) from rotting logs in the coastal peninsula of northern Sweden has a somewhat better dispersal than the epiphytes mentioned above where the tree substrate is stable for a longer period of time. Söderström and Jonsson (1989) found that only 43% of the spores of log-dwelling *Ptilidium pulcherrimum* produced remained within 2.5 m of the source, suggesting that 57% were able to travel far enough to reach logs at a greater distance than that.

Figure 17. *Ptilidium pulcherrimum*, a log- and soil-dwelling species that relies on superior dispersal. Photo by Michael Lüth, with permission.

The soil-dwelling *Atrichum angustatum* (Figure 5) seems to be less adapted for dispersal than the log-dwelling *Ptilidium pulcherrimum* (Figure 17), with 94% of the spores of the former falling within 2 m of the colony center, and another 1% falling in the range of 15 m (Stoneburner *et al.* 1992). Hence, the soil-dwelling populations of *P. pulcherrimum* are prepared for dispersal to a greater distance as their habitat becomes uninhabitable. It is therefore not surprising to find it among the early colonizers of disturbed soil banks and other newly cleared soil in forests as well as on decaying logs.

Herben, *et al.* (1991), likewise using rotting logs, considered the number of spores needed to give rise to

enough new colonies that a bryophyte species could persist in this system of temporary habitat patches. To answer this question, they studied the invasive moss *Orthodontium lineare* (Figure 18) in southern Sweden. This species invades rotting wood, and based on model simulations, its success depends primarily on spore transport and establishment. Disturbance rate, competition, and colony growth are of lesser importance.

Figure 18. *Orthodontium lineare* with numerous capsules that help it to be an invasive species. Photo by David Holyoak, with permission.

If a species thrives in a periodically disturbed habitat such as an arable field or floodplain, then it needs a means of surviving and distributing to suitable substrata when favorable growing conditions occur. But the most favorable circumstances typically are those where it currently exists, and although it is likely that nearby areas are suitable, many distant areas most likely are not. Hence, such species are often adapted for rapid colonization and short-distance dispersal. With these considerations in mind, it is somewhat surprising that diaspore banks in these habitats are typically dominated by spores, such as those of *Physcomitrium sphaericum* (Figure 19; During 1997). On the other hand, habitats with small scale but somewhat regular disturbances usually have species that mostly reproduce asexually.

Figure 19. *Physcomitrium sphaericum* with capsules, a common species in diaspore banks. Photo by Li Zhang, with permission.

In peatlands, disturbances from mining are large scale and recolonization occurs on a bank of peat. The disturbance exposes deep peat where propagules have collected for centuries (Poschlod 1995). Poschlod found that some *Sphagnum* spores can germinate from these older peats following disturbance that exposes them to light. He found that the species appearing after these disturbances are typical of the original vegetation, are represented in the diaspore bank, and are often absent in the diaspore rain. This was likewise true in a dry heath, where the dominant bryophyte re-colonizer was *Campylopus pyriformis* (Figure 20-Figure 21).

Figure 20. *Campylopus pyriformis* with abundant capsules. Photo by Jan-Peter Frahm, with permission.

Figure 21. *Campylopus pyriformis* showing detached leaves that can serve as propagules. Photo by Michael Lüth, with permission.

Richards (1988) considered all substrata useful for bryophyte colonization in tropical forests to be impermanent. He therefore considered it important for those species inhabiting such substrata to have efficient short-distance dispersal. The same will be discussed below (Spore Size and Number) for *Archidium* (Figure 22) species, with large spores, cleistogamous capsules, and poor dispersal ability.

Figure 22. *Archidium alternifolium*. Photo by Andrew Spink, with permission.

Kubisch *et al.* (2014) summarized the importance of interacting factors in facilitating or preventing successful dispersal. Such factors include abiotic factors (wind, air currents) and adaptation to the new environment. They describe these as a "dynamic equilibrium of colonization and local extinction events." These principles should apply to bryophytes.

Long-Distance Dispersal (LDD)

For many bryophytes, there is at least indirect evidence that long-distance travel occurs. On Signy Island in the Antarctic, Marshall and Convey (1997) trapped spores of all five taxa of bryophytes at distances of 0.5-1 km from the nearest known sources, attesting to their ability to travel beyond a short distance. In this case, the spores were more abundant than bryophyte plant fragments in the trappings, and the representation of both was proportionately smaller than that of lichens.

A number of studies have demonstrated that typical bryophyte distance curves for spore dispersal are **leptokurtic** (Mogensen 1981). That is, they look like an exponential curve, but with a fat tail, *i.e.*, the numbers are greater close to the source and again at substantial distances than would be expected (Figure 23).

Lessons from Tracheophytes

Nekola and White (1999) took a comprehensive approach to evaluating the long-distance dispersal of bryophytes by comparing them to tracheophytes. They examined bryophytes in North American spruce-fir forests and Appalachian montane spruce-fir forests to estimate the rates of "distance decay." Predictably, the similarity of numbers compared to the source decreased significantly with distance. They found that the rate of similarity decay was 1.5-1.9 times as high for tracheophytes as for bryophytes, *i.e.*, bryophytes disperse farther. They considered that two factors cause distance decay: decrease in suitable habitat and limits to dispersal. Since the habitats were the same for both the bryophytes and the tracheophytes, it would imply that either the bryophytes have broader ecological amplitude for such factors as soil type, temperature, moisture, and day length, or they have greater dispersal ability. It is likely that both are true.

Figure 23. Hypothetical leptokurtic data graph showing asymmetrical distribution of data with a fat end on the right. Based on graph by Audrius Meskauskas through Wikimedia Commons.

Iwatsuki (1972) had a somewhat different perspective on the dispersal of bryophytes and their geographic isolation, particularly among the islands of eastern Asia. He considered the distribution of mosses to be comparable to that of tracheophytes and assumed that bryophytes lack an effective means of long-range dispersal. He also considered that bryophytes evolve very slowly, a factor that appears to be true for their morphology but not for their biochemistry and physiology (Glime 2011), and that this lack of evolution results in most moss species having wider ranges than the tracheophytes, *i.e.*, they have not evolved into new species. This perspective made sense based on our morphological understanding of species, but forty years later, with more recent techniques, we are learning that there are DNA differences and that many disjunct or distant populations represent microspecies that differ genetically, and presumably also biochemically. Hence, bryophytes have evolved to occupy somewhat different niches as they have spread to more distant lands. It seems that these wonderful plants have conjured up a million ways to confound us!

In support of Iwatsuki's 1972 premise, Mateo *et al.* (2013) examined the biogeographic regionalization of European bryophytes. They failed to support their first hypothesis, that regions defined for bryophytes would differ from those defined for other taxa due to the highly specific ecophysiology of the bryophyte group, thus adding credence to the suggestion of Iwatsuki. I'm not convinced that they have such a highly specific ecophysiology anyway. Mateo and coworkers concluded that their findings support a greater similarity between migration

patterns of tracheophytes and bryophytes than previously considered. They did, however, find that bryophytes had a substantially lower optimal number of clusters and an absence of nested patterns within primary bryogeographic regions, supporting their second hypothesis. Nevertheless, they cautioned that there are so many regions lacking data that such conclusions are tentative until some of the assumptions and data gaps can be removed.

Certainly some records confirm that bryophytes have broader distributions than do tracheophytes. Jerry Jenkins (Bryonet 6 March 2013) has observed the colonization of his own farmland and second-growth forest in New York State, USA. This area has been invaded by about 100 bryophyte species and a similar number of tracheophytes. He has found a striking contrast in the distributions of the invading species of these two groups. Approximately half of the bryophytes are species known from two or more continents, whereas most of the tracheophytes are restricted to North America, and many to eastern North America. This leads us to examination of the concept that "everything is everywhere."

Everything Is Everywhere!

Baas-Becking (1934) formulated this hypothesis for micro-organisms, promulgating the notion that "everything is everywhere, but, the environment selects." This concept will be discussed later (Interactions volume) for protozoa and small animals. But is the concept applicable to bryophytes, where single-celled spores are among these small, airborne propagules?

The concept of everything is everywhere assumes that small propagules are able to travel the world over, but that once they arrive, they must locate in a suitable environment to survive. Santos-González (2007) discussed this concept for fungi, which, like the bryophytes, can spread by single-celled spores. It is easy enough to show for both fungi and bryophytes that the environment selects, but to demonstrate that everything is everywhere is more challenging. Not only must we demonstrate that air patterns are capable of distributing and redistributing bryophyte spores (and even asexual propagules) to all locations, but we must also demonstrate that they survive the journey. Such experimentation has rarely been attempted.

Bryophyte species are generally more widely distributed than those of tracheophytes (Pisa *et al.* 2013).

Lazarenko (1958) considered the remote transport of moss spores as doubtful in explaining the formation of discontinuous moss ranges. Rather, he, like Iwatsuki (1972), asserted that moss distribution has followed the same principles as that of tracheophytes, following continental drift theory. He uses radiation of species from two distribution centers of *Syntrichia ruralis* (Figure 24) to illustrate the role of the separation of the continents. He rejects the significance of long-distance transport to explain such patterns. While I agree that he has offered a plausible explanation, I do not agree that it is the only one, and I consider it possible that *Syntrichia ruralis* could have been transported from a northern location prior to the Ice Age to

both Europe and North America or been transported at some point in time from one of those continents to the other, perhaps when the species was young, then diverged into the various lineages of similar species, resulting in several degrees of differences. Such transport could have occurred by wind passage. Nevertheless, Lazarenko argues that the ranges of mosses show the same zonal regularities as seed plants. While that may be true, many bryophytes have much wider distributions than seed plants, suggesting a different or easier mode of dispersal. Most bryologists do consider that many bryophytes are capable of long-range dispersal, accounting for the presence of many species on both sides of the Atlantic Ocean and others at both poles. Van Zanten and Pócs (1981) considered it likely that long-distance transport was common for spores under 25 μm . On the other hand, they considered transport across the equator to be difficult, if not impossible.

Figure 24. *Syntrichia ruralis*. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Pisa *et al.* (2013) used *Bryum argenteum* (Figure 7) to demonstrate the Baas-Becking hypothesis. This species has a wide (**cosmopolitan**) distribution. They found that genetic diversity demonstrated environmentally driven genetic variation, with the greatest genetic diversity above 1900 m. There was a significant genetic variation correlation with elevation, but the genetic diversity did not correlate with geographic distance, supporting the concept of long-distance dispersal rather than stepping-stone distribution.

Spore Size and Range

One question that arises in dispersal is that of **effective size** of the dispersal unit. Because of their dominant haploid generation, bryophytes do not conform well to the general genetic models. Bengtsson and Cronberg (2009) investigated the size effect in bryophytes and found that the effective size corresponds well with the smallest size of scored individuals. When only a small number of sporophytes is produced by females in a male-dominated community, the decrease in effective size is most severe. They concluded that the **harmonic mean** (obtained by

dividing number of observations by reciprocal of each number in series) of diploid sporophytes per individual gametophyte is the more relevant measure in determining minimal size needed for effective dispersal.

One way to test "everything is everywhere" and support or refute Lazarenko's assertion is to examine the correlation between spore size and species range. This correlation remains to be done on a broad scale. And this correlation might not be instructive if nearly all bryophyte spores are small enough to travel everywhere. As Schuster (1969) concluded, the evidence of distributions seen at our present point in time does not really permit us to distinguish ancient overland dispersal from more recent dispersal by spores. Delgadillo (1993) discussed this same problem in trying to explain the bryogeographic relationships between the Neotropical flora and that of Africa, areas that share about 334 taxa. These decisions are complicated by rapid evolution vs slow evolution. It is interesting that while the Afro-American liverworts number 74 species, these are all in one family, the **Oxymitriaceae** (Figure 25) (Gradstein 2013). Nevertheless, these constitute about 5% of the Neotropical liverwort flora and 8% of the African liverwort flora. Gradstein treats these as primarily the result of long-distance dispersal.

Figure 25. *Oxymitra incrassata* (Oxymitriaceae), representing the only Afro-American liverwort family. Photo by Michael Lüth, with permission.

Distribution Stories

Schuster (1979) attempted to understand the distribution of liverworts in the Southern Hemisphere, where "old" families seem to predominate. He considered dispersal there to be the result of short-range or "step-wise" (referred to herein as "**stepping stone**") dispersal. This explanation relies on the separation of populations due to the fragmentation of Gondwanaland (Figure 26) and makes assumptions about the rate of speciation and efficiency of long-distance dispersal compared to the presumed geological background. Schuster (1982) explained the origin of plant groups in the southernmost Gondwanaland with the continental fragments (Figure 26) as "floating Noah's arks."

Figure 26. Gondwanaland breakup. Redrawn from Richard W. Hughes.

Ceratodon purpureus (Figure 27) arrived on one of the outer Aleutian Islands within less than a year of eruption (Rod Seppelt, Bryonet 11 March 2013). Surtsey was colonized by bryophytes by 1967 following the island's emergence from the sea off the Iceland coast in 1963 (Fridriksson & Magnússon 1992). However, the first vascular plant was found there in just two years after eruption, in 1965.

Figure 27. *Ceratodon purpureus* with capsules. Photo courtesy of GERALYN MERKEY.

In New Zealand populations of *Sphagnum plumulosum* (= *S. subnitens*; Figure 28), Eric Karlin, Jon Shaw, and Dick Andrus (Karlin *et al.* 2011) found that only two genetic signatures existed, representing two founding parents (Rogers 2011). In northwestern North America, they found 100% of the gene pool was derived from one individual! This means that to colonize the widespread areas in these two regions required considerable dispersal. They determined that this dispersal involved both vegetative fragments and spore dispersal. They also concluded that the spread of this species from Europe to North America and to New Zealand was by humans within the last 300 years, followed by non-human dispersal to reach their present ranges in those two regions.

Island Colonization Stories

Surtsey, off the southeast coast of Iceland, provided a natural experiment in colonization following its volcanic emergence from the sea. The primary colonizers were mosses and lichens on the hardened lava and tracheophytes on ash. Colonization on Surtsey compared to Katmai in having few Cyanobacteria, but differed from Krakatau, where the primary colonizers were Cyanobacteria (Brock 1973). Tracheophytes arriving and becoming established were inversely proportional to the distance from the available source, the nearest being a rock 5.1 km away (Fridriksson 1987). However, distance to the mainland is more than 35 km.

Bryophyte invasion lagged behind that of tracheophytes. This may be the result of dispersal types, with most of the tracheophytes arriving with birds (Magnússon *et al.* 2009). Nevertheless, by 2008 on the block lava on the eastern part of the island, tracheophytes were still poorly represented. Instead, the lichen *Stereocaulon* and moss *Racomitrium* (Figure 29) predominated. By 1994, the Lesser Black-backed Gull invaded the southern barren lava and used the *Racomitrium* as nesting material. The effect of these birds in spreading the moss on the island is unknown.

The Northern Stockholm archipelago in the Baltic Sea can provide a test of dispersal and "everything is everywhere." Among the 19 islands, Sundberg *et al.* (2006) found 500 patches of *Sphagnum* in 19 species in 83 rock pools on 14 of these islands. The species richness on the islands correlated positively with island area and degree of shelter by surrounding islands, emphasizing the importance of habitat even when other locations might be more accessible. Supporting this habitat importance, they found that distance from mainland, connectivity, height, and age did not add to the predictability of the island flora. This suggests the importance of aerial dispersal over long distances. Furthermore, spore size did not add to the model, supporting my suggestion that most bryophyte spores might be small enough to be "everywhere." However, individual species did differ in the habitats they occupied, supporting the concept of "the environment selects." Species frequency (number of colonized islands and rock pools) was predicted primarily by spore output of the species on the mainland.

Figure 29. *Racomitrium lanuginosum* on rock. Photo by Janice Glime.

The choice of *Sphagnum* from these Baltic islands is a good one to support the Baas-Becking hypothesis. *Sphagnum* has no specialized asexual reproductive structures (Sundberg *et al.* 2006), although the importance of fragmentation in this genus is poorly known. Furthermore, only 2% of the *Sphagnum* patches on the islands produced sporophytes, and these were mostly on *Sphagnum fimbriatum* (Figure 30). Hence, we can be reasonably certain that there has been little or no stepping stone dispersal (discussed below) and that colonization is the result of spore dispersal from the mainland. Sundberg *et al.* concluded that the *Sphagnum* on the island is the product of centuries of colonization, but that it is not dispersal limited.

Figure 30. *Sphagnum fimbriatum* in Europe. Photo by Michael Lüth, with permission.

Reverse Colonization

For whatever reasons, ecologists have tended to consider islands to be the end of the journal for dispersal of species. But Bellemain and Ricklefs (2008) challenged that concept. They reasoned that if propagules could get to the island, their descendants could get from the island to the mainland. In most cases, we could expect their dispersal abilities to be as good as those of their ancestors. They supported this hypothesis with molecular phylogenies that revealed several examples of **reverse colonization** from islands to continents. But their work was based on animals. What does it mean for bryophytes?

Hutsemékers *et al.* (2011) addressed this question for spore-producing plants. They noted that arguments against reverse colonization focussed on the assumption that island colonizers lose their dispersal power and that back colonization is unlikely due to prior occupation of the niche. Using the Azores, Canary Islands, and Madeira, they found that the aquatic moss *Platyhypnidium riparioides* (Figure 31) does not lose its dispersal ability on the islands. This is not surprising since its primary means of dispersal is by fragments that travel downstream. They further found that mainland populations experienced a severe bottleneck during the last glacial maximum. Hence, instead of being dead ends for the propagules, these islands serve as major sources of biodiversity for postglacial recolonization of Europe, at least for this spore-bearing moss.

Figure 31. *Platyhypnidium riparioides* in a typical stream habitat. Photo by Hermann Schachner, through Creative Commons.

In the aquatic moss *Platyhypnidium riparioides* (Figure 31) there was a significant correlation between the strong genetic variation among populations at a regional scale and the genetic distances (Hutsemékers *et al.* 2010a). However, at a landscape scale, strong dispersal limitation seems to result different histories between southern and northern groups. Furthermore, ecological and genetic variation correlate, suggesting there is reproductive isolation among ecotypes.

Laenen *et al.* (2011) also supported the reverse colonization concept from nearby islands to Europe. They found that Macaronesia exhibited low rates of endemism for bryophytes. Using *Radula lindenberiana* (Figure 32) as a model, they found that European populations share a common Macaronesian ancestor, supporting the view that this island served as a source to repopulate the species in Europe in the postglacial time. They further suggested that the reduced size of bryophytes could account for the diminished amount of morphological variation in these Macaronesian populations. They concluded that islands such as these could have served as refugia during glacial times.

Figure 32. *Radula lindenbergiana*; European populations share a common Macronesian ancestor. Photo by Hermann Schachner, through Creative Commons.

I raised this question of reduced morphological variation many years ago and suggested that bryophytes diversified biochemically as they struggled to persist against the advances of herbivory, fungal attack, and competition with larger plants (Glime 2011). Laenen *et al.* (2014) suggested another explanation. They used statistical rate analysis with time calibration to support the hypothesis that both mosses and liverworts experienced bursts of diversification since the mid-Mesozoic. The current low number of extant species is the result of mass extinctions, with fossil finds not adequately representing their history.

Cronberg *et al.* (2006) explored the variation in the genetic clonal structure of the **dioicous** *Hylocomium splendens* (Figure 33). Using five 10x10 cm plots monitored for five years, they determined the allozyme haplotype of 157 ramets and those from an additional four neighboring plots. They found only four haplotypes within the plots. One female type occurred in all plots and one male type occurred in four plots. Genets were growing intermingled. Although sporophytes were abundant, they found no evidence of recruitment from spores. Their evidence suggests that clonal diversity within patches is determined by vegetative reproduction, in this case by branching and fragmentation. Among patches, sexual processes, *i.e.* production of spores, dominates diversity.

Figure 33. *Hylocomium splendens*, a species that has little recruitment from spores. Photo by Daniel Mosquin, with permission.

In their analysis of range disjunctions and speciation of the leafy liverwort *Leptoscyphus* (Figure 34), Devos and Vanderpoorten (2009) found that rather than having its evolution triggered by episodic shifts in habitat conditions, diversity in this liverwort genus seems to be the product of morphological and molecular divergence that has accumulated gradually. This contrasts sharply with the rapid diversification known in at least some tropical trees.

Figure 34. *Leptoscyphus normalis*, in a genus that seems to have accumulated its genetic diversity gradually. Photo by Jeremy Rolfe, through Creative Commons.

Hutsemékers *et al.* (2010b) noted that our traditional way of viewing maintenance, diversity, and evolution of aquatic plants has been:

1. decreasing or erasing patterns of isolation by distance
2. increasing outbreeding
3. resulting in downstream increase of genetic diversity.

In the aquatic moss *Platyhypnidium riparioides* (Figure 31), the geographic partitioning of genetic variation at the scale of the river basin and indirect measures of dispersal fail to support these principles. Instead, the results suggest an overall weaker dispersal ability of the moss compared to that of pollen or wind-dispersed seeds. Unlike the flowering plants, dispersal of sperm to the egg is more difficult in aquatic species of flowing water. Instead, dispersal of fragments is the more common means of arriving at new sites, accounting for the lower degree of diversity among sites for *Platyhypnidium riparioides*. But overall, bryophytes are considered to be more mobile than flowering plants (Preston & Hill 1999).

One of the predictions for island floras is that they would be subject to **Baker's Law**, that colonization by self-compatible organisms is more likely to be successful than colonization by self-incompatible organisms because of the ability for self-compatible organisms to produce offspring without "pollination" agents. By extension, this would mean that monoicous bryophytes would be more successful in colonization than dioicous taxa.

Patiño *et al.* (2013) examined whether loss of dispersal power and bias toward self-compatibility (Baker's Law) were true for island bryophytes. They found that life history traits of oceanic bryophytes differed statistically from those on continents. On the other hand, life history traits between continental bryophytes and those of continental islands were similar. In this regard, monoicous species of bryophytes were in significantly greater

proportion on oceanic islands than on continents. At the same time, oceanic islands had a greater proportion of species that produced specialized asexual propagules, favoring short-distance dispersal. Nevertheless, for the four species examined, the relative frequency of fertile shoots was higher on islands than on continents. They conclude that this evidence indicates a global loss of long-distance dispersal among oceanic island bryophytes, just as seen with the development of flightless birds!

Factors Contributing to Dispersal

Distance from Source

One of the most obvious factors limiting dispersal is distance to be travelled. Sundberg (2005) found that the spore deposition patterns of *Sphagnum* fit the inverse power law (deposition per unit area is proportional to the distance ($R^2 > 0.99$)). Nevertheless, when the curves were extended to infinity, they failed to account for all the spores dispersed. For example, in *Sphagnum squarrosum* (Figure 35), only 11% could be accounted for. Therefore, something else must be occurring. Sundberg suggests that this "something else" is thermal updraft.

Figure 35. *Sphagnum squarrosum* with capsules. Photo by Michael Lüth, with permission.

Sundberg (2012) used cotton cloth traps to assess the *Sphagnum* spore density in spore rain. He estimated that densities were approximately 6 million per m^2 over the season in a large area, but were only 1000 m^{-2} in Svalbard, northern Norway, indicating that all rains are not equal. Spore rain was strongly related to distance from source, especially relating to sources within 200 km. It is interesting that he found larger spores at isolated island sites, suggesting that they originated from distant, humid areas. In boreal areas, *Sphagnum* accounts for immense numbers of spores, a factor that accounts for its ability to colonize quickly in the wetlands there. Most striking to our consideration of long-distance dispersal is his estimate that 1% of the spores were of a trans- or intercontinental origin and that these spores originate from multiple locations.

Hutsemékers *et al.* (2008) used colonization of 52 slag heaps to assess distance and rate of travel of bryophytes. They found that the number of species per slag heap correlates significantly with time elapsed and area size. Of

these colonizers, 44% of the species were recruited from within 6 km. Recruitment from 6-86 km accounted for the remaining 56% that were recruited within 50 years. New slag heaps are mostly colonized by fugitive, weedy species. Those colonized for more than 50 years accumulated perennial species with a **stayer life strategy**. Rare species tend to occur at intermediate stages, experiencing a tradeoff between probability of dispersal and limitation by increasing competition.

Dispersal Pathway

Just as wind-pollinated trees are adapted to disperse their pollen in spring before the leaves come out on the trees to avoid that interference, bryophytes are limited in their dispersal by similar obstructions. Fenton and Bergeron (2006) found that *Sphagnum* (Figure 35) spore abundance in boreal forests of northwestern Quebec, Canada, was inversely correlated with local tree stand density, and suggested that this was evidence that wind intensity may play a role in limiting dispersal. I would add to that the ability of trees to serve as spore traps.

Renner (2004, 2005) used data on direction, strength, and speed of both sea currents and wind jets to explain dispersal of plants across the tropical Atlantic Ocean. He used data from genera, partly because of data availability and partly, as he argued, because families may have broken up (evolved) before dispersal and species had too much anthropogenic influence. Nevertheless, 110 genera contain species on both sides of the tropical Atlantic. Dispersal patterns and disjunctions can be related to water currents between Africa and South America and to exceptional westerly winds from northeastern Brazil to northwest Africa. Although dispersal by water in both directions seems to be more common for these genera than wind or animal dispersal, bryologists have considered the saltwater to be lethal to bryophyte spores. Furthermore, wind dispersal seems to have facilitated spread from South America to West Africa, but not in the opposite direction.

Air Currents

Van Zanten and Gradstein (1988) summarize the air currents that can facilitate long-distance dispersal:

4. dry air streams at relatively low altitudes (<3000 m)
5. hurricanes, tropical storms, or depressions
6. wet air streams at relatively low altitude (< 3000m)
7. dry air streams at high altitudes, *e.g.* jet streams (ca 10,000-12,000 m asl)

These means of transport vary in their limiting factors: high UV, desiccation, wet freezing, low atmospheric pressure, ozone. The two dry airstreams subject the diaspores to desiccation, with the jet stream causing dry freezing and strong UV radiation, but the low altitude transport has only moderate UV radiation. Likewise, the wet air stream at low altitude has even lower UV radiation due to absorption and reflection by clouds. Hurricanes and storms can have wet-freezing and lower atmospheric pressure, accompanied by different air composition. These storms are likely to be less effective for long-distance dispersal because of the heavy precipitation that can clean the air of the diaspores. The wet air streams at low

altitudes seem to be the safest mode of travel, with only moderate desiccation and low UV intensity.

Molecular Clocks

Molecular clocks have become useful tools to determine not only the pathway, but also the timing of transport of propagules (Renner 2005). Using molecular sequences (gene regions), one can estimate the age of a particular lineage and determine its approximate arrival time. Using fossils, models can analyze the change in substitution rates of a lineage by combining molecular data with known time constraints, particularly with fossils. These fossil/molecular "clocks" are termed **relaxed clocks**. These molecular clocks become effective tools that can be combined with information on prevailing wind and water currents, position of land mass, and size of land mass.

Weather

One might assume that wind dispersal is going to be affected by weather. Fungi might serve as a model for expectations of the effect of weather on bryophyte dispersal. In a study on fungal dispersal, Gregory and Hirst (1957) determined that airborne spore concentrations were dependent on weather and the phenology of the local flora. Lönnell (2011) considered horizontal wind speed and thermal updrafts/turbulence as factors that influence the dispersal distances.

Fungi demonstrate the importance of intermittent and gusty wind in spore dispersal (Aylor 1990). And like wind-pollinated trees, canopy plants with leaves can trap the spores and thus must be avoided unless they are indeed the target. For tropical bryophytes, this may be the case, but in temperate zones, tracheophyte leaves are rarely the target substrate. Hence, like the windborne pollen seeking a stigma, the bryophyte pollen must avoid the canopy traps in order to travel any great distance. Aylor points out the importance of gusts of wind in once again removing trapped spores and putting them back into the air. He assumes that gusts can enhance the air movement by a factor of five in the canopy compared to the average air movements. In the fungi, and likely in the bryophytes, half the spores that have ventured only a few meters from their source can escape the canopy if they are released from mid-canopy or higher. If this premise holds, then epiphytes gain considerable dispersal advantage by their high starting location.

A further simulation shows that fluid motion such as that of smoke can cause an ejection type of flow that enhances spore escape from its source. In fact, Aylor (1990) contends that movement of smoke (and similar cloud-type movements of spores) create features similar to release from the top of the canopy. Aylor suggests that the most difficult aspect to model is the "takeoff" from the source and "integration into the transport process," in the bryophyte case being from the capsule.

Fires

I must wonder if forest fires play any role in distribution. Certainly there are tremendous updrafts (Figure 36), but are there updrafts that are cool enough for diaspores to survive? Based on my observations in

Yellowstone after a massive fire, I have to suspect there might be. There were patches of trees burned on one side, but live on the other, suggesting that bryophytes might also survive there but be subjected to the updrafts. But better evidence came from patches of *Pleurozium schreberi* (Figure 37) that were burned on part of a clump but green and healthy only millimeters away. Surely those nearby burned portions were creating updrafts, even if only small ones. It took only a glance at the mountainside to understand the patchiness of the burn itself. Surely these patches of fire created considerable turbulence that could thrust diaspores for considerable distances. If the soot can reach a location, so can the diaspores. And the smoke itself might offer protection from UV light. We need to examine temperature and air movement patterns to further assess the feasibility of these updrafts as dispersal agents.

Figure 37. 1989 view of *Pleurozium schreberi* next to burned soil from a 1988 fire at Dunraven Pass, Yellowstone, Wyoming, USA. Photo by Janice Glime.

Diaspore Characteristics

Not all bryophytes are created equal. Individual characteristics can determine the likelihood of the spores becoming part of the spore rain. Lönnell (2011) lists diaspore size, shape, weight, type of abscission (active or passive), abscission height, and abscission time to contribute to dispersal distances.

Most experiments on bryophyte dispersal have suffered from distance limitations of only a few meters. Lönnell *et al.* (2012) conducted a novel experiment in which they eliminated the possibility of multiple spore sources by isolating a pot of *Discelium nudum* (Figure 38) on a raised bog where its normal clay habitat was unavailable. Hence there was little possibility of other colonies contributing to the experiment. Pots of clay, numbering 2000, were placed at various distances between 5 and 600 m from the mother colony. Within 10 m of the mother colony, the mean colonization rate was greater than 50%. In the 10-50 m range, the colonization rate dropped sharply, but for pots between 50 and 600 m the colonization rate was stable, ranging 1-3%. The estimated number of spores (2-6 per m²) in that most distant segment was commensurate with the spore output of the mother colony. Lönnell considered this to be evidence that the majority of spores of this species escape the parent colony to travel greater distances. Thus, establishment into new locations at distances measurable in kilometers is likely for this and probably a number of other species with similar spore output and dispersal characteristics.

Figure 38. *Discelium nudum* with red antheridia. Photo by David T. Holyoak, with permission.

Work by Hutsemékers *et al.* (2008) adds credence to this assertion of kilometers of dispersal. Using 52 slag heaps in Belgium as pristine soil, they tracked the invasion by bryophytes to heaps at various distances and inferred rate of dispersal by the distance and time of arrival. As expected, the number of species per slag heap is significantly correlated with area size of the heap and time since colonization. It is the weedy species that arrive first, exercising a superior dispersal ability and generally large numbers of spores.

Evidence from Geophysics

Diffusion Models

Levin (1992) contends that generalized diffusion models can explain dispersal of seeds, pollen, and even invertebrate larvae, where winds, currents, and gravity play the major roles. Even organisms that are able to use detailed environmental cues may be dispersed primarily according to diffusion models. Adding habitat-dependent movement can improve the model. Nevertheless, an adequate model can be developed on diffusion alone to explain the spread of oaks and muskrats (Skellam 1951)!

However, Levin (1992) suggests that the diffusion model does not apply well on broader scales and that more refined models are needed. He lists the percolation model for fragmented habitats (Gardner *et al.* 1987; Durrett 1988), the correlated random walk for the movement of insects (Kareiva & Shigesada 1983), or clonal growth for branching organisms (Cain 1990, 1991).

It is likely that models mentioned by Levin (1992) apply as well to a number of bryophyte species. Certainly clonal growth is common among bryophytes and can account for small-scale distribution patterns. The percolation model or the correlated random walk may account for distribution of *Splachnaceae* (dung mosses; Figure 39-Figure 40), where the fly may follow a random pattern of visiting dung piles, but the moss dispersal would be closely correlated to that pattern. It would seem as if these fly-dependent taxa might disperse in a manner similar to that of host-specific parasites.

Figure 39. *Splachnum ampullaceum* capsules on dung in southern Europe. Photo by Michael Lüth, with permission.

Figure 40. Fly visiting capsules of *Tayloria mirabilis* near Cape Horn. Photo by Adam Wilson NYBG, through public domain.

Numerous phytogeographic papers have suggested dispersal patterns over broad areas and linked modern distribution patterns to earlier geologic events. Since major air movement patterns are known, and Van Zanten's work (1975, 1976, 1977a, b, 1978a, b, 1983, 1984, 1985, van Zanten & Gradstein 1987, 1988, van Zanten & Pócs 1981)

provides us with data on aerial survivorship of a number of species, it should be possible to test the diffusion model on bryophytes.

Dust Storms

In their discussion of the global transport of dust, Griffin *et al.* (2002) describe the massive movement of bacteria, viruses, and fungi along with suspended dust particles (and soil pollutants). Just as an example, they estimate that about 13 million metric tons of sediment from Africa land in the North Amazon Basin of South America in a year. Just one dust storm can deliver 200 metric tons.

Charles Darwin, in 1846, expressed the situation as follows: "From the several recorded accounts it appears that the quantity of dust which falls on vessels in the open Atlantic is considerable and that the atmosphere is often rendered quite hazy; but nearer to the African coast the quantity is still more considerable. Vessels have several times run on shore owing to the haziness of the air; and Horsburgh recommends all vessels, for this reason, to avoid the passage between the Cape Verd Archipelago and the main-land." (in Griffin *et al.* 2002). Miles Berkeley (in Griffin *et al.* 2002) concluded that the trade winds could carry fungal spores for thousands of kilometers. German scientists, in 1908, found that the most common bacteria were highly pigmented and all were spore-forming (Griffin *et al.* 2002), suggesting adaptations for aerial dispersal. By 1921, the record height for finding viable bacteria was 21 km above the earth. But these collections had been over land. Finally, in the mid 1930's, Fred Meier, a scientist with the U.S. Department of Agriculture, persuaded Charles Lindbergh to contribute to our knowledge by flying a plane with a metal arm holding microscope slides with a sterile coating of oil while he flew over uninhabited ice, water, and mountains from Maine, USA, to Denmark. These collections revealed fungal spores, pollen, algae, diatoms, and insect wings. Meier then planned sampling over the Caribbean Sea and the Pacific Ocean, but he died in a plane crash in 1938 while doing fieldwork. All these data suggest that bryophytes, too, could enter the jet stream and accomplish long-distance travel.

Not All Storms Are Equal

The next important revelation was that storms of tropical origin were far more likely to enter the upper atmosphere than those of polar origin, carrying nearly 100 times as many fungal spores (Griffin *et al.* 2002). Microbes in the dust in the Virgin Islands show a ten-fold increase during African dust storms. Then a new record for height was set – 77 km above the Earth's surface for some pigmented fungal spores. Of more relevance to the bryophytes is the presence of pollen grains, which might be expected to have similar size and structure to that of bryophyte spores, at 17-19 km above the Earth. This understanding of particle movement is important to our understanding of bryophyte distributions, helping to explain why some tropical bryophytes may appear in polar geothermal areas.

Aloina Example

Numerous authors have attested to the long distance travelling capabilities of bryophyte spores. Kimmerer

(1991) found that many spores were trapped 2 m from the plants and contended that spores ensured long-distance dispersal. Pettersson (1940) filtered spores from precipitation in Finland, then grew them to identify them. Large numbers of spores from *Aloina brevirostris* (Figure 41) were present, as well as those of *A. rigida* (Figure 42), but the genus *Aloina* was unknown in Finland. Both species prefer calcareous substrata and thus are limited in their distribution. Pettersson suggested that they came from Siberia, citing the absence of *A. rigida* in nearby European countries, but Persson (1944) and Bergeron (1944) both rejected that hypothesis.

Persson argued that Pettersson ignored the other species that accompanied the *Aloina* (Figure 42). Among these, *Bryum pallens* (Figure 43), *Leptobryum pyriforme* (Figure 44), and *Marchantia polymorpha* (Figure 45) present no problem, all being common in both Europe and Siberia. However, *Metzgeria* was not known from Siberia, although *Echinomitrium furcatum* (= *Metzgeria furcata*) (Figure 46) is common in Europe. Persson's second argument was that the *Aloina* spores were quite common in the rain (est. at least 60,000,000,000 / km²). That would be an incredible number to come from such a distance as Siberia. The final complication was that an *Aloina* from neighboring European countries had been misidentified as *Aloina ambigua* when in fact it was *Aloina rigida* (Figure 42), making a European origin of *Aloina rigida* quite possible; furthermore, he considered identification of *Aloina rigida* without capsules to be difficult, if not impossible.

Figure 41. *Aloina brevirostris* gametophytes. Photo by Michael Lüth, with permission.

Figure 42. *Aloina rigida* gametophytes and sporophytes. Photo by Michael Lüth, with permission.

Figure 43. *Bryum pallens* showing red pigmented phase. Photo by David T. Holyoak, with permission.

Figure 44. *Leptobryum pyriforme* with capsules. Photo by Michael Lüth, with permission.

Figure 45. *Marchantia polymorpha* with gemma cups. Photo by Michael Lüth, with permission.

Bergeron's (1944) arguments against a Siberian origin for the *Aloina* (Figure 42) were meteorological rather than biological. First, the weather conditions in Siberia during the preceding week were not likely to have had the force needed to bring the spores into the airstream where they were needed to travel to Finland. Second, rather, the air masses arriving on the day in question originated to the north from other European countries. Third, the air masses leaving the Siberian region did not travel in the direction of

Finland. Fourth, the conditions at the collecting site in Finland on the days of sampling did have the right weather conditions to bring down spores, and these were most likely to have come on air currents from the NNW or SSE, either of which would have traversed areas where *Aloina* grows and neither of which would have passed over Siberia or joined forces with air from that region. There are lots of factors to consider when attempting to determine the origin of propagules.

Size and Falling Velocity – Distance and Laws of Physics

The first condition of passive dispersal by wind for a diaspore is to get caught by the wind before reaching the ground. For the tiny distances that bryophyte diaspores fall to their substrate, this is a challenge. The laws of physics would predict that atmospheric density of dispersed spores will decrease with increasing distance and increasing height from the colony.

For whatever reason, it appears that when spores exit hanging capsules they can rebound and are elevated (Figure 47) (Cronberg *et al.* (2008)). This gives the spores from hanging capsules the same advantage as those from upright capsules. But what causes this upward movement?

Figure 47. *Bryum argenteum* spore release, showing upward movement of spores. Photo by Nils Cronberg, Hans Berggren, & Rayna Natcheva, with permission.

This can be helped somewhat by animals (I'm guessing especially squirrels and other rodents) that bump them and cause clouds of spores to become airborne. In rangeland, hoofed mammals surely contribute. Once airborne, the falling velocity is important. Small spores like those of bryophytes typically have a falling velocity less than those of larger objects, permitting them to stay airborne longer and have greater opportunity for capture by moving air.

One approach to examining long-distance dispersal is to develop a trajectory model. Trackenberg (2003) developed such a model (PAPPUS) to consider the potential of wind as a dispersal vector. The model included effects of topography, turbulence (including thermal updrafts), and weather conditions. Simulations included initial release height and falling velocity. It improved on most approaches by modelling turbulence. The model was tested against distances measured in the field. Trackenberg considered that sunny weather with thermal turbulence and updrafts would cause a high proportion of long-distance dispersal, even in periods of low horizontal wind speed.

Not only does the model suggest that sunny weather with thermal turbulence and updrafts may be most important, Trackenberg (2003) concluded that stormy weather may have little importance for long-distance dispersal, especially for species with falling velocities less than 1.5 m s^{-1} . Horizontal wind speed seemed to have no effect on diaspores dispersing more than 100 m; frequency of updrafts was positively correlated. I became aware of this importance myself during a blizzard. I'm not suggesting that spores get distributed in blizzards, but the wind patterns can be seen then without equipment. My "aha" moment came as I watched wind and snow swirl around my house and carve a funnel in the snow, raising the snow into the airstream. While this 1 m wide funnel was caused by an L corner of my house, smaller funnels can occur around rocks and other obstructions where bryophytes grow. Snow is a good marker for wind patterns, and it is common for us to see the snow "falling" upward as wind whirls around buildings and other obstructions. Such wind conditions are not restricted to winter. If it is not a rainy day, such conditions would seem ideal for getting the spores away from the ground and putting them into the airways.

Trackenberg (2003) considered the improved predictability of his model to result not only from the addition of turbulence to the model but also to the effect of topography. Those bryophytes that are elevated either by living on trees, rocks, or walls or by living at high elevations have a greater chance of entering the atmosphere. This improvement is in part due to the slow falling velocity of the tiny diaspores of bryophytes. With falling velocities of less than 1.5 m s^{-1} , unstable atmospheric conditions and thermal updrafts under low humidity provide the greatest contributions to dispersal. If diaspore abscission is coupled with these conditions (**xerochasy**), bryophytes can optimize their dispersal capabilities.

In their predictions for immigration into a milled peatland, Campbell *et al.* (2003) assumed that diaspores released from higher altitudes are typically exposed to greater wind velocities (Greene & Johnson 1996) and thus are likely to be carried farther. As discussed above, this probably only matters once they have been lofted into the

wind stream by updrafts or other short-distance mechanisms. To determine terminal velocity, Campbell *et al.* (2003) assumed a density of 1 (Gregory 1973) and applied Stoke's law for a sphere with a low Reynolds number. They also assumed that propagules with a slower falling velocity (including bryophytes) and/or with a higher release height from the ground would have a greater probability of dispersing into the mined peatland (Campbell *et al.* 2003; Trackenberg *et al.* 2003). Trackenberg and coworkers warned against using morphology as an indicator of dispersal ability, emphasizing the importance of location of growth and consequent falling distance and upwinds as being of greater importance. For plants in general, Campbell and coworkers found that dispersal distance was most sensitive to falling velocity and weather conditions. Since bryophytes in general have slow falling velocities, we might expect weather to be of greatest importance for them.

Evidence from Restoring Peatlands

Campbell *et al.* (2003) assessed the immigration potential of plants into a mined peatland in southeastern Quebec, Canada. They selected 32 species, including both bryophytes and tracheophytes, as potential colonizers, based on presumed dispersal capabilities. They developed an index of immigration potential based on:

- propagule release height
- falling time (propagule release height/settling velocity)
- propagule wing loading (probably not applicable to bryophyte spores, but possibly to gemmae and bulbils).

Their evidence supported these attributes. Those bryophytes with the higher immigration potentials by wind were usually the more frequent colonizers in the mined peatlands. *Sphagnum capillifolium* (Figure 48) and *Sphagnum fuscum* (Figure 49), however, were exceptions, with less than a 1% occurrence but relatively high immigration potential. Campbell *et al.* (2003) attributed this to an establishment problem. Rochefort (2000) found that *Sphagnum* is particularly vulnerable to drought and the instability of the substrate in the early establishment stages. But Campbell *et al.* found that mosses in general had less of a recolonization constraint than did the herbaceous species in this environment.

Disjunct Distributions

The large number of disjunct taxa in the Andes and Atlantic coastal region of Brazil might lend support to the air current hypothesis (Gradstein & Reiner-Drehwald 2007). Major flyways for birds, especially raptors, often follow mountain ridges because these areas often have air currents that propel the birds forward, saving energy on long migrations. It is reasonable to assume they can similarly provide "flyways" for bryophyte diaspores.

Directional (**anisotropic**) dispersal seems to play a role in Southern Hemisphere distribution. Using data from global winds coverage from the National Aeronautics and Space Administration SeaWinds scatterometer, Muñoz *et al.* (2004) found that the correlation of floristics of bryophytes, lichens, and ferns with wind patterns and wind connectivity is stronger than the correlation with geographic proximity, suggesting that spores travel with the wind.

There seems to be an interesting contrast between the arrival of two species of bryophytes [*Ulota phyllantha* (Figure 50) and *Sanionia uncinata* (Figure 51)] on Macquarie Island in the Antarctic. *Sanionia uncinata* has spores only 10-18 μm in diameter, whereas *Ulota phyllantha* has cigar-shaped spores 100 μm long. As Rod Seppelt pointed out on Bryonet (6 March 2013), *U. phyllantha* occurs abundantly on the coastal rocks along the western side of Macquarie Island (Antarctica) but is rarely seen on the east coast. Its distribution on the island has led to the assumption that it has been distributed by the jet stream from southern South America. On the other hand, *Sanionia uncinata* appears to have migrated to Macquarie Island from Australia or New Zealand, matching their genotypes, and differing genetically from other subAntarctic island populations to the east that seem to match the southern South America-Antarctic Peninsula genotypes (Lars Hedenäs, Bryonet 6 March 2013). This migration, contrary to prevailing winds and having a larger dispersal unit, suggests that dispersal by wind will not always follow prevailing winds. Wind directions do change, and Rod Seppelt (Bryonet 6 March 2013) explained that cyclonic low pressure cells can center off the southwest side of Tasmania, pass through the southeast mainland Australia, miss New Zealand and reach to the Ross Sea area of Antarctica. These heavy winds are likely to carry all sorts of propagules from Australia and New Zealand to Antarctica, thousands of kilometers away. Furthermore, during drought periods, huge dust clouds in

Australia can reach New Zealand, no doubt carrying spores along with the dust.

Figure 51. *Sanionia uncinata* with capsules. Photo by David T. Holyoak, with permission.

Shaw (1982) provides us with more convincing evidence of "everything is everywhere" and the flyway hypothesis. The rare circumboreal *Plagiobryum zieri* (Figure 52) has been found in the Huehuetenango Province of Guatemala, far from its nearest neighbor in Colorado, USA. Shaw suggested that the tendency of the spores in this species to remain in tetrads may be a preadaptation to its ability to survive such long-distance travel and become established in its high altitude homes.

Such disjunctions as 28 species of bryophytes common to Central America and the Himalaya Mountains (Sharp 1974) likewise lend credence to long distance dispersal of bryophyte diaspores. They not only support "everything is everywhere," but also emphasize the importance of the "environment selects."

Figure 52. *Plagiobryum zierii* from southern Europe. Photo by Michael Lüth, with permission.

Finding a species at both poles of the Earth tends to make one think of long-distance dispersal, and *Pohlia nutans* (Figure 53) not only supports the concept that "everything is everywhere," but it clearly supports the "environment selects." Present in Iceland in geothermal areas, common in the Northern Hemisphere, and present on the geothermal areas of the continent of Antarctica, it is the epitome of the environment selects because it is absent in other (non-geothermal) habitats in Antarctica (Skotnicki *et al.* 2002). The Antarctic populations of *P. nutans* exhibit low levels of genetic diversity (RAPD & DNA sequences of conserved nuclear ribosomal RNA), supporting the conclusion that they have been derived from a single dispersal event leading to vegetative growth, mutation, and stepping stone dispersal within the continent, a pattern also discernible for the geothermal *Campylopus pyriformis* (Figure 21, Figure 54).

Figure 53. *Pohlia nutans* with abundant capsules. Photo by Michael Lüth, with permission.

Lewis Smith (1991) considered southern South America to be a continuous source of diaspores for the Antarctic and attributes this to relatively frequent storms that track eastward over the southeast Pacific Ocean. They gain momentum over the southern part of South America where they pick up spores. Sometimes a blocking anticyclone over the South Atlantic Ocean deflects the winds, sending them off to Antarctica.

Figure 54. *Campylopus pyriformis* with capsules. Photo by Michael Lüth, with permission.

Perhaps the best explanation is one from Schofield and Crum (1972), that continental drift, long-distance dispersal, and fragmentation of a previously continuous landscape all have been considered meritorious explanations. But "no single hypothesis is sufficient to accommodate all species within any disjunctive pattern." Nevertheless, many of the bryophyte disjunctions are similar to those of tracheophytes, suggesting that similar mechanisms are at play.

Long-range dispersal in bryophytes is supported primarily by their distribution patterns and our knowledge of air movement patterns and the ability of updrafts to carry particles of various sizes. Survival of a number of taxa at atmospheric low temperatures and UV radiation suggests that such long distances may occur, but probably infrequently.

Stepping Stones

It is likely that many species disperse through relatively short distances most of the time, reaching distant locations eventually through a series of dispersal events from location A to location B, then from location B to location C, a means I shall call **stepping stones**, as that term has been used in the literature several times.

At least in some species, we can document evidence of a stepping stone means of species range expansion. For example, Derda and Wyatt (1999b) found that *Polytrichum commune* (Figure 55-Figure 56) had a high mean genetic identity between populations (0.867-0.998), but that there was significant differentiation among regions that increased with distance. This, coupled with region-specific genotypes, suggested that this species dispersed from location A to location B and then from location B to location C, *i.e.*, the "stepping stone" method. At the same time, some distant populations had multilocus genotypes that were very similar, suggesting that an occasional long-distance dispersal event had occurred.

Figure 55. *Polytrichum commune* in its typical abundance, facilitated by new shoots from rhizomes. Photo by Christopher Tracey, through Creative Commons.

Bischler and Boisselier-Dubayle (1997) provide us with an example that supports the concept of stepping stones. They found that in liverworts, there are few differences among the alleles within a population. Rather, intrapopulation differences are more typically an expression of phenotypic plasticity. But over a larger area, a species typically consists of a series of small populations that are reproductively isolated from each other, presumably due to dispersal limitations on the sperm. They considered that these facts are consistent with repeated dispersal and founder events. Further variation can arise from genetic drift. They found a contradiction in the restricted gene flow between populations and the limited genetic differences among geographically disjunct populations.

Figure 56. *Polytrichum commune* with abundant capsules that provide spores for long-distance travel. Photo by David T. Holyoak, with permission.

Could it be that rather than stepping stones or multiple dispersal events there could have been a single event that left a number of isolated founder populations that were further divided by genetic drift? Such a proposal is not unreasonable. We know that certain weather events can carry dust for long distances [for example from the Sahara in Africa to Texas in the USA or to California, USA

(Reardon 2013) or to southern England (Ken Adams, Bryonet 6 March 2013)] or change the usual direction of weather patterns. Tornadoes can certainly pick up propagules and drop them off in a number of distant locations, sometimes far distant. Hurricanes can make similar deposits, particularly on oceanic islands. Bischler and Boisselier-Dubayle (1997) point out that liverworts have lower levels of genetic variability than do mosses. Rather, they seem to respond to habitat variation by more non-genetic responses through plasticity. Although they consider this to support a history of repeated dispersal and founder events, it does not rule out the possibility of a single dispersal event populating a number of isolated locations, then differing due to genetic drift, founder principle, or subsequent genetic modification. Their success may be due to a genetic complement that permits phenotypic plasticity.

Disjunct distributions always raise questions as to their causes – extinctions, land drift, or incomplete dispersal? Delgadillo (1987) reported that there is evidence of "extensive floristic exchange" in Mexico among the major alpine areas of the Neovolcanic Belt. However, floristic differences and ages among the mountains indicate that dispersal has not been unidirectional nor occurring through a single event. This would seem to indicate that it is not a **flyway** unless air currents change directions, perhaps with seasons. Nevertheless, this range of mountains seems to have provided a **barrier** to the dispersal of some mosses in a north-south direction, but not in the opposite direction. This might be interpreted as an example of "the environment selects," but more ecological information is needed to support that conclusion. In any case, it is likely that mountains present barriers to species that disperse through "stepping stone" pathways and that are unable to survive the climate of the mountain tops.

Dispersal by birds for any instance seems to be discounted by many researchers for a number of regions. Cruden (1966) sums up some of the concerns for transport of seeds:

1. Internal carriage is highly unlikely because it takes at least a month for migration from, for example, California, USA, to Chile, whereas the gut contents are dispelled within a few hours.
2. External carriage is likewise unlikely because the birds frequently preen themselves.
3. The disjunct plant groups do not seem to have any special qualifications for long-distance dispersal. Rather, they live in open, unstable habitats; their seeds can be dispersed by animals; and they are self-compatible.

But some of the objections applied to bird dispersal for tracheophytes do not seem to apply as well to bryophytes. It is unlikely that internal carriage of bryophyte diaspores occurs on long flights, but it could occur in a stepping stone fashion. External carriage is more likely. If a bird in fact walked through a patch of dispersing capsules, numerous spores could adhere. Because of their fine nature and small size, it seems unlikely that preening could remove all of them, and some are also likely able to continue adherence even through the splashing of a bird's bath. Furthermore, like seed plants, only a single spore is needed in the right place to begin a new population, and the birds are likely to

seek out the same kind of habitat as the one where the spore first joined the journey, *i.e.*, a suitable habitat. Cruden (1966) has noticed a correspondence between wintering areas of the birds and plant distributional ranges. He likewise suggests that mountain hopping has been undervalued as a possible migrational route for the plants, in some cases at least following the flyways of the birds. Whereas shorebirds seem to satisfy the long-distance requirements, mountain hopping could account for distribution by a larger number of birds. This latter mechanism could follow the long-distance travel on a shore bird, and at least for bryophytes, seems like a plausible mechanism.

Gene Flow

Gene flow is an indirect measurement of dispersal. While it cannot tell us distance values, it can suggest the magnitude of gene dispersal, hence spore dispersal (assuming that spore dispersal is greater than gamete dispersal). Gene flow results in increased genetic variation within the population and prevents that population from exhibiting genetic differentiation from other populations. For *Leucodon temperatus* and *L. luteus*, both epiphytes, the gene diversity between populations relative to the total diversity was low (Akiyama 1994). Akiyama interpreted this as evidence of extensive gene flow between populations. He considered the low genetic divergence to be a result of their epiphytic habitat, which would suggest that lots of new invasions by spores occurred.

Genetic diversity can be maintained even as a result of small remnant populations in *Trichocolea tomentella* (Figure 57). The apparent infrequent gene flow among populations of this species indicates that it suffers dispersal limitations, even on a small spatial scale. On the other hand, new colonization within a population is not affected by its isolation, suggesting that it benefits from random short-range dispersal of fragments. It furthermore appears to have a long life span that permits it to spread through branching. On the other hand these characteristics suggest that it is not a good colonizer because of its limited dispersal.

Figure 57. *Trichocolea tomentella*, a leafy liverwort. Photo by Michael Lüth, with permission.

Korpelainen *et al.* (2005) evaluated gene flow in bryophytes in a broader context. They found that most bryophyte species (*i.e.*, mostly mosses) have a fair amount of gene flow between populations, based on the genetic differentiation that exists among populations. That suggests that there is a fair amount of invasion of populations by spores of other populations.

On the other hand, Derda and Wyatt (1990, 1999a, b) found genetic evidence in *Polytrichum* species to indicate that distribution of genetic variation by spores was limited. For *P. commune* (Figure 55-Figure 56) the mean genotypic diversity was 0.546. For *P. piliferum* (Figure 58) the mean genetic diversity within populations was only 0.037 (Derda & Wyatt 1999a), whereas in *P. commune* it was 0.061 (Derda & Wyatt 1999b). Derda and Wyatt (1999b) concluded that long distance dispersal did occasionally occur, based on "region-specific multilocus genotypes" that occasionally occurred distant from the apparent parent population. The fact that this species has a worldwide distribution suggests it is capable of at least some long-distance dispersal. More commonly, it appeared that genotypes moved from location to location in a "stepping-stone" fashion. As one would expect, the genetic similarities between regions generally decreased with the distance between the regions. Evidence from *Polytrichum juniperinum* (Figure 59) and *P. strictum* (Figure 60) suggests that dispersal distances and gene flow may depend in part on latitude (Derda & Wyatt 2003). For *P. juniperinum*, Derda and Wyatt found that spore dispersal in the upper Midwest and Pacific Northwest of the USA and Canada was apparently low and relatively less effective south of the Pleistocene glacial margins, whereas colonization from distant refugia seems to have been more effective in the northern latitudes. Members of the **Polytrichaceae** are unique in having an **epiphragm** stretched across the peristome teeth, providing only tiny holes from which spores can be dispersed (Figure 61). Van Zanten (1973) considered that long-range dispersal was unlikely in the **Polytrichaceae** genus *Dawsonia* (Figure 10), citing horizontal spore ejection by raindrops or other agents that strike the mature capsule. It is likely that other members of the family suffer the same problem.

Figure 58. *Polytrichum piliferum* with young capsules. Photo through GNU free documentation license.

Polytrichum strictum (Figure 60), a species that has often been treated as a subspecies of *P. juniperinum* (Figure 59), has some of the highest gene diversity levels

known for mosses (HTP = 0.205), with strong regional partitioning of the genetic structure (Derda & Wyatt 2003). This might be explained by the lack of re-invasion of spores into a colony, permitting genetic drift and gene divergence. This lack of re-invasion is consistent with the poor spore dispersal predicted by Van Zanten (1973).

Figure 59. *Polytrichum juniperinum*. Photo by Li Zhang, with permission.

The story for *Hylocomium splendens* (Figure 33) in Scandinavia seems to be quite different from that of *Polytrichum* (Figure 58-Figure 61). Cronberg *et al.* (1997) found that among populations from four vegetation zones, eleven out of thirteen loci screened by allozyme electrophoresis demonstrated variation. The relative differentiation among the populations was low ($G(ST) = 0.073$), indicating a high level of gene flow between populations. Furthermore, although the Subarctic-alpine population was apparently a single widespread clone, it was comprised of many rare genotypes that often occurred together within 10 x 10 cm patches. Cronberg *et al.* concluded that this population had spread by dispersal of vegetative fragments. In the lowland populations, identical genotypes often occurred in multiple patches, which Cronberg *et al.* interpreted to indicate that these had arisen by independent sexual recombinations, not dispersal. Hmmm...Why not by fragments?

Figure 61. Capsule of *Polytrichum commune* showing epiphragm stretched across the 64 short teeth. Photo with permission from Botany Website, UBC.

It appears that even annual shuttle species that would seemingly rely on dispersal of much more than a few meters may have little genetic mixing between populations. Roads and Longton (2003) found no field germination of spores in *Tortula acaulon* (= *Phascum cuspidatum*; Figure 4) and spores only inconsistently produced gametophytes in *Tortula truncata* (as *Pottia truncata*; Figure 2). As discussed above for the latter species, 67% of the spores never left the clump and 70% were deposited within 2 m. Nevertheless, that left 30% to be deposited farther away. However, there were no genotypes in common between populations and no variation within populations, suggesting that all members of the population had come from a single spore or clone.

Grundmann *et al.* (2007) obtained what seems like conflicting data for *Pleurochaete squarrosa* (Figure 62). Using allozymes, they showed no isolation by distance, but using DNA sequence data instead, there was evidence of isolation based on distance. Shaw (1995) used 15 allozyme loci to assess *Scopelophila cataractae* (Figure 63) and concluded that it was native to both America and Asia, having spread by long-distance dispersal.

Figure 63. *Scopelophila cataractae*, a species that seems to have spread by long-distance dispersal. Photo by David T. Holyoak, with permission.

Many bryophytes exhibit little variation within populations and reasonable variation between populations, suggesting that most within-population members are derived from the same clone. Genetic differences between populations suggest that most have arisen by a single invasion of a single propagule.

Spore Size and Number

Size matters. Aerosols – particles suspended in air like those in smoke – disperse easily to great distances, but the particles typically have a diameter less than 5 μm (Lönnell 2011). Size affects the terminal velocity of falling objects, with increasing size causing a greater terminal velocity (Lönnell 2011). But does this have any meaning for a bryophyte propagule? And if so, how is it affected by updrafts, vortices around the substrate, hydration, or surface ornamentation?

There seems to be an assumption that dispersal declines rapidly as diaspore size increases. As Frahm (2009) reminds us, bryophyte spores, typically only one cell, mostly range in size from 7 μm to 100 μm . Schmidt (1918) considered that spores smaller than 20 μm are easily dispersed, a position supported by van Zanten and Pócs (1981) who thought the small spore size permitted them to lift into the air column more easily. Mogensen (1981) tells us that theoretically, wind that would carry a 20 μm spore for 1000 km would only carry a 55 μm spore approximately 40 km. But experimental evidence for this seems to be lacking, and the large spore size of some ephemeral taxa, such as *Ephemerum* (Figure 64-Figure 65), would seem to suggest that occasionally these large spores do travel. In fact, van Zanten and Gradstein (1988) found no correlation between spore size and species range for neotropical liverworts. They cited three species with some of the largest spores [*Brachiolejeunea phyllorhiza*, *Cheilolejeunea unculoba*, and *Leucolejeunea xanthocarpa* (Figure 66) as having transoceanic distribution

Figure 64. *Ephemerum serratum*. **Upper:** Leafy gametophytes with capsules. **Lower:** One spore. Photos by Michael Lüth, with permission.

In describing dispersal of testate amoebae in the Arctic and Antarctic, Wilkinson (2001) found that the large species (up to 230 μm) were confined to only one of those areas, whereas the cosmopolitan species had a maximum size of 135 μm . Size matters. The same principle of smaller travels farther should be applicable to bryophyte propagules. But most bryophyte spores have a diameter that is less than 50 μm (Lönnell 2011; Figure 67), with liverworts generally having larger spores than mosses, presenting a greater number of species with spore diameters in the 40-100 μm range than do mosses. Among the species for which I could easily find numbers, the liverworts tended to produce fewer spores than the mosses, a factor one might expect to accompany larger spores (Table 2).

Figure 65. *Ephemerum serratum* (formerly *E. minutissimum*) spores. Photo by David T. Holyoak, with permission.

Figure 66. *Leucolejeunea xanthocarpa*, a transoceanic species with large spores. Photo by Jia-Dong Yang, through Creative Commons.

Despite the widespread assumption that small spores lift more easily, hence disperse more easily, than large spores (Van Zanten & Pócs 1981), there seems to be no empirical evidence for the assumption (McIntosh 1997).

McIntosh points out that producing smaller spores permits production of more spores, and just by that increase, the probability of going farther increases.

In their examination of 24 Asian bryophytes, He and Zhu (2010) concluded that mosses have a higher spore output than liverworts (Table 2). They further observed an inverse relationship between spore size and spore number, a conclusion also supported by Lönnell (2011; Figure 68). This is especially borne out in the genus *Archidium* (Figure 22), which may have as few as four spores and these are the largest found among bryophytes (Crum 2001).

Noguchi and Miyata (1957) asserted that mosses that have abundant spores can have wide geographic ranges, but tend to have rather confined habitats. This relationship might relate to spore size, with small spores being more abundant than larger ones. And small spores do not bring with them the nutritional reserve that could give them a good start in their new location. Could this be the explanation for their "confined habitats?"

Lönnell (2011) compared spore sizes among spore-producing organisms, considering those of bryophytes to range 10-50(-100) μm , fungi 3-10(-300) μm , and ferns 30-100 μm . Crum (2001) gives a broader range from 5 (*Dawsonia*; Figure 10) to 310 (*Archidium*; Figure 22) μm , but few are greater than 30 μm . The generalization still holds that those taxa that produce small spores produce lots of them and those with large spores produce few (Schuster 1984) (50 million in *Dawsonia*, 4 in *Archidium*; (Table 2).

Figure 68. Inverse relationship of number of spores produced per capsule to spore size. Redrawn from Lönnell 2011.

Large Spores

Archidium (Figure 22), as a genus, sets the record for spores size in mosses. This larger size permits it to maintain a large food reserve that becomes available when the moss germinates. In its open habitat, this permits it to develop quickly and complete its life cycle before conditions once again become unfavorable for growth. *Archidium brevinerve* has the largest average spore diameter (235 μm); *A. ohioense* (Figure 69) has the largest measured spore (310 μm) (Snider 1975). In Europe the most widespread species in the genus is *A. alternifolium* (Figure 22) with an average spore size of 162 μm and range of 139-223 μm (Boros *et al.* 1993). Among the liverworts, *Asterella* has spores 135-160 μm in diameter (Figure 70). *Sphaerocarpos* (Figure 71-Figure 72) sheds its spores in tetrads, making those spore dispersal units quite large. They furthermore are highly decorated, creating air spaces that could increase surface area without adding weight and increasing floatability. Some spores are **precocious** (Figure 75), *i.e.*, germinating within the spore wall and typically before leaving the capsule. Such spores are consequently larger and presumably heavier, as for example those of *Tuyamaella molischii* (Lejeuneaceae; Figure 73-Figure 75) that are up to 140 μm long (Rui-Liang Zhu, Bryonet 6 March 2013).

In *Archidium alternifolium* (Figure 22), little or no protonema develops when the spore germinates (Miles & Longton 1992a). Rather, a germling shoot arises from the dehiscing spore(!), or shortly thereafter from a short protonema. This ability most likely arises through the complements of an adequate food supply in the large spore, precluding the need for a protonema to store such energy before a shoot can be formed. But other factors might also be at play. Could it be that necessary hormones to stimulate the shoot growth are carried in this large spore, sacrificed in small spores to make room for the little bit of nutrient matter it can provide? Such hormones, in the case of small spores, might then be provided by the protonema, or in the surrounding environment (see discussion on Delayed Germination in subchapter 4-7).

It appears that the large size of the spore in *Archidium alternifolium* (Figure 22) might afford other advantages as well. When Miles and Longton (1992a) cultivated the spores on agar, germination spanned a period of several months. Furthermore, the spores remained viable for up to four years following field collection of fresh material. But it is interesting that in the field these spores seem to lack what it takes for any dispersal. Rather, they remain in the capsule, attached to their parent plants. Despite the spore longevity and size, according to Miles and Longton, it is the fragments that predominate in the diaspore bank and form the recolonizing population following disturbance.

Convey and Lewis Smith (1993) suggested that large spore sizes observed in short-lived species may be important in local colonization in the Antarctic. Those taxa that are annual or short-lived invest more in spore dispersal than those in most perennial taxa. Nevertheless, on Signy Island in the Antarctic, spore size did not seem to influence dispersal potential in the five taxa identified (Marshall & Convey 1997).

For whatever reason, acrocarpous spores of Michigan, USA, mosses are generally smaller (mostly <25 μm in diameter) than those of pleurocarpous taxa (mostly >25 μm), based on sizes provided by Crum (1973). These evolutionary trends may not relate to habitat, but we do know that pleurocarpous mosses are perennial and rely less on spores for their reproduction than do many of the

acrocarpous taxa. Having larger spores provides more energy for a better start in life. Liverwort taxa may have a similar division between leafy and thallose taxa, if Schuster's table (Table 3) on spore size is any indication, but the number of taxa represented is far too small to draw any generalizations.

Table 3. Spore size (μm) in liverworts. The first six are leafy. Based on Schuster (1966).

<i>Scapania</i> (= <i>Diplophyllum</i>) <i>albicans</i>	10-14
Blepharostomaceae	8-16

<i>Conocephalum conicum</i>	70-90
<i>Riccia glauca</i>	80-100
<i>Riccia gougetiana</i>	180-200

The number of spores per meter square is a function not only of the number of spores per capsule, but also the density of the capsules present. Some of these numbers are enormous (Table 4).

As already noted, spore number is determined not only by the number per capsule, but also by the number of capsules produced. More capsules can correlate with wider dispersal and wider distribution. Robinson (1990) pointed out this relationship in the **Leucobryaceae**, where *Octoblepharum albidum* (Figure 76) typically has many sporophytes and has one of the widest distributions in the family. In many genera in this family, sporophytes are reduced, but propagation by leaves and leaf fragments is common. Robinson suggests that birds and other arboreal animals could facilitate dispersal among the epiphytic members of the family.

Spore size is an integral part of life history strategies. Longton (1988) summarized some of these relationships for arid regions. He found that perennial stayers are typically acrocarpous mosses with small spores, long spores, and "other features promoting dispersal." Annual shuttle species, conversely, produce large spores, often in submersed capsules, promoting rapid germination and establishment *in situ*, but not well adapted for dispersal. Perennial shuttle species are mostly marchantialian liverworts with large spores. Fugitives stay at a given site and are able to do this by having small, easily dispersed spores.

Jenkins *et al.* (2007) attempted to use existing data from many data sets to answer the question of size vs dispersal distance. They divided organisms into active and passive dispersers, defining active dispersers as those that arrived at a new location under self-propulsion. This includes most vertebrates and arthropods, but many other animals depend primarily on passive sources. Plants, including bryophytes, are mostly passive dispersers.

Jenkins and coworkers found that active dispersers, as expected, dispersed significantly farther and were significantly greater in size ($P < 0.001$). Passive dispersers, on the other hand, had random dispersal distances compared to mass/size. They concluded that while size is important for active dispersers, it is not for passive dispersers. But could there still be a relationship for dispersal units less than a certain size that permits them to be dispersed by air currents? Jenkins *et al.* consider that dispersal-size relationships for microbes cannot be tested by direct observation. Perhaps that for bryophytes will be somewhat easier. In their analysis for passive dispersers, Jenkins and coworkers used organisms weighing in the range of 10^{-8} to 10^{-9} g, dominated by plant seeds. This hardly seems a good model for bryophytes with single-celled spores as their dispersal agents.

Spore Weight

Hughes *et al.* (1994) developed a set of provisional conclusions regarding the relationship of dispersal mode and other attributes of plants and their habitats. Although these were developed with seed plants in mind, examining them for bryophytes might be instructive in developing our own hypotheses. They concluded that seeds larger than 100 mg tend to be adapted for dispersal by vertebrates, whereas those less than 0.1 mg tend to be unassisted.

Bryophyte spore weights do not seem to have been a priority for bryologists, so it is necessary to estimate. Most spores range from 20 to 100 μm in diameter (Boros *et al.*

1993). A 20 μm spore has a radius of 10 μm . Knowing that, we can calculate its weight by assuming it is a sphere, starting by determining the volume ($V = 4/3 \pi r^3$). Hence, the volume would be $4.188 \times 1000 = 4188$ cubic microns. Assuming that a spore is mostly water, and knowing that the weight of water is 1000 g per liter, a cubic micron is 10^{-15} L or 10^{-9} μL . Hence, 1 cubic micron weighs 10^{-12} grams or 10^{-3} nanograms. A 20 μm spore would weigh only 4.2×10^{-9} g (0.0042 μg , or 4.2 nanograms) when fully hydrated ($V = 4/3 \pi r^3 = 4188$ cubic μm ; 1 cubic $\mu m = 10^{-9}$ μl ; 1 $\mu l = 1$ μg of water; 1 μg weighs 1 million picograms). Using a sphere as our model, we can derive the formula:

$$\begin{aligned} \text{spore weight} &= 4/3 \pi r^3 (10^{-3}) \text{ nanograms} \\ \text{or} \\ \text{spore weight} &= 4/3 \pi r^3 (10^{-6}) \mu g \end{aligned}$$

It is rather easy to do this calculation at <<http://www.wolframalpha.com>> and inserting "weight of sphere of water 20 microns in diameter."

Spores that are 100 μm in diameter would weigh 0.524 μg and often travel only downward by gravity, as in *Archidium* (Figure 22). Since bryophyte spores therefore fall in the less than 0.1 mg category, they support the hypothesis of Hughes *et al.* (1994) that diaspores less than 0.1 mg tend to be dispersed unassisted. Nearly all of the spores of bryophytes are apparently unassisted in their dispersal (*i.e.*, unassisted by animals, with only undirected wind and water for assistance).

Even at 300 μm diameter in *Archidium* (Figure 22) (Snider 1975), the spores of such bryophytes would weigh only 14.1 μg . Spores are usually dry when they travel, making them even less in weight.

The formula provides an estimate of the maximum weight of a spore with the density of water. Most spores are not fully hydrated and the spores may be slightly flattened into a tetrahedron with one rounded side. Whitaker and Edwards (2010) assumed a spore shape of a tetrahedron with a circular base to calculate the weight of a *Sphagnum* spore and determined a weight of 1.7 nanograms for a spore with a base diameter of 28 μm . If we assume that this spore is all water and spherical with a diameter of 28 μm , it would weigh 11.5 nanograms, a rather substantial difference in estimation caused not only by the shape assumption, but also by the water assumption.

Spores vary in weight between species, even at the same spore sizes. These variations depend on food reserves and water content (Jeff Duckett, Bryonet 6 March 2013). Green spores are short-lived, commonly remain hydrated, and typically store their food as starch, giving them a specific gravity greater than 1 and making them heavier than brown spores. Brown spores are generally smaller, long-lived, and use both protein and lipid reserves. They are usually very dehydrated and have a specific gravity considerably less than 1. Hence, green spores usually sink in water; brown ones usually float and, presumably, more easily become airborne.

But Gradstein (Bryonet 11 March 2013) argues that green vs non-green spores from nearly 100 tropical species do not correlate with range sizes or with long-range dispersal, based on an experimental study (van Zanten & Gradstein 1988). No differences correlated with drought or

low temperatures for exposures from a few hours to a year or more.

We can estimate weight by the size of the spore, but as noted, not all spores are created equal. The specific gravity is a more important measure of the transportability than the weight (mass) alone. Peter Poschlod (pers. comm. 6 March 2013), like Duckett, points out that some spores float on water whereas others sink. Among the ones that sink immediately are those of *Sphagnum*. Using spore traps in peatlands, Poschlod (1995) was unable to find any *Sphagnum* spores. Rather, the traps produced vegetative parts, especially those of *Sphagnum* (Figure 77). Dry *Sphagnum* is especially light weight and easily becomes airborne, as I witnessed one day while watching ants trying to repair their mound during a windstorm. In grasslands, on the other hand, vegetative diaspores tended to be the exception. Nevertheless, in the grasslands it appeared that grazing animals, especially sheep, transported the mosses, particularly ones such as *Abietinella abietina* (Figure 78) that in Central Europe does not produce capsules.

Figure 77. *Sphagnum* protonemata growing on a *Sphagnum* branch in the field. Photo by Andras Keszei, with permission.

Survival and Longevity

Some spores, under the right conditions, can survive extremely long periods (Table 5). Gubin *et al.* (2003) reported viable moss spores from permafrost sediments in northeast Eurasia, citing ages of tens to thousands of years of preservation.

Figure 78. *Abietinella abietina*, a species that seems to be transported by sheep in grasslands. Photo by Michael Lüth, with permission.

Van Zanten and Pócs (1981) surmised that spores from taxa in dry habitats had a generally greater drought resistance than those from wet habitats. Since liverworts tend to live in wetter habitats, grow where there is less air turbulence, and have larger spores, they further concluded that moss spores should be expected to travel farther.

Most spores that arrive at a given area will not have travelled terribly far. The majority will land within a few cm to a meter of the parent, but some are carried by air currents to far off places. In this longer transport, they will be subjected to high UV radiation and extremes of moisture and temperature.

Table 5. Known longevity for bryophyte spores, based mostly on Crum 2001 and arranged from least to most. Liverworts are in bold face.

Lejeuneoideae	7-8 d	Gradstein 1994

Sphagnum in experiments suggest that *Sphagnum* spores may have a half-life of 1-20 years, but that individual spores may survive for several decades and possibly even centuries (Sundberg & Rydin 2000). Refrigerated spores retained 15-35% viability for 13 years.

Some of the records of spore longevity from herbarium specimens have been suspect due to the possibility for contamination. However, Bristol (1916) reported germination of spores and development of protonemata from spores that had been collected from the top 24 cm of soil in Great Britain 49 years earlier and stored in bottles.

Egunyomi (1979) tested the germination success of tropical moss spores that had been stored at room temperature for various periods of time from 1-3.5 years. Of the 22 species tested, 15 failed to germinate at all. Five species had better than 50% germination. He chose four of

these (*Microcampylopus nanus*, *Weissia papillosa*, *Mittenothamnium overlaetii*, *Weisiopsis nigeriana*) that had been stored at least two years for further experimentation of extreme conditions for 4 weeks: -2°C, 8°C, continuous immersion in water at room temperature, alternate wetting and air drying every 24 hours. None of the species at -2°C survived for 4 weeks. At 8°C, all survived four weeks, with survival percentages ranging 43-81%. Continuous immersion, like the -2°C, resulted in 0% survival after 4 weeks, but alternate wetting and air drying resulted a range of 45-76% survival with the success ranks by species being the same as in the 8°C treatment.

Atmospheric Conditions – UV and Desiccation

It is likely that conditions that favor the dispersal of protozoa and algae also favor the dispersal of bryophyte spores. Hence, we might expect cloudy or overcast skies to help filter UV light (Schlichting 1961). Fires and volcanoes can put particulates in the atmosphere, likewise serving as UV filters. Clouds also can prevent severe desiccation.

Drought Tolerance

Drought tolerance has the greatest correlation with transoceanic distribution (van Zanten & Gradstein 1988). Van Zanten and Gradstein found that only 5% of the transoceanic species had lost the ability to germinate after five days (the minimum time calculated for crossing the Atlantic), whereas 32% of the endemic species exhibited that limitation. Among the transoceanic species, half were able to germinate after 70 days, whereas among the endemic species only half could still germinate after 25 days. Six transoceanic species could still germinate after 100 days of desiccation: *Anastrophyllum auritum* (60% germination), *Andrewsianthus jamesonii* (50%), *Gymnocoleopsis multiflora* (50%), *Herbertus subdentatus* (Figure 79) (40%), *Dumortiera hirsuta* (Figure 80) (10%), and *Chiloscyphus* (as *Lophocolea*) *muricata* (Figure 81) (5%). Some even lasted 150 days. Nevertheless, three endemic species germinated after 100 days of desiccation: *Cephalozia crassifolia* (Figure 82) (10%), *Marchantia chenopoda* (Figure 83-Figure 84) (80%), and *Fossombronia* sp. (Figure 85) (80%), with the latter species even germinating after 150 days. These three endemic taxa have large, dark-colored spores, suggesting they could also survive UV light, but van Zanten and Gradstein suggest that these are probably adaptations for surviving adverse climatic periods, not long-distance dispersal.

The liverwort *Gymnocoleopsis multiflora* has unusual spores that are very durable despite thin spore walls and hygrophytic habit (van Zanten & Gradstein 1988). Both spores and sporelings are fairly resistant to UV radiation, as well as being very durable. These appear to be adapted to the high alpine habitat where it lives. By contrast, *Riccardia amazonica* and *Stictolejeunea balfourii* live in the understory of wet primary rainforest and their spores have very poor drought resistance. Such examples suggest that the spore adaptations may be more related to the habitats of the parents than to dispersal capabilities. In fact, most of the transoceanic species van Zanten and Gradstein tested came from more open habitats such as forest margins – habitats that would require more of the

same habitat adaptations as long-distance space travel, and where getting into the airstream may be easier than in the forest.

Frost Resistance

Van Zanten and Gradstein (1988) found that spores of transoceanic species had significantly better frost tolerance than endemic species, especially among spores that were desiccated for one week before the freezing treatment. Those spores that had been dried had better resistance in small-spored species than in large-spored ones, suggesting again that small-spored species should travel farther.

Nevertheless, wet freezing does not seem to favor the transoceanic species more than the endemic species (van Zanten & Gradstein 1988). Hence, it is not likely to affect the dispersability of liverworts. Interestingly, fresh spores are less likely to survive dry freezing, and this danger is more pronounced in the endemic species.

UV Protection

The greatest danger, considered by van Zanten (1976) and van Zanten and Gradstein (1988), is that of UV radiation damage. This poses a special problem because dry conditions that make them light in weight are also usually sunny conditions. Schlichting (1961) considered the greater success of UV-sensitive organisms (algae and protozoa) under humid and cloudy conditions to be due to the diminished impact of UV radiation, a concept supported by van Zanten and Gradstein. The added moisture also counteracts the severe desiccation often experienced in the upper atmosphere. The fact that algae have been collected by aircraft from 2000 m above the Earth suggests that bryophyte diaspores likewise occur there. Schlichting (1958) even reported viable moss spores from fingerbowls exposed at 2 m above the ground over periods of 45 minutes to 32 hours.

But we also know that UV light is used to kill cells, and bryophyte spores are no exception. Van Zanten and Gradstein (1988) tested the effects of UV radiation on spores in nearly 100 tropical liverwort species by flying them from Amsterdam to Los Angeles on the wings of a commercial 747 jet. Only two species, both from above 3000 m asl in the Andes, survived the journey, suggesting that the jet stream is not an available avenue to most species, at least among liverworts. This greater resistance to UV damage displayed by high altitude species may explain the distribution of species along mountains – perhaps a better explanation than the flyway explanation. But the two aspects could work together. In short, most species seem to be unable to survive the dosage of UV radiation required for long-distance dispersal under most conditions.

Some spores travel with chlorophyll. But van Zanten and Gradstein (1988) found no correlation between chlorophyll presence and species range. Furthermore, they found no relationship between precocious germination and local dispersal or between non-green and long-distance dispersal. There also seemed to be no dormancy effect.

Some spores have dark pigments; others have cuticular ridges or other extrusions, including papillae. It would be interesting to correlate those characters with success of the spores in travelling long distances where they must survive the greater desiccation and UV light of the atmosphere.

We need to understand just what levels of UV are present under dispersal conditions, what levels kill spores and other diaspores, and how long the exposure must last to cause damage. On the other side, we need to understand what characteristics of spores protect them from this damage, how moisture affects that damage potential, and is there a set of conditions and adaptations that would permit long-distance dispersal.

Liverwort Spore Survival

Fulford (1955 in Schuster 1966) considered that spore survival of leafy liverworts was short, but she actually had only one citation (Figure 86; Bernstein 1928) – for one species (*Blepharostoma* sp; Figure 87) – to back up this assumption; since then we have learned that some have considerable longevity. Inoue (1960) tested spore longevity in six liverwort taxa (Table 6) and found survival up to 18 months in three of them. Malta (1922) failed to obtain germination of spores from *Plagiochila asplenioides* (Figure 88) or *Pellia epiphylla* (Figure 89-Figure 90) after four years or of *Preissia quadrata* (Figure 91) after eight years of storage. Nevertheless, as van Zanten and Gradstein (1988) have demonstrated, those species with transoceanic distributions typically have longer viability.

Figure 86. Decline in spore germination in *Blepharostoma* from the first day after collection onward. * refers to one spore that germinated out of 512 after 23 months. Based on data from Bernstein 1928.

Schuster (1983) has suggested that many liverworts that survive as relict populations are limited in their dispersal success by being dioicous, being unable to withstand desiccation, and lacking asexual reproductive structures. He suggested further that successful dispersal can be enhanced by 1) formation of sexual propagules (*Lophozia-Scapania* model), 2) production of large numbers of very small spores per sporophyte (numerically overwhelming), 3) dispersal of spores mixed as monads, diads, and tetrads (*Haplomitrium* model) (see Figure 92), 4) spores permanently united in tetrads (*Cryptothallus-Sphaerocarpos* model), 5) acquisition of desiccation tolerance coupled with numerical overwhelming (xerothermophyte model), and 6) monoicium (*Calypogeia-Isopaches* (= *Lophozia bicrenatus-Cololejeunea* model).

Adaptations for Survival

Many bryophyte spores seem to be particularly endowed to survive extremes during their travels. The first evidence of this is that they have resisted decay and remain in huge numbers in deposits from the Silurian and Devonian periods. But biochemical evidence tells us more of their survival capabilities. Each spore obtains a **callose** (glucose polymer related to cellulose) deposit before the **exine** (outer layer of spore) completely forms (Crum 2001). Then the exine attains a **polysaccharide** deposit impregnated with **sporopollenin** (that waxy substance similar to cutin that covers pollen). Last, the **intine** develops with cellulose and other polysaccharides. Once

the formation of the wall is complete, **Takakiopsida**, **Sphagnopsida**, **Andreaeopsida**, and **Bryopsida** spores deposit a **perine** layer that creates ornamentation. As Crum (2001) describes it, this layer is the "detritus" from the walls of the spore mother cells and remains of the columella. Thus, liverworts and hornworts, lacking a columella, also lack the perine deposit. It is the sporopollenin layer that affords all these spores their resistance to water and decay (Crum 2001).

There is considerable documentation that under the right conditions, some spores can survive for considerable periods. Green spores, typical of species that occur in moist habitats, have a shorter viability due to their higher metabolic rate (Crum 2001). Green spores store starch as their food reserve, but yellow spores, those of longer viability, typically store oils and these species are common in drier habitats. Marin (1981) reported that among 120 species of mosses, green spores were more common (87%) than non-green spores. All epiphytic mosses had green spores, whereas non-green spores occurred in taxa of drier or disturbed soils and rocks. Some taxa use protein for their food reserves [the liverwort *Blasia* (Figure 93-Figure 94) and hornworts], but this form seems to be slower to metabolize and cannot be used for quick growth (Crum 2001).

Figure 94. Open capsule of *Blasia pusilla* showing spores and elaters. Photo by Walter Obermayer, with permission.

Sundberg and Rydin (2000) found that buried *Sphagnum* spores could survive at least three years at various depths in peat. Curiously, light-colored spores of *S. balticum* (Figure 95) and *S. tenellum* (Figure 96) had higher survivorship than the darker spores of *S. fuscum* (Figure 49) and *S. lindbergii* (Figure 97), suggesting possible differences in stored food reserves. Spore size did not seem to influence longevity between species, but within a single species (*S. balticum*, *S. tenellum*) the small spores from small capsules seemed to have a greater longevity than those from medium-sized and larger capsules, something that seems counter-intuitive.

Survival in Water

Waterways offer a means of rapid dispersal. In streams they can carry diaspores great distances. In flood plains (Figure 98), diaspores can be buried in mud or travel with a river, germinating at some later point in time when they somehow reach the surface. Spores and gemmae require light to germinate, permitting these diaspores to remain dormant as long as their energy stores permit and their ability to fend off other organisms that might use them for a food source (bacteria, fungi, small animals).

Figure 98. Eroded material transported by water to River Baihe, a tributary of Yellow River Tibet. Such flood plains can house dormant bryophyte diaspores that are ready to grow when the water recedes. Photo by Sven Bjork, with permission.

To test the viability of spores and fragments of bryophytes from various habitats, Dalen and Söderström (1999) stored sets of these from *Ceratodon purpureus* (Figure 27), *Codriophorus* (= *Racomitrium*) *aciculare* (Figure 99), *Dicranoweisia crispula* (Figure 100), *Oligotrichum hercynicum* (Figure 101), and *Schistidium rivulare* (Figure 102), and for six months in water or dry. All species except *S. rivulare* exhibited reduced spore germination frequencies at all time intervals when stored in water compared to stored dry. *Schistidium rivulare*, a species that includes rocks in the splash of rivers and streams, demonstrated longer spore survival than did the other species. This species also had the highest regeneration frequencies from fragments. Nevertheless, diaspores of all these species survived at least some time in the water. In all species, the regeneration frequencies of fragments tended to be lower than those of spores. On the other hand, fragments did not experience any reduction in survival when stored in water compared to stored dry.

Survival of Spores vs Asexual Diaspores

Egunyomi (1978) compared viability of spores with that of gemmae in *Octoblepharum albidum* (Figure 76, Figure 103). He found that spores retain high viability for more than 8 months at temperatures of 22-30°C, 60-75% humidity, whereas gemmae lose viability at about 6 months under those conditions. Germination did not occur in darkness, suggesting that the propagules would not germinate within a diaspore bank. Nevertheless, some germination occurred in as little as 1 lux, suggesting that the species might be able to germinate among a heavy plant cover, but the question remains whether it could grow enough to survive and thrive there. Furthermore, if spores or gemmae were exposed to light, then cultured in dark, a light intensity of 800 lux for 48 & 36 hrs respectively was necessary for them to germinate at all.

Figure 103. *Octoblepharum albidum* gemmae. Gemmae of this species survive for a shorter period than do the spores at temperatures of 22-30°C and 60-75%. Photo by Li Zhang, with permission.

Germination of spores from herbarium specimens suggest that weedy species may remain viable longer than other taxa. *Ceratodon purpureus* (Figure 27) spores were the oldest to germinate – after 16 years (Malta 1922) – but this species surprisingly does not appear in the diaspore bank (Lönnell 2011). Most of the spores in the study by Malta did not germinate if they were more than 10 years old, and the greatest number were viable for only 5 years. In fact, within only 50 days of dry storage, a 30-40% loss in viability can occur (Löbel 2009). But perhaps it is the unnatural storage conditions of a lab or herbarium that causes such loss of viability. For *Sphagnum* spores, 15-35% survived 13 years of storage in humid, refrigerated conditions (Sundberg & Rydin 2000). On the other hand, tubers of *Anisothecium* (= *Dicranella*) *staphylinum* (Figure 104) remained viable for 50 years of storage (Whitehouse 1984). Keever (1957) found that herbarium specimens of *Grimmia laevigata* (Figure 105) still had 20% viability after ten years. Malta (1922) found survival of 19 years in plants of *Anoetangium aestivum* (Figure 106) and Maheu

(1922) found protonemal growth from plants of *Syntrichia ruralis* (Figure 24) after 14 years of storage.

Species from flood plains and other disturbed habitats may have some of the longest dispersal times. They may have considerable distances to traverse to reach a new location, and they may have long periods of unsuitable habitat requiring long survival. *Riccia* provides a good example of such a need. Breuil-Sée (1993) found that specimens of *Riccia macrocarpa* from Tunisia survived in a dry state in the herbarium for more than 23 years. Within three days of rehydration they exhibited new cells at the apices.

Long-distance Survival

Van Zanten, in his numerous papers on dispersal (1975, 1976, 1977a, b, 1978a, b, 1983, 1984, 1985, van Zanten & Gradstein 1987, 1988, van Zanten & Pócs 1981), has shown the possibilities for long-range dispersal based on experimental evidence of survival. Van Zanten (in Gradstein & Pócs 1989) showed that New Zealand **endemics** (growing only in that area) had less resistant spores than those of wide-ranging taxa and that spores of tropical moss species, especially lowland rainforest taxa, are less resistant to drought than are temperate taxa, but surprisingly, the tropical taxa survive wet-freezing at -30°C! Tropical liverworts had similar relationships, but in general were less viable under extreme conditions than were the mosses (Van Zanten & Gradstein 1987). Trans-oceanic liverworts from Colombia have better resistance to desiccation and wet-freezing than endemic taxa. Nevertheless, only spores of *Marchantia chenopoda* (Figure 83), of the 61 species tested, survived travel on the wing-tips of an airplane. But death rates were also very high for the spores transported inside the wing. Van Zanten and Gradstein concluded that jet-stream altitudes were not favorable to long-distance dispersal, but that travel in wet air currents at high altitudes was a possibility for most of these liverworts. Dry air currents were more lethal.

Van Zanten (1977b, 1978b) found one puzzling relationship in longevity. After testing survival of drought, dry freezing, and wet freezing (up to 3 years), he found that spores from Northern Hemisphere bryophyte species tended to have a longer viability than those from the Southern Hemisphere. Not surprisingly, species with restricted distributions tended to have shorter periods of viability than species that occurred on multiple continents.

It appears that some spores, perhaps even the majority, can survive for many years provided they remain dry and in the dark. A false start in which they become hydrated and begin germination can be fatal if they are not permitted to continue development and produce sugars photosynthetically.

Establishment Success

As Brent Mishler pointed out on Bryonet (6 March 2013), particulate matter from China commonly reaches California. Dust from the Sahara reaches Texas. The opportunities for worldwide dispersal seem sufficiently common that most bryophytes should be everywhere, but "the environment selects." Once the propagules enter the transport stream, they must survive, arrive, germinate, and establish (SAGE).

Greater success of spores as a means of establishment through dispersal seems to be correlated with a lower age of first reproduction and greater phenological flexibility, but suffers a tradeoff, being correlated with decreased longevity (Longton 1997). For the conservation of rare species, the conditions of establishment upon arrival are particularly important (Cleavitt 2005). Hutsemékers *et al.* (2008) determined that rare species not only require specific habitat conditions, but that they typically are unable to compete. Therefore, when new habitats, such as slag heaps, are created, the rare species tend to enter at intermediate stages, after establishment of widespread species, but before the perennial competitors become established.

Buck (1988), in his study of the Tepui of Venezuela, hypothesized that the lack of moss flora on the summit of the Tepui was due to lack of dispersal from great distances and that available spores came from surrounding lowlands. Thus, failure of a diverse moss flora on the summit must be due to lack of adaptation for germination and survival on the summit. He was fortunate enough to be able to test this hypothesis when he discovered a "world within a world" on top of a Tepui. A sinkhole, 352 m wide and just as deep, provides a haven away from wildly fluctuating moisture and temperature conditions of the summit. In this sunken world, a forest similar to that of the lowland exists. He did indeed find that the moss flora in this sunken forest reflected that of lowland and not that of the summit, supporting his hypothesis that it was ecological conditions and not lack of dispersal that created the depauperate flora.

Germination success seems to be a major problem for spores, and much less so for vegetative propagules. Miles and Longton (1990) found no evidence of spore germination for *Polytrichum strictum* (Figure 60) in the field, but did find new shoots arising from vegetative fragments. By contrast, in *Funaria hygrometrica* (Figure 107-Figure 109), spore germination and establishment occurred frequently. Intermediate results were evident in *Atrichum undulatum* (Figure 6) and *Bryum argenteum* (Figure 7), with frequent regeneration from shoot fragments, and spores germinating, but sporelings usually failed to develop. Shoots seemed to develop easily in the latter two from protonemata planted in the field.

In the Negev Desert, it may be the ants in the genus *Messor* (Figure 110) that ensure the success of at least some moss spores (Loria & Herrnstadt 1980). They carry the capsules of *Crossidium crassinerve* (Figure 111) away to their nests, thus greatly increasing the likelihood that at least some spores will arrive in a suitable site for protonematal survival.

Spores can be a means of surviving while competitors make living conditions impossible. Newton and Mishler (1996) found evidence of inhibition by mature plants on the germination of spores. However, if something were to destroy those mature plants, the sporebank could provide a new source of propagules for re-establishment. In fact, it appears that mature plants can have a sneaky way of prolonging time until germination of their spores. Mishler and Newton (1988) found that germination rates of both *Dicranum* (Figure 112) and *Tortula* (Figure 113) were greatly lowered on substrates of their parents. Although both *Dicranum* (Figure 98) and *Tortula* were severely affected by the presence of their parents, fragments were less affected than spores. *Dicranum* had an even greater inhibitory effect than did *Tortula*. Mishler and Newton compared this to the inhibitory effect that female *Dicranum scoparium* (Figure 112) has on spores that produce dwarf males when they germinate on the female plants. Mishler and Newton (1988) found that spores did better in continuously hydrated conditions, whereas fragments fared better when they had occasional drying.

Figure 112. *Dicranum scoparium* on the forest floor where it grows dwarf males on its own leaves. Photo by Janice Glime.

Keever (1957) found that spore germination of *Grimmia laevigata* (Figure 105) does occur on granite rock, but even there, fragments were more successful. One factor that influences the success of fragments vs spores is state of hydration, and this may have played a role in the establishment of *Grimmia laevigata*.

Hedderson (1992) found that rare mosses in the Terra Nova National Park, Newfoundland, Canada, were typically representatives of temperate, Arctic-montane, or montane floras. They are species at the edges of their ranges. He found that dispersal potential was negatively associated with rarity. These species have a narrow range of habitats and therefore are likely to have establishment problems.

Adherence

Arrival on the proper substrate is pretty much the end of the transport part of the story for most substrata, but for epiphytes and bryophytes on other vertical surfaces, or for those in flowing water, the problems don't end there. They must next adhere so that wind and rain don't take them once again on their journey. Van Zanten and Gradstein (1988) found that for Neotropical liverworts, the spore surface of epiphytes typically had finely verrucose spores with rosettes of large papillae (Figure 114). They suggested that these decorations were an adaptation that permitted them to adhere to rough surfaces such as bark. Epiphyllous and desert taxa, on the other hand, typically have spores that lack these rosettes (Figure 115). Both groups may gain further advantage by having precocious spore germination (Figure 75), permitting them to continue growth upon landing and gain a wider surface of adhesion.

Adherence may also be a problem in some aquatic habitats, such as streams and flood plains. But here the relationship is not so clear. Spores of *Riella* (Figure 116) are clearly spiny, possibly permitting them to adhere to the substrate more easily, but those of *Fontinalis* (Figure 117), a genus that typically adheres to rocks or underwater roots, are nearly smooth, having only small, rounded papillae.

Conditions Matter

It is clear that survival while getting there is only part of the battle. Although the spores may arrive in viable condition, they may not succeed in germinating. Hassel and Söderström (1999) collected spores from *Pogonatum dentatum* (Figure 118) and germinated them in the laboratory. They had 96.6% germination within 21 days. They tested success in the field by sewing spores from 0.5, 1, and 2 capsules on 37 replicate quadrats of 10x10 cm. Considering the large estimated number of spores per capsule of 712,000, germination success was abysmal, with means of 11, 10, and 12 shoots produced, respectively, in the first year. They suggested that they had exceeded maximum density for successful protonemata. But it could also mean that some other field condition was not conducive to protonema development.

During (1986) found a similar problem in *Funaria hygrometrica* (Figure 107-Figure 109). In the greenhouse, shoots emerged from chalk grassland soil samples, even after two years, but in the field, none emerged. During considered that this failure in the field might be due to insufficient water or nutrients.

Figure 118. *Pogonatum dentatum* in Norway. Photo by Michael Lüth, with permission.

Drought tolerance of liverwort sporelings is significantly different between transoceanic and endemic species. This is a critical period for many species, with 30% of transoceanic species germinating after 50 days of desiccation and 30% of endemic species reduced to 30% germination after only 13 days. Both groups have a sporeling longevity of only about half that of spore longevity.

The problem of crowding, as suggested by Hassel and Söderström (1999) for *Pogonatum dentatum* (Figure 118), is only one problem faced by germinating spores close to the parent, and is one of little significance for long distance dispersal. The low numbers are more likely due to other problems in the field as well, including perhaps too much UV light, insufficient nutrients or moisture, or unsuitable temperatures. Noguchi and Miyata (1957) pointed out that at least some mosses with wide geographic ranges have abundant spores but are confined in their frequency by having rather specific habitats.

Multiple factors contribute to the success of a species upon its arrival. The conditions required for germination and development of the protonema and gametophore buds may differ, and are all part of the niche of a species, a topic that will be discussed in more detail in another volume. But it is appropriate to consider some examples here as we define limits of establishment.

Wiklund and Rydin (2004) compared spore establishment of two forest bryophytes, one [*Neckera pennata* (Figure 15-Figure 16)] an epiphyte and the other [*Buxbaumia viridis* (Figure 119)] an inhabitant of decaying logs. Using *in vitro* experiments, they determined that *Neckera pennata* was less successful at germinating at a low pH than was *Buxbaumia viridis*. The tradeoff was that *N. pennata* exhibited earlier germination at low water potential and survived longer when desiccated. They suggested that the higher pH would speed up germination and enable the spores to exploit short moist periods. This niche separation at the time of establishment is often not apparent by the range of tolerance of mature plants but can be critical to establishment of spores.

Figure 119. *Buxbaumia viridis* capsules on log. Photo by Hermann Schachner, through Creative Commons.

Sphagnum spores under wet, anaerobic conditions had much lower survivorship (dying within 2-3 years) than those under wet or periodically desiccated aerobic conditions, suggesting that respiration not only continued but was necessary for their survival (Sundberg & Rydin

2000). Refrigerated spores lasted up to 13 years. This infra-species size difference, coupled with the ability to survive freezing in upper atmosphere conditions, might permit the small spores, already better adapted for long-distance transport, to survive the greater time they are likely to be in transport.

Sphagnum provides a good example of the need for a specific nutrient. Despite the apparently good longevity of spores of *Sphagnum* species, few protonemata (Figure 77) have been observed in the field (Sundberg & Rydin 2002). Sundberg and Rydin attribute this absence to the need for phosphorus in greater concentrations than that typically found in natural waters. Various peat substrata were tested and it appeared that the amount of phosphate released was the determining factor in successful germination. Moose dung increased the success rate, as did litter from *Betula pubescens*. *Pinus sylvestris* litter did not help.

It appears that *Sphagnum* has other establishment needs as well. *Sphagnum* spp. fragments that arrived at a restoration project were unable to succeed unless they joined a *Polytrichum strictum* (Figure 120) carpet (Groeneveld *et al.* 2007). Apparently the carpet was important in keeping the developing *Sphagnum* moist. Groeneveld *et al.* considered that buffering of the temperature, making it cooler in daytime and warmer at night, may have been important as well.

Figure 120. *Polytrichum strictum* with *Sphagnum* growing between the stems. Photo by Andrew Hodgson, with permission.

Cleavitt (2002) tested the stress tolerance of fragments of pairs of rare and common species of mosses in view of their asexual dispersal potential. Habitat specificity in the three common species was more likely to correspond to physiological differences. For example, the common *Mnium spinulosum* (Figure 121) was intolerant of high light conditions and therefore only became established in the deep shade of conifer stands. The common *Bryum pseudotriquetrum* (Figure 122) was intolerant of desiccation and only became established on stream banks and other moist areas. The striking observation was that the rare *Mielichhoferia macrocarpa* (Figure 123) was tolerant of both high light and desiccation, but had the slowest rate of recovery, suggesting that some other factor contributed to its rarity, such as competition during its slow recovery, or insufficient time to recover in natural conditions before again suffering desiccation. And other factors in the environment could also be important establishment factors.

Bryophytes can be slow colonizers compared to some of the other taxa. Nevertheless, on Surtsey, they were among the first arrivals on the solidified lava. The typically early colonizers among the Cyanobacteria were remarkably scarce. Their most common locations were near steam vents, usually near moss clumps, particularly *Funaria hygrometrica* (Schwabe 1974; Figure 107-Figure 109). These nitrogen-fixing blue-green bacteria were especially attached to the protonemata. The moss *Racomitrium* (Figure 29), however, seemed to inhibit the growth of Cyanobacteria.

Slow Establishment

As we have noted above for *Mielichhoferia macrocarpa* (Figure 123), slow recovery may account for the lack of success in some species that arrive by diaspores. Leck and Simpson (1987) noted this problem for species recovered from a wetland diaspore bank. They identified 14 mosses, 2 liverworts, 7 ferns, and 1 horsetail, with *Bryum* sp (Figure 122) and the fern *Onoclea sensibilis* having the greatest densities. The highest densities occurred in the surface samples. Germination of spores and/or growth of these diaspores was slow compared to that required for seeds from seedbanks and they considered this slowness to be a factor in the absence of the bryophyte species on the surfaces of the wetlands.

Dispersal Limitation

A number of studies suggest that dispersal limitation is the best explanation for the patterns of abundance and distribution of bryophytes in some fragmented habitats (Pharo & Zartman 2007). But edge effects can also play an important role. Because of their small size, fast colonization-extinction rates, high substrate specificity, and dominant haploid condition, Pharo and Zartman consider them to be ideal model systems for testing the effect of fragmented landscapes on bryophyte community structure.

Nearness of source has been shown repeatedly as an important determinant of colonization, although Hylander (2009) found no relationship between colonization rate and nearness to mature forest stands for boreal forest bryophytes. This nearness component was well illustrated by Zartman and Shaw (2006) in their study of two epiphyllous species [*Radula flaccida* (Figure 124), *Cololejeunea surinamensis*] in the Amazon tropical rainforest. While extinction rates were the same for these species in both fragmented and continuous forests, colonization rate was much greater in the continuous forest sites (Figure 125).

Kimmerer (2005) demonstrated the importance of dispersal at a small scale in the colonization of treefall mounds in the Adirondack Mountains, USA. When spores and fragments of *Polytrichum ohioense* (Figure 126), *Dicranella heteromalla* (Figure 127), *Atrichum angustatum* (Figure 5), *Diphyscium foliosum* (Figure 128), and *Pogonatum pensilvanicum* (Figure 129) were sown on the mounds, these species became established, with the highest success occurring with fragments. Under natural conditions, only 1-2 of a possible 13 species established on any single mound and likewise, in the experiment, sown propagules were far more successful than natural dispersal to mounds with no added propagules.

Kimmerer considered this to be strong evidence of dispersal limitation on treefall mounds.

Recolonization

In some habitats, bryophytes are among the first organisms to colonize a disturbed site. These are generally fugitives and other species that cannot tolerate the competition of tracheophytes. They take advantage of the sun but must tolerate greater drying than the species living in forested habitats. But they must also have good dispersal capabilities to arrive there and thrive before the competition arrives.

Arrival in disturbed habitats can be extensive, as Greven (1994) observed in an experimental garden. Between 1972 and 1991, 91 species arrived in the garden. The greatest number of taxa occurred on the chalk soils (40 spp), with peat having the fewest (6 spp). Even several rare taxa arrived.

In an urban environment, a community can re-establish itself in 1-2 years (Nehira & Nakagoshi 1987). Thalloid liverworts and pleurocarpous mosses were the first to regenerate, ahead of the acrocarpous mosses. This is somewhat unusual as the acrocarpous mosses typically have more asexual diaspores than do pleurocarpous mosses, but regeneration may have occurred from remnants and fragments, a dispersal mechanism common among pleurocarpous taxa. Regrowth occurred primarily in the spring and autumn, despite little seasonal variation in the number of airborne diaspores, suggesting the importance of rainfall and perhaps cool temperatures.

Forests

The slow rate of recolonization in harvested regrowth forests is illustrated by the smaller number of species present, presumably due to the slow rate of dispersal and establishment of species common in old-growth forests (Cooper-Ellis 1998). In the Central Cordillera of Colombia, Corrales *et al.* (2010) considered the dispersal of propagules among the various forest types to be the primary mechanism driving the regional pattern of bryophyte distribution.

Proximity to other suitable bryophytes seems to be a major factor in what species will become established after a disturbance. Even in the limited microcosm of a leaf, Cobb *et al.* (2001) found that bryophytes colonizing *Acer macrophyllum* leaves (epiphyllous) in Olympia, Washington, USA, after experimental removal of the epiphylls, were primarily due to lateral encroachment (75%). Only ~8% of the exposed area had been recolonized one year after removal of bryophytes, reaching 27% after three years. The 25% not colonized by encroachment included incompletely removed plant parts and aerially dispersed diaspores.

On the other hand, in young boreal forest stands, there was no indication of higher colonization by bryophytes close to the mature stands where bryophytes were undisturbed (Hylander 2009). Following a forest fire, bryophytes that recolonize can either arrive anew or survive the fire. Survival of the fire could be the result of migrating to a safe site during the fire (*i.e.*, local dispersal to safety) or by enduring the conditions (Hylander & Johnson 2010). Endurance can be due to wetness, burial, or positioning in the protection of logs, rocks, or other blockades to the fire. Hylander and Johnson (2010) found an average of three refugia per 50 x 50 m reference plot,

with a mean of 4.8 bryophytes associated with them. But in the area that had been burned, only a mean of 1.5 species could be found in the refugia. However, other factors seemed to be more important than refugia. There was no correlation between the number of refugia and the number of forest species that colonized the plots. The refugia were mostly on rocky or mesic sites, not wet sites. The importance of these refugia most likely depends on the intensity and nature of the fire. A ground fire will have a very different effect from a crown fire.

Schmalholz and Hylander (2010) examined a similar question regarding the role of forest floor refugia in response from clear-cut logging. They found survival differences based on microtopography. The shelter of boulders and stumps resulted in significantly more survival (~30%) than on level forest floor (10%) for transplanted bryophytes. These boulders and stumps also resulted in less change in species composition.

Evidence from Europe suggests that the same forest can be colonized by a bryophyte species multiple times. Cronberg *et al.* (2002) found repeated recruitment among populations of *Hylocomium splendens* (Figure 33) on 10 Baltic islands. He identified 103 haplotypes among 694 shoots with number of clones increasing significantly with increasing age of the islands. He likewise showed that the number of genotypes of *Plagiomnium affine* (Figure 130) correlated with the age of the forest stand in Europe (Cronberg 2005). Using 23 allozyme loci and six populations of *P. affine*, they sampled 602 shoots and found 16 haplotypes. Among these, 12 were unique to single populations. Allelic richness and diversity were significantly correlated with forest age at the ramet level but not quite so at the genet level.

Patch Fragmentation

Logging has an impact on the distribution of bryophytes. Isolated patches that remain may be invaded by new species and disturbed areas will both lose old species and gain new ones. In the temperate rainforest of British Columbia, Canada, Baldwin and Bradfield (2007) compared bryophytes on the forest floor, downed logs, and tree bases. They found that the dispersal-limited groups

such as perennial stayers and the microclimate-sensitive groups declined in species richness or frequency as patch size decreased. These microclimate-sensitive groups included those from closed canopy, log-dwelling species, and liverworts. Colonists and open canopy species showed little relationship to patch size. In the patch size range of 0.6–63.6 ha, most of the patch size effects disappeared when the three smallest patches (0.6–1.8 ha) were not included in the analysis. Therefore, patch sizes of at least 3.5 ha seem to provide suitable habitat to sustain the diversity of bryophyte functional groups in this temperate rainforest habitat. It is likely that part of this decrease in diversity is due to dispersal limitation.

Summary

Most bryophytes are adapted for wind dispersal, with the occasional updraft or gust permitting somewhat greater distances. Epiphytes gain height through their host. However, the majority of spores seem to land within 2 m of their parents. It follows that spore density in the atmosphere decreases with distance from the source and increases with height of the colony.

Members of the **Polytrichaceae** have a membrane connecting their teeth and disperse spores by disturbance such as rain drops. These are ejected horizontally and apparently do not travel far.

Bryophytes that live on temporary and disturbed substrata, such as logs and arable land, require either good dispersal or the ability to survive in diaspore banks.

Tracheophyte dispersal models have limited applications to bryophyte dispersal. Bryophyte spores are much smaller than seeds and lack multiple layers of tissues to protect them. Vegetative diaspores may mimic some of the elongate shapes, but spores tend to travel farther than vegetative propagules.

Bryophytes seem to support the concept that "everything is everywhere, but the environment selects." Unfavorable light, photoperiod, substrate, temperature, and moisture conditions can prevent establishment of a species once it arrives. This concept is supported by the small size of spores, the distribution patterns, and patterns of establishment on newly formed islands.

Molecular Clocks can be used to estimate time of arrival and help us to trace the dispersal routes.

Weather, dust storms, and fires can play a significant role in creating air currents, protecting from UV, and maintaining moisture.

Even diffusion models can help us understand dispersal, but size, falling velocity, and access to the air stream all have roles in the distance travelled. Long-range dispersal is facilitated by wind, requiring updrafts to get spores into the atmosphere. There the spores must survive UV light, desiccation, and extremes of temperature, especially sub-freezing temperatures. In some areas there is clear evidence of **stepping stone** progression once the first propagule arrives and succeeds in the area.

Small spores travel the farthest; large spores provide more energy for the start of growth. Spores

range from 5 μm in *Dawsonia* to 310 μm in *Archidium*, with numbers per capsule ranging from 4 in *Archidium* to 50 million in *Dawsonia*. Most bryophyte spores range about 20–100 μm and hence weigh about 0.004 μg to about 0.52 μg , all falling in the size category where wind dispersal is expected. Few animal dispersers are known for bryophytes. Most spores seem to fall within 2 m of their parents, but only a few need be caught into updrafts in order to accomplish long-distance dispersal. Limited **gene flow** between populations, demonstrated by genetic variation between them, suggests that most populations arise from a single propagule and that there is little mixing. This is further supported by the lack of genetic variation within populations.

Height of origin, such as epiphytes or species on walls and boulders increase dispersal effectiveness. Many dispersal periods are correlated with dry weather, especially for small spores, but at least in some locations, spores can be trapped from the atmosphere year-round. Some capsules require more than a year to develop whereas others mature in a few weeks. Few data exist that identify the species of atmospheric travellers, but certainly *Funaria hygrometrica* is one of them. Often the spores that are travelling are different from the species of a particular environment.

Long-distance dispersal is limited by drought tolerance and UV radiation (lethal for most species). For Neotropical liverworts, there is no dispersal advantage based on spore size, bisexuality among small-spored species, presence of chlorophyll, verrucosity of spore wall, and presence of gemmae. Bisexuality seems to have a positive advantage in large-spored (>35 μm) species. Species with greater source distributions and greater area of suitable destination habitats have greater dispersal potential. Dark-colored spore walls may protect against UV radiation. **Callose** deposits on the spore, waxy **sporopollenin** on the surface, and in most mosses a **perine** layer, all may contribute to protection of the spore.

Wet freezing has equal effect on transoceanic and endemic species. Both spores and sporelings survive longer with good drought tolerance. Among large-spored species (>25 μm), xerophytes survive dispersal better than mesophytes or hygrophytes. Dispersal by water is possible in many taxa, with survival times ranging from a few days to many months. **Spore longevity** is known from 7 days to 50 years.

Once arriving, spores and vegetative diaspores must adhere. For spores, verrucose surfaces can facilitate catching on something, such as tree bark.

Because of the limits of dispersal, ability to remain viable in soil banks, and changes in environmental conditions, the bryophytes that become established following a disturbance may differ considerably from the original flora.

Acknowledgments

This chapter has benefitted greatly from the wonderful discussion on Bryonet in March 2013. Thank you also to the helpful comments of a novice bryologist, Tatiany

Oliveira da Silva, on places that needed to be clearer for international and novice readers. I also thank Tatiany, Tami Olson, and Rod Seppelt for helping me think through the conversion from spore diameter to spore weight and for assessing the clarity of its presentation. Steve Trynoski offered several suggestions after a critical reading of this subchapter.

CHAPTER 4-9

ADAPTIVE STRATEGIES: SPORE DISPERSAL VECTORS

TABLE OF CONTENTS

Dispersal Types.....	4-9-2
Wind Dispersal.....	4-9-2
Splachnaceae.....	4-9-4
Liverworts.....	4-9-5
Invasive Species.....	4-9-6
Decay Dispersal.....	4-9-6
Animal Dispersal.....	4-9-9
Earthworms.....	4-9-9
Insects and Spiders.....	4-9-10
Ants.....	4-9-10
Aquatic Insects.....	4-9-11
Sticky Spores.....	4-9-12
Muscidae and Dung Mosses.....	4-9-12
Diversification of Spore Dispersal Strategies.....	4-9-14
Molluscs.....	4-9-20
Fish.....	4-9-22
Birds.....	4-9-22
Mammals.....	4-9-30
Water Dispersal.....	4-9-31
Common Adaptations.....	4-9-32
Marine Dispersal?.....	4-9-33
Flood Plains and Dry Flats.....	4-9-33
Raindrops.....	4-9-34
Exploding Capsules?.....	4-9-35
Vortex Rings.....	4-9-35
Role of Stomata.....	4-9-36
Is This an explosion in <i>Sphagnum</i> ?.....	4-9-39
Falling Rate.....	4-9-40
A <i>Sphagnum</i> Spore Mimic.....	4-9-40
Summary.....	4-9-40
Acknowledgments.....	4-9-40
Literature Cited.....	4-9-40

CHAPTER 4-9

ADAPTIVE STRATEGIES: SPORE DISPERSAL VECTORS

Figure 1. Capsules of *Splachnum ampullaceum*, adapted for fly dispersal by both red colors and their odor. Note the special landing platform (**hypophysis**) below the cylindrical capsule. Photo by Michael Lüth, with permission.

Dispersal Types

Gao *et al.* (2000) examined the Chinese bryophyte flora and concluded that there are five classes of spore dispersal. These are wind dispersal, vapor-wind dispersal, water dispersal, decay dispersal, and insect dispersal. But more digging reveals that additional dispersal agents may be at work among the animals, including earthworms, spiders, molluscs, birds, and even mammals.

Hughes *et al.* (1994) concluded that the availability of specific dispersal vectors seems to have no influence on dispersal mode. I think that one could use flies that visit the **Splachnaceae** on dung to argue against that conclusion, but there do not appear to be any studies that attempt to correlate dispersal mode with availability of the vector.

For spores to gain access into the atmosphere, they must be expelled away from the capsule and join wind currents before they fall to the ground. One can flick a newly opened capsule and see clouds of spores emitted. It is likely that deer, rabbits, squirrels, and various small rodents bump these extended capsules, likewise sending up clouds of spores. To this end, the **peristome teeth** (Figure 2-Figure 4) of many mosses work like a saltshaker and permit only a portion of the spores to escape in one event. This helps to insure that dispersal takes place over an extended period of time and may then encounter more climatic conditions wherein some are suitable for good or even long-distance dispersal.

Wind Dispersal

Wind dispersal is assumed to be the rule among most bryophytes. But few data were available to support that concept for long-distance dispersal.

As we discussed in examining long distance dispersal, any propagule released from a greater height or elevation has a greater probability of being exposed to greater wind velocities (Greene & Johnson 1996). This means that greater heights increase the opportunities for wind dispersal. Campbell *et al.* (2001) contend that mosses have high immigration potential due to the wind-dispersal ability

of their spores. This would seem to argue against the conclusions of Hughes *et al.* (1994) that the availability of specific dispersal vectors has no influence on dispersal mode. As already discussed in the previous sub-chapter, successful wind dispersal relates to release height and falling time (slow for spores due to small size). Wing loadings in bryophytes are very low and probably have insignificant effect. Release height can be increased by explosive behavior of some capsules, and location on trees or at higher elevations likewise increases the opportunities to become airborne..

Lönnell (2011) reminds us that according to Stoke's law (Figure 5) spores can travel farther than larger diaspores of the same shape and density, given the same wind speed. [Stoke's Law: If particles are falling in a viscous fluid by their own weight due to gravity, then terminal velocity, also known as settling velocity, is reached when this frictional force combined with the buoyant force exactly balance the gravitational force.] Lönnell compared small seeds to large seeds, stating that, even if larger seeds can increase the buoyancy with features like pappi or wings, small seeds can still travel farther. Bryophyte spores lack such features as wings, but do possess pappi and other surface features. I am unaware of any study that has examined the role of variations in these markings as a means to facilitate wind dispersal. Perhaps they do, however, create buoyancy in water, permitting them to float and thus get dispersed farther.

Figure 5. Stokes sphere showing movement of fluid around it. F_d is the frictional force, known as Stokes' drag. F_g is the force by gravity. Image from Wikimedia Commons.

Cronberg *et al.* (2008) were able to capture the effects of wind on the initial dispersal of spores of *Bryum argenteum* when they filmed the life cycle. They found that the release was rapid. The peristome opened and closed in response to minor changes in atmospheric moisture conditions. The capsules in this species hang down, with gravity causing the spores to collect over the peristome, but on the inside. When the peristome teeth open, a group of spores fall out and are dispersed in a cloud. Air movements can carry the spores upward (Figure 6).

Figure 6. *Bryum argenteum* spore release, showing upward movement. Photo by Nils Cronberg, Hans Berggren, & Rayna Natcheva, with permission.

We lack measures of density of bryophyte spores in the atmosphere, but experience with other organisms and particles are instructive. Schlichting (1978) tells us that there are 0.3-7.5 billion particles greater than 0.2 μm in diameter in one cubic meter of "clean air." And joining these organisms are spores of bryophytes. Puschkarew (1913) found an average of 2.5 protozoan cysts in a cubic meter of air, attesting to the success of somewhat larger structures being transported.

In sampling airborne algae in Michigan, USA, Schlichting (1964) found the greatest numbers of algae and protozoa between noon and midnight on cloudy days, with more during July and August than during September through May, although this may have related more to innate life cycles than to that year's weather conditions. The wind elevation angle (*i.e.*, horizontal vs vertical) seemed important in determining the number of organisms present; wind direction and speed seemed less important. Updrafts were more important than downdrafts or horizontal wind. Rainfall during the preceding 24 hours was detrimental to organism presence, most likely quickly washing them from the atmosphere. Sizes of the most common propagules ranged from the one-celled alga *Chlorella* with diameters of ca. 2-8 μm to those of cysts of the protozoan *Oikomonas*, for which living cells range up to 100 μm or more (without knowing the species, we cannot determine the size of the cysts, but they are likely to be similar). This range encompasses the majority of spore sizes of bryophytes.

But wind is constantly changing, and averages can be misleading. Sudden changes in direction can stir up tiny tornadoes that may dislodge and uplift spores. This might be especially true on glaciers. Bonde (1969) collected plant propagules from wind-blown debris on St. Mary's Glacier at 3350 m. He found 35 species of seed plants, but he also found viable parts of the moss *Polytrichum piliferum* (Figure 7), lichens, and *Selaginella*.

Figure 7. *Polytrichum piliferum*, a moss whose fragments are known from wind-blown debris. Photo by David T. Holyoak, with permission.

In the Southern Hemisphere, it appears that wind has played an important role in geographic distribution of bryophytes. Muñoz *et al.* (2004) found that there was a stronger correlation of floristic patterns with wind patterns than with geographic proximities, supporting wind dispersal for the arrival of many organisms in the Southern Hemisphere. These wind patterns followed "wind highways" that resulted in directional dispersal and distribution.

Felicísimo *et al.* (2008) attempted to understand the role of global wind patterns in dispersal by not only wind data but also the pathway of a tracked seabird, the Cory's Shearwater (*Calonectris diomedea*). Birds are able to locate the pathways that require the least energy to carry them to their destination, going higher or lower, following mountains or other areas where updrafts and wind movement help to carry them where they need to go. The shearwaters followed the pathways predicted by the air pattern model, but when they reached the Atlantic sector of the Intertropical Convergence Zone, they were hindered by the near-surface westerlies. Only after these westerlies ceased were the birds able to cross this zone. Hence, we have evidence for seasonal differences in the most energy-effective pathways.

To understand the diaspore rain, it is necessary to trap the propagules, then culture them. Ross-Davis and Frego (2004) report success with diaspore traps using nutrient agar plates. These trapped diaspores grow well from both spores and vegetative propagules at indoor ambient conditions – so well that they need to be transplanted due to crowding. But patience is required; it takes nine months for them to reach a recognizable stage.

Splachnaceae

This family is best known for its spore dispersal by flies. But Walsh (1951; see also Bryhn 1897) has observed an alternative method – wind dispersal. He observed that in *Splachnum sphaericum*, when the capsule dried, the

peristome teeth became reflexed, adhering to the outside of the capsule. From the inside, the spores were pushed out as the capsule dried and shrank. And the **columella** extruded from the capsule – a phenomenon known in only a few mosses. The spores form a ring around the top of the capsule and adhere to each other in clusters. The teeth remain hygroscopic and withdraw when moisture returns. Furthermore, the spores likewise withdraw and the capsule once more becomes turgid and swollen. This extension and intrusion of peristome and spores can continue to occur as moisture changes occur. When the peristome reflexes, it typically carries adhering spores away from the capsule.

Figure 8. Young capsules of *Splachnum rubrum* with **operculum** (cap) still intact on all but one capsule. Note that the umbrella-shaped structure is a **hypothesis** that occurs at the base of the capsule. Spores are housed inside the cylindrical structure above it. Photo by Michael Lüth, with permission.

Figure 9. Capsules of *Splachnum rubrum* that have shed their opercula. Note the exerted teeth and the ring of spores at the capsule opening. Photo by Michael Lüth, with permission.

When struck by a strong wind, the extruded clusters may extend from the capsules in either clumps or threads. Sometimes the wind causes the threads to bend back upon themselves, in which case the thread more closely resembles a clump. But in some cases the clusters or threads may break loose, effecting dispersal. The stickiness of the spores is important in assuring that both genders arrive on the new substrate, hence making spore

production possible in that generation. But Walsh was unable to observe the fate of these escaped spores. The dung substrate necessary for the life cycle to continue is rare relative to all the other possible landing substrates available. I would think that even though wind dispersal is possible, it would be rare that successful landing on a suitable dung substrate would occur.

Liverworts

Schuster (1966) considered liverwort dehiscence and spore dispersal to be timed to occur when there would normally be strong, drying winds to dry the outer layer of the capsule wall, causing the valves to curl backward. Since outer walls would dry first, they would be more contracted than inner walls.

Liverworts are aided in spore dispersal by elongate structures with spiral thickenings called **elaters** (Figure 12). These respond to changes in moisture, causing walls of cells between spirals to contract, thus resulting in twisting of elaters and contortion or bending of cells. When the elater reaches a certain point of tension due to remaining water adhering to walls of drying cells, it

suddenly releases the remaining water and jerks into its original shape, thrusting nearby spores into the air. There are variations on this theme, discussed in the subchapter on Marchantiophyta. Schuster (1966) considers that in liverworts, numerous small spores (6-18 μm in diameter) are an adaptation for wind dispersal.

Figure 12. *Hymenophyton* sp. spores and elaters. Photo by Karen Renzaglia, with permission.

Invasive Species

The invasive *Campylopus introflexus* (Figure 13) has spread rapidly over Europe, apparently by its small spores (Hassel & Söderström (2005). Once there, it spreads rapidly by programmed fragmentation of deciduous leaves. *Orthodontium lineare* (Figure 14), another invasive species in Europe, spreads by numerous small spores. It lacks vegetative reproduction, although its ability to grow from fragments remains to be tested. Because it must establish and spread by spores, it requires about thirty years before it is able to produce mature spores; *Campylopus introflexus* requires only ten. It appears that the spread of spores in both species is predominantly (or entirely) by wind.

Decay Dispersal

Some capsules lack peristome teeth and do not dehisce (**cleistocarpous capsules**; Figure 15-Figure 18). In these cases, the capsule must decay or be eaten for spores to escape.

Figure 15. *Goniomitrium enerve* with cleistocarpous capsules. Photo by David Tng, with permission.

Even some capsules with an operculum and peristome may use decay as a means of releasing spores. In *Fontinalis novae-angliae* (Figure 19) and *F. dalecarlica* (Figure 20), abrasion by flowing water and debris (in New Hampshire, USA) often erodes the capsule wall away with the operculum still intact. The capsules in this genus tend to be quite thick, perhaps an adaptation against premature erosion. But the question remains, are the spores still viable in these older capsules that seem to be heavily endowed with phenolics, or are these capsules that aborted before reaching the maturity needed for normal dehiscence and dispersal? Since these spores disperse in late winter, observations on the actual dispersal seem to be lacking, my own included.

I have observed capsules in these two species, still submersed, but not yet mature. Korsteli (2003) observed very different behavior in *Fontinalis antipyretica* (Figure 21) from the dense capsule walls I observed after spring runoff. He reported that sporophytes in this species are produced under water, but that dry conditions were needed for the capsule to dehisce. Under such conditions, the operculum tears loose, lifted by hygroscopic movements of the exostome teeth. Spores are released by reversible changes in the shape of the capsule! Misha Ignatov

(Bryonet 29 March 2013) observed the teeth in the lab and watched them gyrate as they dried (Figure 22).

Buxbaumia aphylla (Figure 23) seems to disperse its spores more commonly by having the capsule split across the broad, flat upper surface. The capsule wall peels back, exposing the spores (Figure 23). In my observations, this appears to be the typical case – I have not found capsules with intact walls and exposed teeth, the condition one would expect for dispersal through the capsule opening. In fact, my early observations led me to think these capsules were being eaten, but careful periodic observations by my graduate student, Chiang-Liang Liao, proved me wrong. Nevertheless, once the spores are exposed, it appears some insects may indeed feed on them and potentially disperse them. Müller (2012) found that adult fungus gnats (Mycetophilidae; Figure 24) in Germany feed on these spores (Figure 24-Figure 25) and thus might carry spores on their bodies, consequently dispersing them.

It may surprise the novice to find that in the fly-dispersed family Splachnaceae exist non-fly-dispersed species that require capsule decay for release of spores from the capsules. In these species, there are no teeth and the capsule does not dehisce. Among these are *Voitia nivalis* (see Figure 26) (Goffinet & Shaw 2002) and *Tayloria callophylla* on soil (Figure 27); others are epiphytic except for two additional coprophilous but **cleistocarpous** (capsule not opening) species.

Figure 27. *Tayloria callophylla* with capsules, from New Zealand. This is a species that occurs on soil and lacks the expanded hypophysis typical of *Splachnum*. Photo by Zen Iwatsuki, with permission.

Carrión *et al.* (1995) cite xerophytic *Phascum* spp. (Figure 28), *Pterygoneurum* spp. (Figure 29), and *Acaulon* (Figure 30) as sharing cleistocarpous capsules, large spore size, and highly sculptured spores. But interesting anomalies exist. *Pterygoneurum sampaianum* (Figure 31) has two spore sizes and spore wall thicknesses. Carrión *et al.* suggest this permits most germinations to occur in suitable habitats of parents while allowing for at least some longer transport to new locations. Vitt (1981) surmised that cleistocarpy was important in ephemeral habitats, where large spores have a better chance of surviving until the conditions become favorable again. Having two types of spores would be advantageous in these conditions.

Surely through such a long period of evolution some of these cleistocarpous capsules must have evolved invertebrate partners that help in the destruction of the capsule wall. Or is it bacteria, or fungi, that do the deed? But certainly some open as a result of torque resulting from drying.

Animal Dispersal

Volk (1984) considered animals to be the most important means of dispersal for the **Marchantiales** in Namibia, suggesting that dispersal was facilitated by the spore ornamentation.

When we think of animal dispersal, we think of "velcro" plants that attach their propagules by small hooks to the fur of their host, or we think of seeds passing through the digestive tract unharmed while the host benefits from the surrounding fruit. But are bryophytes too small to utilize such large animal carriers? Are capsules good substitutes for fruits? We must think on a small scale, and the obvious disperser seems to be insects, those creatures upon which the pollen grain must so often depend. But most people know only about the ability of the **Splachnaceae** to hitch a ride on an unsuspecting insect, the fly, to achieve the dispersal of their spores. It appears we have been missing something.

Earthworms

As earthworms pass soil particles through the gut, they also transport bryophyte diaspores. Van Tooren and During (1988) found that spores were more successful at germination than vegetative diaspores when taken from earthworm castings (Figure 32). Interestingly, During (1986) found that spores from more than 1 cm down were

more likely to germinate than those in the first centimeter. He suggested a higher mortality rate among those in the first centimeter, or that most of the spores were washed down to deeper layers. It is likely that a spore in that first cm would get enough water and light to effect germination, but that they might not remain wet enough, or have enough light, to survive after germination; they might also get water frequently, activating respiration, but having insufficient light to germinate, thus losing considerable energy each time they get wet. Nevertheless, it is also a good hypothesis that many got washed down to lower layers.

Figure 32. Earthworm castings, a potential means of bringing bryophyte diaspores to the surface. Photo by Muhammad Mahdi, through Creative Commons.

Gange (1993), examining primarily fungal spores, found that earthworm castings had higher concentrations of spores than did the surrounding soil. If they likewise concentrate bryophyte spores, this could be an effective dispersal mechanism, perhaps placing diaspores into the diaspore bank, or removing the diaspores from the diaspore bank, despite the high mortality rate seen by Van Tooren and During (1988). A high mortality is not 100%, so those spores that do survive might be effective in later establishment.

Insects and Spiders

It is likely that arthropods such as insects and spiders have a greater role in bryophyte spore dispersal than we had imagined. Such characteristics as hairs on the arthropod or sticky spores facilitate such dispersal.

Ignatov and Ignatova (2001) report that small spiders, mites, and beetles that walk among the cave moss (*Schistostega pennata*) (Figure 87) plants become "more or less dirty" with spores. Smooth-bodied insects seem to be poor carriers, but hairy arthropods such as spiders, especially *Trochosa* spp. (Figure 33), and harvestmen (*Opiliones*) are more likely to carry the sticky spores.

Schuster (1966) reports observing lathridiid beetles feeding on spores of the leafy liverwort *Lophozia porphyroleuca*, but alas, that was in a herbarium. In fact, one of the bits of "evidence" often cited to say that bryophytes are inedible is the lack of dermestid beetles found in bryophyte herbaria, whereas seed plants must be stored with mothballs if we don't want them to disappear into the guts of these beetles. But this one observation of a lathridiid beetle eating liverwort spores does not prove that they ever disperse them in nature, or for that matter, even

eat them in nature. On the other hand, this family of beetles is known to eat fungal spores, digest the exine, and disperse them in viable condition from the other end of the gut. So maybe...

Figure 33. *Trochosa spinipalpis*, a hairy spider that might contribute to dispersal of sticky spores. Photo by Jørgen Lissner, with permission.

Ants

A somewhat more believable story, but one Schuster (1966) considers least credible, is that Szepesfalvy considers ants to disperse spores of the liverwort *Athalamia hyalina* (Figure 34) because ants use spores (Figure 35) as food (Loria & Herrnstadt 1980) and these spores are often found injured. Based on this evidence, it is likely that some are also dispersed unharmed.

Figure 34. *Athalamia hyalina*, a liverwort that serves as food for ants. Photo by Adolf Ceska, with permission.

Figure 35. *Athalamia hyalina* distal spore wall SEM. Photo by William T. Doyle, with permission.

Rudolphi (2009) considered that the ant *Lasius platythorax* might be a passive dispersal agent of the asexual propagules of the moss *Aulacomnium androgynum*. Both the moss and the ants occur on dead wood in Swedish forests. Experiments showed that 33% of the ants has gemmae adhering to them within less than two minutes of exposure to the mosses. Half of these gemmae continued to adhere to the ants for approximately 4 hours, indicating that the ants could be effective dispersal agents.

Figure 37. *Aulacomnium androgynum* showing clusters of gemmae. Photo by Des Callaghan, with permission.

Aquatic Insects

Even aquatic insects may contribute to dispersal. Revell *et al.* (1967) cultured the flora and fauna occupying the surfaces of four aquatic Diptera [*Tipula triplex* (see Figure 38), *Bittacomorpha clavipes* (Figure 39), *Chaoborus punctipennis* (see Figure 40), *Chironomus* sp. (as *Tendipes*; Figure 41)]. Using 51 cultures from washings, they found algae, protozoa, Cyanobacteria, and moss protonemata. *Bittacomorpha clavipes* carried significantly more of these organisms than the other three species.

Sticky Spores

Ignatov and Ignatova (2001) found that spores of *Schistostega pennata* (Figure 42-Figure 43) were covered with a sticky substance, much like spores in the *Splachnaceae* (Figure 44-Figure 47). This substance causes many spores to stick together and prevents effective transport by wind. On the contrary, the spores are better adapted to transport by arthropods and other animals to which they adhere. Although Gaisberg and Finckh (1925) reported their inability to be transported by wind, commenting that they are glued together and are dispersed through animals, it appears that most bryologists have paid little attention to the sticky nature of the spores or their mode of transport until the publication of Ignatov and Ignatova in 2001.

Figure 42. Elliptical spores of *Schistostega pennata* demonstrating tendency to stick together. Photo by Misha Ignatov, with permission.

Figure 43. SEM image of spore surface of *Schistostega pennata* showing sticky perine. Photo by Misha Ignatov, with permission.

The *Schistostega pennata* sporophyte (Figure 87) shares another unique character with *Splachnaceae* (cf. Koponen 1990); its seta continues growth after the capsule has opened. But it also shares with liverworts the habit of producing its capsule before the seta elongates. In fact, it may even lose its operculum before elongation begins. The seta itself is unique, having long-rectangular, thin-walled cells with round chloroplasts scattered in such a way that the seta appears to have be fluorescent.

Using sticky tape to trap insects near *Schistostega pennata*, Ignatov and Ignatova (2001) found spores, probably of *S. pennata*, adhering to adult members of the fly family *Dolichopodidae*. They also found that some ants (*Formica rufa*) and beetles (*Geotrupes stercorarius*; Figure 91) climbed among the *S. pennata* and that the beetles carried spores of this species.

Even the elliptical spore shape is unusual, characterizing both *Schistostega* (Figure 43) and the *Splachnaceae*. This shape increases the surface area relative to volume, making attachment easier. Demidova and Filin (1994) have suggested that the light green color of the bulk of spores contrast to the deeply colored ones near the top of the capsule in this species and *Splachnaceae*. They suggest that these light-colored spores would also help attract insects. The autoicous sexual condition (but with separate male and female plants originating from the same protonema and thus from one spore) insures that both sexes will be available (Ignatov & Ignatova 2001). [Note that many bryologists consider this a dioicous condition because the male and female shoots are different; whichever interpretation or term is used, this presents a special case.]

Muscidae and Dung Mosses

The same nomenclatural problem of separate sexes arising from one protonema exists for *Splachnum rubrum* (Figure 44) and *S. luteum* (Figure 45). The family *Splachnaceae*, discussed also in the chapter on nutrients and Terrestrial Diptera, is the only other group of bryophytes considered to be specially adapted for animal dispersal. The oldest report seems to be that of Bryhn (1897), reporting that flies visited *Splachnum rubrum* (Figure 44) and carried the spores to fresh dung. Wettstein (1921) expanded on this observation, verifying dispersal by flies in additional species in the family. Since then, A Koponen, T. Koponen, Cameron, and Marino, among others, have studied this fascinating family extensively, demonstrating not only that flies carry the spores, but determining the attractants.

Among the 73 species in this family, approximately half are **entomophilous**, being dispersed by flies (Diptera) (Erlanson 1930; Koponen & Koponen 1978; Goffinet *et al.* 2004; Marino *et al.* 2009). These same species are **coprophilous**, growing on feces or carrion. Their capsules are often brightly colored and are known to attract flies through their scent, which typically mimics that of decaying organic matter. The relationship between the fly and the moss is typically species-specific, with the capsules producing a unique odor as its attractant. Furthermore, it is the sporophytes that produce the odors (Erlanson 1930; Pyysalo *et al.* 1978, 1983; Marino *et al.* 2009), with the gametophytes being nearly odorless. Interestingly, there was an inverse relationship between the size of the **hypophysis** and the strength of the odor (Marino *et al.* 2009), but perhaps this is an energy tradeoff.

In this family, the peculiar odor attracts the flies that subsequently walk about on the capsules and the spreading **hypophysis** (Figure 1), getting sticky spores (Figure 46) on their bodies, as in *Schistostega*. The flies are usually attracted to both the dung substrate and the odor of the moss capsules. After investigating the capsules, the flies then travel to other dung, attracted to the odor of the wet dung, and deposit some of the spores as they wander about on the dung.

So why should such an elegant moss choose to live on something as unpleasant to humans as dung, and nowhere else? There seems to be no simple answer, so let's examine the facts. This parasol, modified in various ways among

the species, is sterile tissue of the sporophyte. Perched atop the umbrella, like the knob to which the spokes of a wheel would be attached, is the capsule, housing the spores. The teeth differ in structure from those of most mosses (Koponen 1978, 1982) and are reflexed at maturity, exposing an open tiny canister of spores (Figure 46).

Figure 44. Capsules of *Splachnum rubrum*, showing the broadly expanded, umbrella-like hypophysis under the capsule. Flies are attracted to the iridescent red color and the odor, with the hypophysis providing a landing platform. Photo by Janice Glime.

Figure 45. *Splachnum luteum* with one of its fly dispersers sitting on the hypophysis. Photo from Biopix, through Creative Commons.

Figure 46. Capsule of *Splachnum ampullaceum* showing sticky spores with part of expanded hypophysis at base. Photo by Janice Glime.

This greatly expanded sterile tissue is the **hypophysis**, concealing a spongy tissue similar to a maple tree's mesophyll. The hypophysis itself is generally brightly colored in *Splachnum*, although somewhat more ordinary in other genera, and provides a landing platform for flies. In *Splachnum ampullaceum* (Figure 47) it is yellow to deep pink, and the plants are so crowded that if the colors don't attract your attention, the sheer numbers will. This of course also amplifies the odor. In *Splachnum rubrum* (Figure 44), the hypophysis is an iridescent purple-red, and I have to wonder if it reflects UV light, visible to some Diptera (Bishop 1974; Gerry *et al.* 2009), but not to us.

By this time, the dung is old and dry, emitting no more odor than the soil beneath, so it is not likely to attract would-be dispersers. However, since the moss has a "perfume" of its own (Erlanson 1930), emitting the unpleasantness of rotting food, sour or musty, from its hypophysis, it attracts the flies. Although these odors are generally faint to our insensitive noses, to a fly they are a virtual invitation. Steere (1958) describes some of the odors. *Tetraplodon* (Figure 51) smells of a strong acetic ester, *Splachnum sphaericum* (Figure 48) of lactic acid, and *S. luteum* (Figure 45) of a butyl compound. These chemicals (Table 2) include volatile octane derivatives and organic acids such as acetic, propionic, and butyric acids that are concentrated in the hypophysis (Koponen 1990).

When the capsule is moist, the columella, with a swollen end, serves as a plug after the operculum is shed. But on a dry day, the capsule contracts and the columella extrudes from the capsule, carrying upward with it clumps of spores exposed to the world. Instead of travelling by wind as individuals, typical of most other mosses, the spores of this moss clump together like the pollen of an

orchid, and apparently to the same advantage. They are picked up inadvertently on the hairs of flies (Koponen 1990; Eriksson 1992) exploring the odor and seeking reward. Once leaving the lure of the capsule, the fly, less discerning than a bee, is likely to be attracted to the odor of fresh dung, and hence carries the clumps of spores to their new home. But the story does not end there. It seems that the fly can even gain an advantage that insures its greater success. Scatophagids, the most frequent and effective of fly visitors, reputedly have greater copulatory success after visiting these mosses (Cameron & Wyatt 1986) – an aphrodisiac for flies!

Diversification of Spore Dispersal Strategy

The fly assemblages differ among individuals and among clumps of the **Splachnaceae** species. Koponen and Koponen (1978) experimented with attraction to **Splachnaceae** in Finland and demonstrated that different combinations of *Poliaetes lardarius* (Figure 49) and other dung flies were attracted to sticky traps baited with hidden sporophytes of *Splachnum ampullaceum* (Figure 47), *S. vasculosum* (Figure 50), and *Tetraplodon mnioides* (Figure 51). Marino (1991a) studied **sympatric** (having overlapping distributions) moss assemblages in central Alberta, Canada. Each moss species attracted 10-17 spore-carrying fly species, but visiting fly species assemblages differed by 77-92% among **Splachnaceae** species (Table 1). Furthermore, the Diptera species captured on the dung were less diverse than those captured from the capsules of the mosses (Marino 1988; 1991b). Marino (1991a) concluded that species-specific recruitment of fly guilds appears to result from differences in attraction to sporophytes through distinct odors created by the moss (especially the capsules), visual cues, or combinations of these.

Cameron and Wyatt (1986) studied dispersal for *Splachnum ampullaceum* (Figure 47), *S. rubrum* (Figure 44), *S. sphaericum* (Figure 48), *S. vasculosum* (Figure 50), and *Tetraplodon mnioides* (Figure 51) and found that the fly family *Scatophagidae* (*Scatophaga*; Figure 52) was both the most frequent and most effective visitor to the moss colonies. Other visitors included *Delia* (*Anthomyiidae*), *Myospila* (*Muscidae*; Figure 53), and *Eudasyphora* (as *Pyrellia*; *Muscidae*; Figure 54). They further demonstrated that wind is not an effective dispersal agent for these species.

Troilo and Cameron (1981) consider the transport of spores in the *Splachnum ampullaceum* (Figure 47) by flies [*Eudasyphora* (as *Pyrellia*) *cyanicolor* (Figure 54)] to be passive. This fly species oviposits on carrion, but it will use dung when carrion is not available, whereas *S. ampullaceum* grows almost exclusively on dung. The moss capsules attract them, and if they are chased away, they quickly return. The capsule is adapted by its bright colors, expanded hypophysis that serves both to attract and as a landing platform, a dung-like odor, teeth that extend outward, and a shrinking capsule that forces the adhesive spores outward. Cameron and Troilo (1982) added to this story by documenting that landing by *Eudasyphora cyanicolor* flies demonstrated a 20-fold preference for yellow-colored disks over blue or red disks placed among sporophytes of *S. ampullaceum* in Michigan, USA, suggesting the spore dispersal may not be passive after all. In fact, they never visited the red disks. This is an interesting observation and begs further investigation. Flies are typically attracted to red (don't wear red in mosquito or blackfly season!). And *S. ampullaceum* typically has a mix of yellow and pinkish red capsules (Figure 1). On the other hand, pink flowers do not usually attract flies.

The most activity of *Eudasyphora* (*Muscidae*; Figure 54) on the capsules was on warm days when the odors were strongest (Troilo & Cameron 1981). The moss is a successful odor mimic, as demonstrated by fly visits that equalled those to carrion and exceeded those to a protein source or fly medium (Figure 55). But once there, the visit to the moss capsule was significantly shorter than visits to carrion or protein substitute. Moreover, the flies never exhibited feeding behavior on the capsules, only sampling behavior. Troilo and Cameron consider this to be a **commensal** relationship in which the moss benefits from dispersal but the flies are neither benefitted nor harmed. One could argue that the moss is being a parasite by taking energy from the flies and using it for dispersal while providing nothing in return, but others have argued that the flies may get the benefit of increased mating opportunity.

Many of the fly species associated with the **Splachnaceae** studied by Marino (1991b) are anthomyiids. By mimicking the flower and odor cues typically used by the adult **Anthomyiidae**, a family with seed predators and pollinators, the mosses have achieved what appears to be a very effective means of spore dispersal.

This very targeted means of dispersal may be a tradeoff between energy needed for attraction and that needed for spore production (Marino 1991a). These species have fewer spores **and** smaller spores than most mosses. This high energy requirement may account for the evolution from a specialist such as these entomophilous species to the generalist strategy of the coprophilous species such as *Tetraplodon paradoxus* (Figure 56), and the two *Voitia* species (**Voitioideae**; Figure 57) that lack sporangial dehiscence. In *Tayloria* (Figure 58), both anemophilous and entomophilous species exist.

Figure 56. *Tetraplodon paradoxus*, a species with indehiscent capsules. Photo by Michael Lüth, with permission.

Figure 57. *Voitia nivalis* with capsules. Photo by Michael Lüth, with permission.

It appears that the dung habitat may provide another significant role. One advantage to this dispersal type is that it ensures that both male and female spores will arrive at the same site. In populations of *Tayloria tenuis* (Figure 58) on cattle droppings in the Eastern Pyrenees, the protonemata are at first the only conspicuous stage (Lloret 1991). The plants are clustered and despite high mortality, the entire dung substrate is soon covered with protonemata. Within 1-2 years the leafy plants develop and ultimately produce capsules. These capsules are often numerous, as seen in *Splachnum ampullaceum* (Figure 47). This is in part due to the female:male ratio of 2:1, at least in the *Splachnum* species [*S. ampullaceum* (Figure 47), *S. sphaericum* (Figure 48), *S. rubrum* (Figure 44)] of Isle Royale, Michigan, USA (Cameron & Wyatt 1990). But in experiments, environmental conditions can alter this ratio, with low light, pH, and nutrients favoring the production of males.

Figure 58. *Tayloria tenuis* with capsules, a species that grows on dung. Photo by Michael Lüth, with permission.

In *Splachnum ampullaceum* (Figure 47), males and females can arise from the same protonema, ruling out any bias in dispersal of spores. For this high degree of fertilization success, dispersal of the sperm to the female benefits from the density of the plants. Cameron and Wyatt (1990) found that the average sperm dispersal distance is

less than 5 mm. This proliferation of sporophytes is reminiscent of the Asteraceae, acting as a single unit through the clumping of so many capsules. Furthermore, the early period of establishment has served to eliminate weak genotypes among the protonemata, although there is no guarantee that these same weaknesses would occur among the leafy plants.

As the capsules mature, that moist and smelly dung that once attracted the flies becomes dry and looks more like a cardboard Frisbee, or in the case of moose dung, like a clump of well-done toasted marshmallows. Nevertheless, once spores are sent upon their way, the remaining plants are soon covered by larger pleurocarpous mosses that are typical of the forest soil. This is an ephemeral habitat for the **Splachnaceae**.

All of this attraction is costly, requiring energy to produce the hypophysis and make volatile attractants. To maintain this, the mosses are able to access the higher concentrations of N, P, and Ca that occurs in dung (Webster 1987). Meanwhile, most other mosses typically die in areas with such high nitrogen concentrations resulting from manuring (Geissler 1982). There have also been suggestions that the growth of the protonemata may be promoted by substances such as Gibberellic Acid produced by accompanying fungi (Von Maltzahn & MacQuarrie 1958; Vaarama & Tarén 1959).

Cameron and Wyatt (1986) have suggested that the **Splachnaceae** requirements for dung may actually be a requirement for their fly dispersers, and the flies travel from one dung heap to another. There seems to be an interesting correlation between means of dispersal and substrate that supports this hypothesis. As noted earlier, all of the **entomochorous** (*i.e.* requiring insect dispersal) species are also **coprophilous** (living on dung or corpses); the **anemochorous** (wind-dispersed) species are **humicolous** or epiphytic (Goffinet & Shaw 2002). In the subfamily **Voitioideae**, three taxa are coprophilous but cleistocarpous (capsule not opening), lacking a peristome and dispersing spores only after the sporangial wall disintegrates.

Flies are not restricted to landing on dung, to any particular moss species, or to any particular habitat (Marino 1986), so this diverse behavior would seem to limit successful dispersal. Nevertheless, spore success is typically very low among mosses, so even this hit-or-miss mechanism may be better than wind dispersal. And certainly it must be for these sticky spores.

In summary, Koponen (1990) considers three categories of adaptations of bryophytes for entomophily in the **Splachnaceae**:

- adaptations to a substrate of animal origin
- morphological adaptations
- chemical adaptations

In support of this, Koponen cites *Splachnum* (Figure 50) and the entomophilous species of *Tayloria* (Figure 62-Figure 63) as being restricted to the dung of herbivorous mammals. *Tetraplodon* (Figure 59-Figure 60) grows on skeletal remains, antlers, stomach pellets of predatory birds, or on dung. The entomophilous *Aplodon wormskioldii* (Figure 61) grows on corpses, on caribou (reindeer) dung, bones and antlers, on owl pellets, or on enriched gravel.

Figure 59. *Tetraplodon angustatus* with capsules on caribou antler at Jasper, Canada. Photo by Janice Glime.

Those of us in the Northern Hemisphere are familiar with this fascinating family of mosses largely because of their ability to attract flies, but in the Southern Hemisphere, such attraction does not exist, or does it?! Mighell (2011) investigated *Tayloria mirabilis* (Figure 62-Figure 63), a South American endemic, because it had been suspected of having fly dispersal. They trapped 218 flies over the plants on dung and found that 63 of them had spores of *T. mirabilis*. The flies comprised seven species from Muscidae and Calliphoridae. Furthermore, germination of the transported spores were 46.7% successful; identity of the spores was verified by DNA analysis. This example becomes more interesting when we realize that the plants (and flies) are associated with more than one kind of forest dung and that all the current large forest mammals there are exotic! Rapid evolution or pre-adaptation?

Figure 63. *Tayloria mirabilis* capsules and fly near Cape Horn, Chile. Note the spores on the front leg and around the eye. Photo by Adam Wilson, through NYBG public domain.

In the same year, Jofré *et al.* (2011) reported a second example of fly-attracting Splachnaceae in the Southern Hemisphere. This time, it was *Tayloria dubyi* (Figure 64) growing on bird dung in the subAntarctic region of Cape Horn, Chile. The bird dung appears to be exclusively that of the Snow Goose *Chloephaga picta* (Figure 65). When Jofré Acevedo (2008) germinated the spores in the lab, they grew much better on snow goose dung than on horse or cattle dung. *Tayloria dubyi* releases its spores in the same months as the highest activity of Diptera (Jofré *et al.* (2010). Based on these findings, Jofré *et al.* (2011) trapped 64 flies, comprised of *Palpibracus chilensis* (Muscidae), *Dasyuromyia* sp. (Tachinidae), and an unidentified member of the Sarcophagidae, in traps above the sporophytes, but no flies appeared in traps above nearby *Sphagnum*, suggesting that *Tayloria dubyi* also attracts the flies.

Once we understood that flies were indeed attracted to the capsules of the Splachnaceae, not just (if at all) to the odors of the dung, work began to elucidate the attracting compounds. Koponen *et al.* (1990) identified 23 compounds in the hypophysis and urn among five Splachnaceae, demonstrating that the individual species were often unique. Data from the setae are not included here. The only volatile compound in the substratum was benzaldehyde, a compound not found in the capsules or setae.

Molluscs

Could it be that slugs that consume capsules (Figure 66) do indeed carry spores to new locations? But alas, a slug by its very nature is slow, and such dispersal would not move the spores very far from home. Nevertheless, consumption can result in movement of spores to a new location, even if not very far away. But can they live?

Figure 66. Slug preying on capsules of *Leucolepis acanthoneuron*. Photo from Botany website, UBC, with permission.

Boch *et al.* (2013) tested the possibility that slugs could eat bryophyte spores, and that the spores could subsequently germinate. They fed capsules of four bryophyte species to three slug species. Overall, approximately in half (51.3%) all 117 bryophyte samples fed to slugs, representing four bryophyte species [*Bryum pallescens* (Figure 67), *Funaria hygrometrica* (Figure 110), *Leptobryum pyriforme* (Figure 68), *Pellia endiviifolia* (Figure 69)], spores did germinate from feces. It is interesting that there was no difference between bryophyte species, but there were large differences among the three slug species (Figure 70). Spores from the feces of the slugs *Arion lusitanicus* (Figure 71) and *A. rufus* (Figure 72) had 76% and 74% success, respectively. Those from *Limax cinereoniger* (Figure 73), on the other hand, were only 12.9% successful. This mechanism would enhance the population size by moving spores away from the parent, but at the same time being more likely than wind dispersal to deposit them in places where they can grow successfully. Türke *et al.* (2013) found that slugs could transport seeds in the gut for 5 m, giving us an estimate of potential bryophyte dispersal distance.

Figure 71. *Arion lusitanicus*, a species that disperses bryophyte spores through its feces. Photo by Håkan Svensson, through Wikimedia Commons.

In an experiment to determine success of spores that travelled through the digestive tract of slugs (*Arion* spp.; Figure 71), all plates containing eaten spores of *Mnium hornum* (Figure 74) and *Brachythecium rutabulum* (Figure 75) produced shoots, whereas only 80% of the plates with uneaten mature *Mnium hornum* spores and 70% of those with uneaten *Brachythecium rutabulum* spores produced shoots (Davidson 1989). Furthermore, the eaten spores showed little infection, suggesting some antibiotic property acquired from the digestive tract. Nitrogen, secreted in mucus and disposed in feces, may have enhanced the success of these spores.

Figure 75. *Brachythecium rutabulum* with capsules. Spores of this species are eaten by slugs. Photo by David Holyoak, with permission.

Using 11 species of mosses and 1 of liverworts, Boch *et al.* (2014) supported the concept that slugs can increase bryophyte establishment. They demonstrated that through their herbivory, the slugs reduce light competition, permitting a greater diversity of bryophytes to establish. Furthermore, the spores they ingest are able to germinate

after passing through the digestive tract of the slug (**endozoochory**). After 21 days in an experimental setup, bryophyte cover was 2.8 times as high in enclosures with slugs that had previously been fed sporophytes when compared to enclosures with slugs that had not been fed sporophytes or with no slugs.

After 21 days the bryophyte cover was on average 2.8 times higher (3.9% versus 1.4%) and after eight months the bryophyte species richness 2.6 times higher (5.8 versus 2.2) in enclosures containing slugs previously fed with bryophyte sporophytes than in the other treatments. After 8 months, the increased vascular plant cover reduced the bryophyte diversity. Enclosures that had no seed sowing had 1.6 times as many bryophyte species compared to those receiving seeds.

But if we look further, we find that long distance travel by slugs and snails is indeed a possibility. Malone (1965) determined that fresh-water snails were able to attach to the feed of the killdeer (*Charadrius vociferus*) and travel there for sufficient time to accomplish overland dispersal, remaining alive. Adults of the snail *Lymnaea obovata* could survive at least 14 hours. It is likely that other birds, both aquatic and terrestrial, could carry snails as well, providing considerable time for dispersal and making long-distance dispersal possible. And how long might the spores survive in a snail or slug eaten by a bird? Will those spores also be viable?

Fish

The ability of fish to transport bryophytes remains to be demonstrated. My student experimented with rainbow trout, known to strike at almost anything, to see if they would eat mosses in their attempts to remove aquatic insects. The student was unable to get the fish to attack the moving moss or eat it to get at insects. Finally, in desperation, he force fed it *Fontinalis duriaei* (Figure 76). Then he waited to collect the feces. The moss did appear in a cylindrical package of feces. It emerged in bright green color and looked healthy. We put it in a jar of stream water from which the moss had been collected, kept it cold, and waited expectantly. Alas, the second day the *Fontinalis* was pale and appeared to be dead. No growth ever ensued.

Figure 76. *Fontinalis duriaei*, a species refused by rainbow trout and that does not survive in feces from force-fed fish. Photo by Michael Lüth, with permission.

Birds

Until recently, birds were barely considered as dispersers of bryophytes. Ducks are dispersers (Proctor 1959), but we have no idea how important they are. Spores of *Riella* (Figure 77; Tenge 1959) pass through the digestive tract of Mallards (*Anas platyrhynchos*; Figure 78) and remain viable (Proctor 1961). Assuming a mean residence time similar to that of seeds, which is about 7.5 hours, a migrating Mallard could move spores of this liverwort 20-30 km easily, and at times up to 1,400 km (Mueller & van der Valk 2002). It could, but does it?

Figure 77. *Riella cossoniana* showing sporangia (dark spheres) that can be dispersed by ducks. Photo by Jan-Peter Frahm, with permission.

Figure 78. *Anas platyrhynchos* (Mallards) female and male, potential dispersal vectors for aquatic bryophyte diaspores. Photo by Richard Bartz, through Wikimedia Commons.

Proctor (1961) suggested that the rarity of *Riella americana* may result from very specialized dispersal. Griffin (1961) found a large population of this species in a playa lake in Texas, USA, where its population measured 60 cm in width and approximately 1.7 km long. The production of gemmae may contribute to such large populations (Studhalter 1931). He examined 25 nearby similar lakes within a 25 km radius and could find no trace of the liverwort.

Following these observations, Proctor (1961) experimented with the possibility that this liverwort was dispersed by ducks. He used three Mallard ducks (*Anas platyrhynchos*; Figure 78) that had been used previously for similar experiments with the alga *Chara*. These ducks were provided with approximately 57 liters of the *Riella americana*, which they readily ate. The plants had abundant sporophytes with what appeared to be mature brown spores. The feces were collected after approximately 1 hour and handled according to treatments in Table 3. The feces contained many spores that had separated from their masses, no intact sporophytes, and thallus fragments that were clearly dead. Feces were collected for three days, and on the third day they were separated by individual duck. It was interesting that one male and one female had numerous spores in their feces, but the second female had none! Germination success ranged from 0 - >30%.

Table 3. Various storage effects on germination of *Riella americana* spores collected from Mallard duck feces. Germination follows 60 days of treatment, then 14 days of inoculation at 24°C on sterile tubes of soil and water in light. + = <10% germination; ++ = 10-30% germination; +++ = >30% germination; - = no germination; blank = not enough spores for test. Based on Proctor 1961.

	day 1	day 2	day 3 male	day 3 female
ice (-10°C)	++	+		
water at 1°C	+++	+++	+++	+++
water at 24°C	+++	+++	+	+
water at 37°C	+++	+++	+++	+++
dried, stored at -10°C	-	+	++	++
dried, stored at 24°C	+++	+++		
dried, stored at 37°C	+++	+++		

Proctor (1961) found that the spores of *Riella americana* (Figure 79) from feces germinated as well as fresh spores (not eaten). These spores mature at the time ducks and other water birds are migrating through that area of Texas in early autumn, so their transport through water bird guts is quite possible. Proctor (1961) suggests that many spores can be transported in the gut for up to 80 km. Furthermore, as already suggested by Studhalter (1932) and Persson and Imam (1960), external transport of spores and even fragments on feathers, beaks, and feet is a likely possibility. This notion is supported by the presence of spines on the spores (Figure 79) (Studhalter 1933). Furthermore, the spores have sufficient longevity to survive in muds or on birds (3 years for *R. americana*, 12 years for *R. capensis*). And it is possible that some remain in tetrads during dispersal, further protecting them from UV light and desiccation. Considering these dispersal potentials, it seems that something else must explain the rarity. Perhaps there is too much herbivory before they can become established? Could timing be important to avoid herbivory during establishment?

Figure 79. *Riella americana* spore tetrad SEM, exhibiting spines that could attach to feathers of ducks. Photo by William T. Doyle, with permission.

Riella is not the only bryophyte to experience dispersal by ducks. Des Callaghan (Bryonet 26 August 2016) reported that his friend had sent him a moss shoot grown from a fragment in a Mallard dropping (*Anas platyrhynchos* (Figure 78)). This turned out to be the moss *Didymodon insulanus* (Figure 80).

Recent studies have revealed that other birds may also be dispersers. Using fecal samples from the herbivorous Upland Goose (*Chloephaga picta*; Figure 65) and White-bellied Seedsnipe (*Attagis malouinus*; Figure 81), Behling *et al.* found vegetative diaspores, including various moss fragments. Experiments continue to determine their viability. *Attagis malouinus* feeds among the low vegetation, sits among the mosses, and may even spread its wings across the mosses in the tundra, affording numerous opportunities for snagging the local bryophytes.

Just imagine how far diaspores might travel by **ecto-zo-o-cho-ry** (on the outside of an animal) among the bird plumage. We know birds survive airplane travel, so bird travel is not a stretch. And the idea is not so far-fetched when we consider the number of bipolar species of bryophytes and the number of birds that travel those same distances from Arctic to the Antarctic. Lewis *et al.* (2014) developed a method to screen feathers of wild birds that travelled these long distances in their annual migrations. They concluded that the entire flock of migrating birds may leave their northern breeding grounds carrying potentially viable propagules, providing opportunities for dispersal everywhere they land to feed or rest.

Szepesfalvy (1955 in Schuster 1966) found *Riccia frostii* (Figure 82) concentrated along goose paths in central Hungary and suggested that the spores of this species were distributed on feet and beaks of these domestic geese. And we cannot, without testing it, eliminate the possibility of distribution of spores in feces (Figure 83), although it would require having the geese eat something that ate the spores or carried them on its surface. Szepesfalvy also suggested that spores and overwintering thallus pieces of *Riccia bischoffii* var. *ciliifera* (Figure 84) are distributed by pheasants, but both of these suggestions are based on circumstantial evidence and the correlation may be one of habitat rather than dispersal agent. Furthermore, these birds are surely not the only animals to frequent these paths. Szepesfalvy also suggested a relationship between presence of hares and distribution of *Oxymitra paleacea* (Figure 85), but this meets the same problem of verification.

Brandon Stone reported to Bryonet (9 April 2003) that he found sporophytes of the moss *Pyrrhobryum spiniforme* (Figure 86) in a bird's nest at 1300 m on Moloka'i in Hawai'i. A bird expert told him the bird was most likely not a native bird. Transport of such sporophytes at the right stage could contribute to dispersal over more than the normal range of dispersal from capsules on the ground.

Several birds frequent upturned roots where *Schistostega pennata* (Figure 87) is common in Russia, and there is evidence that these may transmit spores (Ignatov & Ignatova 2001). The tiny Winter Wren (*Troglodytes troglodytes*; Figure 88-Figure 89) visits upturned roots to look for insects and sometimes nests there. Above one nest near a convenient perch, there were protonemata of *S. pennata*, suggesting they may have arrived as spores on the birds.

Figure 85. *Oxymitra paleacea*. Photo by EncycloPetey, through Creative Commons.

Figure 86. *Pyrrhobryum spiniforme* showing sporophyte that is used in making birds' nests in Hawaii. Photo by Michael Lüth, with permission.

A more convincing case of bird dispersal is that of the cock *Tetrastes bonasia* (Hazel Grouse; Figure 90) (Ignatov & Ignatova 2001). These large birds take dust baths near the upturned roots. Feathers collected there did have spores of *S. pennata* attached. However, no chloroplasts seemed to be present, so it is unlikely that they were still viable. The birds also help in dispersal of spores by capturing beetles such as *Geotrupes* (Figure 91) with adhering spores and distributing their parts to other locations. Mice and frogs also visited tip-up areas, but there was no direct evidence that they transported spores.

We have already noted that slugs can carry viable spores in their digestive tracts. Birds eat snails. Could it be that the spores could survive both digestive tracts? Wada *et al.* (2011) addressed this very question. Japanese land snails are preyed upon by birds, including the Japanese White-eye (*Zosterops japonicus*; Figure 92) and the Brown-eared Bulbul (*Hypsipetes amaurotis*; Figure 93). Of the 119 snails (*Tornatellides boeningi*; Figure 94) fed to Japanese White-eyes and 55 snails fed to Brown-eared Bulbuls, 14.3% and 16.4% of the snails, respectively, passed through the gut alive. For us, the logical next question is whether this provides an additional means of dispersal for bryophyte spores, potentially giving them a free ride to greater distances while being protected from the bird's digestive system by the snail. Kawakami *et al.* (1965) suggested that it is.

Griffin *et al.* (1982) suggested that *Dendrocryphaea latifolia* may have reached the high Andes of Colombia by wind or birds, but there is no direct evidence to support this.

As Ken Adams suggested on Bryonet (5 March 2013), birds might occasionally be responsible for long-range bryophyte dispersal. Spores could lodge on or among feathers or feet, especially in mud, protecting them from both desiccation and UV light. Michael Richardson (Bryonet 5 March 2013) suggested that this could occur as short hops (stepping stones), with birds depositing spores at resting or feeding points along the way. When those establish, they provide a new and closer source for dispersal to more distant locations. Richardson suggested that gulls might be good vectors because of their need for fresh-water baths and their puddle-hopping behavior. Terry McIntosh (Bryonet 5 March 2013) suggested that birds may account for some of the wide disjunctions in western North America for species that are restricted to open soil in the grassy edges of saline ponds and depressions. This could explain the distribution of such species as *Entosthodon rubiginosus* and *Tortula nevadensis*.

Fife and de Lange (2009) suggested that shearwaters (e.g. *Puffinus bulleri*, *Procellariidae*; Figure 97) may have been responsible for transporting propagules of the pan-tropical *Calymperes tenerum* (Figure 95) to the

Chatham Islands and Kermadecs off the coast of New Zealand. These fantastic birds fly from Alaska to Australia and other parts in the deep Southern Hemisphere, then back to Alaska each year. Buller's Shearwater is endemic to New Zealand and is a regular visitor to the Chathams (Allan Fife, pers. comm. 11 June 2017). It has also been considered to responsible for transporting the fern *Asplenium pauperequitum* to the Chathams (Cameron *et al.* 2006).

Figure 95. *Calymperes tenerum* with gemmae. Photo by Jan-Peter Frahm, with permission.

Jesús Muñoz (Bryonet 15 March 2013) studied the effects of wind on Cory's Shearwater (*Calonectris diomedea*; Figure 96) migration and suggested that it might be worth investigating those same wind patterns for bryophyte dispersal. Earlier in this chapter I suggested that propagules might follow "wind highways." Could this following be in the protection of the feathers and mud of birds? Felicísimo *et al.* (2008) used a model to show that the Cory's Shearwaters closely follow the "wind highways" that require the least energy to reach their breeding and wintering areas. The Manx Shearwaters (*Puffinus puffinus*; Figure 97) chose a route that was 25% longer, avoiding turbulence on the shortest distance (González-Solís *et al.* 2009). The wind patterns (not the shortest route) drive the shearwaters in their movements and could do the same for bryophytes (Felicísimo *et al.* 2008; González-Solís *et al.* 2009).

Brent Mishler (Bryonet 5 March 2013) suggested that vegetative fragments could travel in mud on birds' feet as well, and that molecular testing could be used to track such long-distance dispersal. Rob Gradstein (Bryonet 11 March 2013) suggests a less molecular, more challenging approach: 1) capturing migratory birds to look for bryophyte spores, gemmae, and fragments on their feathers, feet, and beaks; 2) flying spores, gemmae, and fragments on birds across long distances to test for germinability of the diaspores after the long trip.

Even feet of terrestrial birds can carry spores, and probably other propagules. Davison (1976) reported finding spores of bryophytes on the feet of the Song Thrush (*Turdus philomelos*; Figure 98) in beechwood in Great Britain, although he considered that these were transported only a short distance.

Even the tiny hummingbird may contribute to long-distance dispersal of bryophytes. Torres-Dowdall *et al.* (2007) reported the use of bryophytes in the construction of nests of the hummingbird called Picaflor Rubi (*Sephanoides sephanioides*; Figure 99-Figure 100) in Chile. Osorio-Zúñiga (2012) later examined the nests of the Picaflor Rubi (also known as Picaflor Chico). He identified *Lophosoria quadripinnata* (a tree fern), appearing as the "garment" in 100% of the nests, and three moss species, all pendent species, that frequently comprised the outside of the nests [*Weymouthia cochlearifolia* (16.6% of nests) (Figure 101), *W. mollis* (26.6%) (Figure 102), and *Ancistrodes genuflexa* (100%) (Figure 103-Figure 104). These outside mosses all produced sporophytes in both the old and new nests (Figure 107-Figure 109). In addition to these species, old nests also had *Eriodon conostomus* (Figure 105), *Ptychomnion ptychocarpon*, and *Dicranoloma robustum* (Figure 106), all producing sporophytes (Figure 109). For species present in 100% of the nests, the growing heights were 10-18 m above ground and were not the most abundant species in the forest.

In continuing this study, Osorio-Zuñiga *et al.* (2014) introduced the concept of **synzoochory** for bryophyte dispersal as an intermediate between endo- and ectozoochory. In **synzoochory**, the propagules are deliberately transported, usually by mouth or beak, but without ingestion. These researchers found seven species of mosses were transported this way by the hummingbird

Sephanoides sephanoides (Figure 99). These likewise were to be used in nests, but the researchers found that the birds were selective, choosing mosses with capsules in greater frequency than their appearance in the habitat. They also preferred the fern *Lophosoria quadripinnata* and the moss *Ancistrodes genuflexa* (Figure 103-Figure 104), with the other mosses [*Weymouthia mollis* (Figure 102), *Weymouthia cochlearifolia* (Figure 101), *Eriodon conostomus* (Figure 105), *Ptychomnion ptychocarpon*, *Dicranoloma robustum* (Figure 106), *Rigodium toxarion*] being minor components. This behavior of the birds gave two opportunities for greater dispersal – first from one tree to another in the beak, then for longer distances for the spores from the elevated position of the nest. In some cases the mosses were elevated from the ground to the nest.

As noted above, members of the **Splachnaceae** are known for their ability to attract flies that subsequently disperse their spores. But it appears that this is not always the case. Lewis *et al.* (2014) considered the long-distance dispersal that was evidenced in *Tetraplodon* (Figure 56, Figure 59-Figure 60). The amphitropical disjunctions required explanation. The researchers compared stepwise migration along the Andes, direct long-distance dispersal, and ancient vicariance. Using four loci from each of 124 populations throughout the global range, they analyzed genetic evidence for the dispersal pathway. Three clades emerged, indicating three pathways of dispersal. There is no evidence of modern or historical wind connectivity between the polar regions, and these spores are not easily dispersed by wind. The researchers concluded that migratory birds most likely accounted for the long-distance dispersal of *Tetraplodon*, suggesting that the order Charadriiformes were the most likely dispersers.

Additional information on birds that eat capsules is in Volume 2, Chapter 16-2.

Mammals

Both large and small mammals step on bryophytes. Fur and hooves are likely to carry at least some forms of bryophyte propagules. Pauliuk *et al.* (2011) investigated dry grassland dispersal by sheep. They collected gametophyte fragments from the fleeces and hooves of 12 sheep, including two breeds. They also grew microscopic diaspores collected from soil that adhered to the hooves. Among the species in the pasture, 40% were transported, comprising 16 moss species. Sheep breeds collected different arrays of species, with dense, curly fleece carrying more fragments and larger species than sheep with smooth and fine hair. Pleurocarpous species, small species, and mats were represented more frequently in proportion relative to the vegetation; large species, acrocarpous life forms, wefts, and turfs were underrepresented. Hooves carried mostly acrocarpous colonist species.

In the Arctic, *Voitia hyperborea* (sometimes considered a variety of *V. nivalis*; Figure 26) has a capsule that does not open (Steere 1974). It appears that musk oxen and caribou may help in dispersal by chewing on the capsules as they graze other plants. In any event, it would seem that some animal agent is necessary for the dissemination of spores. During (personal communication, 29 May 2006) suggested that whole capsules may possibly be dispersed, but that the spores in *Voitia nivalis*, at least, have a structure that suggests they are sticky like those of other genera of the **Splachnaceae** and may adhere to beetles or even larger animals once the capsule begins to decay and expose them. More detail on the dung mosses is in the habitat subchapter on dung mosses.

In the Alps, *Voitia nivalis* is apparently dispersed by ruminants. It can be found in shelters or on the trails of sheep, chamois, and ibex, often on dry cliff ledges (Geissler 1982). This dispersal could carry fragments and other diaspores trapped on the feet and among fur or through feces holding spores inadvertently eaten along with forage.

There is some evidence that rodents contribute to the dispersal of fungal spores through ingestion and subsequent

deposit of feces (Trappe & Maser 1976; Cázares & Trappe 1994; Janos *et al.* 1995). It is likely that rodents likewise contribute to bryophyte spore dispersal, not only through ingestion, but also by transporting spores in their fur. Others are likely to hitch a ride in mud on the feet. Nevertheless, it appears that direct data to support this role are lacking for bryophytes. We do know that rodents eat bryophytes, as shown for this mouse dining on *Funaria hygrometrica* capsules (Figure 110). Andrew Spink photographed a vole eating mosses (Figure 111).

Figure 110. Mouse eating *Funaria hygrometrica* capsules on Isle Royale, Michigan, USA. Photo courtesy of Steve Juntikka.

Matt Dami (Bryonet 26 August 2016) reported providing mice with capsules of the mosses *Dicranum flagellare* (Figure 112) and *Polytrichum commune*. They consumed the capsules and the fecal samples were collected and cultured on nutrient agar. Both species grew from the ingested spores, but *P. commune* (Figure 113) had much more germination success and far more vigorous growth.

Figure 113. *Polytrichum commune* with capsules. Their spores seem to thrive when passed through the digestive tract of a mouse. Photo by Bob Klips, with permission.

Spores adapted for animal dispersal are sticky and elliptical, as in *Splachnaceae* (dung mosses) or *Schistostega pennata* (luminous moss), these being dispersed by flies. Beetles, earthworms, and slugs are likely dispersers, albeit for short distances. Ducks are known to carry spores, and small nesting birds may use setae and capsules in nests, but the effectiveness of these dispersal agents is unknown.

Water Dispersal

Conrad (1996) examined water samples in a *Taxodium* (bald cypress) swamp biweekly for spores. He also cultured both herbarium specimens and propagules from the diaspore bank. Although two other liverwort species regenerated from soil diaspores, *Ricciocarpos natans* (Figure 114) grew only from the spores (Figure 115) in the water samples and Conrad concluded that its presence in the swamps is entirely due to water dispersal.

Figure 114. Floating thalli of *Ricciocarpus natans*. Photo by Janice Glime.

Figure 115. SEM of *Ricciocarpus natans* spore, a spore most likely transported by water. Depressions in the surface may aid in flotation. Photo by William T. Doyle, with permission.

Aquatic liverworts often have spines on their spores. Porsild (1903) believed that these served as attachment aids for spore dispersal by aquatic animals. However, other scientists believe that they instead act as anchors to hold the spores onto rough surfaces so that not all are lost during heavy flows of streams (Studhalter 1933). In any case, some aquatic species, e.g. *Ricciocarpus natans* (Figure 115) and *Riccia fluitans* (Figure 116), do not have these spines, suggesting that the surface configuration may have more to do with phylogeny than with environment. On the other hand, they may aid flotation, permitting the water to carry them off.

It is fairly common for rock-dwelling bryophytes of streams and rivers to project their sporophytes above the water level where they can be wind dispersed (Figure 117). This requires timing to produce sporophytes at a time when the water level is down.

Figure 116. *Riccia fluitans* spore distal view SEM. Photo by William T. Doyle, with permission.

Common Adaptations

Mahabalé (1968) reviewed the characteristics of spores of aquatic tracheophytes. He found that the spores are short-lived and germinate quickly. These are water-dispersed. Those that are semi-aquatic or are facultatively aquatic have spores with thick outer walls and are dispersed by either insects or wind.

Cox (1983) tested the hypothesis that aquatic spores would have large, long axes and move in planes such as the water surface, rather than in three dimensions. He also predicted a greater incidence of dioicisism. He found that data supported these hypotheses for a variety of aquatic spores, including bryophytes. He also found that many spores had flotation devices. Cox considered these traits to provide "an efficient search vehicle." He considered dispersal in the aquatic environment to be a random search and that movement in one plane reduced that search territory.

As Mahabalé suggested, spores of the liverwort *Riccia gougetiana* (Figure 118) are over 200 μm in diameter (Schuster 1966); those of *Riella* (Figure 79) are 70 μm, nearly four times as large as the diameters of most air-dispersed spores (Mahabalé 1968; Cox 1983). *Pellia epiphylla* (Figure 119-Figure 120), a common streamside species, disperses its spores as a single mass (Cox 1983),

but it also has elongate spores (Figure 120). *Gymnocolea* (Figure 121) uses deciduous perianths as its floating dispersal unit. Elongate dispersal units are seen in vegetative dispersal units such as fragments of *Fontinalis* (Figure 122) (Glime *et al.* 1979).

Marine Dispersal?

No species is known to grow in marine waters, but Engel and Schuster (1973) raised the question of marine dispersal. They reasoned that species subject to tidal action or ocean spray were the best candidates. They assumed that bryophytes would not survive long exposures to salt water and presumed that freshwater drainage from adjacent forests above the beach and high rainfall made it possible for species subjected to saltwater to survive. Hence, they concluded that marine dispersal was not possible, but this has not been tested.

Flood Plains and Dry Flats

Volk (1984) suggested that the distribution of spores by animals is most important for genera like *Riccia* (Figure 118) that inhabit seasonally dry habitats, particularly in southwest Africa and the Mediterranean. Whereas annual species of *Marchantiales* produce large numbers of spores, in the perennial species spore number is typically reduced and is even more rare among species with bulbils. Those that do support significant spore production can have ornamented spores that facilitate transport by animals, or perhaps aid in flotation. Despite the periodic invasion by water, this may not be an effective means of dispersal to carry the spores to new locations. Large flooding episodes can bury spores and other propagules so much that they may not resurface for decades (Figure 123-Figure 124).

Figure 123. Eroded material transported by water to River Baihe, a tributary of Yellow River, Tibet. Photo by Sven Bjork, with permission.

Figure 124. Floodplain on Isle of Wight. This magnitude of flood is reached once in ten years. Photo through Wikipedia Creative Commons.

Schuster (1966) considered the dispersal of *Riccia* (Figure 125) and *Ricciocarpos* (Figure 115) spores by mud and water to be very frequent. They typically grow at the margins of rivers and streams in the floodplain, where their spores mature in spring or in late summer or fall when flooding is common. The hornwort genus *Notothylas* (Figure 126) is also likely to be dispersed in this way. In *Riccia* (Figure 125) and *Sphaerocarpos* (Figure 127), the spores are exceptionally large (65-200 μm diameter), are accompanied by elaters, and are dispersed by water.

Raindrops

The genus *Diphyscium* (Figure 128) has a flat side on its capsule. Crum (1983) reports that raindrops hitting this flat side can cause "little puffs" of spores that are propelled up to 5 cm from the capsule. It could be that the same phenomenon occurs in *Buxbaumia*.

Figure 128. *Diphyscium foliosum* flat-topped capsules where raindrops expel spores. Photo by Hermann Schachner, through Creative Commons.

Exploding Capsules?

Lacking peristome teeth, *Sphagnum* has an explosive capsule that behaves much like an air gun. It exerts an internal pressure of 4-6 atmospheres, a pressure equal to that of the "huge tires of heavy trucks" (Crum 1973). If you place mature capsules under a lamp with a tin cup or other "roof" to catch the spores, you can hear the capsules pop as the lids strike the cover, a phenomenon reported by one of the bryologists following a *Sphagnum* collecting trip at a *Sphagnum* conference in Great Britain. Some bryologists claim to have heard the capsules popping in the field, with the sound being generated entirely by the explosions of the capsules.

Vortex Rings

This explosion is a necessary event for the toothless *Sphagnum* to get its spores above the **laminar flow** region near the capsule and into the **turbulent flow** that can carry the spores away from their parent. But it seems that this is more than just a straight shot. Whitaker and Edwards (2010) report what seems to be the first evidence of plants using a **vortex ring** (Figure 130-Figure 129). The vortex ring is a self-sustaining flow field that can carry one fluid (in this case, a mass of spores) through another (in this case, the surrounding atmosphere) without significant drag. The result is that spores go farther.

When the spores explode from a *Sphagnum* capsule, this vortex ring, shaped like a mushroom cloud, forms and dissipates very quickly above the capsule (Figure 129-Figure 131). As the spores are ejected from the capsule, they are "entrained by the co-moving vortex bubble that forms at the lip of the capsule and moves upward" (Figure 131). The advantage of this vortex ring is that it moves the spores much farther than an air-gun mechanism could. This is the result of a self-sustaining flow field that moves the donut-shaped mass of spores upward.

Figure 129. *Sphagnum* spore vortex taken as a time series every 100 microseconds. Photo by Clara Hard, Joan Edwards, and Dwight Whitaker from Whitaker & Edwards 2010, with permission.

The large number of spores (~100,000) in a single capsule form a bubble with a radius of 5 mm (Whitaker & Edwards 2010). These vortex rings cause a thrust augmentation by acceleration of the additional ambient fluid created at the time of the explosion (Krueger *et al.* 2008). The ring itself is "generated by the transient

ejection of a jet from a tube or orifice" such as the opening of the *Sphagnum* capsule.

Figure 130. The development of a vortex ring with its mushroom cloud and trailing wake following the expulsion of a *Sphagnum* operculum. Redrawn from Whitaker and Edwards at <www.math.lsa.umich.edu>.

Figure 131. *Sphagnum* spore capsule from fresh to drying to release of the operculum. Redrawn from Miller 2010.

As Mustain (2010) points out, it is these vortex rings that help the squid speed through the water and the human heart to push blood from chamber to chamber. They are present in the clouds arising from an erupting volcano and propel jellyfish in the sea (Krueger *et al.* 2008). For *Sphagnum*, it permits this short plant to place its spores (Figure 132) into the winds that start about 10 cm above the surface (Whitaker & Edwards 2010). The ring keeps the spores together, preventing their useless descent to the ground. They calculated that the vortex ring typically

shoots more than 11 cm into the air, sometimes as high as 17 cm. Furthermore, Johan L. van Leeuwen from the Netherlands' Wageningen University (in Mustain 2010) reports that this shot of spores reaches about 144 kph!

Figure 132. *Sphagnum* spores SEM. Photo by Dwight Whitaker and Joan Edwards, with permission.

Role of Stomata

Unlike many of the other bryophytes, *Sphagnum* has its stomata located away from the base and top of the capsule, suggesting that their function might be different. Boudier (1988) reported that the stomata of *Sphagnum* were not, as assumed, involved in any respiratory function in this genus, but rather that they are "false stomata" that give the capsule hardness and give the capsule wall flexibility. Beerling and Franks (2009) added to this that they were of importance in controlling and facilitating water loss from the capsule. Chater *et al.* (2011) determined that the stomata of bryophytes, like those of tracheophytes, are under the control of ABA and respond to environmental signals in the same way as guard cells of tracheophytes. Duckett *et al.* (2009, 2010a) conducted further experiments by pricking the *Sphagnum* capsules and demonstrating that both intact and pricked capsules dried out and dehisced over an 8-12 hour period. During this time the stomatal guard cells gradually collapsed. This seems to be in direct contradiction to the assertion of Ingold (1959), who concluded that the dehiscence mechanism of *Sphagnum* capsules depends on a capsule wall that is impermeable to gases. Ingold suggested that cuticularization of the guard cells with age could block the air passage. Duckett *et al.* (2009, 2010a) contend that, rather than an air-gun explosion (as understood by Ingold), the spore discharge results when differential shrinkage of the capsule walls causes the rigid operculum to pop off.

The shrinkage of the *Sphagnum* capsule wall has been known for some time. Maier (1974) described the importance of a rigid zone of resistance in the capsule wall that permits the capsule to maintain its diameter even as the remainder of the capsule shrivels as it dries. This rigid wall tissue causes the shape of the capsule to change from spherical to cylindrical. This causes maximum stress in the area of the operculum, causing the wall (line of dehiscence) to break.

Duckett *et al.* (2009, 2010a) concluded, as did Boudier (1988), that the only role for the stomata in *Sphagnum* is to aid in capsule drying and thus shrinkage. Duckett *et al.* determined that there is no potassium-regulating mechanism for these guard cells.

The behavior of guard cells in *Anthocerotophyta* (Figure 134-Figure 137) seems to be support for the dispersal role. Lucas and Renzaglia (2002) found that the guard cells in this group do not respond to abscisic acid (ABA). Furthermore, in young tissues K^+ and malate are localized in all epidermal cells, but once the tissues mature, they occur only in the guard cells. This permits them to serve as an osmoticum that causes the guard cells to swell due to water influx. This behavior is coupled with a pattern of function in which the guard cells do not respond to light (Lucas & Renzaglia 2002; Duckett *et al.* 2010b). Rather, they begin closed in young tissues, then open as tissues mature, and remain open. This behavior permits older epidermal tissues to dry out (Figure 137). Duckett *et al.* (2010b) suggest that the same mechanism is at work in mosses. Such drying could contribute to dispersal.

The functioning of bryophyte guard cells has been largely ignored. Pressel *et al.* (2014) followed their development in hornworts and determined that the guard cells contain giant, starch-filled chloroplasts as they begin to differentiate. These chloroplasts divide, regaining their spherical shape after the aperture opens. After opening of the guard cells, wall material accumulates over them and wax rodlets line the pores. Pressel and coworkers considered it unlikely that the guard cells moved after maturity, based on the widespread presence of open guard cells. This propensity to remain open suggests that the stomata may function in facilitating the desiccation of the sporophyte, ultimately facilitating dehiscence and dispersal.

If guard cells do indeed function to facilitate dispersal by drying the capsule, then those species with few guard cells should have diminished dispersal capacity. Sundberg (2010a) cites some species within the *Sphagnum* section

Subsecunda, including *Sphagnum cyclophyllum* (Figure 138), *S. microphyllum*, *S. macrophyllum* (Figure 139), and *S. pylaesii* (Figure 140), as species that have small, thin-walled capsules with short pseudopodia, large opercula, and no or few pseudostomata. Hence, they have no explosive discharge of spores (Andrews 1960, 1961; Shaw *et al.* 2004). These same species have only limited geographic distribution, suggesting that the lack of stomata and explosive discharge may contribute to a limited dispersal. On the other hand, Sundberg (2010a) found that 14 boreal species with circumpolar or amphi-Atlantic distributions, including four species with a distribution also in the southern Hemisphere, (Daniels & Eddy 1990) have the explosive dispersal mechanism.

But what about the role of stomata in other bryophytes? Only *Sphagnum* has the reputation of an explosive discharge. Stomatal density in non-*Sphagnum* mosses can depend on the environment, at least in some members of the **Polytrichaceae** (Figure 141-Figure 142). Szymanska (1931) found that even within the same species, plants in moist habitats had more stomata per mm². This supports the concept that the stomata are used to help dry the capsules, although not necessarily resulting in any "explosion." Abella *et al.* (1999) found no taxonomical value for the stomata in ten species of **Pottiaceae**, so perhaps these numbers too respond to the environmental humidity or differ with habitat dryness among species within a genus.

Egunyumi (1982) found correlations between stomata number and seta length in tropical African mosses, represented by 29 species in 12 families. These stomata ranged in number from 2 to more than 200 per capsule. This relationship might also reflect humidity of the habitat, but more data are needed to support this idea. Egunyumi found that stoma size correlated significantly with epidermal cell size, a taxonomic character. Stomatal position differed among species, with *Wijkia trichocoleoides*, *Trichosteleum microcalyx*, *Stereophyllum radiculosum* (Figure 143), and *Stereophyllum virens* having stomata raised above the level of epidermis,

whereas in *Brachymenium leptophyllum* and *Bryum coronatum* (Figure 144) they were sunken.

Figure 142. Stomata on neck of *Polytrichum juniperinum* capsule. Photo courtesy of Jeff Duckett and Silvia Pressel.

In their work on *Funaria hygrometrica* (Figure 145), Sack and Paolillo (1983) found that subsidiary cells in that species actually have thickened walls close to the guard cell at maturity. They reported that the guard cell walls have thin areas that are capable of flexing. The guard cell also has fibrillar layers that are oriented both axially and radially with respect to the pore. It seems that few guard cells in bryophytes have been described in such detail, but the structure is sounding a lot like that of tracheophyte guard cells. The role of stomata in spore release seems to be a promising area for research.

Is This an Explosion in *Sphagnum*?

Here we may have a semantic problem, with Duckett *et al.* (2009, 2010a) attempting to dispel our long-held

interpretation of the method of spore expulsion by declaring it "not an air gun." But is it an explosion? While explosion can be defined as "a release of mechanical, chemical, or nuclear energy in a sudden and often violent manner with the generation of high temperature and usually with the release of gases" – certainly not descriptive of this event – the term has gained much broader meanings. Among these, we might be more comfortable with "a violent blowing apart or bursting caused by energy released from a very fast chemical reaction, a nuclear reaction, or the escape of gases under pressure." The question to be resolved is whether there are gases under pressure. Whereas Duckett *et al.* have demonstrated that the operculum is released by the distortion of the capsule, an internal pressure is necessary to qualify this as an explosion. If indeed Crum (1973) is right and the internal pressure is 4-6 atmospheres, then the release of this pressure upon dehiscence of the capsule fits at least one definition of an explosion. In any case, a vortex ring results, and that seems to be visual proof that pressure has been released.

Sundberg (2010b) disagrees with the interpretation of Duckett *et al.* (2009, 2010a) and contends that it truly is an air-gun ejection of spores. He points out that approximately 35% of the *Sphagnum* capsule volume is air. To test the role of the stomata in producing this gun, Sundberg used *S. centrale* (Figure 146) and *S. fuscum* (Figure 147). Using 16 capsules of each species, he pricked half of them in the lower half into the interior (ca 1 mm deep). Within 12 hours, all but one of the capsules had dehiscid, with the ones not pricked presenting audible snaps. Spores from not-pricked capsules were ejected 50-150 mm, leaving the capsules nearly empty. The pricked capsules, on the other hand, also opened their lids, but no snap could be heard and the spores only spilled in clumps in a heap below the capsule opening, discharging only 5 mm or less. He considered this evidence that the normal discharge was explosive.

Falling Rate

Using a filming technique similar to that of Whitaker and Edwards (2010), Sundberg (2010a) examined the settling speed of spores from 14 species of *Sphagnum*. They determined a maximum discharge speed of 3.6 m s^{-1} and a maximum height of 20 cm (mean 15 cm). The cloud (vortex ring) size was positively related to capsule size, giving species with larger capsules a dispersal advantage. Half the spores remained in clumps, usually of 2-4 spores. Single spores, with a deltoid shape, settled at $0.84\text{--}1.86 \text{ cm s}^{-1}$, a speed about 52% slower than would be expected for spherical spores of the same diameter. Larger spores settled faster, following Stokes' law. Sundberg suggested that the combination of the added height from the explosion and the slow settling speed serve to increase dispersal distance and may account for the wide distribution of boreal *Sphagnum* species. On the other hand, Fenton and Bergeron (2006) suggested that *Sphagnum* invasion into young dense forests might be dispersal limited, but they allowed for the possibility of unsuitable available substrata. It is likely also that the forest interfered with dispersal, trapping spores on bark and among the leaves.

A *Sphagnum* Spore Mimic

This spore dispersal mechanism is so good that it has been stolen by the fungus *Bryophytomyces sphagni* (Ascomycota) (Currah & Davey 2006). This parasite grows in the capsules of *Sphagnum*, replacing the *Sphagnum* spores with its own. This does nothing to interfere with the capsule explosion. Hence, the fungal spores are dispersed in that same manner as would have been for the *Sphagnum* spores.

Summary

Spores are the most successful agents of long-distance dispersal in bryophytes, whereas vegetative means help the population to become established and spread once having arrived. **Peristome teeth** in mosses, an **explosive capsule** in *Sphagnum*, and **elaters** in liverworts help in dislodging spores and dispersing them. Most bryophytes are adapted for wind dispersal, with the occasional updraft or gust permitting

somewhat greater distances. However, the majority of spores seem to land within 2 m of their parents. Invasive species seem to benefit from both rapid vegetative dispersal and long-distance travel.

Cleistogamous capsules require capsule decay for dispersal, relying on distribution by animals, especially invertebrates, or becoming established near home. Capsules of taxa like *Buxbaumia*, on the other hand, often split despite having teeth and may rely on such insects as fungal gnats to disperse spores.

Earthworms can transport spores on their moist surfaces or through the gut, and theme may be transported further if the earthworms are eaten while carrying the spores.

Animal dispersal in **Splachnaceae** and *Schistostega pennata* is facilitated by sticky, elliptical spores, and in the case of **Splachnaceae**, also by odors. Other animal dispersal appears to be chancier, with ducks, beetles, ants, slugs, earthworms, and small nesting birds contributing.

Water dispersal is important for water-dwelling species, and in floodplain taxa, a dormancy mechanism is usually necessary. Dormancy also provides spores with the ability to survive in the soil below 1 cm where they do not receive light and therefore will usually not germinate in the presence of water. Dispersal may be facilitated by decorations on the spores that create air pockets, aiding flotation. Others have spines and hooks that may aid in animal attachment and dispersal.

Raindrops on the flat side of a *Diphyscium* capsule help to discharge the spores.

Stomata seem to play a role in dispersal by facilitating drying of the capsule. In *Sphagnum*, the ejection of spores is explosive, forming a **vortex ring** that drives the spores about 10 cm into the air, enough to get them into the air stream. This mechanism is so effective that the fungus *Bryophytomyces sphagni* lives in the *Sphagnum* capsule and is dispersed by the same mechanism.

Acknowledgments

I thank Joan Edwards for her patience in helping me to understand the vortex ring mechanism. Juan Carlos Villarreal sent me literature that was not available to me. Karen Renzaglia provided images that I requested for specific purposes. Jeff Duckett and Silvia Pressel permitted me to rummage through their images to find ones I needed to illustrate this chapter. Steve Trynoski offered several suggestions after a critical reading of this subchapter.

CHAPTER 4-10

ADAPTIVE STRATEGIES: VEGETATIVE PROPAGULES

Figure 1. Deceduous branch tips of *Campylopus cryptopodioides*. Photo by Michael Lüth, with permission.

Vegetative Reproduction

Vegetative reproduction comes in many forms. These range from breakage of leaves and stems that have become brittle through desiccation to specialized gemmae that occur on leaves or special stems and are nurtured by the parent plant, ready to go when finding a suitable substrate, to tubers that occur on roots and protonemata.

Such asexual structures seem to have evolved through **heterochrony** (developmental change in the timing of events, leading to changes in size and shape), including **neoteny** (retention of juvenile characteristics in adults of species) Newton & Mishler 1994). Hence, we can see gemmae that look like reduced leaves, as in *Aulacomnium* (Figure 2).

We might assume that in disturbed habitats, such as industrial areas, vegetative means to reproduce might offer advantages over more fragile-seeming protonemata necessitated by spore dispersal. But this is not always true. Nordhorn-Richter (1982) found the extent of bryophyte distribution in an industrial area of Germany was not improved by presence of asexual propagules except among members of *Plagiothecium* (Figure 3-Figure 4). On the other hand, vegetative reproduction offers the advantage of being ready to start developing an adult plant, reaching maturity much more quickly than a plant from a spore. Furthermore, bryophytes produce asexual propagules at a younger age than that needed for sexual reproduction.

Figure 2. *Aulacomnium palustre* gemmae that are modified leaves. Photo by Zen Iwatsuki, with permission.

Figure 3. *Plagiothecium laetum*. Photo by Christian Peters, with permission.

Figure 4. *Plagiothecium laetum* leaves with scattered gemmae. Photo by Kristian Peters, with permission.

Longton and Schuster (1983) listed six basic means of asexual reproduction in bryophytes:

1. multiple gametophores from the protonema of one spore

2. decay of older gametophyte parts with the separation of younger parts
3. development of multiple shoots by rhizomes and stolons
4. development of gametophores from rhizoids
5. regeneration from fragments
6. production of specialized "propagula."

Frey and Kürschner (2011) shortened and summarized this list, identifying three types of asexual reproduction that are recognized today:

1. asexual reproduction *s. str.* by **regeneration** from somewhat specialized caducous organs (leaves, leaf apices, shoots, branches, bulbils) and by production of specialized propagules (gemmae, protonemal brood cells, tubers)
2. **fragmentation** of plants or parts of plants into essentially unspecialized fragments
3. **clonal** reproduction (cloning from branches, stolons, and rhizomes).

Cloning results when a branch of a protonema or a plant becomes separated from its parent. This can occur by decay of the protonema or disintegration of plant modules. In gametophores, cloning requires the formation of **ramets** (individuals, "daughter plants"). Frey and Kürschner (2011) consider cloning to be a "keystone factor for asexual reproduction, habitat colonization, and habitat maintenance." While this cloning mechanism is not dispersal in the usual sense, it does contribute to placing the species in new locations. For example, when we (Zhang, Raeymaekers, and Glime, unpublished) mapped the locations of *Pleurozium schreberi* (Figure 5) in m² plots and followed them yearly for five years, we found that they appeared to "move" from one location to another within the plot, often changing position by several centimeters, sometimes forming two clumps.

Figure 5. *Pleurozium schreberi* in the boreal forest. Photo by Janice Glime.

Although sexual reproduction may provide the opportunity for new gene combinations, a number of bryophytes [e.g. *Cyrtomnium hymenophylloides* (Figure 6; Miller & Mogensen 1997)] persist without any evidence of sexual reproduction. In reviewing the literature, Rolstad & Gjerde (2003) considered that some bryophytes have poor dispersal capability due to the absence of spore production. In this case, vegetative diaspores and even fragments

maintain the species and carry it to new locations. As in *C. hymenophylloides*, the absence of sexual reproduction may only occur through part of its range, whereas other species seem never to produce capsules (Miller & Mogensen 1997). Rather, in *C. hymenophylloides* of North America and Greenland new growth arises from axillary and apical buds that appear to be the principal means of reproduction. Miller and Mogensen assumed that these were dispersed by wind but considered that water and gravity were also possible. It is interesting that populations may be all male, or more typically, all female.

Figure 6. *Cyrtomnium hymenophylloides*. Photo by Michael Lüth, with permission.

In general, not counting fragmentation, there seems to be only one type of asexual reproduction within a species (Li Zhang, Bryonet 16 March 2010). Nevertheless, many exceptions occur. Pressel *et al.* (2007) reviewed the propagules in *Bryum* (see below) and related genera. In this genus one can find rhizoidal and chloronemal tubers, axillary bulbils, chloronemal brood cells, and foliar and protonemal gemmae. *Ptychostomum* (= *Bryum*) *capillare* (Figure 7) and *Bryum dichotomum* (Figure 8) have three types, but only one type has been found in any individual at a given time (Imura 1994). However, Zhang found two types on the same individual of *Fissidens* sp. (Figure 9-Figure 12, Figure 117) – rhizoidal gemmae and tubers. Gemmae (Figure 10-Figure 12) in this species come in a variety of shapes and types. *Octoblepharum albidum* (Figure 13) has three modes (Zhang *et al.* 2003). In this species, new plants can grow from the leaf tips where first rhizoids are produced and then buds. These buds grow into plants and may, in turn, produce another "generation" of leaf-tip shoots, much like the walking fern *Asplenium rhizophyllum*. These walking mosses may constitute 5-20% of the population. *Leucobryum glaucum* (Figure 14-Figure 15; *Leucobryum* Figure 16) has a similar behavior in which the terminal rosette of leaves may produce rhizoids and new plants. But in this case, so far as is known, the new plants drop off and grow if they land on a suitable substrate.

Figure 15. *Leucobryum glaucum* with mature apical rhizoids that can serve as propagules. Photo by Sean Edwards, with permission.

Figure 16. *Leucobryum* showing rhizoids developing from leaf tips. Photo courtesy of Andi Cairns.

Pfeiffer *et al.* (2006) identified three types of vegetative morpho-types in the pleurocarpous moss *Rhytidium rugosum* (Figure 17): **ramet** (individual plant that has grown vegetatively from another individual, *i.e.*, a

branch, becoming part of a clone of that plant) that can become separated when they decay, brood **branch**, and **caducous** (easily detached) shoot apex. They demonstrated successful dispersal of vegetative diaspores through AFLP (amplified fragment length polymorphism) fingerprinting, wherein samples from one clone occurred on both studied plots in Germany. Furthermore, the close relationship of the fingerprinting between the two plots suggest clonal rather than sexual (spore) origin for the populations.

Figure 17. *Rhytidium rugosum* from Europe, showing what appear to be several ramets. Photo by Michael Lüth, with permission.

Dispersal of vegetative propagules seems to be more of a passive process than that of spores. Few special mechanisms are documented for removal of asexual propagules from the plant. *Tetraphis pellucida* (Figure 18-Figure 19), with apical gemmae in splash cups is a notable exception among mosses, with *Marchantia* (Figure 20-Figure 21) and *Lunularia* (Figure 22) species likewise having gemma splash cups. Others easily "pop" as they become detached by some intruder bumping them, as in *Dicranum flagellare* (Figure 23). The extent of transport by animals that brush against them has seldom been documented.

Herben (1994) considers habitat to be the important parameter for assessing the role of the reproductive mode of bryophytes, with those in small and unstable habitats showing more frequent formation of propagules. Löbel and Rydin (2009) found that among epiphytes the habitat conditions had no influence on production of asexual propagules, whereas they did influence sporophyte production. Furthermore, sexual colonies had to reach a specific size before they could reproduce sexually, whereas there was no such limit for asexual reproduction. Despite the dispersal limitations of large asexual diaspores, asexual dispersal is still common among epiphytes, with higher growth rates for the asexual diaspores partially compensating for the limited dispersal. Furthermore, habitat turnover most likely favors asexual diaspores that start growth rapidly.

Löbel and Rydin (2009), working in the temperate zone, further considered that competition was not an important character in the epiphytic habitat because of the difficulty of dispersal and ability to spread vegetatively. Yu and Wilson (2001) pointed out the importance of patchiness and arrival times in plants, a concept that seems appropriate for bryophytes, especially epiphytes. They suggest that "trade-offs between different stages of colonization could be far more common in nature than a trade-off between competitive ability and colonization ability."

Botanists have traditionally considered vegetative reproduction (Figure 1) as making only limited contributions to genetic variability and new adaptation. But is this really the case, in particular, of bryophytes? Laaka-Lindberg *et al.* (2003) consider asexual propagules to have a significant role in bryophyte genetic dynamics.

In view of the vegetative propagation sources, Scrosati (2002) has offered a new definition of **genet** to allow for those plants such as bryophytes and algae that routinely propagate from vegetative cells: "For clonal autotrophic macroorganisms, in general, genet may be defined as a free-living individual that develops from one original zygote, parthenogenetic gamete, or spore and that produces ramets vegetatively during growth."

In bryophytes, only a few living cells may start a new plant. And it may be those very cells that are different, different in ways that endowed them, and them alone, to survive whatever killed the remainder of the plant. Through somatic mutations, individual cells may indeed be more adapted than the plant they occupy. And because of their small size, such fragments in bryophytes can be dispersed and serve as propagules. Each individual or part of an individual gametophore in the clone is capable of renewed growth upon relocation. However, while this scenario is theoretically possible, we have no clue how often it occurs.

While spores are the sexual means of reproduction and dispersal of mosses, providing a mechanism for recombination and variation, it is likely that most mosses rely more heavily on various vegetative means for their propagation (Anderson 1963; Steere 1965; Schuster 1966; Longton 1976, 1982; Selkirk 1984; Schofield 1985). For example, in three *Octoblepharum* (Figure 13) species in Panama, Korpelainen (1999) found that most populations consisted of a single genet, hence resulting from a single colonization event by one individual.

Clones can be very important in recolonization of minor disturbances. Frego (1996) reported on four boreal bryophytes and their ability to do so. *Pleurozium schreberi* (Figure 5) often has pure colonies in black spruce forest (*Picea mariana*). But it also has colonies with minor species as seeming invaders (Figure 24). Frego found that these minor species are able to persist by occupying small disturbance gaps in the *P. schreberi* colony. All of the species were able to colonize by encroachment of vegetative shoots. Propagules were important for this encroachment. *Pleurozium schreberi* was the most rapid colonizer, probably due to a combination of rapid growth and abundant vegetative propagules.

Figure 24. *Pleurozium schreberi* (center) and *Dicranum polysetum* (lower left), a common species combination in the boreal forest. Photo by Janice Glime.

Such reliance on asexual reproduction is due in part to the difficulty of completing sexual reproduction in many bryophytes. Since nearly 60% of the bryophytes are dioicous (Wyatt & Anderson 1984), and the monoicous habit usually provides more opportunity for sexual reproduction than the dioicous habit, it is easy to understand the importance of vegetative reproduction (Schofield 1985). Furthermore, some widely distributed species have never been found with sporophytes.

Dispersal potential is a major limiting factor on the distribution of bryophytes (Pohjamo *et al.* 2006). Hence, those species with mixed reproductive strategies have a greater chance of success. Pohjamo *et al.* suggest that such mixed strategies are particularly useful in a heterogeneous landscape where different means of reproduction have different levels of success in each of the microhabitats, and possibly in different years. Traditional thinking suggests that long distance dispersal is generally best by spores, whereas vegetative dispersal places the diaspores close to the parents, generally in the same environment. But what occurs when both are the same size?

Using trapping techniques, Pohjamo *et al.* (2006) tested this propagule size relationship for the leafy liverwort *Anastrophyllum hellerianum* (Figure 25-Figure 26), a dioicous inhabitant of **decorticated** (lacking bark) logs in their study area. This species produces gemmae on the branch apices, and these gemmae approximate the size of the spores. In their study, spore dispersal had little dependence on distance in the field or forest. The dispersal of gemmae was more strongly dependent on distance in the open than in forest sites. Rainy periods favored gemmae deposition compared to dry periods, perhaps due to effects of splashing. But weather seemed to have no effect on the dispersal pattern of either spores or gemmae. Gemmae provided the advantage of nearly continuous availability, whereas spore dispersal was seasonal. The striking revelation from this study is that gemmae, at least those of the same size as spores, can contribute to long-distance dispersal.

Figure 25. *Anastrophyllum hellerianum* with gemmae. Photo by Michael Lüth, with permission.

Figure 26. *Anastrophyllum hellerianum* gemmae. Photo by Des Callaghan, with permission.

Adaptations

There seems to be little information on adaptations of asexual propagules for dispersal or establishment. Thiers (1988) examined morphological adaptations of tropical rainforest **Jungermanniales**, including diaspores. She found that these diaspores had a secretion of sticky mucilage with discoid gemmae production. We can guess at some adaptations – projections that help bulbils adhere, dense starch storage in gemmae, thicker cuticles to reduce water loss, physiological ability to withstand desiccation, hormones (ABA) to induce dormancy, but these are guesses and remain to be tested as actual factors.

Fragmentation

Bryophytes have the ability to produce new plants from almost any part, making fragmentation a viable means of reproduction. Such a process requires that at least some cells lose their specificity (**dedifferentiate**), then differentiate into a new plant (Giles 1971). Giles considered that as long as cells remain on the parent plant, they will not dedifferentiate. But there are some indications among the leafy liverworts that such detachment is not always necessary before new plantlets are able to grow, particularly if the leaf is attached to a fragment rather than an attached plant (Fulford 1936; Glime 1970). This might suggest that the cells require a continuing source of an inhibitor to prevent dedifferentiation.

Fragmentation is the simplest form of asexual reproduction, a method used by the Japanese for the development of moss gardens (Ando 1971, 1987). Cells detached from virtually any part of a moss or liverwort are capable of regeneration into a new plant. This is true of leaves in which the tips dehisce to function as propagules (Reese 1997). Some of these devices are highly specialized, as for example, the caducous branchlets of *Leucodon andrewsianus* (Figure 27) where sporophytes are unknown (Reese & Anderson 1997).

Figure 27. *Leucodon andrewsianus* on bark near Twin Lakes, Michigan. Arrow indicates caducous branchlets. Photo by Janice Glime.

Correns (1899) recognized the importance of the regenerative capacity of vegetative parts. They have historic importance in fossils as well. Miller (1985) reported fossil evidence that the dispersal and establishment of mosses had occurred as gametophyte fragments, suggesting that this is an ancient mechanism of reproduction and dispersal. This contention was supported by Lindskog and Eriksen (1995) who found fossil plant fragments in the debris layers of the ice core of a glacier in northern Scandinavia. These fragments compared well with the composition of the surrounding vegetation. Olga Belkina has supplied me with photographs indicating the presence of fragments and the establishment of colonies of *Hygrohypnella polaris* (Figure 28-Figure 30) on a glacier at Svalbard (Belkina & Mavlyudov 2011). Mosses are scattered across the glacier, as shown in Figure 31.

Because vegetative reproduction tends to be more successful than that from spores, having fragments or specialized structures can be a safety net. For example, in experimental plantings of *Polytrichum juniperinum* (as *P.*

alpestre) (Figure 32), Miles and Longton (1990) could find no evidence that spores germinated in the field. However, new shoots formed readily from shoot fragments. In the same experiment, production of shoots from spores in the short-lived *Funaria hygrometrica* (Figure 33-Figure 34) was readily apparent. In *Atrichum undulatum* (Figure 43) and *Bryum argenteum* (Figure 35), many spores germinated, but often the gametophores failed to develop. Rather, those species, like the *Polytrichum juniperinum* (Figure 32), regenerated more easily from fragments.

Leaves and Stems

Peter Poschlod (pers. comm. 6 March 2013) considers fragmentation to be the most important dispersal diaspore in peatlands, citing the absence of *Sphagnum* spores in traps, but the frequent presence of vegetative fragments (Poschlod 1995). Furthermore, he has regenerated protonemata and shoots from leaf fragments of both *Sphagnum* from peatlands (Poschlod & Pfadenhauer 1989) and brown mosses from fens (Poschlod & Schrag 1990).

In most cases, regeneration from fragments starts with a protonema. Longton and Schuster (1983) reported that even apparently dead or dark, moribund lower shoots of *Pleurozium schreberi* (Figure 5) and *Bryum argenteum* (Figure 35) are capable of producing protonemata. Clymo and Duckett (1986) likewise reported the development of protonemata and/or shoots from lower shoot tissues that appeared to be dead or moribund. Using cores from at least 30 cm depth of *Sphagnum papillosum* (Figure 36), *S. magellanicum* (Figure 5), and *S. recurvum* (Figure 37) they were able to culture numerous new shoots. They estimated that the fragments in the cores were 25-60 years old. The growths appeared to arise from both fragments and spores, with the latter producing protonemata first. Nevertheless, some protonemata arose directly from old stems, whereas most of the growths from fragments directly produced stems and leaves. Regeneration required both light and air, explaining the lack of growth prior to removal through coring. These cores also gave rise to five species of leafy liverworts, but it is unclear if these came from fragments, gemmae, or spores.

Polytrichum species seemed to be incalcitrant to growth from leaf fragments, but in 1980, Wilmot-Dear succeeded in demonstrating regeneration from leaves in four species of the former *Polytrichum*, growing them at 20°C in a 12:12 light:dark cycle. *Polytrichum commune* (Figure 38), *P. juniperinum* (Figure 32), and *Polytrichastrum formosum* (Figure 39) developed long, much-branched secondary protonemata that produced buds. *Pogonatum urnigerum* (Figure 40) directly developed buds with no initial protonema. *Polytrichum piliferum* (Figure 41) produced short, unbranched protonemata, each with a single terminal bud. These regenerants arose

primarily from the large cells at the bases of lamellae, but some arose from the basal cells of the lamellae themselves. In *Pogonatum urnigerum* regeneration tended to decrease from the tip to the base of the leaf, whereas in *Polytrichum* and *Polytrichastrum* it decreased from base to tip. Only *Pogonatum aloides* (Figure 42), a species with persistent protonemata, did not regenerate from leaves. Wilmot-Dear advised that more experiments should be conducted on temperature prior to regeneration. *Atrichum* seems to regenerate from leaves rather easily. Gemmell (1953) reported leaf regeneration in *Atrichum undulatum* (Figure 43). I have seen it in *Atrichum angustatum* (Figure 44).

Newton (1972) likewise found differences in regeneration from detached leaves in *Mniaceae* species. Those of *Plagiomnium undulatum* (Figure 45)

experienced more rapid regeneration than did *Mnium hornum* (Figure 46). Fragments of both species survived frost before and during regeneration. But males failed to survive desiccation of young gametophyte regenerants from leaves, whereas 77% of the females survived.

Early reports of regeneration from deciduous leaves or branches of leafy liverworts are provided by Cavers (1903) and Watson (1964, p. 94). I have observed the development of a young plant from a leaf in the stream-dwelling leafy liverwort *Scapania undulata* (Figure 47-Figure 48; Glime 1970). In this case, some of the plantlets developed from the center of the leaf while it was still attached to a stem fragment (Figure 48). This was not an isolated incident – several such plantlets or buds were collected in debris in drift nets being used to capture stream insects. It is interesting that this collection occurred on 1 March in Plymouth, NH, USA, before the spring melt. At this time most of the plants would be completely submerged and the stream would typically have a moderate flow from intermittent snow melt. Greatest stream flow usually occurs in this area in early April, providing a dispersal means for the plantlets. The species typically grows submersed or on rocks where it is kept moist most of the year by flowing water that splashes against the rocks. *Bazzania denudata* (Figure 49) develops plantlets on normal leaves still adhering to the plant (see Figure 50) (Fulford 1936), as in the case of *Scapania undulata* (Figure 47-Figure 48). *Plagiochila* (Figure 51), on the

other hand, can form similar growths, but these usually occur on deciduous leaves (Schuster 1960, 1966).

Herbarium specimens often are not as dead as they look, and even bryophytes in nature in desert types of habitats can remain desiccated for many years. Maheu (1922) rehydrated *Syntrichia ruralis* (Figure 52) after 14 years of continuous desiccation. The shoots of this species regenerated from their leaves.

Figure 52. *Syntrichia ruralis* hydrated, a species that regenerated from leaves after 14 years of desiccation. Photo by Misha Ignatov, with permission.

Stark *et al.* (2004) found that dried plants do not regenerate as quickly as fresh material. In the desert moss *Syntrichia caninervis* (Figure 53), fresh material

regenerated in 3-14 days (Figure 54). They used juvenile, green, yellow-green, and brown leaves, representing 0, 2, 6, and 12 years old respectively, to determine regeneration. The 0-2-year-old leaves had somewhat greater viability, regenerated more quickly, and extended their protonemal filaments farther in the 58 days of the experiment. They likewise produced shoots more quickly and accumulated a greater biomass. They also found that female leaves were more likely to produce a shoot than were male leaves. The sexes did not differ in time required to produce a protonema, linear extension of the protonema, or in rate of biomass accumulation. Nevertheless, protonemata derived from male leaves tended to emerge more quickly and produce greater total biomass, ultimately resulting in predominately protonemata. As a consequence, females had a higher success of shoot production, perhaps explaining rarity of males in *S. caninervis*.

Regenerants

Many leafy liverworts produce **regenerants** (new plants) (Barbara Crandall-Stotler, Bryonet 24 April 2021). In *Lophocolea* sp., these are produced along the leaf edges (Figure 55) (Emmett Judziewicz, Bryonet 23 April 2021). These tend to occur as the growing season is ending or the plant is in a less than favorable habitat (Barbara Crandall-Stotler, Bryonet 24 April 2021), such as this *Lophocolea* species (Figure 55) growing at a higher, drier, cooler than usual altitude. The regenerants develop like a sporeling (Figure 56), causing the leaves to resemble the juvenile leaves of the species. In *Lophocolea* sp., these are bilobed (Figure 56). These regenerants are able to re-establish the population once suitable growing conditions return.

Protonemata

Protonemata have been largely ignored in the ecology of bryophytes. This is not surprising due to their inconspicuous nature, difficulty in identification, and often short life. But Pasiché Lisboa (2014) has contributed to our knowledge by studying their dispersal potential in the moss *Callicostella belangeriana* and *Taxiphyllum taxirameum* (Figure 57). Spores from wild-collected capsules were cultured axenically to get protonemata in the lab. These

protonemata were placed on cardboard and splashed by three sequential drops of dyed water from 1 and 2 m height. This resulted in dispersal up to 80 cm, and it was more likely that a protonema hit by a drop would move than that it would remain stationary. These dispersed protonemata had a high survival rate, and even though most stayed within 10-12 cm, it provides an additional means for a colony to spread. I do wonder if the same dispersal would occur from soil instead of cardboard.

Figure 57. *Taxiphyllum taxirameum* with capsule, a species for which raindrop dispersal of spores has been demonstrated up to 80 cm. Photo by Bob Klips, with permission.

Perianths

But leaves and branches are not the only dispersal units through fragmentation. In *Lophozia* (= *Gymnocolea*) *inflata* (Figure 58), non-fertile **perianths** (leaves surrounding female reproductive structures) become more globose and are shorter than the fertile ones, and they develop a line of dehiscence where they are constricted at the base (Schuster 1966). Almost any disturbance will break them free. On dry days, these may drop to the ground, but more typically, when they are struck by raindrops, the perianths become free, or may already be free, and with their included air bubble they easily float. Such perianths then are carried away by water. But one could argue equally well that this light weight would permit them to be carried by wind should they be broken free on a dry and windy day. However, there is little documentation of regeneration from liverwort parts, so we can only guess that these perianths are able to form new plants. Perianths of *Chonecolea doellingeri* likewise are easily dislodged, but these do not become inflated (Schuster 1966).

Calyptrae

Britton (1902) reported that *Fissidens fontanus* (as *Octodicerus julianum*) (Figure 59) is able to regenerate from its calyptra, producing protonemata. The capsules of this species fall off just before maturity while they are still green and the calyptra is still attached. Together they are able to float, hence creating a potential dispersal unit of the

calyptra. Its vegetative dispersal capabilities may account for its widespread occurrence in many kinds and locations of aquatic habitats.

Figure 58. Perianth (arrow) of *Lophozia* (= *Gymnocolea*) *inflata*. Photo by Michael Lüth, with permission.

Figure 59. *Fissidens fontanus*, a species that can regenerate from its calyptra. Photo by Jan-Peter Frahm, with permission.

Kortselius *et al.* (2017) reported that the aquatic moss *Fissidens fontanus* is known to achieve asexual reproduction through the calyptra, developing gametophytes.

Wynne and Budke (2012) took the calyptrae one step further in *Funaria hygrometrica* (Figure 62). They looked at the ability of the calyptra to produce protonemata as a function of time and discovered several things: 1) The calyptrae remain alive and capable of producing protonemata for at least 28 days after detachment from the capsule; 2) the younger calyptrae produced significantly more protonemata than the oldest of three developmental stages.

Figure 61. *Fissidens fontanus* calyptra with germination. Photo courtesy of Hans Kruijer.

Figure 62. *Funaria hygrometrica* young sporophytes with calyptrae. Photo by Michael Lüth, with permission.

Involucres

The **involucre** (protective sheath originating from thallus and surrounding single gametangium or sporophyte) is not a structure one would normally consider as a dispersal unit. Nevertheless, in *Metzgeria* (Figure 63), this seems to be the case (Kuwahara 1968, 1973). Eight species in this genus, including *M. acuminata*, *M. agnewii*, *M. arborescens*, *M. filicina*, *Echinomitrium* (= *Metzgeria*) *furcata* (Figure 64), *M. grollei*, *M. imberbis*, and *M. liebmanniana*, all have demonstrated the ability to grow branches from female involucres into normal vegetative thallus. These liverworts have come from Europe, Africa, South America, and North America, suggesting that the phenomenon might be present in other taxa that produce involucres. Since these are early papers, it is likely that other examples are known. But do these have any significance for fragmentation and dispersal?

Figure 63. *Metzgeria conjugata* with sporophyte and basal involucre. Photo from Botany website, University of British Columbia, BC, Canada, with permission.

Figure 64. *Metzgeria furcata*, a species that can regenerate from the involucre. Photo by Des Callaghan, with permission.

Paraphyses

Many mosses produce paraphyses that surround the antheridia and archegonia. These are usually considered to

help maintain more constant moisture conditions than would be possible without them, help to squeeze sperm out of the antheridia, and may also function to protect against frost, solar radiation, and herbivore damage. But the presence of chlorophyll in a structure that would not seem to need it caused Correns (1890) and Hill (1903) to suspect that they might also serve as propagula. Hill even observed protonema-like branching in paraphyses (Figure 65) from *Rhodobryum roseum* (Figure 66-Figure 67). But early attempts to actually grow new plants from these paraphyses failed (Heald 1898; LaRue 1930).

Figure 65. *Zygodon intermedius* archegonia among paraphyses. Photo by Tom Thekathyl, with permission.

Figure 67. *Rhodobryum roseum* perichaetium. Arrow indicates paraphysis. Photo by George J. Shepherd, through Creative Commons.

Finally, Reese (1955), also convinced that a regenerative function was implied by the presence of chlorophyll in the paraphyses, managed to culture paraphyses of three species and successfully produce regeneration: *Ptychostomum* (= *Bryum*) *capillare* (Figure 7) 10%; *Aulacomnium palustre* (Figure 68) 12.5%; *Funaria hygrometrica* (Figure 69) 25%. *Ptychostomum capillare* and *Funaria hygrometrica* required only one month for the first evidence of regeneration, whereas *Aulacomnium palustre* required two months. Reese suggested that the ease of obtaining regenerants from these three mosses suggests that other mosses with green paraphyses might also regenerate in this way. But this leaves one question remaining, how are they dispersed?

Falling Epiphytes

In the tropics, where epiphytes abound, bryophytes can fall from the canopy. Within dense canopies, these bryophytes can fall to another branch that is within their tolerance range for light, temperature, and humidity. Others will fall to the ground. Clumps of plants in the Neotropics ranged in size from 90 cm³ to 36,000 cm³ with the number of individual plants per clump ranging 2-9 (Matelson *et al.* 1993). Unfortunately for us, data for bryophytes were not separated from the general assessment. Matelson *et al.* found that these falling epiphytes can contribute to the NH₄⁺ and K⁺ of the forest floor. There were no significant differences in longevity among the eight plant categories (bryophytes being one category), suggesting that perhaps some of the bryophytes could continue to live and possibly be re-dispersed by wind or animals.

Moss Balls

Some fragments get dispersed by snow and ice and may even blow around as moss balls on glaciers. McDaniel and Miller (2000) reported both bryophyte and vascular plant fragments in late-spring snowbeds in the Adirondack Mountains, NY, USA. The alpine fragment diversity far exceeded that from a forested site, and the bryophyte diversity exceeded that of the vascular plants. Among the bryophytes, 82% were sufficiently healthy and complete to permit identification to genus or species. An interesting revelation was the presence of liverworts from the alpine samples, suggesting that their absence from late-glacial sediments may be due to the fossilization process (taphonomy) rather than their absence in the flora or their inability to disperse by fragments. Although rare, some of the fragments in the alpine areas came from lower elevation balsam fir and red spruce-balsam fir forests. Fragments deposited on the snow would be available for immediate establishment when the snow melted, with cool temperatures and plenty of water to get started. The bryophytes will be there when the glaciers melt.

Cushions of mosses from large basalt outcrops can create moss balls when they become detached from their substrate (Pérez 2010), particularly due to activity of the Dark-rumped Petrels (*Pterodroma phaeopygia*) that burrow

to make nests under outcrops. Such detachment can be facilitated by rainfall, desiccation, wind, frost, and animal disturbance. These balls can form as the clumps are transported down steep slopes (26-34°) by geomorphic processes such as frost (especially needle ice activity), runoff, and wind. At the Haleakala crater, Maui, Hawaii, USA, these balls contained *Grimmia trichophylla* (Figure 71) and *G. torquata* (Figure 72). Pérez found that the larger mosses tended to become flattened because they were less disturbed by needle ice, hence remaining immobile for longer periods of time. These potential moss balls generally moved less than 100 cm (83%); only 5% moved 200-839 cm. Trapping of dust grains and small soil particles, combined with water-holding capacity of the mosses, created a greater water storage capacity in these balls (310%) compared to that in the soils of the site (16.8%). Pérez interpreted this as a self-replicating dispersal system on these slopes.

Figure 70. *Pterodroma phaeopygia* (Galapagos Petrel, Dark-Rumped Petrel) that burrows and disrupts mosses, causing moss balls to form. Photo by Lip Kee, through Creative Commons.

Figure 71. *Grimmia trichophylla* on a boulder. Clumps such as this are easily broken off and can become moss balls. Photo by Michael Lüth, with permission.

Figure 72. *Grimmia torquata*. Once free, a clump can become a moss ball; lower branches grow toward the center of an upside down plant. Photo by Michael Lüth, with permission.

I have seen moss balls that fell from the talus slopes near the Red River in New Mexico, USA. There were numerous balls on the ground near the base of the slope, some quite rounded and others irregular in shape (Figure 74-Figure 73).

Figure 73. Detached moss ball formed by rolling down the talus slope shown in Figure 74. Photo by Janice Glime.

Animals – Breaking or Ingesting Bryophytes

Some fragments have a little help from the animals in the vicinity. We are finding an increasing number of animals that ingest bryophytes, including insects, earthworms, molluscs, rodents, and occasionally larger mammals. (See next subchapter.)

Extreme Environments

In extreme environments, fragments may be important in dispersal. They can be produced under the most harsh conditions and be blown around in an arrested state until landing in a suitable microhabitat.

Antarctic & Arctic

On the continent of Antarctica, only three bryophytes were known to produce sporophytes: *Bryum pseudotriquetrum* (as *Bryum algens*; Figure 75) (Filson & Willis 1975), *Hennediella heimii* (as *Bryum antarcticum*; Figure 76) (Kanda 1981), and *Grimmia trichophylla*

(Figure 71; Selkirk 1984). However, birds and other animals scratching among the plants dislodge numerous fragments (Selkirk 1984). When Selkirk (1984) set out Tauber traps (Tauber 1974) to collect the diaspores on the surface of the snow in the Antarctic, she found that only two species had been dispersed by specialized structures: *Ulota phyllantha* (Figure 77) by gemmae (Figure 77-Figure 79) and *Dicranella cardotii* by stem tips. Most of the plants, however, had been dispersed by various fragments of leaves and stems. She further verified that many of these moss taxa were actually growing from vegetative fragments at all the types of sites she observed where bare, colonizable areas were available.

Figure 78. *Ulota phyllantha* gemmae at tip of leaf. Photo by Dick Haaksma, with permission.

In Arctic Canada, Miller and Howe Ambrose (1976) estimated a total of 33,820 bryophyte fragments per cubic meter of granular snow! Of these, 97% were less than 2.25 mm, so small that airborne dispersal was likely. They found that almost all the viable fragments were leaf-bearing moss stem tips. Based on their experiments and the number of fragments available, they estimated that over 4000 viable propagules occurred per cubic meter of granular snow. They suggest that the same winds that serve to disperse these fragments serve as the agent to break the fragments from the plants. Cold air and desiccating conditions make the plants more fragile and contribute to the breakage.

Figure 79. *Ulota phyllantha* gemmae at tip of leaf. Photo by Dick Haaksma, with permission.

Alpine

Many bryophytes seldom or never produce sporophytes in harsh environments such as that of alpine summits, requiring them to rely on asexual means for reproduction and dispersal. Robinson and Miller (2010) compared two species of *Sphagnum* from the Adirondack Mountains and other high altitude sites in eastern North America. These two species [*S. pylaesii* (Figure 80), *S. tenellum* (Figure 81)] live in similar habitats, but their life strategies differ. Robinson and Miller used 17 microsatellite loci to infer dispersal from the gene flow estimates. Branch fragments of *S. pylaesii* were coated with UV-fluorescent dye and released from two alpine summits. Fragments were located after 12 and 24 h and 1 week using UV LED light sources in the evening. Both species exhibited more genetic variation than expected. However, the species differed, with *S. pylaesii* having high differentiation and low gene flow between populations throughout its North American distribution. *Sphagnum tenellum* was less differentiated and showed higher levels of gene flow. Robinson and Miller concluded that fragments played an important role in transport both on summits and to other alpine summits.

Vegetative Diaspores

Correns (1899) examined 915 types of mosses with **vegetative diaspores** (specialized propagula of Longton and Schuster). Since then, usage of terminology has diverged among the countries of the world, and even within one country. In the recent *Glossarium Polyglottum Bryologiae* (Magill 1990), bryologists from around the world attempted to standardize terminology. In that edition, Magill used the concept of Goebel (1905) that divided vegetative diaspores into two groups based on their development at germination. He applied the term **propagula** to those diaspores that have an apical cell and can grow directly into a leafy shoot if the apical cell is reactivated (Figure 83, Figure 95). Unfortunately, this definition is clouded by its impracticality and because even these diaspores usually produce protonemata.

Köckinger and Kucera (2007) considered that *Barbula amplexifolia* (Figure 82) reached the Austrian Alps by vegetative gemmae across the cold Pleistocene steppes from Central Asia. They support this conclusion by the absence of male plants and sporophytes in the Alps and the low level of morphological and anatomical variability. They suggest that extensive road construction through the forests may be facilitating their recent increase in distribution.

Figure 83. Deceduous branches (**propagula**) of the moss *Campylopus pilifer*, representing a common means for its reproduction. Photo by Michael Lüth, with permission.

Magill (1990) likewise used the concept of Goebel to define **gemmae** as vegetative diaspores with no apical cell and that always must begin growth with a protonemal phase (Figure 19, Figure 95). These units then include caducous leaves and endogenous gemmae, as well as those specialized, oval, round, or irregularly shaped structures we have always called gemmae in the strictest sense.

Among the **propagula**, Imura and Iwatsuki (1990) identified four aboveground types:

1. **Deceduous shoot apices** (Figure 35, Figure 84) result from an area weakened by a cleavage in the cell walls. These often already have rhizoidal initials at their basal parts. Such shoot apices occur in *Bryum argenteum* (Figure 35) and *Campylopus sinensis* (= *C. japonicus*) (Figure 84).

Figure 84. *Campylopus sinensis* (= *C. japonicus*) with broken tips. Photo from Hiroshima University website, with permission.

2. **Caducous branchlets** (caducous = deciduous) seem like deciduous shoot apices, except that they are branchlike structures with minute leaves and are attached to the parent plant by one-celled stalks. A good example of these is in *Pterigynandrum filiforme* (Figure 85; Bergamini 2006). Although such branches are not common among pleurocarpous bryophytes, they can also be found in *Pseudotaxiphyllum* (= *Isopterygium*) *elegans* (Figure 86), *Leucodon*

sciuroides (Figure 87), *Platygyrium repens* (Figure 88-Figure 89), and *Pseudoleskeella nervosa* (Figure 90).

Figure 90. *Pseudoleskeella nervosa* showing bulbils (caducous branchlets) at branch tips. Photo by Hermann Schachner, through Creative Commons.

3. **Flagella** are slender branches with reduced leaves and occur in the axils of upper leaves. The basal portion is multicellular, thus separating them from caducous branchlets. These are common in *Dicranum flagellare* (Figure 23).
4. **Bulbils** (Figure 91-Figure 95) usually occur on one-celled, short stalks and have what appear to be partially developed leaves. Some are round and bulb-like, others are thread-like. They are common in *Pohlia* (Figure 91-Figure 94).

Gemmae can be filamentous, spindle-shaped, globular, discoid, or multi-horned (Figure 95). They occur on various parts of the gametophyte and sometimes have pale, thin-walled cells at the base. Protonemal and rhizoidal "gemmae" are usually labelled **bulbils** on materials from biological supply houses. Two types of gemmae can be identified based on their origin on the plant:

1. **Caducous leaves** are very specialized leaves of reduced size that may or may not differ from normal leaves in basic structure. In *Aulacomnium*, most of the taxa produce special branches with gemmae (caducous leaves) that are easily detached, reduced leaves (Imura *et al.* 1991). In *Campylopus fragilis* (Figure 98-Figure 99) and *Syntrichia laevipilum* (as *Tortula pagorum*; Figure 96-Figure 97), the caducous leaves are on short branches at the axils of upper leaves (Imura & Iwatsuki 1990). *Thuidium cymbifolium* (Figure 100) produces caducous flagella (Akiyama 2009).

2. **Endogenous gemmae** (Figure 101-Figure 111) are produced inside a cell initial. Most of the taxa among the mosses with these structures are in the **Grimmiaceae**, but they are common among the **liverworts**, often occurring as patches of non-green color at leaf tips or margins.

Stem and Leaf Gemmae

As one might expect, at least in some cases, the environmental conditions can have a strong effect on forms and numbers of gemmae. For example, the species *Bryum dichotomum* has several forms that previously have been named as different species (Dolnik 2006). These species, including the synonym *B. bicolor* (Figure 112), have been separated based on the forms and numbers of gemmae. Dolnik germinated the bulbils in culture in the greenhouse under a variety of conditions. In the form of *B. dichotomum* identified as its synonym *B. barnesii* (Figure 113-Figure 114), environmental conditions had no effect on number of bulbils per leaf axil, but the shape varied with seasonal variability, causing taxonomists to initially consider them to be different species. Both these bulbils and those developing on protonemata can float for several days and remain viable, providing a potential means of long-distance dispersal to locations along streams and shorelines where water levels vary.

Figure 114. *Bryum dichotomum* (*B. barnesii* form) bulbil from leaf axils. Photo by Kristian Peters, with permission.

In the genus *Fossombronia*, two species are known to produce budlike vegetative propagules from leaf cells (Zhang *et al.* 2003). In South Africa, *Fossombronia gemmifera* has this behavior (Cargill 2000). In Australia, sterile plants of *Fossombronia cerebriformis* produce adaxial leaf gemmae at the bases of leaves (Scott & Pike 1984).

Newton (2002) found flagelliform propagules that were ready for dispersal in *Pilotrichella flexilis* (Figure 115). These developed from primordia in leaf axils where they had minute juvenile leaves and in some cases rhizoids were present on some branchlets. Although miniature branches often serve as propagules, this is the first time they are known to develop from moss leaves (Schuster 1966). In *P. flexilis* these develop directly from the alar cells and do not develop protonemata. The phenomenon of developing miniature shoots from leaf cells is known among the liverworts in the genus *Plagiochila*.

Rhizoidal Gemmae

As I began working on this section, I quickly realized I had a nomenclature problem. I had a number of images of rhizoidal tubers – no problem there. But I also had a number labelled **rhizoidal gemmae**, all from bryologists. All but one of these gemma images resembled the tubers. After consulting the *Glossarium Polyglottum Bryologiae*, I was comforted to learn that in mosses, rhizoidal tubers were defined as gemmae born on rhizoids. But one of these images was quite different, that of *Fissidens macaoensis* (Figure 116-Figure 118). In this species, the rhizoidal gemmae are elongate filaments that are narrow at the base and expand toward the tips (Figure 117; Zhang & Hong 2011). And it develops **rhizoidal tubers** (Figure 118) at the same time, a seemingly unique character among mosses. Zhang and Hong suggest that these two types of gemmae on the soil surface could be an adaptation that permits easy dispersal up to several hundred m during floods created during the typhoon season in Macao, China.

Figure 118. *Fissidens macaoensis* rhizoidal tuber. Photo by Li Zhang, with permission.

Risse (1986) observed the development from rhizoidal gemmae of *Dicranella rufescens* (Figure 119) and reviewed the rhizoidal gemmae of 82 European moss species and 3 additional ones from outside Europe (Risse 1987). Pressel *et al.* (2007) reviewed the protonemal propagules in *Bryum* (Figure 120-Figure 121, Figure 127-Figure 130) and related genera. Lepp (2008) reports over 100 species with rhizoidal gemmae, but most likely there are many more that have not been investigated.

Figure 119. *Dicranella rufescens* with rhizoidal gemmae. Photo by David T. Holyoak, with permission.

Figure 120. *Bryum* rhizoid with gemma tubers. Photo courtesy of Javier Abaigar Martinez.

Nordhorn-Richter (1984a) discovered that many parts of bryophytes, including asexual propagules, could be distinguished with the fluorescence microscope. She found this to be especially important in finding rhizoidal tubers and other propagules in the genus *Pohlia* (Nordhorn-Richter 1984a-d, 1985, 1988).

Figure 121. *Bryum* rhizoid gemma tuber. Photo courtesy of Javier Abaigar Martinez.

Whitehouse (1961) reported rhizoidal gemmae from *Henediella* (= *Tortula*) *stanfordensis* (Figure 122) in Cornwall, Great Britain, and later Reese (1967) reported them in *Chenia leptophylla* (= *Tortula vectensis*; Figure 123-Figure 124) from North America. *Henediella stanfordensis* forms a band nearly 1 km long on the coast

near Lizard Point. Male plants seem to be absent, so this species depends on its gemmae, also chloronemal gemmae, and probably fragments. It is a winter annual, surviving the summer primarily through these rhizoidal gemmae.

Rhizoidal Tubers

Rhizoidal tubers (Figure 125-Figure 131) occur on the rhizoids and are usually filamentous, branched, or spherical and have diverse origins. Whitehouse (1966) described these for 29 species of European mosses. He considered them to be a means of survival in arable fields and a means of dispersal for taxa living by streams. These often occur on species where sporophytes are unknown. Arts (1994) reported both rhizoidal tubers and protonemal gemmae in nine species of *Ditrichum* (Figure 125-Figure 126). They are common in the genus *Bryum* (Figure 127-Figure 130), and are likewise known in *Pohlia* (Figure 131). Arts (1986a) cultivated tubers of *Fissidens dubius* (= *F. cristatus*; Figure 132) and established that they are drought resistant. The large tubers of *Campylopus pyriformis* (Figure 133) are likewise drought resistant and contain large quantities of starch (Arts 1986b). Their dark color may indicate antiherbivore compounds or may serve as a filter against light, decreasing chances of germination under a small amount of soil.

Protonemal Gemmae

Because of identification difficulties, we seldom examine protonemata closely in the field. Hence, to many of us, protonemal gemmae are all but unknown. Nevertheless, Pressel *et al.* (2007) consider them to be relatively common. These protonemal gemmae occur in a variety of families. The moss *Trematodon brevicalyx* (Bruchiaceae) produces them (Dhingra & Chopra 1983) and they are known in 36 species of *Bryum* (Chopra & Rawat 1977; Pressel *et al.* 2007).

It is likely that many species have protonemal gemmae or other reproductive structures that remain to be discovered. For example, these were unknown until recently in the Splachnaceae. Following the discovery of protonemal bulbils in *Splachnum ampullaceum* (Figure 134) (Mallón *et al.* 2006), Martinez and Price (2011) studied the development of the protonemata of the epiphytic *Tayloria rudolphiana* (Figure 135), likewise a member of the Splachnaceae. In culture, they observed protonemal brood cells for the first time in this species, occurring at the ends of caulonemal filaments where they formed chains of short, somewhat thick-walled spherical cells. These brood cells developed after four months in culture and had abundant chloroplasts and some lipid droplets.

Zygodon forsteri (Figure 136) is only known from beech bark (*Fagus sylvatica*), often occurring with *Z. viridissimus* (, and is rare (Adams & Rumsey 2005). *Zygodon forsteri* occurs on rain tracks on trees, on roots in places that collect water, and on callus tissue where squirrels make grooves that aid establishment (Figure 139-Figure 140). The authors suspect that slug herbivory on the capsules of *Z. forsteri* is responsible for poor reproduction, but they have documented that the running water disperses its bountiful chloronemal gemmae.

Even the aquatic moss *Fontinalis antipyretica* (Figure 158) produces protonemal gemmae (Ares *et al.* 2014). Thus far, this has only been observed in culture, but few or no observations have been made in the field. These are produced in ageing and desiccating cultures, and the authors suggest that in nature they may be produced in response to diminishing water levels.

Figure 141. *Fontinalis antipyretica* chloronemal gemma. Photo modified from Ares *et al.* 2014.

The production of protonemal gemmae seems to be environmentally controlled. Vashistha and Chopra (1984) found that in *Didymodon recurvus* the production of protonemal gemmae was favored by low light and high temperature, whereas high light and low temperature resulted in development of gametophore buds. This experimental observation is consistent with the assertion of Whitehouse (1980). He found that the protonemata of *Barbula trifaria*, *Gyroweisia tenuis*, and *Eucladium verticillatum*, as well as those previously reported in *Schistostega pennata* (Edwards 1978), seem to be

adaptations for survival and propagation at low light intensities of deep shade. Perhaps this is a mechanism to provide an opportunity for dispersal from an unfavorable location to one with more favorable light?

Pressel and coworkers (2007) found that in culture the protonemal gemma production increased with high nutrient availability and suggested that this may be true in nature as well. They assumed that the protonemal gemmae were both less long lived and less desiccation tolerant than tubers. They suggested that these diaspores helped in initial establishment as well as local spread of the species. The role in the diaspore bank and longevity of these structures remain to be investigated.

It is interesting that development of protonemal gemmae may also be controlled by the hormone **IAA** (Ahmed & Lee 2010). Ahmed and Lee found that both IAA and kinetin controlled the production of gemmae vs gametophore buds in *Palustriella decipiens* (= *Cratoneuron decipiens*) cultures from chopped up gametophores, serving as concentration-based external regulators. This does not necessarily imply that the same behavior would occur from protonemata produced by spores because chopped plants could provide hormones that might not be available to a spore germling.

Figure 142. *Bazzania trilobata* showing stolons with very reduced leaves. Photo by Dick Haaksma, with permission.

Liberation Mechanisms

Even the mechanisms of liberating the diaspores differ among species. Duckett and Ligrone (1992) identified five liberation mechanisms:

1. random breakage of thin-walled stalk cells
2. formation of new internal walls that separate from old
3. severance along middle lamella of basal cell with or without rounding off of cells
4. formation of highly specialized abscission (**tmema**) cells
5. breakage along intercalary region of thin-walled living cells

In contrast to these specific liberation mechanisms, rhizoidal gemmae lack any separation mechanism, being freed only by decay of the filament that has produced them.

Some bryophytes don't require any special cells or mechanisms to release fragments. For example, the leafy liverwort *Pycnolejeunea* will lose a shoot with only a light touch. Others may produce special branches that release with only a touch. This adaptation usually results from reduction in number of cells at the point of attachment. The ease-of-breakage method includes many leafy liverworts. One such species is *Lejeunea cardotii* that grows in mats on tree trunks and dead wood. Its stems produce small-leafed branches and these may in turn produce more small-leafed branches. These are fragile and break off easily. Other leafy liverworts, e.g. *Bazzania trilobata* (Figure 142), likewise get such specialized branches, often originating from under the branch.

Protonemal Gemmae

Most of the protonemal gemmae separate from the parent **chloronema** (part of protonema giving rise to buds) by a **tmema** (abscission) cell (Figure 147-Figure 149). Other taxa with this tmema mechanism include *Mielichhoferia bryoides* and *Rhodobryum roseum* (Figure 66). Other bryophytes use **schizolysis** to detach their gemmae. This requires the splitting from the parent plant by **lysis** of the cellular connections through rupture of adjoining cell walls. Genera with this strategy include *Epipterygium* (Figure 143), *Plagiomnium* (Figure 144), *Rhizomnium* (Figure 145), and *Mnium* (Figure 146).

Figure 146. *Mnium arizonicum*, representing a genus that uses lysis to disconnect its gemmae. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Tmema

A **tmema** (Figure 147-Figure 149) is a specialized abscission cell that permits portions of a protonema to operate independently and create a position of easy breakage (Correns 1899; Duckett & Ligrone 1992). This mechanism seems to be important in the release of protonemal gemmae, with a variety of different developmental patterns (Duckett & Ligrone 1992). Schnepf (1992) reported these from the chloronemata of *Funaria hygrometrica* (Figure 150), where they serve to fragment the protonemal filaments. In *Zygodon* (Figure 151-Figure 152), *Bryum pallens* (= *B. flaccidum*; Figure 153), and *Dicranoweisia cirrata* (Figure 154), they occur at

the bases of axillary gemmae, and they are characteristic of foliar gemmae in *Calymperes* (Figure 155-Figure 156) (Duckett & Ligrone 1992).

Figure 155. *Calymperes erosum* with leaf gemmae. Photo by Li Zhang, with permission.

The tmema cell in *Funaria hygrometrica* protonemata results from unequal cell division and is followed by the loosening of the old proximal cell wall (Bopp *et al.* 1991). Addition of 10 μ M IAA prevents the formation on tmemata, indicating that the formation of this cell results from inadequate IAA. The result of this fragmentation is to create several separate protonemata. In gemmae, the tmemata connect the gemmae to the plant and permit its abscission (Figure 156-Figure 157) (Stapper 2006).

Diaspore Bank

Unfortunately, it is difficult to determine whether spores or asexual diaspores contribute to the growth of new plants from the diaspore bank. During (1995) suggested that tubers of some moss species may be very abundant in the diaspore bank, and as seen earlier in the discussion of diaspore banks, these species often are not represented above ground or are sparse there. During contends that such populations seem to rely completely on occasional recruitment. Long rhizoids help to extend the range of some species within a location. He considers population regulation of these species to be a density-dependent mortality of the tubers in the soil.

The forest is often disturbed, whether by fire or by harvesting. Bryophytes are important in maintaining soil moisture and as reservoirs of nutrients that often get released toward the later part of the growing season. Following disturbance, forest floor bryophytes are often recovered from diaspore banks. Caners *et al.* (2009) cultured mineral soil samples from both mixed and coniferous forest stands in northern Alberta, Canada, following harvesting. They found that forest type was not the determinant of the species composition, nor was harvesting intensity. Rather, edaphic variables and geographic space determined the regenerant flora. Nevertheless, light intensity exerted a significant influence on both the species responses and the species assemblages. Low light caused significant reduction in richness and cover of acrocarpous mosses – the fugitive, colonist, and shuttle life-history strategies. Pleurocarpous mosses (perennial stayers), on the other hand, seemed unaffected by light intensity. Higher light intensities supported significantly greater **Shannon diversity** and the frequency of reproduction. Caners *et al.* concluded that diaspore banks were an important repository for forest floor species and provided a source for recovery after harvesting.

Ross-Davis and Frego (2004) found 10 of the 36 species of a forest floor community in both the diaspore bank and the aerial diaspore rain. Of the extant taxa, 36% were not present in either diaspore source. The two dominant mosses, *Pleurozium schreberi* and *Hylocomium splendens*, were present in both the diaspore bank and aerial diaspore rain.

Hence, bryophytes are able to colonize disturbed areas from both the diaspore bank and from the diaspore rain. These two sources contain both spores and vegetative propagules, but not necessarily both from the same species. Distinguishing which type of diaspore germinated is quite difficult and is not usually included in diaspore bank studies.

The Antarctic undoubtedly has many well-preserved bryophyte diaspores buried in the ice and deep in bryophyte mats. Bergstrom and Selkirk (1999) were able to culture propagules from substrate samples 5.5 cm deep on Macquarie Island. They succeeded in germinating 15 bryophyte taxa. They hypothesized that bryophytes that arrived on bare patches in the fieldmark, they were able to colonize stable ground but unable to colonize areas subject to surface movement. Instead, some of these propagules became buried. Spherical moss balls, however, were tolerant of the surface movement and disturbance. Of the 15 species that germinated, 10 were not local and came

from populations at the warmer lower altitudes. They suggested that such propagules will permit areas respond quickly to climate change by providing species that were tolerant to the new climate.

Propagule Dispersal Distances

It appears that little is known about actual distances that vegetative propagules might travel. Although studies have suggested that the distances are short, *i.e.* measured in centimeters rather than meters (Kimmerer 1991, 1994; Kimmerer & Young 1995), it appears that extensive measurements are lacking. Kimmerer (1991) found that gemmae of *Tetraphis pellucida* (Figure 18-Figure 19) travelled to a maximum of 10 cm in her study, and that 50% fell within 1 cm. But surely moss balls (see subchapter on growth forms) can travel great distances. And fragments of bryophytes on glaciers likewise travel hundreds of feet, and potentially much more. In my study on *Fontinalis* (Figure 158) vegetative dispersal, one piece had re-established upstream about 20 m from its origin, presumably carried there by some animal (bear or human?).

Figure 158. *Fontinalis antipyretica*, a moss that spreads vegetatively by rhizomes and disperses by fragments. Photo by Andrew Spink, with permission.

Convincing evidence of long-distance propagule dispersal is that of *Marchantia polymorpha* (Figure 159) on the crater of Deception Island, Antarctica. The crater was formed in 1969, exposing new ground following the eruption. In 1971, Young and Kläy reported this species on the new ground approximately 1000 km from the nearest known population in South America. No other colonies on Deception Island of this conspicuous liverwort were known to the scientists. Perhaps more surprising, the thallus had the distinctive dumbbell shape that is typical of a young thallus developed from a gemma! This example supports a conclusion of rapid long-distance dispersal that in this case arrived at a suitable habitat. (Let's hope this wasn't a case of inadvertent human dispersal!)

Figure 159. *Marchantia polymorpha* with gemma cups. Photo by Andrew Spink, with permission.

Propagule Survival/Longevity

The first question that comes to mind for long-distance dispersal of vegetative propagules is whether they can survive. These are living, often active fragments, gemmae, bulbils, and other structures that may or may not be dormant. Presumably, living fragments would be the least adapted among these to survive the conditions of the stratosphere. Studlar *et al.* (2007) tested fragment survivability by sending four mosses into the stratosphere on a weather balloon. These were subjected to temperatures as low as -30°C over a period of 4 hours, 2 of which were in the stratosphere. Subsequent culture for 28 days in the lab revealed the ability of these species to survive the stratosphere ride. *Sphagnum magellanicum* (Figure 160), *S. fallax* (Figure 161), and *Atrichum angustatum* (Figure 44) all regenerated with secondary protonemata and juvenile shoots. *Sphagnum girgensohnii* (Figure 162), however, did not. These results suggest that at least some vegetative diaspores, including fragments, could travel by wind into the stratosphere.

Figure 160. *Sphagnum magellanicum* in Europe, a species that survived travel in a weather balloon. Photo by Michael Lüth, with permission.

Figure 161. *Sphagnum fallax*, a species that survived travel in a weather balloon. Photo by Michael Lüth, with permission.

Some bryophytes may survive in a dry state for years, providing a larger set of opportunities for the wind or water to distribute them to new locations. Whitehouse (1984) reported that tubers of *Anisothecium* (= *Dicranella*) *staphylinum* (Figure 163) survived in stored soil for 50 years. Zander (1979) successfully cultured *Anoetangium* (Figure 164), *Barbula* (Figure 165), *Desmatodon s.l.* (Figure 166), *Didymodon* (Figure 167), *Gymnostomum* (Figure 168), *Hymenostylium* (Figure 169), *Leptodontium* (Figure 170), *Molendoa* (Figure 171), *Oxystegus* (Figure 172), *Pleurochaete* (Figure 173), *Pseudocrossidium* (Figure 174), *Tortella* (Figure 175), *Tortula* (Figure 176), and *Trichostomum* (Figure 177) species, all members of **Pottiaceae**, from herbarium plants (not spore) specimens. These were all less than 5 years old.

Buried propagules must somehow remain dormant in an environment (diaspore bank) that varies both their temperature and their state of hydration. The only factor they lack for germination appears to be light. Risse (1987) reviewed 82 species of European mosses with rhizoidal propagules and demonstrated that tubers and rhizoidal gemmae do not germinate in absence of light. Their germination is dependent upon the intensity of light, not the photoperiod. If the propagules are hydrated for more than ten days without successful germination they do not survive. After fifteen days, their fat reserves are depleted. Furthermore, imbibition of water causes the gemmae to lose their dormancy and become sensitive to dehydration, causing irreversible damage if they are more than 12 hours into their pre-germination phase when they dry out again. This can explain the absence of viable propagules in the first cm of soil where frequent wetting and drying are certain.

Egunyomi (1978) found that spores have longer storage longevity than do gemmae for *Octoblepharum albidum* (Figure 13). Even at room temperature and 60-75% humidity, spores were viable after eight months, but gemmae began to lose viability at six months. Light is of utmost importance for germination, with only 8.0% of gemmae germinating at 1 lux, but 90% at 1375 lux.

Imura and coworkers (1992) experimented with the rhizoidal tubers of a moss, *Leptobryum pyriforme* (Figure 178-Figure 183), found on the ice surface of a lake near the Syowa Station in the Antarctic. Both protonemata and leafy shoots developed from these tubers after the tubers had been stored for two years in a freezer. This illustrates the tremendous tolerance of these species and the extraordinary survival abilities.

Figure 182. *Leptobryum pyriforme* rhizoidal tubers. Photo by Victoria Rozhina.

John Spence (Bryonet 22 November 2010) actually tested long-term viability of tubers in *Rosulabryum capillare* (Figure 184) and *Gemmabryum* (= *Erythrocarpa* sp.; Figure 185). Tubers of these species remained viable up to 15 years and germinated in distilled water and normal daylight. Such propagules can remain dormant in soil banks and other locations, germinating after unknown periods of time when they are disturbed and brought to the surface (e.g. During 199). Although there are a number of studies on propagules from such situations, the longevity of

these propagules is unknown. Herbarium specimens provide a means of checking longevity, but the conditions of a herbarium are quite different from the natural habitat. And even if the propagules could survive the conditions there, they may become dinner for hungry invertebrates.

Mishler and Newton (1988) experimented with four *Tortula* s.l. species (Figure 96-Figure 97; Figure 122-Figure 124) and found that fragments, while being less successful at germination than spores, usually developed numerous stems, whereas the spores did not during the 2.5 months of experiments. The protonemata looked different between the spore-derived and the fragment-derived ones. Perhaps they differed physiologically and those derived from spores required a day length or other condition not present in the experiment.

I have observed diatom-covered mosses being eaten by a dipteran larva in the **Rhyphidae** family. These went in "dirty" and came out the other end clean and still bright green. But I have no evidence that these actually survived the digestive tract as viable propagules. Insect guts can have extremely high or extremely low pH (Nation 2002) to adapt them to digestion of the few remaining nutrients in detritus, and the particular diet of this larva suggests it might be so-adapted. These extreme pH levels are likely to be detrimental to the living cells of the moss.

The potential of a delayed response of the moss to such a detrimental gut environment is exemplified by our experiment on *Fontinalis duriaei* (Figure 186). In an experiment to determine if rainbow trout (*Oncorhynchus mykiss*) could be dispersal agents of *F. duriaei*, we brought in fresh moss with lots of aquatic insects, but the fish did not eat the moss, so we force-fed it. The moss was expelled later through the anus in a neat cylindrical package (Figure 187), still bright green. We isolated it in a cooled jar of its own stream water, but 24 hours later, the moss had lost its green color and appeared to be dead.

Figure 186. *Fontinalis duriaei*. Photo by Jan-Peter Frahm, with permission.

Vegetative propagula are less likely to survive travel through the gut than spores, and they may be more susceptible to damage when they begin to germinate as well. Hydration without successful germination can kill them. But if they are able to germinate successfully, both fragments and specialized propagula have better chances than spores of producing gametophores, albeit only one per propagule. Propagule banks typically reflect not only the present vegetation, but also past vegetation, providing ready sources following disturbance.

One prerequisite for propagules with long dormancy or lengthy travel is desiccation tolerance. Understanding this is necessary for cryopreservation to maintain species that may become extirpated in the future. Rowntree *et al.* (2007) have used cryopreservation successfully for many species and in doing so have added greatly to our understanding of the mechanisms the bryophytes are able to use to survive. They have found that survival can be enhanced by pretreatment with ABA and sucrose, the latter perhaps providing an energy source upon rehydration. Surprisingly, the pioneer moss *Ditrichum plumbicola* had low survival of cryopreservation and likewise responded poorly to pretreatment. With further experimentation, they discovered that the pretreatment with sucrose and ABA caused significant changes in the protonemata. Growth was greatly reduced and propagules had pronounced morphological and cytological changes. Although most cells died, those that survived were markedly different from normal. The surviving cells had thick walls that were darkly pigmented and there were numerous small vacuoles and lipid droplets in the cytoplasm. When there was no ABA-sucrose pretreatment, desiccation and cryopreservation caused minimal cytological changes. These untreated tissues returned to their pre-dehydration state within 2 hours of rehydration. On the other hand, rehydration was normal once ABA and sucrose were removed from the pretreated propagules. Rather, these propagules (from the protonemata) became highly desiccation and cryopreservation tolerant, a behavior similar to that of rhizoids that function as perennating organs in the field. Rowntree and coworkers considered this as evidence that the propagules used ABA to increase their desiccation tolerance.

In *Marchantia inflexa* (Figure 189) both water and desiccation affect mortality (Chris Stieha, Bryonet 27 February 2016). In his lab, there was less than 10% mortality of gemmae maintained in water for three months, but 20% mortality after only four days of desiccation. In the field they can turn brown within an hour of desiccation. Stieha *et al.* (2014) found that male plants of this species produce the most gemmae and more quickly when compared to females, but the male gemmae have less ability to survive desiccation. Gemmae in this species can move up to 20 cm from the parent plant in a light rain, permitting expansion of the population.

Propagule Establishment

Once a propagule reaches its final resting place, it must begin growth and become established (Figure 190). Due to both edaphic and climatic differences, the success of this establishment is less predictable as the distance increases (Karlson & Taylor 1992; Ronsheim 1997; Laaka-Lindberg *et al.* 2003).

Figure 190. Gemmae germinating. Photo by Li Zhang, with permission.

The conditions at germination can be critical. Risse (1987) tested rhizoidal gemmae of mosses, citing their importance in environments that are frequently disturbed by natural or anthropogenic influences. McCutcheon (1978) reported that light is required for germination, and that if the gemma of *Bryum rubens* (Figure 191-Figure 194) becomes imbibed for more than ten days without receiving light, it will die. Its fat storage reserves are

depleted in 15 days, so that imbibition can trigger that loss. Furthermore, after imbibition, tubers become sensitive to desiccation and do not regain their pre-germination tolerance if they have entered their pre-germination phase (imbibed) for more than 12 hours.

Desiccation

A key factor in establishment is maintenance of sufficient moisture in early stages of development to permit development of a reproductive adult. An interesting example of this is *Pseudoscleropodium purum* (Figure 195). One habitat where this species grows is on ant hills of the yellow meadow ant, *Lasius flavus* (Figure 196), that is, on the north-facing sides of the ant hills (King 2003). Fragments detached by grazing animals are common on the mounds. After experimentation, King concluded that inability to establish on the south-facing side was most likely due to desiccation and metabolic drain leading to cell death. Transplanted adult mosses, on the other hand, seemed capable of survival.

Inhibitors

Gemmae do have a safeguard against competing with their parents. Most are inhibited by the presence of the parent (Figure 197) and are often even inhibited by related species [e.g. *Bryum rubens* (Figure 191-Figure 194) by *Bryum alpinum* (Figure 198) (McCrutcheon 1978)]. Ashton and Raju (2001) demonstrated inhibition of rhizoidal gemmae in *Gemmabryum* (= *Bryum*) *violaceum* (Figure 199) by the soil associated with the parents, but gemmae germinated while still attached if placed in fresh soil. This suggests that whatever served as the deterrent may have accumulated in the soil to a greater level than that in the plant. It would be interesting to attempt growing these in the same soil with charcoal as an adsorbant.

Figure 198. *Bryum alpinum* showing competition. Photo by David T. Holyoak, with permission.

Figure 199. *Gemmabryum violaceum* with rhizoidal tubers. Photo by David T. Holyoak, with permission.

Risse (1987) suggested that this inhibition might be caused by sugars, particularly mono- and disaccharides, shown by McCutcheon (1978) to inhibit tuber germination in *Bryum rubens* (Figure 191-Figure 194). Christianson (2000) showed that ABA (abscisic acid) is able to inhibit bud formation in *Funaria hygrometrica* (Figure 200), so it could also be the cause of inhibition by parents. This same self-inhibition (inhibition by parents) is known from *F. hygrometrica* (Figure 200). On the other hand, the cytokinin hormones leaked from one individual can stimulate bud formation on other nearby individuals of the same or related species (Bopp 1982).

Figure 200. *Funaria hygrometrica* showing the distinct margins where colonies contact each other. Photo by Janice Glime.

ABA is a common hormone in tracheophytes, having a variety of functions. It is best known in bryophytes as a responder to desiccation. Mallón *et al.* (2006) examined the effect of various concentrations of ABA on the production and behavior of gemmae in *Splachnum ampullaceum* (Figure 134). This species is best known for its ability to attract flies that disperse it among piles of dung, but its ability to produce vegetative propagules was previously unknown. The researchers managed to induce both brood cells and chloronemal bulbils in their protonemal cultures, as well as vegetative propagules, and their results suggest a bet-hedger strategy. The brood cells produced new chloronemal filaments when they were transferred to new media. There was a direct positive relationship between the concentration of ABA and brood cell formation, while at the same time increasingly inhibiting the growth of the protonemata. Furthermore, no buds developed on protonemata grown on media with ABA. Mallón and coworkers suggested that production of the vegetative structures on the protonema might be a desiccation response and would permit the plant to spread rapidly, a behavior that might also help to conserve moisture, if not then, in the future.

Establishment and Rarity

Cleavitt (2002) attempted to determine the factors that contributed to rarity of species [*Mielichhoferia macrocarpa* (Figure 201), *Didymodon johansenii*, and *Mnium arizonicum* (Figure 146)] and compared three rare

and common species pairs in the Front Ranges of Alberta, Canada. She found that propagule viability did not relate to establishment ability. Rather, establishment of rare species may be a function of a complexity of mechanisms that create a narrow realized niche. For example, *Mielichhoferia macrocarpa*, which occurred in the darkest and wettest sites, was tolerant of high light intensity and desiccation, suggesting that additional factors narrowed its establishment niche. She suggested that the broader apparent physiological tolerance found in these rare species may be due to their greater reliance on asexual reproduction. This suggests that we should look for other physiological factors and dispersal as causes of rarity.

Figure 201. *Mielichhoferia macrocarpa*, a species that appears to have broad environmental tolerances, but with limiting requirements of some factor(s). Photo by Robin Bovey, with permission through Dale Vitt.

In contrast, Cleavitt (2002) found that the three common species [*Mnium spinulosum* (Figure 202), *Bryum pseudotriquetrum* (Figure 203), *Didymodon rigidulus* (Figure 204)] were more likely to occupy habitats that agreed with their physiological requirements. *Mnium spinulosum* was limited by high light and thus occurred only in deeply shaded conifer stands; *Bryum pseudotriquetrum* was intolerant of desiccation and was thus found in moist areas such as stream banks.

Figure 202. *Mnium spinulosum*, a common species that is intolerant of high light and lives in conifer forests. Photo by Michael Lüth, with permission.

Figure 203. *Bryum pseudotriquetrum* at streamside. Photo by Michael Lüth, with permission.

Figure 204. *Didymodon rigidulus*, a common species. Photo by Michael Lüth, with permission.

Cleavitt (2002) suggests that rare species may have broader physiological tolerance because they rely on vegetative reproduction largely as fragments. In particular, they have a high tolerance to desiccation in both whole colonies and in fragments. This suggests that they may be rare due to dispersal limitations, slow establishment rates

that permit competitors to overpower them, or special environmental factors that were not examined.

Reproductive Problems

But the problems don't end with germination or even successful production of gametophores. These gametophores must likewise be able to reproduce, whether by vegetative means or spores. This is particularly problematic for dioicous species because they must have the successful invasion of both male and female spores for any further reproduction by spores to occur. And if they did arrive at a distant location by spores, it is likely that this is their primary means of dispersal. The same problem exists for vegetative propagules. For dioicous taxa, it is possible that only one gender arrives, whether by specialized structures or by fragments.

Perhaps there are species where the spores travel in tetrads, as is known for *Haplomitrium gibbsiae* (Figure 205) (Van Zanten & Pócs 1981). Nevertheless, a tetrad of spores is larger and hence sacrifices ease of transport by air currents. Van Zanten and Pócs suggest that this limitation might also be overcome by having spores remain in relatively compact clouds during transport – a notion that is certainly worthy of consideration. We need to consider if this compact cloud approach might also work for vegetative diaspores.

Figure 205. *Haplomitrium gibbsiae*, a species where spores travel in tetrads. Photo by Jan-Peter Frahm, with permission.

Epiphytes

It is hard enough to land in the right microhabitat on the ground, but even more challenging to land on a vertical surface. Hence, highly structured bark has more chance of trapping the somewhat large vegetative propagules. But the problems are just beginning at landing. The vertical surface of almost anything is subject to drying, and tree trunks are particularly exposed. Fortunately, the tropical cloud forests manage to maintain a higher moisture content than other types of forest habitats and thus are endowed with dense bryophyte cover on everything (Figure 206).

As one can imagine, establishment of tracheophytes can be more difficult than that of bryophytes. Hence, many depend on bryophyte establishment to provide them with a suitable substrate (Nadkarni *et al.* 2000). Nadkarni and co-workers dropped epiphytic bryophyte fragments 50 cm

above branches of saplings and mature trees of *Ocotea tonduzii*. Only 1% of these fragments were returned for the six months of the experiment. During the same time period, branches in the canopy with intact epiphyte loads retained 24% and branches that had been stripped of their epiphytes retained 5%. They found that a larger surface area and presence of other bryophytes helped in the retention of the fragments.

Figure 206. Mossy forest, Malaysia, where high moisture levels make it easy for epiphytic bryophytes to establish. Photo by Vita Plášek, with permission.

Rosso *et al.* (2001) found that *Antitrichia curtispindula* (Figure 207-Figure 209) grows faster in the canopy (60% faster) than in the understory, making it easier for it to become established there than when it falls on lower branches. These researchers considered that its absence in young stands may be due to dispersal limitations compared to that in old growth stands. In old growth stands it has both greater height to launch dispersal and more time to get there.

Symbionts Needed

For some bryophytes, a symbiotic relationship is important to survival. *Blasia pusilla* (Figure 210) and *Cavicularia densa* (Figure 211) have solved this problem by producing gemmae that include their *Nostoc* symbiont (Figure 212) (Rikkinen & Virtanen (2008). Others benefit from the presence of soil Cyanobacteria such as *Anabaena variabilis* and *Nostoc muscorum*, as is the case for *Funaria hygrometrica* (Rodgers & Henriksson 1976). These Cyanobacteria are able to capture atmospheric nitrogen and make it usable for the bryophytes.

Figure 212. *Nostoc* colony on *Blasia pusilla* thallus. Photo by Dick Haaksma, with permission.

Other bryophytes need fungal partners (Figure 213) (Bidartondo *et al.* 2003; Martinez-Abaigar 2005; Bidartondo & Duckett 2010; Pressel *et al.* 2010; Bidartondo *et al.* 2011; Desirò *et al.* 2013). Although there

have been a number of studies on fungi associated with various bryophytes, these have not dealt with the need for partners at the time of establishment of vegetative diaspores. Are vegetative dispersal structures able to carry their partners with them? Even if so, the conditions must be right for such a partner to flourish along with the bryophyte.

Figure 213. *Mylia anomala* rhizoid tip with symbiotic Ascomycete. Photo courtesy of Silvia Pressel, Robert Ligrone, and Jeffrey Duckett.

A somewhat similar problem occurs for *Dicranum flagellare* (Figure 23) on logs. It seems to be dispersal limited and can only colonize gaps caused by disturbance when other populations occur nearby (Kimmerer 1994). Therefore, older forests where there are more colonized logs provide a better source of propagules for dispersal. But once it reaches a substrate, it germinates much more rapidly than *Tetraphis pellucida* (Figure 18-Figure 19) and persists there longer, perhaps through competition.

Bacteria are important for the development of some bryophytes from spores (Spiess *et al.* 1984), so it is likely that these are also needed for some propagules to complete development, particularly those forming protonemata first.

Tradeoffs

Size matters in dispersal of propagules, but it invokes a tradeoff. Small propagules have the advantage of being produced in large numbers, *e.g.* 500-700 gemmae per leaf in *Scapania nemorea* (Figure 103-Figure 107) with 1-celled gemmae or 1000-7000 1-celled gemmae in *Lophozia ventricosa* var. *silvicola* (Figure 108) compared to only 15-45 in *Jubula* (= *Radula*) *complanata* (Figure 109-Figure 110) with discoid, multicellular gemmae (Laaka-Lindberg *et al.* 2003). Larger gemmae, on the other hand, have a greater chance for successful establishment where they arrive due to more stored energy.

It is also possible that the vegetative tissues of the vegetative diaspores may provide greater protection against germination in the wrong environment. Spores need only light and water to germinate. Hence, when they are brought to the surface and get a good rain, they germinate. As far as we understand, they do not, as spores, detect whether any other aspect of the environment is suitable. Some vegetative propagules, on the other hand, may be

able to detect inappropriate conditions of pH, insufficient nutrients, absence of a fungal partner, absence of hormones from associated bacteria, inappropriate temperature, or toxic metals and other substances. Examining these possible controls on germination of vegetative propagules may help us to understand both longevity of diaspores in the diaspore bank and the comparative success of spores vs vegetative diaspores.

Summary

Vegetative reproduction includes fragments, gemmae, and vegetative diaspores. A genet is therefore those individuals that arise from a single zygote, parthenogenetic gamete, or spore and that produce branches vegetatively. There are six basic means of reproducing vegetatively: 1) multiple gametophores from the protonema of one spore, 2) decay of older gametophyte parts with the separation of younger parts, 3) development of multiple shoots by rhizomes and stolons, 4) development of gametophores from rhizoids, 5) regeneration from fragments, 6) production of specialized propagula. The success of vegetative propagation is due to selection in the face of the difficulty of accomplishing sexual reproduction in a terrestrial environment. Fragmentation is especially common among pleurocarpous, perennial mosses where the dioicous condition and small spore size reduce the success of sexual reproduction. Such fragments can reach densities of 4000 viable propagules per cubic meter of snow. Propagula differ from gemmae in having an apical cell that can grow directly into a leafy shoot without a protonema stage. Propagula include deciduous shoot apices, caducous branchlets, flagella, and bulbils. Rhizoidal tubers can occur underground and many kinds of protonemata produce gemmae.

Splash cups are useful in dispersing gemmae in several liverworts and one family of mosses. Bryophytes getting frozen in ice or caught by flood waters can be carried considerable distances and vegetative dispersal in flowing water environs is essentially guaranteed. But vegetative diaspores have few mechanisms that aid in their liberation and dispersal. Among these are **tnema**, small cells that form a weak link and permit breakage.

Propagules must survive the desiccation, temperatures, and UV light of travel, be able to remain dormant upon arrival until the habitat or weather is suitable for germination, then survive after germination for the dispersal to be successful. Some have inhibitors such as ABA. Some require bacteria or fungi as partners. Some must land and become attached to vertical substrates. The usually larger vegetative structures sacrifice long distance dispersal for the ability to carry more with them and become established more easily. In addition to ABA, sucrose may also help in the survival of desiccation.

Acknowledgments

This chapter has benefitted from several email discussions with Peter Poschlod, especially on *Sphagnum*. Thank you to Bryonettors for interesting discussions on diaspores. A special thanks to Stefan Rensing and his associates Marco Göttig and Anne Genau for inducing and photographing the tnema cells for this chapter.

CHAPTER 4-11

ADAPTIVE STRATEGIES: VEGETATIVE DISPERSAL VECTORS

Figure 1. *Pohlia annotina* with bulbils in leaf axils. Many species survive on dispersal of vegetative propagules. Photo by Dick Haaksma, with permission.

Dispersal

Laaka-Lindberg *et al.* (2003) stated that dispersal pattern of vegetative propagules (*e.g.* Figure 1) is affected both by the microtopography of the habitat (Kimmerer & Young 1996) and by the type and size of propagule (Söderström & Herben 1997). Kimmerer (1994) further demonstrated that two log-dwelling species [*Orthodicranum flagellare* (Figure 2) and *Tetraphis pellucida* (Figure 35)] differed in the dispersal ability of their propagules.

Conditions upon arrival can play a role in which species can become established following dispersal. Gradstein (2006) demonstrated this with the lowland cloud forest of French Guiana. Vegetative propagules there are protected from desiccation by the daytime fog, permitting good photosynthesis despite high temperatures. Asexual reproduction is significantly more common in the understory than in the canopy despite the greater

constraints on dispersability in the understory. The canopy seems to experience better dispersal by spores.

Figure 2. *Orthodicranum flagellare* with broken brood branches lying on top of the cushion. Most likely some of these have travelled with an animal that broke them off. Photo by Janice Glime.

Gravity

Whereas spores are light weight and therefore easily lofted away on a slight air current, vegetative structures are often much more bulky and heavy. Shed parts, unless caught in a gust that can even blow heavy maple fruits up into the air, are likely simply to fall to the ground. This seems to be a common means for structures like gemmae, deciduous perianths, and other bulky forms of brood bodies and fragments.

"Galloping mosses" have an intriguing movement, leaving behind a trail of changed rock (Figure 3). The actual method of movement and time required is unknown, but they seem to move rather slowly, staying long enough in one place to chemically change the surface of the rock. Hence, it appears that gravity plays at least a partial role, but water most likely also helps in the movement. Mosquin (2011) reported these slowly moving mosses from the Arctic, where the mosses *Sphagnum* and *Grimmia ovalis* (Figure 3), and *Racomitrium ericoides* (Figure 4) are known for this behavior. When they reach a crack, they may be stopped and remain there (Figure 5).

Figure 3. *Grimmia ovalis* "galloping." Photo by Wouter Bleeker, with permission.

Wind Dispersal

Imagine being a small fragment of a leaf or stem being blown by the wind. Lacking the protection of surrounding plants, desiccation is imminent. Bouncing on the ground or off trees or rocks could impose a significant blow to tissues that may be only one cell thick. Exposure to UV radiation is likely to be greater than in their normal niche. Nevertheless, using a weather balloon Studlar *et al.* (2007) showed that at least some species [*Sphagnum fallax* (Figure 6), *S. magellanicum* (Figure 7), *Atrichum angustatum* (Figure 8)] can survive these conditions and regenerate from fragments.

Figure 4. *Racomitrium ericoides*, a moss that contributes to galloping mosses. Photo by Janice Glime

Figure 8. *Atrichum angustatum*, a species that regenerates from leaf fragments. Photo by Bob Klips, with permission.

This demonstration gives credence to a number of studies that have inferred vegetative dispersal of bryophytes. And we have already seen viability in 12% of the fragments blown about on the snow in Canada by wind (Miller & Howe Ambrose 1976).

In the Antarctic, Skotnicki *et al.* (2000) found evidence of propagule dispersal from elsewhere, with the RAPD technique indicating short-distance dispersal by both wind and water and long-distance dispersal by wind across the ice caps. The genetic similarities of *Chorisodontium aciphyllum* (as *Sarconeurum glaciale*; Figure 9) from three locations on Ross Island, Antarctica, with those of Arrival Heights, Scott Base, and Crater Hill, a few km away suggest wind dispersal, a concept supported by the prevailing wind direction and absence of the species in areas in between.

Des Callaghan (Bryonet 11 May 2019) demonstrated the wind dispersal of *Plagiochila exigua* (Figure 10) in Britain. This rare oceanic plant produces only males, making spore dispersal impossible. But it has **caducous** (deciduous) leaves that are easily dispersed in the wind (Figure 11; see <<https://youtu.be/YCHhANT0dUM>>).

Figure 11. *Plagiochila exigua* dispersing leaves. Photo by Des Callaghan, with permission.

Water Dispersal

Water aids in the dispersal of bryophytes in multiple ways. Aquatic mosses most likely depend primarily on water dispersal. Sexual organs can easily be damaged by abrasives in the water, as for example those in *Platyhypnidium riparioides* (Figure 12; Lewis 1973). These same abrasives can free leaves and branches that are possibly able to lodge on a substrate and regenerate. Conboy and Glime (1971) found similar abrasion in stream populations of *Fontinalis novae-angliae* (Figure 13).

Figure 12. *Platyhypnidium riparioides* in Europe, showing darkened and scoured leaves on lower parts of stems. Photo by Michael Lüth, with permission.

Figure 13. *Fontinalis novae-angliae* scoured by stream flow and suspended particles. Photo by Janice Glime.

Fontinalis species in streams are faced first with the problem of producing few sporophytes (Sayre 1945; pers. obs.), then of having spores lodge in a suitable place to stay put and begin new growth, whereas branches can easily get caught against rocks or snagged by submerged branches and roots, giving them an opportunity for new establishment (Figure 14; Sayre 1945; Welch 1948; Glime *et al.* 1979). Once these fragments get lodged against a rock or other suitable substrate, the contact stimulates the growth of rhizoids that eventually attach them to the substrate (Welch 1948; Glime *et al.* 1979; Figure 15-Figure 16). But this takes time, and experiments indicate that it requires at least nine weeks of impingement before the actual attachment (Figure 17; Glime *et al.* 1979). Temperature and flow rate influence the development of these rhizoids in *Fontinalis duriaei* (Figure 18) and *Hygroamblystegium fluviatile* (Figure 19), with flowing water conditions causing the mosses to produce more rhizoids than pool conditions (Glime 1980).

Figure 14. *Fontinalis novae-angliae* becoming established from a rhizome fragment in Fox Run, Grafton County, NH, USA. Photo by Janice Glime.

Figure 15. Rhizoids developing from stem wound tissue of *Fontinalis squamosa*. Note the spiral growth. These have not yet contacted a substrate. Photo by Janice Glime.

Figure 16. Rhizoids from wounded stem tissue of *Fontinalis squamosa*, showing the branched growth at their tips where they have contacted a substrate. In this case, the substrate is filter paper in contact with a glass test tube. Photo by Janice Glime.

Figure 17. Comparison of times required and percentage of attachment for *Fontinalis duriaei* and *Hygroamblystegium fluviatile* in contact with rocks in an artificial stream (n=48) compared to rocks placed in Coles Creek, MI, with *F. duriaei* held in contact with netting. Based on Glime *et al.* 1979.

Figure 18. *Fontinalis duriaei* in Europe. Photo by Jan-Peter Frahm, with permission.

Figure 19. *Hygroamblystegium fluviatile* fragment in culture, showing dense rhizoids that formed, possibly in response to the substrate. Photo by Janice Glime.

In these early experiments, the moss fragments were held against the rocks with netting (Glime *et al.* 1979). But the field application of this concept was then tested by tagging 750 stems of *Fontinalis duriaei* (Figure 18) growing in Big Valley Creek, a forested stream in the Keweenaw Peninsula, Michigan, USA (Glime *et al.* 1979). Within the two years following tagging, many mosses could not be found again. But the proof of dispersal lies in two tagged mosses that were found in a different location. One of these was relocated downstream 60 weeks after the tagging date. The second was found nearly 100 m upstream! Possible upstream dispersal agents were fishermen and the black bear (*Ursus americanus*; Figure 20) that chased my graduate student; there was no evidence of beaver activity. And this moss was found attached in its new location only 9 weeks after it was tagged. In both cases, the mosses were attached by rhizoids and were

wrapped around fallen tree branches where they most likely were held in place by the flow of water. Several other fragments were found in new locations, but these lacked rhizoid attachments.

Figure 20. *Ursus americanus* catching salmon in Alaska stream. Dark patches of mosses can be seen by its feet, suggesting an opportunity for dispersal. Photo by J. Brew, through Creative Commons.

In experiments with *Fontinalis*, I have observed that stems with broken tips will often produce protonemata or several apical branches (Figure 21-Figure 22).

Figure 21. *Fontinalis hypnoides* broken shoot apex producing protonemata. Photo by Janice Glime.

Figure 22. *Fontinalis antipyretica* apical wound with new growth and rhizoids. Photo by Janice Glime.

In the winter, aquatic mosses can get frozen in the ice (Figure 23). When the ice breaks up, chunks may carry a number of fragments downstream where some may become impinged on suitable substrata.

Figure 23. Fragments of *Fontinalis dalecarlica* frozen in ice that has broken up in a New Hampshire, USA, headwater stream. Photo by Janice Glime.

Sayre (1945) demonstrated that connections of waterways could account for the dispersal of *Fontinalis* in a series of moraine ponds. Using Polymerase Chain Reaction (PCR) and involved amplification of DNA sequence with several ISSR primers, Korpelainen *et al.* (2004; 2013) found little variation in several bryophytes between lakes and concluded that *Fontinalis antipyretica* (Figure 22), *F. hypnoides* (Figure 21), and *Calliergon megalophyllum* (Figure 24) were dispersed by water between the lakes. This can occur by streams connecting lakes or by flooding that connects them. They did not rule out waterfowl, but found that the direction of flow and genetic patterns indicated that stream flow was a major contributor to the dispersal.

Figure 24. *Calliergon megalophyllum*, a species that is likely to be dispersed by water. Photo by Julita Kluša <daba.dziedava.lv>, with online permission.

Arts (1982) used circumstantial evidence to show that *Fissidens fontanus* (Figure 25-Figure 26) is dispersed by water. All the canals where he found them in Belgium and the Netherlands were fed by water from Maas and this source apparently dispersed them through the Albert Kanaal and the Zuid-Willemsvaart.

Figure 26. *Fissidens fontanus* frond. Photo by Michael Lüth, with permission.

Fragments may be the most important means of dispersal in many aquatic bryophytes. For submersed species that produce submersed capsules, capsules are relatively rare and it is likely that most spores never lodge on a suitable substrate. As a result, some of these species are somewhat rare. *Dichelyma capillaceum* (Figure 27) is one such rare species in Europe (Hylander 1998). Only two populations are known with sporophytes. In Sweden it occurs along rivers, streams, and lakeshores – only in places that are inundated and then exposed annually. Hylander suggested that it was probably dispersed by fragments and more rarely through long-distance dispersal of spores.

Figure 27. *Dichelyma capillaceum* on a tree base in Europe where it gets flooded. Photo by Michael Lüth, with permission.

Antarctic researchers have used the RAPD technique to track populations and determine their genetic relatedness. For example, Dale *et al.* (1999) found *Hennediella heimii* (Figure 28) in Miers Valley, Antarctica, along melt streams within the valley, constituting a single large population, whereas it was distinct from populations in nearby valleys. RAPD indicates that *Chorisodontium aciphyllum* (Figure 9; as *Sarconeureum glaciale*) from three locations on Ross Island, Antarctica, appear to all be from one population and differ genetically from populations elsewhere (Skotnicki *et al.* 1999a). Dispersal was apparently in small, meltwater drainage streams. *Bryum argenteum* (Figure 29), likewise, has apparently been transported in the Antarctic by water (Skotnicki *et al.* 1999b).

Figure 28. *Hennediella heimii* with capsules, a moss that gets transported by melt streams in the Antarctic. Photo by David T. Holyoak, with permission.

Figure 29. *Bryum argenteum*, a worldwide taxon that seems to be transported by water in the Antarctic. Photo by Dick Haaksma, with permission.

It appears that some species may respond adaptively to being submersed. *Leptobryum pyriforme* (Figure 30) produces rhizoidal gemmae (tubers; Figure 31) when the protonema grows in water (Schofield 1981), suggesting a possible secondary dispersal by water movement, or a way of surviving until the water recedes.

Figure 30. *Leptobryum pyriforme* with capsules. Michael Lüth, with permission.

Figure 31. *Leptobryum pyriforme* rhizoidal tuber. Photo by Victoria Rozhina.

Water dispersal is a likely avenue for aquatic thallose liverworts. Patidar *et al.* (1986) studied effects of stream velocity on the floating liverwort *Riccia fluitans* (Figure 33-Figure 32). They found that a decrease in number of sporophytes was related to increase in water velocity, a likely consequence of reduced fertilization. Nevertheless, increased vegetative dispersal is likely in this species.

Splash Cups

Water dispersal is not confined to plants living in or near water. Some bryophytes take advantage of splashing raindrops for their dispersal, providing cups or platforms from which asexual propagules can be splashed. The best-known method of dispersal is that of the **gemma cup** or **splash cup**, commonly taught in introductory botany courses. Although the splash cup and splash platform are somewhat frequent as a means of dispersing sperm, they are relatively rare as mechanisms of propagule dispersal. Several bryophytes have specialized cups where the gemmae are produced and from which they are subsequently dispersed by raindrops (Figure 34, Figure 35). The splash cup mechanism seems to be engineered to maximize the distance its contents can splash, thus forming an effective dispersal mechanism with the help of raindrops. The significance of its size and shape was apparently not recognized until Buller (1942) described its function in the bird's nest fungus, *Cyathus*. Brodie (1951) followed up on the observations of Buller and noted that splash cups commonly form 60-70° angles with the horizontal surface, the cups have a broad basal attachment, and the dispersed objects are lenticular. Gemmae of *Marchantia polymorpha* (Figure 34) can travel up to 120 cm when splashed from these cups, and Equihua (1987) suggests that this mechanism partly accounts for the worldwide distribution of this species. This ability to splash with water drops has made the species one of disdain for greenhouse owners who constantly find it invading their pots, spreading farther and farther from the original source through successive generations.

Gemmae in the splash cups of the moss *Tetraphis pellucida* (Figure 35) and the liverworts *Lunularia cruciata* (Figure 36-Figure 37) and *Marchantia polymorpha* (Figure 34) are lenticular. It seems to be a common feature for the splashing to carry the contents about 60 cm in *L. cruciata* and *M. polymorpha* (Brodie 1951), but in *T. pellucida*, they seem only to go about 10 cm (Kimmerer 1991). Brodie (1951) considered *T.*

pellucida too frail to benefit from raindrops striking its apex, finding that the plants bent under the weight.

Figure 34. Lens-shaped gemmae of *Marchantia polymorpha*. Photo by Michael Lüth, with permission.

Figure 35. Gemma cups of the moss *Tetraphis pellucida*. Photo by Michael Lüth, with permission.

Figure 36. Gemmae in half-moon-shaped pouches of *Lunularia cruciata*. Photo by David T. Holyoak, with permission.

Figure 37. Pouch of *Lunularia cruciata* showing lenticular gemmae. Photo by Martin Hutten, with permission.

Stieha *et al.* (in prep.) quantified the production and dispersal of gemmae in the clonal thallose liverwort *Marchantia inflexa* (Figure 38). They found that these asexual propagules could move great distances during even a light rain, with some most likely leaving the parent clonal population. Further dispersal can occur in a stair-step fashion over time, providing long-distance dispersal. In this species, survival of female gemmae is greater than that of male gemmae.

Animal Dispersal

The dispersal of vegetative parts by animals may be an important mode of travel, at least occasionally. Various insects use fragments of mosses and lichens to build "houses" that they carry on their backs.

Even mammals may eat (perhaps not intentionally) bryophytes, as indicated by ^{14}C studies on animal remains of late Pleistocene large herbivorous mammals (Ukrainitseva 1979). But we have no evidence that these bryophyte fragments remain viable after passing through the mammalian digestive tract.

Earthworms

Dispersal in the guts of earthworms (During *et al.* 1987; van Tooren & During 1988) can surely at times beat the 10 cm record for splashing in *Tetraphis pellucida*

(Figure 35) reported by Kimmerer (1991); these and other invertebrates that eat bryophytes will deposit fragments in new locations. These could be distances of centimeters to hundreds of meters. Not only earthworms, but moles, voles, and ants have underground activities that can bring diaspores from their dormant state below ground to a position of activity above ground. Van Tooren and During (1988) found that eight species of bryophytes from the Netherlands appeared frequently in castings (Figure 39) from the earthworms *Allolobophora caliginosa*, *A. chlorotica* (Figure 40), and *Lumbricus terrestris* (Figure 41).

Figure 39. Earthworm castings on moss. Photo by Ken Gergle at Moss and Stone Gardens, with permission.

Figure 40. *Allolobophora chlorotica*, an earthworm that can transport bryophytes in its feces. Photo by Jacopo Werther, through Wikimedia Commons.

Figure 41. *Lumbricus terrestris* on mosses, a species known to ingest mosses and re-deposit them, still viable, in their feces. Photo by Michael Linnenbach, through GNU Free Documentation.

Since the light travels at most only a few centimeters into the soil, these diaspores remain dormant until some disturbance brings them to the surface and light. The species that survived the enzymes, crushing, and scarification of the earthworm guts, then grew to be identified, were *Bryum klinggraeffii* (Figure 42), *Dicranella schreberiana* (Figure 43), *Ephemerum recurvifolium* (Figure 44), *Pottia* spp., *Pottia lanceolata* (Figure 45), and *Weissia* spp. (Figure 46) (van Tooren & During 1988). *Bryum rubens* (Figure 47), common in the castings, never produces capsules in the area and presumably survived as rhizoidal tubers. Most of the other taxa probably also survived as vegetative diaspores except for *Pottia* sp. and *Weissia* sp., which probably originated from spores. Among these, tubers of *Bryum klinggraeffii* (Figure 42), *Bryum rubens* (Figure 47), and *Dicranella schreberiana* (Figure 43) successfully germinated, but in general, there was high mortality among tubers and other vegetative structures. Van Tooren and During suggested that spore survival was higher than vegetative diaspore survival in earthworm guts, but they did not have quantitative measures of this.

Arthropods

Isopods

I suspect that isopods (pillbugs, sowbugs, wood lice, roly pollies) play a greater role in bryophyte dynamics than we understand. They make good experimental animals, and in our experiments, we have learned that both aquatic and terrestrial isopods readily eat some bryophytes (Figure 48-Figure 52), but avoid others, depositing their feces elsewhere. Some fragments can break off during the feeding and others are likely to be broken by their movements. We have not, however, observed any fragments being carried on their bodies and viability of mosses in their feces needs to be tested.

Figure 52. Evidence that *Porcellio scaber* prefers leaves to stems in feeding experiments on *Rhytidiadelphus triquetrus*. Photo by John Hribljan, with permission.

Mites (Acari)

Edwards (1978) found protonemal gemmae of *Schistostega pennata* (Figure 53) attached to the legs of mites. The gemmae, like the spores of this species, are very sticky (Ignatov & Ignatova 2001). While mites themselves most likely do not travel far, they can become passengers on other animals – birds and mammals – that might travel considerable distances. Risse (1986, 1987) suggested that this might also be a possible vector for rhizoid tubers, presumably because the mites move about amid the spaces in the soil.

Figure 53. Protonemal gemma (arrow) of *Schistostega pennata*. Photo by Misha Ignatov, with permission.

Zhang *et al.* (2002) observed spider mites (*Halotydeus* sp.; Figure 54) eating the gemmae of *Octoblepharum albidum* (Figure 54) in Hong Kong. It is possible that some of these gemmae will get trapped among the hairs on the legs, thus getting transported by the mite. Others might be knocked off, falling to a new substrate.

Figure 54. *Halotydeus* sp. feeding on gemmae of *Octoblepharum albidum* in Hong Kong. Arrow indicates bases remaining where gemmae have been chewed. Photo by Li Zhang from Zhang *et al.* 2002, with permission.

Harvestmen

Some arthropods have an unusual mode of transporting bryophytes – they grow them on their bodies. These include liverworts on Neotropical harvestmen (Machado & Vital 2001).

Insects

Insects are often responsible for releasing small fragments of bryophytes (Lepp 2008). Larger insects can break dry bryophytes due to the insect weight, and a number of insects actually eat the bryophytes. Some live among the cushions where they often find food and thus move around, potentially transporting the fragments from a cushion to an open space.

Slocum and Lawrey (1976) report that the green lacewing larva (*Nodita pavidata*) carries about a "packet" of camouflage constructed of bits of lichen, lichen soredia, pieces of bark, pollen grains, fungal spores, moss gametophyte fragments, and other debris. They demonstrated that the lichen fragments were viable but did not test the mosses. It is likely that they not only were alive, but that some of these fragments also would land somewhere and grow. Larvae of Diptera (flies, especially craneflies) and Trichoptera (caddisflies) construct houses of various shapes and may incorporate bryophyte fragments in them, as will be discussed later in the chapter on aquatic insects.

Aquatic organisms can be dispersed by aquatic insects that carry adhering cells on their bodies (Stewart & Schlichting 1965, 1966; Stewart *et al.* 1970), but their role in bryophyte dispersal is mostly unknown. For example, some caddisfly larvae may construct their homes from mosses, leafy liverworts, or narrow thallose liverworts like *Riccia fluitans* (Figure 33; Glime 1978). When these homes (cases) are discarded, the bryophytes can potentially grow in this new location.

Cairns and Wells (2008) reported that the microcaddisfly *Scelotrichia willcairnsi* (Figure 55) in Australia fed on the moss *Platyhypnidium muelleri* (Figure 56), an activity that could permit transport of fragments that survive travel through the gut. But in addition, and more likely to survive, are fragments that they weave into their case. The case travels with the caddisfly, which may travel considerable distance if it breaks loose from its substrate and becomes part of the drift.

Weevil Gardens – A few insects disperse mosses in an unusual way. Certain weevils (Curculionidae) have pits on them where mosses are able to grow. This is the case for the moss *Daltonia angustifolia* (Figure 57) that attaches in pits on the hardened exoskeletons of weevils, including the weevil *Gymnopholus reticulatus* (Figure 57; Gradstein *et al.* 1984).

Gressitt and coworkers (1965, 1968) reported gardens on the backs of several species of weevils, including *Gymnopholus* spp. (Figure 57) among others. These weevils live in areas with moss cover on forest ridges and summits in eastern New Guinea (Gressitt *et al.* 1965, 1968). *Gymnopholus* species with epizotic bryophytes live more than three years and have hairs or specialized scales not present on species without plants growing on them (Gressitt & Sedlack 1970). In experiments where weevils were kept in cages, older weevils lost their plants, demonstrating the usefulness of these species as dispersal vectors. They are usually sedentary, but they can travel up to 0.25 km in half an hour by walking.

Figure 57. The moss *Daltonia angustifolia* living epizootically on the weevil *Gymnopholus reticulatus*. Photo courtesy of Rob Gradstein.

Ants – Rudolphi (2007) found that ants on stumps served as dispersal vectors, passively carrying the bryophyte dispersal units for a significant time. Rudolphi (2009) used experiments to demonstrate that the ant *Lasius platythorax* (Figure 58) may disperse the gemmae of *Aulacomnium androgynum* (Figure 59). Both the ants and the *A. androgynum* occur on dead wood in Sweden. When the ants were permitted to run over a moss tuft, gemmae adhered to 33% of the ants within only two minutes! Half the gemmae remained attached for about four hours. This is most likely passive dispersal, with no special adaptations by either organism. Since these are active organisms that can travel considerable distances quickly, this could be an important dispersal mechanism.

Figure 59. *Aulacomnium androgynum* gemmae, known to sometimes have dispersal by ants. Photo by Des Callaghan, with permission.

One interesting way that ants (*Formica rufa* group; Figure 60) contribute to dispersal is in their nest building. Heinken *et al.* (2007) sampled nesting material from 25 ant nest mounds in Germany. They found fragments of 20 bryophyte and 10 lichen species in these mounds. Among the bryophytes, wefts were particularly well represented, whereas tall turfs were poorly represented relative to their abundance. The researchers suggested that fragments lost along the way provided a means of dispersal. Other successful dispersal may occur among fragments in the

mound when the mound decays. Healthy mounds with live ants do not provide a safe site for the bryophytes. The ants are active in maintaining the mound and keep burying the fragments. Any that do manage to remain at the surface are subject to greater drying than those on the surrounding soil. In addition to these problems, disturbance by the ants, birds, and even boars further dislodges them, interrupting growth and detaching the fragments.

Figure 60. *Formica rufa*, an ant that disperses bryophytes through its nest building. Photo by Richard Bartz, through Creative Commons.

The most common species on these ant mounds were *Hypnum cupressiforme* s.l. (Figure 145) in 16 of the 25 samples (Heinken *et al.* 2007). These accounted for 67.5% of the fragments. In addition, *Brachythecium* spp. (Figure 144) and *Pleurozium schreberi* (Figure 61) were often abundant. Species differed by forest type. Five of the 20 bryophyte species rarely produce any spores or vegetative structures, making fragments important in their dispersal. The territory size for this species ranges 200-1500 m² and the travelling ranges extend 20-30 (65) m from the nest, making a reasonable dispersal distance.

Figure 61. *Pleurozium schreberi*, a moss known from ant mounds. Photo by Janice Glime.

Modern genetic techniques permit us to learn even more about insect roles. Korpelainen *et al.* (2011) studied *Barbilophozia attenuata* (Figure 62) in an area traversed by ant trails, using spatial genetic structure to unravel the history of the liverwort dispersal. They found significant kinship of colonies along the trails up to 8 m. At distances greater than 25 m, kinship correlation was nearly zero. Gemmae were most important up to 8 m, but spores were important for distances of 25 m or greater. Plants on logs

and other raised surfaces can achieve even greater distances by spores. They considered that the large gemmae permitted greater opportunity for establishment than the small sexual spores and gemmae account for the aggregated distribution of the species in the study area. They also concluded that gemmae are favored over spores in areas with frequent disturbance, such as ant trails. Nevertheless, at greater distances, spores become important.

Figure 62. *Barbilophozia attenuata* with apical gemmae. Photo by Michael Lüth, with permission.

Lepidoptera – Larvae of *Aenetus virescens* (Figure 63) feed on the leaves and rhizoids of both live and dead mosses and liverworts, among other things (Grehan 1984). These bryophytes have the potential of being dispersed in feces, but tests must be made to see if they survive the gut. It is also possible that fragments adhere to these larvae, thus being dispersed.

Figure 63. *Aenetus virescens* adult, looking perfectly suited to living among bryophytes, where it might complete its emergence, but it lives only 48 hours as an adult. Its larvae feed on bryophytes, among other things. Photo by Tony Wills, through Wikimedia Commons.

Molluscs

Mollusks such as slugs eat bryophytes, but their sticky surfaces also cause fragments to adhere, effecting their dispersal. The moss *Orthodicranum flagellare* (Figure 2) lives on logs and stumps where snails can readily gain

access and contribute to dispersal of the flagelliform branches that serve as propagules (Stolzenburg 1995). Kimmerer and Young (1995) found that this species depends on its asexual brood branches to colonize new logs, with slugs as their primary dispersal vector. In fact, the propagules adhere to the slime trails, with evidence that the slugs (*Philomycus* sp.; Figure 64) can transport them at least 23 cm. However, the distance is more commonly only about 3.7 cm. The slime helped the propagules adhere to the substrate without interfering with success of germination.

Figure 64. *Philomycus carolinianus* on a log, crawling over worms. Photo by Rebekah D. Wallace, through Creative Commons.

Aquatic molluscs also facilitate the dispersal of bryophytes. Both *Fissidens fontanus* (Figure 26) and *Leptodictyum riparium* (Figure 65) are known from the shells of mussels, a moving substrate that is likely to drop off fragments as it moves (Neumann & Vidrine 1978). Species of *Fissidens* are especially vulnerable to grazing by snails and slugs (Figure 66), so it is likely that fragments also get dispersed in the feces of the bodies of these molluscs.

Figure 65. *Leptodictyum riparium*, a moss that is known to grow on mussel shells. Photo by Michael Lüth, with permission.

Amphibians

Like slugs, most amphibians have moist, sticky skin (Evans & Brodie 1994). Therefore, it is likely that bryophyte fragments and propagules get broken off as they traverse the bryophytes and that many of these same fragments and propagules get transported to new locations. My own pet frog was usually covered by empty seed coats dropped by the finches that shared the room. Evans and

Brodie found moss fragments were among the debris they washed from amphibians at the beginning of their sampling. In their experiments, Evans and Brodie found that *Dyscophus antongilii* and *D. guineti* had the strongest glue among the eleven amphibians tested. D. Bruce Means has captured this adherence to *Ceuthomantis smaragdinus* in the image below (Figure 67).

Figure 66. *Fissidens* sp. being traversed by a slug. Photo by Janice Glime.

Figure 68 through Figure 73 demonstrate some of the variety of anurans that are able to carry bryophyte fragments. These six images were selected from my collection of 494 anuran images based on discernible adhering debris, giving a very crude estimate of the frequency of such passage. Figure 74-Figure 75 demonstrate that salamanders are also able to carry bryophytes that adhere to the sticky surface.

Turtles

I have experienced this dispersal first-hand by inference. When I (Glime, unpubl) grew *Conocephalum conicum* (Figure 76) and *Fissidens* (Figure 77) in my garden room in the company of a box turtle (*Terrapene*; Figure 78), both bryophytes spread quickly around the room, something they never did in the absence of the turtle. But eventually the zebra finches discovered the liverwort and each day it grew smaller, with triangles cut from its edges. Alas, the birds seemed to be agents of destruction and not dispersal because *C. conicum* soon disappeared completely. The *Fissidens* likewise stopped spreading and within some months it too disappeared.

Figure 78. *Terrapene carolina*, a potential bryophyte dispersal vector. Photo through Wikimedia Commons.

McGregor (1961) has a more documented story. He found living thalli of *Riccia rhenana* (Figure 79) on the carapace of a snapping turtle (*Chelydra serpentina*; Figure 80) that had ventured nearly 1 km from the nearest pond. This liverwort species grows among cattails, sedges, rushes and grasses of shallow water where it multiplies by growth and division of thalli, mostly in April. The thallus dries up to its growing apex in summer, and McGregor observed it in that dry state for up to 33 days, when it was rehydrated by rains and resumed growth. Its ponds often freeze solid, freezing the thalli in ice. Once again, the thalli die except the growing apex. McGregor reports that these thalli can survive more than five weeks in the ice.

Birds

Aquatic organisms living in isolated wetlands could have real difficulty being dispersed. But Figuerola and Green (2002) found that widespread distributions of aquatic organisms typically coincide with pathways of migratory waterbirds. They considered that small propagule size would favor dispersal, but we have seen that birds are important dispersers of bryophyte fragments (Lewis *et al.* 2014). Behling *et al.* (2002) have further demonstrated dispersal through **endozoochory** – ingestion of fragments by birds. Birds travel long distances, and rather quickly. Their frequent stops for food makes them ideal dispersal agents because in most cases any adhering bryophyte parts won't be in the atmosphere for very long. (See further details of long migration flights in Chapter 4-8.)

The introduction of the aquatic liverwort *Ricciocarpus natans* (Figure 81) into Norway may be the result of transport by waterfowl or some other form of epizooic transport (Skulberg 1978). This has been shown for a number of algae that travel on the feathers and feet of ducks, arriving in viable condition (Schlichting 1958). Both mechanisms seem reasonable for bryophyte spores and leaf fragments, or even small branches.

Figure 81. Thalli of *Ricciocarpus natans* floating with the duckweeds *Lemna minor*, *Wolffia* sp., and *Spirodela polyrrhiza*. Since duckweeds are common foods for waterfowl, it is likely that *Ricciocarpus* gets mixed in with the food and stuck to feathers or feet as the birds wade and eat. It may also be eaten, if only inadvertently, and could possibly be dispersed in feces. Photo by Janice Glime.

The **Kelp Gull** (*Larus dominicanus*; Figure 82) in the Argentine Island region of the Antarctic uses bryophytes and other plant material for building its nest (Parnikoza *et al.* 2012). Some of these bryophytes are able to establish in their new locations. If the gull can survive a long flight, most likely the bryophyte can as well.

McGregor (1961) actually found evidence that ducks indeed disperse living bryophytes. A fragment of *Riccia fluitans* (Figure 33) was attached to a feather at the back of the neck of a pintail duck (*Anas acuta*; Figure 83) that was soon to become a hunter's dinner. The duck was intercepted just before it descended to land on the Kansas River.

In Hungary, geese (Figure 84) are known to carry such fugitives as *Riccia frostii* (Figure 85) on their feathers, feet, or muddy bills, making these liverworts common – you

guessed it – along goose trails (Crum 1973). But might they also be transported in the feces? Bryophytes such as *Riccia fluitans* (Figure 33-Figure 32) exist among duckweeds (Lemnaceae) and thus will almost certainly be eaten along with them. With 0.7 kg of defecation (French & Parkhurst 2009) occurring every 20 minutes (Bowen & Valiela 2004), there is considerable opportunity for transport, albeit not very far if it has only 20 minutes of residence time. Jasmin *et al.* (2009) found that bryophytes increased in areas of goose foraging in the Arctic, but this may have been due to an increase in available habitat.

Crows seem to be favorites as the villains in moss destruction. Misha Ignatov (Bryonet 23 February 2013) reports seeing the rare (in Moscow) moss *Dicranum viride* (Figure 86) scattered over the ground rather than in place on the tree trunks. As he wondered who the destructive villain was, he heard crows overhead, then noticed a number of crow nests. He concluded that the crows were the likely vandals. He hoped that they might be forgiven if in the process the crows succeeded in dispersing the mosses to new locations where they could establish.

Figure 86. *Dicranum viride* on tree trunk in Michigan, USA. Photo by Janice Glime.

Erkamo (1976) reported observations of mosses being upturned, especially on flat, open rocks. These were mostly only a few cm in size, but some were 10-15 cm across. He considered the agents of this upheaval to be possible by voles, pheasants, seagulls, or crows, but considers crows (Figure 87) to be the most likely. He has actually seen crows in such activity, and considered that they were probably looking for food such as insects or worms under the moss cover. Erkamo lamented the destruction of beautiful rock scenery that will most likely take years to recover.

Figure 87. *Corvus brachyrhynchos*, a crow that scatters mosses to find food. Photo by Walter Siegmund, through GNU Free Documentation.

Blackbirds (*Turdus merula*; Figure 88) have found another use for bryophytes that is likely to disperse them. Robin Stevenson (Bryonet 15 April 2010) reported observing **displacement activity** in this species. He observed a male throwing clumps of moss off a rooftop, alternating the activity with altercations with another blackbird. This displacement behavior was most likely part of a fight over territory and the mosses permitted them to take a break that prevented them from killing each other. The battered mosses included *Grimmia pulvinata* (Figure 89), *Hypnum cupressiforme* (Figure 90), and *Syntrichia montana* (Figure 91).

Terrestrial bryophytes may get transported, at least for short distances, by bird behavior. For example, blackbirds (*Turdus merula*; Figure 88) forage among mosses to find insects or worms, tossing them aside to gain access (Davison 1976). It is likely that such food items and earthworms are closer to the surface under mosses where the moisture is greater. Davison reports that *Mnium hornum* (Figure 92) and *Polytrichastrum formosum* (Figure 93) may be tossed 1-2 m in these activities. In an area of 5 sq m, Davison found that 34 clumps with an average diameter of 2 sq cm were displaced in this way over a two-month period in Great Britain. Furthermore, an additional 18 clumps were moved into that same 5 sq m during the same time period (October-November).

Figure 92. *Mnium hornum*, a moss that can be a victim of crow scavenging. Photo by Janice Glime.

Figure 93. *Polytrichastrum formosum*, a moss often disturbed by crows seeking food. Photo by Michael Lüth, with permission.

Gathering bryophytes for nests is a likely means of dispersal for nearly every kind of nest in which bryophytes are used, *e.g.*, the Picaflor Rubi (*Sephanoides sephaniodes*; Figure 94-Figure 95) and White-sided Hillstar (*Oreotrochilus leucopleurus*) construct their nests primarily of mosses, especially those with falcate leaves (Calvelo *et al.* 2006). Fragments are likely to be dropped on the way, and many more are broken off or dropped or discarded during the construction of the nest and subsequent usage. For some, the lofty position of a nest in a tree provides the advantage of more opportunity to gain access to air movements that can carry the fragments even further.

When Surtsey was colonized after its ascension from the sea, the moss *Racomitrium* (Figure 96) was among the first invaders (Magnússon *et al.* 2009). The Lesser Black-backed Gull (*Larus fuscus*; Figure 97) invaded the island, forming a dense colony. Its primary nesting material was *Racomitrium*, but it is unclear if it was brought to the island by the birds or it arrived by fragments or spores and spread.

Figure 97. *Larus fuscus* (Lesser Black-backed Gull) adult and juvenile, probably dispersal agents for *Racomitrium* sp. to Surtsey. Photo by Pline, through Wikimedia Commons.

Even when bryophytes are not transported to make nests, the nearness of a nest to bryophytes increases the chances that the bryophytes will become dislodged, and some may adhere to the birds. For example, the Peg-billed Finch (*Acanthidops bairdi*) is a rare bird in Costa Rica and Panama (Elizondo C. 2000). It has rarely been observed, but Mathias Jaschhof was able to photograph four fledglings in the nest (Figure 98). The nest was built in myrtle (*Vaccinium consanguineum*) and consisted of a bulky cup developed from *Frullania* sp. (Figure 99) with amendments of *Leptodontium* sp. (Figure 100), *Pilotrichella*, and *Plagiochila* sp. (Figure 102) as well as fruticose lichens and a mix of unidentified leafy liverworts and mosses (Elizondo C. 2000). The egg chamber had a layer of fern rhizomes, a thin layer of grass inflorescences, and finally an external layer of *Thuidium* sp. (Figure 107).

This latter layer may extend to the outside of the nest and may be surrounded by *Frullania*.

Mammals

The role of mammals in dispersal of propagules seems to have gotten less attention than it deserves. Only recently are we seeing documentation that mammals can serve as dispersal vectors through feces, fur, and hooves, and in some habitats these may play a major role. Among these dispersal units are fragments that cling easily to the fur and feathers of some animals. Dispersal of fragments is most likely more important than we have considered (Heinken *et al.* 2001).

Rodents

I have blamed the chipmunks in my moss garden for tearing up my recent moss plantings. They seem to like frolicking across the bryophytes, and more than occasionally the bryophytes end up upside down as the chipmunks (Figure 103-Figure 104) kick them up or drag them with their feet. They seem to especially like *Leucobryum glaucum* (Figure 105-Figure 106) and *Thuidium delicatulum* (Figure 107). At least those are the most likely to get torn up in my garden, and one chipmunk insisted on making an entrance to a burrow in the middle of the *T. delicatulum*, destroying the integrity of the mat, hence causing its death. *Leucobryum* species have the ability to develop rhizoids on the upturned surface that contacts the soil (Figure 106) and may recover as a moss ball. Mine did not. Gray squirrels (Figure 108), and certainly others, have the same potential to serve as dispersal agents.

Figure 103. *Tamias sciurus* (eastern chipmunk) is responsible for kicking up loose mosses and most likely transports fragments. Photo by Oleksii Voronin, through Wikimedia Commons.

In the Arctic, rodents, including moles and lemmings, eat the bryophytes (Ericson 1977), so dispersal of spores and fragments in their whiskers and fur is likely. Hribljan (unpubl) has cultured feces of rodents, collected from Alaska, that had protonemata germinate from them (Figure 109). It is likely that these came from fragments that were present in the feces, but could also have been from spores. Kimmerer and Young (1996) suggested that rodent activity may help *Orthodicranum flagellare* (Figure 2) disperse in two ways, by helping to produce gaps among the bryophytes on the logs and possibly by carrying the flagelliform propagules among the locations visited. In this regard, squirrels and chipmunks are likely agents. Could it be that they also inadvertently eat bryophytes as they forage and thus carry them in their guts? At the very least, they probably dislodge epiphytes, aiding their dispersal.

Figure 109. Protonemata and young gametophores germinated from microtine rodent scat collected in Alaska. Photo by John Hribljan, with permission.

Ericson (1977) showed that many of the most abundant forest mosses in northern Sweden are a preferred food for *Myopus schisticolor* (wood lemming; Figure 110). *Ptilidium ciliare* (Figure 111) and *Plagiothecium denticulatum* (Figure 112) are rejected, as are most herbaceous species. When the snow is gone, they feed on green tips of mosses, whereas when they are living under snow the lemmings bite the shoots off at the base. In 1974 and especially in 1975, following heavy grazing in 1973, *Dicranum scoparium* (Figure 113) spread to areas where no *D. scoparium* occurred in 1973. These rodents appear to have been the agents of both fragmentation and dispersal.

Figure 110. *Myopus schisticolor* (wood lemming) by its path amid *Hylocomium splendens*. Photo by Risto S. Pynnönen, through Wikimedia Commons

Figure 113. *Dicranum scoparium*, a moss most likely distributed by rodents in northern Sweden. Photo by Janice Glime.

Eskelinen (2002, 2004) likewise demonstrated that mosses are preferred food of the wood lemming in northern Finland, and that they also are selective. They consume *Dicranum* spp. (Figure 113) and *Polytrichum* (Figure 114-115) in greater quantities than would be expected, but avoid *Hylocomium splendens* (Figure 110) and *Pleurozium schreberi* (Figure 61). Nevertheless, Ericson (1977) found that *H. splendens* diminished, presumably due to rodent consumption. Eskelinen (2002, 2004) suggested the preference for *Polytrichum* and *Dicranum* may relate to their higher N content. If so, preferences may change with habitat and available food choices.

Figure 114. *Polytrichum commune* var. *commune*, demonstrating the clone that can result from its branching rhizomes. Photo by David Holyoak, with permission.

Figure 115. *Polytrichum juniperinum*, a moss that spreads by rhizomes. Photo by Janice Glime.

Ericson (1977) followed the changes in moss cover in Scandinavia for four years and discovered that rodents played a major role in the changes. Only the mosses on windthrows and tree stumps maintained constant cover. The fascinating realization was that different species of bryophytes seemed to suffer declines and increases in different years. In 1974, *Ptilium crista-castrensis* (Figure 116) suffered 73% reduction and *Dicranum scoparium* (Figure 113) suffered 57%. However, in 1975, the strongest decrease was in *Hylocomium splendens* (Figure 110), which suffered 49% reduction, while *P. crista-castrensis* increased 43% and *D. scoparium* increased 70%! Ericson felt that this might indicate increased growth as a response to fragmentation caused by grazing. However, to increase cover values so significantly, it would seem that at least some dispersal must have been effected.

Figure 116. *Ptilium crista-castrensis*, a preferred moss for rodent consumption. Photo by Janice Glime.

Ericson (1977) felt that several types of regeneration were common for these species. *Polytrichum commune* (Figure 114) and *P. juniperinum* (Figure 115), as well as others, can recolonize from protonemata, juvenile plants, and rhizoid fragments (Meusel 1935, Wigglesworth 1947). *Hylocomium splendens* (Figure 110; Correns 1899) and species of *Dicranum* (Figure 113; Meusel 1935) grow easily from broken parts of stems, and *Polytrichum commune* and species of *Dicranum* regenerate from isolated leaves (Correns 1899). Callaghan *et al.* (1978) pointed to the need for *Polytrichum commune* to reproduce by underground branching into clones because of its finite life expectancy. *Hylocomium splendens* solves the problem of life expectancy by producing new shoots in a stair-step fashion, with the oldest part of the plant senescing and decomposing (Callaghan *et al.* 1978), a feature seen also in *Pseudocalliergon trifarium* (Figure 117; Bisang *et al.* 2008). However, if the young branch shoot of *Hylocomium splendens* is damaged, the entire plant will die (Callaghan *et al.* 1978). On the other hand, it seems to have a low branching rate for the main stem, limiting its clonal growth.

Bank voles (*Clethrionomys glareolus*) include small quantities of mosses in their diets (Watts 1968). Bank voles were caught in the act of eating mosses in The Netherlands. Andrew Spink was able to capture these on film (Figure 118).

Flying Fox

The spectacled flying fox (*Pteropus conspicillatus*; Figure 119), a fruit bat, passes bryophyte fragments in its feces (Figure 120-Figure 121), including chloronemata, rhizoids, and shoots (Parsons *et al.* 2007). These are capable of germinating (Figure 122) and may even benefit from nutrients in the adhering feces. Fifteen families of bryophytes were represented in these feces. Among the 48 fragments cultured, 52% germinated, producing rhizoids or shoot extensions. Even rotifers among the bryophytes were still alive. Included among the species were *Metzgeria* sp. (Figure 123), *Acroporium* sp. (Figure 124), *Leucobryum juniperoideum* (Figure 125, and *Racopilum* sp. (Figure 126). The germination rate was higher from samples taken during the early part of the season (17 out of 28 fragments) compared to those taken in the later part of the season (7 out of 20). This could represent a shift in diet, change in brittleness of bryophytes (resulting from desiccation) that changes ease of fragmentation, or a change in viability of the bryophytes. It is likely that the bryophytes were eaten unintentionally along with fruit.

Lessons from a Dog

Heinken (2000) conducted an interesting and most instructive study on dispersal of fragments by using a dog. Dogs act as good surrogates to demonstrate the ability of diaspores to adhere to fur, but their habit of wallowing on the ground is unusual among many wild mammals, making some predictions limited. In one year, Heinken walked his dog 49 times in the forest near his home in Germany. He found no seasonal differences in fragment attachments of bryophytes compared to the seasonal pattern observed for seed plant diaspores.

The forest used in the dog study had 20 species of bryophytes occupying 1% of the cover (Heinken 2000). The dog presented 29 bryophyte stem fragments from at least 10 bryophyte species. All the stem fragments had leaves and most had terminal buds. Only 13 of the fragments had branches and these were often numerous. The most frequent species were *Eurhynchium hians* (Figure 127) and *Ceratodon purpureus* (Figure 128). Other taxa included *Barbula* sp., *Amblystegium varium* (Figure 129), *Hypnum cupressiforme* (Figure 145),

Eurhynchium praelongum (Figure 130), *Plagiomnium* sp., *Rhynchostegium* cf. *megapolitanum* (Figure 131), *R. murale* (Figure 132), and *Rhytidiadelphus squarrosus* (Figure 133). On the other hand, two species [*Atrichum undulatum* (Figure 134), *Mnium hornum* (Figure 92)] that were frequent in the study area were not represented at any time on the dog's fur.

Sources of the adhering bryophytes were primarily tree trunks, walls, paved places in the city, a grassland plot, and the lawn of the owner (Heinken 2000). The dog would frequently wallow on the ground, then shake and groom himself to remove annoying diaspores, especially seeds. The bryophytes that adhered were primarily wefts or short turfs with acute and often erect or squarrose leaves. Tall turf species with rounded leaves were very under-represented. Mats were likewise rare. Loose wefts, on the other hand, seemed to hitch a ride rather easily. Heinken concluded by saying that for a moss to be transportable it must fragment and that this most probably occurs when the moss is dry, perhaps explaining the seasonal difference found for flying fox feces.

Hoofed Mammals

Larger animals contribute to dispersal in somewhat different ways. Their fur, hair, spaces between toes, feathers, and other parts can trap bryophyte parts and easily transport them for the distance travelled by the animal. Among these are large, hoofed mammals. Cattle and other farm animals are able to transport terrestrial taxa wedged in their hooves, causing certain bryophyte species to frequent cattle trails and ruts made by machinery (Crum 1973). The fur and hairs of hoofed mammals can provide a protective location for diaspores to hitch a ride and may take these diaspores for long distances (de Pablos & Peco 2007). Erika Péntez-Kónya demonstrated the ability of overturned *Leucobryum juniperoideum* to form rhizoids on the overturned clump (Figure 125, Figure 135) after cattle traffic.

Figure 135. *Leucobryum juniperoideum* cushion with leaf rhizoids after overturn by cattle. Photo by Erika Péntez-Kónya, with permission.

When Poschlod (pers. comm. 6 March 2013) applied diaspore traps in grasslands, he found many fewer vegetative parts than in peatlands. Rather, he found grazing animals, especially sheep, serving as long-distance dispersers of vegetative parts, especially from those moss species which do not form capsules (at least not in central Europe where he is familiar with the flora) such as *Abietinella abietina* (Figure 136). And this species is astonishingly widespread in all the dry calcareous (and man-made) grasslands there.

Figure 136. *Abietinella abietina* in Europe, a moss that is easily broken when dry, as it is here. Photo by Michael Lüth, with permission.

Several researchers have examined sheep and cattle coats (Figure 137) for propagules, primarily seeds, and found that greater seed weight was likely to prevent attachment on vertical surfaces but not on horizontal ones (de Pablos & Peco 2007). The same relationship is not likely to be a problem for the light-weight bryophyte diaspores. Sheep wool held more diaspores than the smoother coats of cattle. Both animals rest by lying down (Figure 138-Figure 139), providing ample opportunity for bryophyte adherence in rocky, mountainous pastures. In addition to clinging to the coats of hoofed mammals, the bryophytes can lodge on the hooves, particularly in the company of mud.

Figure 137. Sheep with full coat of wool before shearing in North Wales. At this stage, bryophyte fragments can easily adhere to the wool. Photo by Janice Glime.

Figure 138. Sheep resting under a tree near Swallow Falls, Wales. In areas where bryophytes are prevalent, this behavior contributes to attaching bryophyte fragments to the wool, facilitating dispersal. Photo courtesy of Kim Barton.

Sheep seem to be particularly good dispersal vectors, particularly those with a dense, curly fleece (Figure 137) (Pauliuk *et al.* 2011). The curly fleece is able to carry more fragments and larger species of bryophytes than those with smooth, fine hair (Figure 139-Figure 140). Twelve sheep representing two breeds were examined and revealed fragments from 16 species of mosses, representing 40% of the species present in the pasture. It is interesting that these were particularly common on the belly and tail! Some species disperse better than others, with pleurocarpous species, small species, and mats being over-represented compared to the pasture vegetation. On the other hand, large species, acrocarpous taxa, wefts, and turfs were under-represented among those cultured. The hooves transported mostly acrocarpous colonists. Short fragments were more likely to occur on the hooves; longer fragments were more common on the wool (Figure 141).

Figure 141. Size distribution of visible bryophyte fragments in fleeces and hooves from 12 sheep grazing on a dry grassland pasture. $n = 2206$. Modified from Pauliuk *et al.* 2011.

Heinken *et al.* (2001) further elucidated hoofed mammal dispersal by examining 25 shot roe deer (*Capreolus capreolus*; Figure 142) and 9 wild boar (*Sus scrofa*; Figure 143) in deciduous forests in Germany. They located a total of 106 bryophyte fragments (102 stem fragments, 4 leaves), representing 12 species, on the animals in their coats and hooves. This was proportionally somewhat less than the representation of tracheophytes based on percent cover (bryophyte:tracheophyte diaspores 1:30; bryophyte:tracheophyte cover 1:22.5).

Mean fragment length on the animals was 3.6 mm, but ranged 0.5-35 mm (Heinken *et al.* 2001). The fragments came mostly from the **terricolous** (on the soil) species, especially *Brachythecium velutinum* (Figure 144), *Hypnum cupressiforme* (Figure 145), *Eurhynchium hians* (Figure 127), and *Ceratodon purpureus* (Figure 128). Robust acrocarpous species in tall turfs were predominantly excluded, whereas the slender pleurocarpous species with erect, acute leaves, growing in wefts, were common. As in the dog study, some species that were frequent in the study area failed to adhere: *Atrichum undulatum* (Figure 134), *Plagiomnium affine* (Figure 146), *Pohlia nutans* (Figure

147), *Polytrichastrum formosum* (Figure 93). Others [*Brachythecium rutabulum* (Figure 148), *Mnium hornum* (Figure 92), and *Plagiomnium* sp.] only had a few fragments attached. The liverworts in the study area were completely absent on the animals, despite the scattered occurrence of *Chiloscyphus profundus* (= *Lophocolea heterophylla*; Figure 149) throughout the study area.

Figure 147. *Pohlia nutans*, a species that failed to adhere to a dog in a German dispersal experiment. Photo by Michael Lüth, with permission.

The bristly coat of the wild boar was more adept at taxi service than the sleek hairs of the deer (Heinken *et al.* 2001). Furthermore, the boars wallow and root in the mud, giving them greater contact for picking up their hitchhikers. In addition to these fur and hair dwellers, they also travelled in the hooves.

Figure 148. *Brachythecium rutabulum* (Rough-stalked Feather-moss), a moss that is uncommon among the fragments on a dog in a German dispersal experiment. Photo by Barry Stewart, with permission.

Figure 149. *Chiloscypus profundus* (= *Lophocolea heterophylla*), a liverwort that does not seem able to hitch-hike a ride on roe deer or wild boar. Photo by Michael Lüth, with permission.

Heinken and coworkers (2001) tested the ability to pick up bryophyte fragments by experimenting with a dummy deer. This dummy was placed on its stomach on the forest floor and used to mimic wallowing by giving it a gentle rolling motion. They repeated the experiment 300 times between July and October, cleaning all adhering fragments each time. This "behavior" produced 51 bryophyte fragment hitchhikers. Four of the six terricolous bryophyte species in the sample plots adhered to the ventral hair, with strong differences among bryophyte species. *Eurhynchium hians* (slender with erect, acute leaves, forming wefts; Figure 127) had 47 adhering stem fragments, whereas the similarly dominant *Plagiomnium undulatum* (robust with rounded leaves, forming tall turfs; Figure 150) had only one adhering fragment.

Figure 150. *Plagiomnium undulatum*, showing its large, rounded leaves that do not adhere easily to fur. Photo by Des Callaghan, with permission.

Heinken *et al.* (2001) concluded that most of the attachment to fur occurs when the animals lie down or wallow on the ground, or when they rub against rocks, walls, or tree trunks. The hooves can also transport fragments, particularly in adhering mud (Figure 151). The type of fur matters. The boar provides further advantages by its frequent rooting and wallowing, extensive resting periods, and difficulties with grooming. Even their feces (Figure 152) could carry diaspores, but we don't know if they will survive. Since wild boars can travel as much as 5 km per day through the European forests, they could facilitate transport for quite some distance.

Figure 151. *Sus scrofa* (wild boar) tracks showing the mud that is a common part of the boar's environment. Mud on the hooves can help to carry bryophyte diaspores. Photo by James K. Lindsey, with permission.

Figure 152. *Sus scrofa* (wild boar) scat, a potential but untested means of dispersal. Photo by James K. Lindsey, with permission.

Pérez (2010) considered goats as contributors to dislodging mosses, particularly *Grimmia trichophylla* (Figure 153) and *G. torquata* (Figure 154) on Haleakala's Crater, Maui, Hawai'i, USA. These were transported downslope to new locations where they could grow, perhaps a combination of fragmentation by goats and gravity.

Bears

When I was searching for images of bears in streams, I found one with a group of bears in a moss-laden tree in the temperate rainforest of Canada (Figure 155). It occurred to me that these bears, and most likely monkeys, big cats, and other climbers, would dislodge some of the bryophytes, hence facilitating their dispersal. Another image of a black bear climbing over a rock with a vascular plant draped around its head suggested that especially for pendent mosses, they could carry them away, perhaps for some distance, and if the bryophyte is lucky, it might even be deposited in another tree.

Figure 155. *Ursus americanus* among pendent mosses in Tongass National Forest. Photo by Interpretive staff, Tongass National Forest, Alaska, USA, through public domain.

In addition to dispersal of plants on the fur, bears may also disperse them through feces. Wilson and Ruff (1999) report that mosses are included among the food, but we have no information on the viability of mosses that pass through the digestive tract of the bear.

Bryophyte vegetative structures generally are not adapted for animal dispersal. Nevertheless, just by their location they are likely to be carried on amphibian skin, turtle carapaces, slug slime, insect guts and surfaces, hairs of mites and spiders, stuck to feathers and beaks of ducks, and on animal hooves and fur. Nest-building birds that line their nests with mosses often drop pieces, or the moss can even grow while within the nest. It appears that most vegetative parts do not survive the guts of most animals well, but some do and can thus be carried to new locations.

Human Dispersal

Humans are often inadvertent dispersal agents. For example, van Zanten and Pócs (1981) report on fragmentation of mosses by lawn mowers. These are then carried further by the lawn mower or by the human raking up the scraps. Others are torn apart during logging operations, adhering to the equipment, and potentially

being carried many kilometers to another site. And certainly back packs and collecting bags carry small scraps of bryophytes that escape the fate of a herbarium packet. Van Zanten and Pócs (1981) noted that when they walked in a dry meadow in New Zealand, their socks became transport agents of fragments of *Thuidiopsis furfurosa* (Figure 156). This suggests that other animals could likewise transport this species on fur or feathers.

Figure 156. *Thuidiopsis furfurosa*, a species that is known to cling to socks of bryologists. Photo by David Tng, with permission.

Bryum argenteum (Figure 29) is commonly dispersed by humans. It has deciduous shoot apices that apparently attach to shoes and other clothing as well as to small animals. It is common along paths in cemeteries, around tennis courts, and in golf courses. Clare and Terry (1960) used matchbooks in an elegantly simple experiment to demonstrate dispersal in this species. They "walked" the matchbook across patches of *B. argenteum*, then across soil. As a control, they walked matchbooks that had not contacted *B. argenteum* across other patches of soil. The *B. argenteum* became established on the plots where the matchbook had previously visited the mosses, but not on the others, demonstrating how easily it could be dispersed on shoes and feet.

There are several documented cases of bryophytes dispersed by humans. One of the most recent reports is that of Ireland and Shchepanek (1993) for the spread of *Hyophila involuta* (Figure 157) in Canada. This species was known only from a few localities in Ontario. However, it is growing abundantly on the sides of most of the locks in the Rideau Canal and the authors suspect that it arrived in both Michigan and Canada from more southern localities by travelling there on boats. The locks are constructed of limestone and sandstone or concrete, and the plants seem to get started along the mortar seams.

Figure 157. Gametophytes of *Hyophila involuta* growing on concrete. Photo by Michael Lüth, with permission.

I still recall Iwatsuki commenting in Japan that he didn't need to check what was growing on the concrete retaining walls along the roads – it was all *Hyophila* (Figure 157). However, on the locks in Ontario it is nearly devoid on the concrete blocks, occurring predominately on the limestone and sandstone blocks which are more similar to the construct in Japan (Ireland & Shchepanek 1993). In the Ontario locks, it grows only below the water level, sometimes even on the bottom of the locks. Frequent wetting and drying and low light intensity seem to favor its growth, but the plants must also survive seven months out of the water in winter when the locks are drained. These plants never have sporophytes, and with only one report of sporophytes in the United States, it appears that they rely on their numerous multicellular gemmae (Figure 158).

Figure 158. *Hyophila involuta* showing numerous gemmae that form at leaf bases. Photo by Michael Lüth, with permission.

Logging vehicles, all-terrain vehicles, and other forest transport have giant tires with the potential to pick up fragments of bryophytes along with soil. Some of these could travel considerable distances to another location before falling off. It appears that hitch hiking is a common mode of travel for *Riccia* – in Michigan, USA, *R. huebeneriana* (Figure 159) and *R. cavernosa* (Figure 160) are often dwellers along disturbed soil of 2-track roads, suggesting a vehicular means of dispersal (Crum 1973).

Horticulture provides several means of introducing species to new locations. *Marchantia polymorpha* (Figure 34) is frequently spread throughout a greenhouse by the force of the watering system. This and other bryophytes then travel in the pots with the purchaser. *Polytrichum longisetum* (Figure 161) is an introduced horticultural weed in West Cornwall, Great Britain (Holyoak 1995).

Figure 161. *Polytrichastrum longisetum*, an introduced horticultural weed in West Cornwall, Great Britain. Photo by Michael Lüth, with permission.

Bryophytes used as packing material are potential propagules. Degener *et al.* (1969) reported such dispersal to explain the "unnatural distribution" of *Sphagnum palustre* (Figure 162). Its appearance in Hawaii seems to be from use of this moss as packing material for tree seedlings. Bryophytes used for packing can escape and become established, as in the case of *Pseudoscleropodium purum* (Figure 163), in widely ranging parts of the world (Allen & Crosby 1987).

Figure 162. *Sphagnum palustre*, a moss that is spread by its use in packing tree seedlings. Photo by Michael Lüth, with permission.

Figure 163. Gametophyte of *Pseudoscleropodium purum*, a widely transported packing material. Photo by Michael Lüth, with permission.

Golf courses and picnic areas seem to be common sites for invasive species because they get considerable foot traffic from a wide range of locations. The first citing of *Fissidens taxifolius* (Figure 77) in Auckland, New Zealand, was reported occurring under a picnic table (Espie 1997). Also *Rhytidiadelphus squarrosus* (Figure 133) first appeared in New Zealand on a Dunedin golf course in 1975, presumably arriving with foot traffic, or perhaps a golf bag.

Paths are often bordered by bryophytes (Figure 164–Figure 165). Such is the case in the Tatra Mountains of the Western Carpathians where one can find 15% of the liverwort species of that area (Górski 2009). Górski refers to "walking down" of high mountain species [*Marsupella brevissima* (Figure 166), *Pseudolophozia sudetica* (Figure 169)] to lower sites, "passing" of alpine scree-bed species to habitats associated with humans [*Anthelia juratzkana* (Figure 170), *Marsupella brevissima*, *Pleurocladula albescens* (Figure 171)], and formation of new combinations of plant communities [with *Cephalozia bicuspadata* (Figure 167)] or expansion of communities already associated with human activity [e.g. *Calypogeietum trichomanis*, *Nardietum scalaris* (Figure 168)]. Although there is no proof or experimentation to support this, it is likely that at least some of these have arrived in these locations due to human dispersal on foot gear. Others are simply opportunists that are able to

occupy a suitable habitat created by humans, possibly facilitated in their dispersal by the openings created by the paths.

Figure 164. Mosses along forest trail at Clear Creek Park in Ohio, USA. The trail opens new habitats on the slopes and foot traffic can bring propagules to the scene. Photo by Janice Glime.

Figure 171. *Pleuroclada albescens*, a scree-bed species that gets transferred to human habitats. Photo by Michael Lüth, with permission.

Bryophytes may even be transported deliberately. My favorite story is one in which *Fontinalis antipyretica* (Figure 22) was introduced into South Africa in an attempt to encourage more aquatic insects as food for fish (Richards 1947). The moss spread rapidly and covered the rocks. But at least initially, the attempt to improve the aquatic insect population failed because the native species were adapted to smooth rocks and they in fact lost their habitat.

Despite the role of humans in dispersal, urban areas often exhibit depauperate bryophyte floras. One of the reasons for this is the fragmented nature of the urban landscape, making dispersal difficult (Korpelainen *et al.* 2006), especially for epiphytes. Of course, the inhospitable nature of the urban habitat, especially exposure, makes establishment difficult once a diaspore arrives.

Mystery Dispersal

Most bryophyte dispersal is in fact mystery dispersal. Few species have actually been subjected to experimentation, tagging, or other means to provide scientific data on their dispersal. Dickson *et al.* (pers comm. 23 April 2013) have provided me with one such

story for *Fissidens fontanus* (Figure 172) in France. This species occurs in many of the abandoned lavoirs that still have flowing clean water; abandoned in the 1960s, the lavoirs were communal wash houses where women did family laundry. They were mainly contracted in the nineteenth century and some villages had more than one. These usually have a roof, but they are open on one or more sides and accessible to birds and insects (and probably an occasional frog). They have become inhabited by algae and bryophytes, the moss *Fissidens fontanus* (Figure 173). No capsules are known for this species in Europe. Recent searches of lavoirs have revealed more locations (Piguet *et al.* 2007; Piguet 2009), and it seems to be increasing along rivers in Germany and perhaps in France. Dickson and colleagues raise the question of its dispersal. There are no known connections among the springs that feed them and no ducks have been seen at any of the lavoirs. How does it spread between lavoirs – I'm guessing it was animals.

Figure 172. *Fissidens fontanus*, a moss that has appeared in lavoirs in France. Photo by Michael Lüth, with permission.

Figure 173. *Fissidens fontanus* in lavoir at Vouchoux, France. Photo courtesy of James Dickson.

Invasive Species

Invasive species represent the epitome of dispersal. Often it is the human species that serves as the dispersal vector. But whatever the vector, these species are good at getting there and successful at establishment.

One of the best known of the invasive bryophyte species is *Campylopus introflexus* (Figure 174) (Fudali 1992; Schirmel & Buchholz 2013). This species is responsible for altering the invertebrate communities in the acidic coastal dunes of Europe where it is able to form dense carpets. It caused changes in both body size and feeding preference among the arthropods, resulting in changes in hunting mode of spiders. Spiders increased in functional diversity, whereas carabid beetles had a reduction in functional diversity.

Another well-known invasive species is *Orthodontium lineare* (Figure 175) (Herben 1994). The key to success for this species is that it seems to be able to grow on whatever substrate is available, being limited only by available space.

Figure 174. *Campylopus introflexus*, an invasive species in Europe and parts of North America. Photo by Janice Glime.

Figure 175. *Orthodontium lineare*, an invasive species in Europe. Photo by David T. Holyoak, with permission.

Essl *et al.* (2013) assessed bryophyte invasions and what makes them work, using 82 regions spanning five continents as their data sources. They identified 139 species (106 mosses, 28 liverworts, 5 hornworts) that they

considered to be alien in at least one study region. They found that alien numbers were significantly higher on islands than on the studied continental regions. They identified 34 species as accidental hitch-hikers and 27 species as accompanying ornamental plants. These invasive species prefer strongly disturbed habitats [ruderal vegetation (growing on waste ground), roadsides, lawns], whereas forests and rocks are typically avoided. They concluded that the pattern of bryophyte invasions is different from that of tracheophytes.

Summary

Dispersal methods of vegetative diaspores of bryophytes include gravity, wind, water, and animals. Although most bryophytes are suitable for wind dispersal, even for fragments and specialized propagules, gravity accounts for the short distances to which most of these vegetative diaspores travel.

Splash cups are useful in dispersing gemmae in several liverworts and one family of mosses. Bryophytes getting frozen in ice or caught by flood waters can be carried considerable distances and vegetative dispersal in flowing water environs is essentially guaranteed.

Animal dispersal is probably more important than has been presumed, and includes earthworms, arthropods (insects, mites, pillbugs, spiders, harvestmen), slugs, amphibians, turtles, water birds, nest-building birds, and animal feet and fur. Birds and rodents often dislodge bryophytes while searching for food items among them and may carry fragments among their feathers/fur or attached to feet. Humans disperse bryophytes through their own footwear, vehicle tires, horticulture, and packing materials. However, none of the bryophyte vegetative propagules seems to be especially adapted for animal dispersal.

Although most bryophytes are best adapted to wind dispersal, even of fragments and specialized propagules, gravity accounts for the short distances to which most of these vegetative structures travel.

Acknowledgments

Andi Cairns kindly provided me with the flying fox and caddisfly stories and pictures. Geert Raeymaekers provided me with the *Fissidens* paper by Arts and Jan Janssens translated it for me. Thank you to Bryonetters for interesting discussions on diaspores. Steve Trynoski offered several suggestions after a critical reading of this subchapter.

CHAPTER 4-12

ADAPTIVE STRATEGIES: SPECULATIONS ON GAMETOPHYTE STRUCTURES

Figure 1. *Plagiomnium affine* leaf border with teeth. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Prologue

As I begin this chapter, I am reminded of a conversation I had with Louis Anderson. It was similar to the one relayed by Brent Mishler on Bryonet (8 May 2012) on the position of Lewis Anderson. When asked about the function of something like a hairy surface, he would point out that it had to have some kind of surface. We must keep this admonition in our minds constantly as we question functions of bryophyte parts, forcing us to ask more precise questions and to **test** our hypotheses.

Not all structures have adaptive value. With this caution in mind, we need to be aware if something is really adaptive or it is simply not an encumbrance. If it persists through more than one taxonomic group, is it more likely it has some adaptive significance than if its presence is rare? And if it occurs in all, might it be a necessity? But I dare not go farther in defining adaptive value. Hence, this

chapter is necessarily speculative. Do keep that in mind as you read.

The descriptions of structural adaptations are largely the product of the human mind to seek explanations for things. Hence, we seek to learn why a certain structure persists in a bryophyte by trying to find a function for that structure. This teleological approach is not all bad. It can form the basis of our alternative hypotheses, the null hypothesis being that there is no special function.

The next step after identifying a hypothesis is attempting to test it, and this is often quite difficult. It often becomes necessary to ask the question, "What would happen if this structure were absent, as for example the teeth shown in Figure 1?" Modern genetic techniques are permitting us to identify the functions of genes that way, using knock-out genes to disable or remove a gene. Some

structures are suitable for removing or disabling as well and can help us test our hypotheses.

Even with such testing, we must also keep in mind that not all structures have functions, and that structures and genes may not work alone. For selection to work against them, there must be some cost for their presence. If there is no cost, a structure may remain, seemingly with no purpose.

Often this cost is expenditure of energy, whereas when we look for adaptive value we tend to look for things like moisture conservation, herbivory protection, or increased dispersal. All of these relate to survival, so testing of adaptations often is a testing of survival value.

In this regard, we need to consider that Lamarckian evolution suggested that giraffes have long necks so they could reach higher branches where there was less competition for food. But there is no genetic mechanism that can cause a gene to arise due to need. Genes arise randomly through mutations or get lost through deletions. Combinations of genes change due to both mutations and recombinations. The recombinations can occur through mixing in meiosis or through mating with an individual with genotypic differences.

Medina *et al.* (2015) explored phenotypic variation in three Antarctic moss populations as a response to local environments. All three species of mosses studied revealed significant differences among populations for all evaluated morphometric characters. They concluded that in the Antarctic, local variation on a small geographic scale behaved in the same way as variation on a large geographic scale in geographic regions where the climate is more homogeneous. This is an example that may reflect random arrival of propagules, followed by selection by the environmental conditions at the site of arrival. But this is a my hypothesis for which the researchers urged the need for common garden studies and further investigation on many more species.

Linked Genes

A second complicating factor in our search for function is that genes may be kept because of their nearness to another important gene. If gene B resides on a chromosome with gene A, it will go where gene A goes unless it gets moved during a crossover event (a common occurrence during meiosis) or other type of rearrangement. The closer it is to gene A, the lower the chances of gene B becoming separated during a crossover event. If gene A is an important adaptive gene, and gene B does little or no harm, then it will be kept as it travels along with gene A, even if it codes for something that offers no adaptive value. But if gene B is harmful, and gene A is not essential or is unable to provide more benefit than the harm caused by gene B, then gene B will begin to disappear from the gene pool – and gene A with it. I could explain this further, but you should be able to see my point – not all structures or physiological mechanisms are necessarily advantageous. They may be non-adaptive. They may even remain from a time when they were adaptive to conditions that no longer exist. Thus, we must keep in mind that not all structures or other phenotypic expressions are adaptive. The evolutionary model would, in fact, predict that some are not adaptive. And those that are maladaptive may take hundreds of years or even eons to disappear from the

population. In the meantime, they may offer us taxonomic characters that are useful to systematists!

It is not easy to associate a given character with a particular gene. Vanderpoorten and Jacquemart (2004) found that most of the morphological variation in the aquatic moss genus *Amblystegium* (*Hygroamblystegium*; Figure 2) result not from genetic differences, but in plasticity of expression. They also found that the evolution of most characters in these aquatic taxa was often independent from phylogeny of the taxon. Rather, the morphological characters in this genus lack independence and stability, making them less useful for distinguishing species.

Figure 2. *Hygroamblystegium fluviatile*. Photo by Hermann Schachner, through Creative Commons.

Evolutionary Drivers

Kürschner (2004) found common adaptive trends among the bryophytes from the Near and Middle East. These represented independent traits that arose in unrelated taxa evolving under similar habitat conditions. Such convergence suggests relationships of evolution with site ecology and niche differentiation.

Hence, this chapter will present more hypotheses than facts with the challenge to our young (and older) bryologists to test these.

GAMETOPHYTE

Schofield (1981) reviewed the literature and concluded that spore germination patterns, protonemal structure, life span, and methods of vegetative propagation are all related to nature of the habitat. Large, multicellular spores and swollen protonemal cells are more common in habitats that frequently experience desiccation. Protonemata are more specialized in deeply shaded environments. More typical types with strongly elongate cells are more frequent in mesic sites or terrestrial sites with favorable moisture conditions during at least part of the day during most of the growing season. Growth forms may be correlated

genetically, or they may be "molded" by the environment. Energy conservation is often accomplished by having production of gemmae at different times from sexual reproduction.

In **ectohydric** (external) conduction systems, water movement is facilitated by leaf shape, arrangement, orientation (Figure 3), and detailed anatomy; branch arrangement, stem cortical cells; and the presence of rhizoids or paraphyllia (Schofield 1981). Surface ornamentation of leaves, stems, and rhizoids also may contribute. In **endohydric** (internal; Figure 12-Figure 13) conduction, the hydrome and leptome facilitate water movement and may be habitat specific, especially in the **Polytrichidae**. Again, there is little experimental evidence to support the conclusions that currently rest on habitat correlations.

Figure 3. *Pohlia* sp. with raindrops large and small, illustrating the way ectohydric water becomes trapped in the leaf axils. Photo by John Game, through Creative Commons.

Wetlands vs Non-wetland Trends

Hedenäs (2001) took compiled data that supports much of the tendencies noted by Schofield (1981) by examining frequencies of 86 character states in 439 species of pleurocarpous mosses on a worldwide scale. These were compared across climatic zones, general habitat, and wetland to non-wetland gradient. He found that 44% of the characters are indeed influenced by climatic zone – the largest sphere of influence in the study. General habitat accounted for 35% and wetland to non-wetland gradient 23%.

In the Hedenäs (2001) study, two complex functions emerged. Water conduction and retention can be measured by differences in stem central strand morphology, leaf orientation, leaf costa type, alar cells, paraphyllia, pseudoparaphyllia, inner perichaetial leaf plications, vaginular paraphyses, capsule stomatal pore, operculum type, and possibly seta length. The second important function is spore dispersal, facilitated by capsule shape and orientation, annulus, exostome and endostome appearance,

spore size and maturation time, and possibly seta length. The importance of phylogenetic history cannot be ignored as a limiting factor on adaptive characters, but other drivers include water availability and exposure to wind.

As seen in Chapter 2, bryophytes have a leafy **gametophyte** generation with one set of chromosomes (**haploid**) and a **sporophyte** generation that produces a capsule atop a short or long stalk and having two sets of chromosomes (**diploid**). The morphology of these two generations is strikingly different, so it is expedient to divide our discussion into these two generations.

Proctor (2010), a very astute bryologist who is familiar with both bryophyte physiology and structure, has summarized his perspective, supported by literature, on bryophyte adaptations.

Without considering how traits got that way, or which bryophytes are their ancestors, let us consider the traits themselves and their possible adaptive roles. Proctor (2010) compares the wide diversity of leaf shape, proportions of costa (see below under Costae) and lamina, and cell shape (Figure 4) in the **Dicranaceae** to the essentially uniform structure of the ecologically diverse **Fissidentaceae** (Figure 5; Figure 107). Such comparisons testify to the complexity of such adaptive considerations.

Figure 5. *Fissidens rivularis*, showing the costa, 2-ranked leaves, and flattened appearance that are present in all members of the genus. Photo by Des Callaghan, with permission.

Other families seem to have structures that adapt the family to narrower environmental circumstances. For example, the **Orthotrichaceae** live in the xeric locations of rocks and tree bark, supported by desiccation tolerance, cushion growth forms (Figure 6), and small isodiametric leaf cells (Figure 7), all of which help them to survive drying. **Hookeriaceae**, by contrast, have large, thin-walled cells (Figure 8-Figure 9) and survive only in moist, shady locations (Figure 10).

Stem

The bryophyte stem offers both support and a way of scavenging into a wider space. Pleurocarpous mosses extend across the ground surface, taking advantage of sunflecks on part of the moss while other parts are in the shade, a phenomenon that has been termed **foraging** (Figure 11). In some mosses, a central strand with specialized elongated **hydroids** and **leptoids** (Figure 12-Figure 13) contribute to transport of water, nutrients, and other substances, whereas in others these must travel from unspecialized cell to cell. Are there habitat conditions when ordinary cells are a better means of providing transport?

Richard Zander (Bryonet 8 May 2012) suggested that it might help to demonstrate a biophysical principle when one is unable to demonstrate an adaptation experimentally. As an example, he suggests that the cross section of a stem of *Aloina hamulus* (Figure 14) shows no central strand or sclerodermis. Rather, only a crowded set of cells is present. Zander compares that crowded set (see *e.g.* Figure 15) to the crowded bubbles of soap froth (Figure

16). And soap films assume the least area or least distance solution to their arrangement. He suggests that a stem with this arrangement therefore uses the least amount of photosynthate to create a plant axis. This would seem to be the simplest unspecialized case.

Figure 11. *Brachythecium buchananii* partly in sun and partly in shade. Connected plant parts can transfer photosynthate, and nutrients, from one part to the other through **foraging**. Photo by Michael Lüth, with permission.

Elumeeva *et al.* (2011) screened 22 abundant subarctic bryophytes from diverse habitats. They found that colony water retention did not correlate with individual shoot properties of leaf cell wall properties, water retention capacity, and desiccation rate. Instead, the colony desiccation rate was dependent on the density of water-saturated colonies of bryophytes. Colony desiccation rate was only marginally related to individual shoot desiccation rate, and was negatively correlated with it, suggesting that shoots with higher desiccation rates benefit from the protection of a colony.

Elumeeva and coworkers (2011) identified six distinct species groups based on habitat choice and phylogenetic relationships. *Sphagnum* (Figure 20-Figure 21) formed a unique group. **Forest mosses** were characterized by relatively big shoots with rather thick cell walls and loose colonies - tall turfs as well as wefts). **Moist to wet open habitats** had two groups: 1) those growing on stones, open soil patches, and somewhat drier parts of fens and characterized by thick cell walls and smaller amounts of internal and external water; 2) those growing in streams and wet fens and characterized by thinner cell walls but with more internal and external water. **Polytrichaceae** (Figure 17), like **Sphagnaceae**, formed its own group due to the small amount of external water. Similarly, *Racomitrium lanuginosum* (Figure 18) stood by itself as a group due in part to its low amount of external water and its unusual cells with thick, sinuose walls (Figure 19) and narrow cell lumen.

Figure 17. *Polytrichum* sp.; the *Polytrichum* species form a separate structural group due to their poor ability to hold external water. Photo by Annie Martin, with permission.

Figure 19. *Racomitrium lanuginosum* leaf cells showing sinuose walls and narrow lumen. Photo from Botany Website, UBC, with permission.

They (Elumeeva *et al.* 2011) found the lowest desiccation rate in species of *Sphagnum* [varying from 208 ± 15 min in *S. fuscum* (Figure 20) to 879 ± 51 min in *S. lindbergii* (Figure 21); mean \pm SE, $w=10$]. The highest rates were in species with small shoots: *Paludella squarrosa* (Figure 22), *Codriophorus fascicularis* (= *Racomitrium fasciculare*; Figure 23), and *Warnstorfia pseudostraminea* (Figure 24) (17 ± 2 , 15 ± 2 , and 20 ± 2 min).

They (Elumeeva *et al.* 2011) suggested that the relationships between the shoot and colony traits could help to predict changes in the hydrological function in bryophyte-dominated peatlands that are experiencing

climate-induced shifts in species abundance. These relationships may also be useful in evaluating feedbacks of species shifts as they affect permafrost insulation and carbon sequestration functions.

Stem Structure

Stems are usually circular (Figure 25), but some are triangular in cross section (Figure 26); others are somewhat flattened (Figure 27). They can have layers of cells that differ in wall thickness and coloration. Some of these differences are expressed by cells in the central strand (Figure 25-Figure 26, Figure 30-Figure 31), but not all bryophytes have a central strand (Figure 15, Figure 27-Figure 29). Others are expressed in the outer cells and can contribute to reduction in water loss and strengthening of stems. But little testing has been done to determine how these outer cells really help. Are they hydrophobic? Do any help in the absorption of water? Do the strengthening cells correlate with habitats where stem strength is an advantage? Do the colors and thickness of the outer layer respond to the environment?

Several studies have addressed the thickness of the stem and the thickness of the outer layer under different environmental influences. See and Glime (1984) compared the stem thickness and stem wall thickness in *Fontinalis flaccida* (quiet water; Figure 32-Figure 33) and *F. dalecarlica* (fast water; Figure 34-Figure 35) after growing them in a common garden artificial stream. The new growth on both species retained their distinctness, with *F. dalecarlica* having both thicker stems and more thickened outer cells (Figure 36). Furthermore, even the central cortex cells of *F. dalecarlica* were thickened, whereas they were not in *F. flaccida*.

Li *et al.* (1992) found that stem width in two *Sphagnum* species was plastic and differed significantly within species between those grown in water and those grown above water (Figure 37). Those above water developed 1-2 additional rows of hyaline cells in the outer layer of the stem (Figure 38). It is interesting that the less drought-resistant *S. papillosum* (Figure 39) had the greater difference in stem width between the two conditions. Despite that difference, *Sphagnum magellanicum* (Figure 40) is better at moving water than is *S. papillosum* and when grown in mixed clumps or alone it remains wet longer, whereas *S. papillosum* dries out quickly when it is in a hummock alone, but retains water as long as *S. magellanicum* when it grows mixed with it in about equal numbers (see Chapter 7-3).

One of the fascinating aspects of plants is their ability to change their structure in response to their environmental conditions. In at least some mosses, the stem diameter is able to increase in diameter in response to added ABA (Figure 41) (Spirina *et al.* 2020). ABA is known as a stress hormone, and one of its roles is to increase in response to drought, causing dehydration stress tolerance (Takezawa *et al.* 2011). Enlargement of the stem can provide strength, as seen by the response of tracheophytes to physical stress such as high wind (Telewski 2021). Already present in bacteria, ABA was of critical importance in adapting plants to land through added strength and adaptation to drought (Takezawa *et al.* 2011; Telewski 2021).

Figure 41. Effects of ABA on moss stem diameter. Modified from Spirina *et al.* 2011, through Creative Commons.

The **thigmomorphogenetic response** is the response to such stresses as mechanical bending or flexing in trees (Jaffe 1973; Telewski 2021). It is caused primarily by wind stress. Typically the trees respond to such bending by a reduction in extension or height growth and an increase in radial growth. A dose-dependent response to ABA contributes to these responses in trees and other plants, and now we know it can happen in bryophytes (Spirina *et al.* 2020).

Paraphyllia

Paraphyllia (Figure 42) are small green outgrowths on stems of some pleurocarpous mosses. They are useful taxonomic characters, permitting us to separate the sometimes look-alikes of *Pleurozium schreberi* (lacking paraphyllia; Figure 43) from *Hylocomium splendens* (having paraphyllia; Figure 44-Figure 45). But what is their function? The most logical is that of increasing water transport and reducing evaporation. There have been no tests to determine the value of their photosynthetic ability. And how often do they function as propagules, easily broken from the stems when dry? Do they form new plants under those conditions?

Figure 42. Stem of *Thuidium* sp. showing paraphyllia. Photo by Paul Davison, with permission.

Figure 45. *Hylocomium splendens* paraphyllia. Photo from Botany Department website, University of British Columbia, BC, Canada, with permission.

Spirina *et al.* (2020) compared paraphyllia in various species of mosses. They found that in the **Leskeaceae** (Figure 46-Figure 47), **Neckeraceae** (Figure 48-Figure 49), and **Amblystegiaceae** (Figure 50-Figure 51) these were distributed along the stem near the branch primordia. In these families, abscisic acid (ABA) stimulates increased production of the paraphyllia. On the other hand, they occur all along the stem in **Climaciaceae** (Figure 52-Figure 53), **Hylocomiaceae** (Figure 54-Figure 56), and **Pseudoleskeaceae** (Figure 57-Figure 58). In the **Thuidiaceae** (Figure 42; Figure 59-Figure 61), both types occur.

Leaf Margins

Margins of leaves can be flat, **involute** (rolled upward; Figure 62), **revolute** (rolled under; Figure 63-Figure 64), and **bordered** or **unbordered**. The borders can be one cell thick or multiple cells thick. The whole leaf can be **inrolled** (rolled upward; Figure 65-Figure 66), folded (see Keels below), or flattened. And the borders can have teeth or be smooth. Some functions for these will be discussed in the chapter on Water Relations (Chapter 7-4, Vol. 1), but this chapter would not be complete without some consideration of them.

Borders or Not

Bryophytes distinguish their leaf borders in a number of ways. While many lack special border cells (Figure 67), they may still have teeth on the border, as discussed below. Others may lack specialized cells but have margins that are more than one cell thick (Figure 74). And those with borders typically have elongate cells (Figure 68-Figure 69) that differ from lamina cells. These specialized border cells may have teeth or lack them.

Figure 67. *Barbula convoluta* leaf with no border and with papillose cells and a costa. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 68. *Mnium spinosum* leaf showing border with colored elongate cells contrasting with nearly isodiametric leaf lamina cells. Photo by Michael Lüth, with permission.

Figure 69. *Plagiomnium insigne* showing border that is several cells wide with elongate cells that contrast with the isodiametric lamina cells. Photo from Botany website, University of British Columbia, BC, Canada, with permission.

Special border cells are rare among tracheophytes, so this suggests that their presence may indicate a function in bryophytes that is not useful in tracheophytes. In fact, it is likely that this is true. Kürschner (2004) described the contortions and shrinkage of the leaf lamina in **Pottiaceae** (Figure 70-Figure 71) and **Grimmiaceae** (Figure 72-Figure 74). These contortions are typically dependent on the leaf border. As the lamina shrinks while drying, the border remains firm and does not shrink. Hence, the shrinking lamina cells pull and tug on the borders and a twisted leaf results. These leaves wind around the stem helically, benefitting from protection by the stem and reducing further desiccation and protecting against solar radiation. In desert habitats, the adhering sand grains are removed as the twisting leaves respond to water uptake and straighten during a rainfall (Scott 1982).

Marginal Teeth

Marginal teeth in tracheophytes seem to have multiple functions. In tracheophytes, marginal teeth are responsive to temperature (Royer & Wilf 2006; Royer *et al.* 2012). Using 3549 tracheophyte species from six continents, they determined toothed species are more likely to be deciduous, thin leafed, of low leaf mass per area, with ring-porous wood, and have a high leaf nitrogen content. Trees in the canopy are most likely to be sensitive to temperature as a determinant of leaf-margin state compared to shrubs and herbs. Hence, leaf thinness and deciduousness as well as temperature are linked to having teeth. Royer *et al.* argue that by being thin and having thin tissues in teeth along the margins, these deciduous leaves can return their contents to the ecosystem quickly. Perhaps the thin margins permit fungal and bacterial colonies to get established quickly?

Yet another hypothesis was tested by Baker-Brosh and Peet (1997). They observed that teeth were rare in tropical moist forests but frequent in temperate deciduous forests. They hypothesized that in those forests where leaves had to grow anew each year the teeth and lobes served as the site of early season photosynthesis in new leaves. Using $^{14}\text{CO}_2$ and autoradiography, they determined that eight species with prominent teeth or lobes did indeed exhibit early season photosynthesis on the margins, whereas in those with entire margins (no teeth; 4 species) there was no early season photosynthesis on the margins. However, seven species that were toothed or lobed likewise lacked early season photosynthesis on the margins. Royer and Wilf (2006) demonstrated that teeth were advantageous for early season photosynthesis in temperate climates. Could there be similar early season photosynthetic behavior to aid growth of new leaves in some mosses, particularly if margins at that stage are predominantly green (Figure 75-Figure 77)?

Figure 75. *Plagiomnium undulatum* leaf border showing photosynthetic marginal teeth. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Figure 76. *Plagiomnium undulatum* showing small leaves at apex where teeth may help in photosynthesis in early development. Photo from <www.aphotofauna.com>, with permission.

Royer *et al.* (2009) further explored the role of teeth in the Australian subtropical rainforest trees. Using 227 sites, they found a correlation between humidity and number of toothed species, with the greatest occurrence of toothed species in the riparian zone and the fewest at the drier ridge tops. They attribute the relationship to the availability of water. Could it be that toothed species of these large leaves lose water more easily due to the increased surface area, negating the early spring advantage in dry sites? Would this incur the same problem in bryophytes, or might the teeth actually confer a water advantage – a site for collecting and absorbing water much like the hair tips discussed below? I am aware of no quantitative study to test this hypothesis in bryophytes.

Applying these tracheophyte principles to bryophytes could bring interesting insights, but I am unaware of any attempt to test the correlations.

In bryophytes, teeth can occur along the margins [singly (Figure 75) or doubly (Figure 77)], but also occasionally projecting from the leaf lamina (Figure 78-Figure 80) or costa (Figure 80-Figure 81).

Among tracheophytes, leaf teeth are postulated to mimic effects of herbivory and thus to discourage additional herbivores on a leaf that has already been eaten. This proposed deterrent may have credence in the fact that antiherbivore compounds often are inducible (Karban & Baldwin 1997; Karban *et al.* 1997; Ceh *et al.* 2005), so a herbivore might recognize that the leaf (or alga) has been eaten and will taste bad without the herbivore having to take a sample. The argument is that the teeth give the appearance that the leaf has been nibbled before.

Could this tracheophyte herbivore deterrent of teeth have a role in bryophytes? Might herbivores consider it a signal that the leaves will taste bad? We don't even know if antiherbivore compounds in bryophytes are inducible. But then, perhaps the insects don't know either and assume the bryophytes behave like tracheophytes. And do these bryophyte teeth really look like evidence of herbivore browsing? Or do they possibly have the deterrent effects that hairs and spines have on browsing by large herbivores? Might they deter such soft-bodied herbivores as snails? It would be easy to see if snails choose to crawl over bryophyte leaves without such teeth in preference to those with them. *Atrichum undulatum* would be a good test subject with its teeth on the lamina (Figure 78-Figure 80).

Liverworts

And what about the lobes and teeth of **leafy liverworts** (Figure 82)? Do they have any adaptive value? Could they also have antiherbivore functions? Do they serve to hold water on the leaf surface? Or are they just useful tools for bryophyte taxonomists?

In the leafy liverwort genus *Plagiochila*, habitats in North America differ from those in the tropics and so do the teeth. In North America, *P. porelloides* (Figure 83-Figure 84) lives next to or in water and has small or almost no teeth. In the tropics, where there are many species in the genus, this genus lives on tree trunks and sides of boulders where conditions may be almost xeric. Most of these species have large teeth (Figure 85). When it rains, these liverworts can become quite saturated. Do the teeth help the leaves to hold droplets of water? Could their added surface area provide evaporative cooling? Or is this again an early season adaptation to enhance photosynthesis?

Figure 82. Leafy liverwort showing lobes that curl toward the stem. One can easily imagine these leaves trapping a cohesive drop of water, then slowly bending inward as that water droplet shrinks. Photo by Bill Malcolm, through Creative Commons.

Figure 83. *Plagiochila porelloides*, a species that grows in moist areas like stream banks in the Northern Hemisphere. Note that the teeth are much smaller than in most tropical species. Could teeth provide evaporative cooling? Photo by Dick Haaksma, with permission.

Figure 85. *Plagiochila raddiana* from the Neotropics. How do these teeth function for the tropical epiphytic and epilithic species? Photo by Michael Lüth, with permission.

Some species of liverworts have deep lobes. In some cases these are curved toward the stem (Figure 86) and one can imagine that they help to hold drops of water, clinging to them and curving further inward as the drop decreases in size (Figure 87). Such structure could provide a water reservoir for the leaf, permitting photosynthesis for a longer period of time. If the convex surface faces the light, the water reservoir could permit photosynthesis to continue for a longer period of time without interfering with light capture, while permitting CO₂ to enter from the surface opposing the water drop.

Figure 86. *Lepidozia reptans*, a relative small species with leaves in a size range where they could trap a cohesive water drop. Teeth may aid in holding that water next to the leaf. Photo by Walter Obermayer, with permission.

Figure 87. Wet *Ptilidium ciliare* showing teeth clinging to the leaf beneath, presumably aiding in water retention. Photo by Des Callaghan, with permission.

Presumably, size affects the utility of teeth and lobes. If one compares the large size of the leaf and its lobes in *Lophocolea* (Figure 88) with those in *Cephalozia* (Figure 89), it appears their functionality should work differently. Small droplets of water are harder to break up than large ones. Does this have any bearing on utility, size, and location of the lobes? Would long, thin lobes on large leaves direct water off the leaf, permitting CO₂ to enter the cells, behaving like the drip tips of some tropical leaves?

Figure 88. *Lophocolea bidentata*, a relatively large species showing leaf lobes. Might these aid in holding drops of water? Photo by Aimon Niklasson, with permission.

Figure 89. *Cephalozia bicuspidata*, a much smaller species than *Lophocolea bidentata*, showing leaf with deep lobes. Could these lobes provide a means of holding onto a drop of water, much as a diving beetle holds onto a bubble of air? Photo by Hermann Schachner through Wikimedia Commons, with permission.

Let's return to the consideration of moisture relationships and number of species with teeth. This might be simplest to demonstrate with epiphytes. In the temperate zone, where epiphytic positions can impose long drought periods, most of the large leafy liverworts have entire leaf margins, e.g. *Frullania* (Figure 90), *Porella* (Figure 91), and *Radula* (Figure 92). In the tropics, *Plagiochila* (Figure 93) is very common, with many species, and most of these have rather large teeth. Tropical rain forests have long seasons of rainy weather that can maintain the moisture among these liverworts, followed by a long season of drought when the liverworts can remain dormant. Temperate species, on the other hand have the risk of drying before they have repaired the damage from the last drought. Which strategy – teeth or no teeth – permits them to hold water longer? What fun for experimentation!

Figure 90. *Frullania dilatata* showing lobules and entire margins (no teeth or lobes). Photo by Walter Obermayer, with permission.

Figure 92. *Radula* from the Neotropics showing entire leaf margins. Photo by Michael Lüth, with permission.

Figure 93. *Plagiochila adianthoides* from the Neotropics showing toothed leaf margins. Photo by Michael Lüth, with permission.

One might argue that in liverworts like *Nowellia curvifolia* (Figure 94), the long lobes provide a stalk for the clusters of gemmae produced at their tips. Such positioning for the gemmae might make it easier for them to escape the plant and travel a greater distance.

Figure 94. *Nowellia curvifolia* showing gemmae positioned at the ends of narrow leaf lobes. Photo by Paul G. Davison, with permission.

Hair Tips

Many bryophytes in dry habitats have hair tips on the leaves (Figure 95-Figure 96). One suggestion for their role is that they are able to reflect sunlight (Kürschner 2004). This can protect the underlying cells from sun damage when they are dry and the leaves are compressed against the stem. And in many species, when the plants are dry the leaves twist around the stems so that each hair overlaps the leaf above it (Figure 97).

Figure 95. *Hedwigia ciliata* leaf showing translucent hair point. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 96. *Hedwigia ciliata* with wet plants on the upper left and dry ones on the edge of the colony (lower right). Note how the dry leaves cling to the stem compared to the spreading wet leaves. Photo by Janice Glime.

Figure 97. *Grimmia decipiens* showing array of hairs that help fill in spaces between stems. Photo by Des Callaghan, with permission.

A second function has been suggested – that the hair points may help to absorb condensed water vapor from fog and dew (Figure 98-Figure 100) (Kürschner 2004). This phenomenon is well known from physics – small droplets accumulate around thin wires – and on fine hairs. To this role, I would add that the hairs may provide additional capillary spaces that gain water in rain as well and hold it there for longer periods of time, preventing evaporation from the leaves.

Figure 98. *Grimmia* cf. *pulvinata*, lightly covered with dew, on churchyard wall. This picture supports the notion that the hairs can act to collect dew that can eventually drip down into the moss mat. In areas with low precipitation and frequent fog, this can be the only source of water for some mosses. Photo by Brian Eversham, with permission.

Figure 99. *Grimmia horrida* habitat at edge of fog in northern Portugal. Photo by Michael Lüth, with permission.

Figure 100. *Campylopus introflexus* collecting water drops on the fine hairs. Photo by Michael Lüth, with permission.

Figure 101. *Tortula muralis* with hair tips trapping water droplets. Photo by Christophe Quintin, through Creative Commons.

If we examine the picture of *Grimmia* from Scotland (Figure 102), we can see a third possible function. Note that the frost is held away from the leaves. Frost and ice crystals are very hygroscopic and can draw water out of the leaves as they do from the foods in your freezer. The hairs seem to function, at least in this case, to keep the frost from contacting the leaves, thus avoiding their potential desiccating effect. The same is often seen in leaves of early spring perennial flowers.

Figure 102. *Grimmia* capsules and frost at Dunkeld, Scotland. Photo by Allan Water.

As I sorted through images, I was struck by another potential purpose for some hairs. As you will learn in Chapter 7, bryophytes survive desiccation much better than their tracheophyte counterparts. But when they are rehydrated, they must repair damaged membranes, and this seems to take about 24 hours. A short misting or very light rain that evaporates right away may not provide enough hours for repair before the bryophyte is once again desiccated, hence wasting the energy expended in its failed attempt. Hairs can fill in spaces between apices (Figure 103), trapping water droplets and keeping them from entering the moss mat, thus preventing a hydrated period that is too short, or perhaps keeping the water at the tip to be absorbed slowly over time (Figure 104).

Figure 103. *Grimmia* at Goudini Spa, South Africa. With hairs in this position, they can capture the cohesive water drops (Figure 104) and prevent them from entering the moss mat during a light shower. When the storm lasts longer, the weight and size of the droplets will finally force them through the hairs. Photo by Janice Glime.

Figure 104. *Pohlia wahlenbergii* with cohesive water drops. Note that these drops are mostly too large to penetrate the mat and hence remain at the surface, held together by their own cohesive forces. Photo by J. C. Schou, through Creative Commons.

Finally, I suggest that hair points, at least in some species, can deter some kinds of herbivores. We know that invertebrate herbivores are deterred by hairy leaves of tracheophytes (Karban & Agrawal (2002) and that spiny leaves deter ungulates (Obeso 1997). It is not unreasonable to assume that they can confer similar advantage to bryophytes, particularly when hair points overlap extensively as in *Grimmia arenaria* (Figure 105).

Figure 105. *Grimmia arenaria*, demonstrating long hairs that might protect from bright sun or prevent desiccation. Photo by Des Callaghan, with permission.

Costae

The **costae** are the moss versions of midribs (Figure 106). They are absent in liverworts. Their functions may include movement of water from base to tip of the leaf, or perhaps from tip to base. This can be surmised by the elongate structure of the cells (Figure 107) compared to the shortness of leaf lamina cells in many species. I have referred to base to tip transport because it is the base where water can accumulate in the leaf axil and receive water from the stem through its external movement of water. But in some plants, water might move into the leaf at the tip, possibly absorbed through the apical leaf hair, but empirical data to demonstrate this seems to be lacking.

Figure 106. *Rhizomnium glabrescens* leaf cross section showing costa. Photo from Botany Department website, University of British Columbia, BC, Canada, with permission.

Figure 107. *Fissidens bryoides* leaf cells showing elongate cells of costa in lower right. Photo by Dick Haaksma, with permission.

I have constantly been struck by the attempts of ecologists to find a single explanation or advantage for a particular strategy for plants or animals. I am convinced that many of these strategies/structures persist because they provide small advantages for multiple functions. And certainly some are advantageous in some situations or years, but not in others. They may at times even be disadvantageous.

Proctor (2010) points out that in **Sematophyllaceae**, some members have a costa and others do not. The same is true in the **Fontinalaceae**. In the latter family, the costa separates the costate genera *Dichelyma* (Figure 108) and *Brachelyma* (Figure 109), both occurring in inundated areas but living mostly above water, from the ecostate genus *Fontinalis* (Figure 110), a genus that spends most of the year under water. Olsson *et al.* (2009) have shown that in the **Neckeraceae** reduction of the costa has recurred in all three main clades. Proctor (1979) concludes that the presence or absence of a costa, as well as the shape of leaf cells, must have functional consequences, but we are uncertain how important these are for mechanical support vs conduction within the leaf, not to mention simply chance occurrence relating more to ancestry than to (current) function.

Figure 108. *Dichelyma falcata*, a member of the **Fontinalaceae** with a costa. Photo by Michael Lüth, with permission.

Figure 109. *Brachelyma subulatum*, a member of the **Fontinalaceae** with a costa and keeled leaves. Photo by Janice Glime.

Figure 110. *Fontinalis hypnoides* showing absence of costa. Photo by John Game, with permission.

I was surprised to find that when grown in my artificial stream with considerable air exposure, *Fontinalis* produced short costae. Bruce Allen once told me he had also sometimes found *Fontinalis* leaves from nature that had short costae. To me this suggests that something suppresses the development of the costa and that under certain conditions that suppression doesn't function. That would imply that the costa came first and that a suppressor developed later. That suppressor is most likely water, which not only affects hydration, but also affects CO₂ uptake, oxygen concentration, and escape of gases such as the developmental hormone **ethylene**.

Costae can provide strength for a leaf. It can represent a tough tissue not eaten by herbivores. It is the structure that remains on leaves of aquatic species such as those of *Hygroamblystegium* (Figure 111-Figure 112) when exposed to rapid flow and suspended solids. But is any of these adaptive in any way? Possibly. If the costa is capable of growth into a new plant, it could become a dispersal agent. It could also provide photosynthetic tissue when leaf lamina tissue has been eaten or eroded. But there is no empirical proof that these things occur or if so, are they of any consequence.

Figure 112. *Hygroamblystegium fluviatile* showing dark costae left from eroded leaves. Photo by Michael Lüth, with permission.

Some amphibious bryophytes actually have reduced or lost costae when they have grown in the water. For example, Rod Seppelt (Bryonet 24 June 2012; Seppelt &

Selkirk 1984) observed that the costae of *Bryum pseudotriquetrum* (Figure 113-Figure 114) were shorter and weaker on aquatic specimens from lakes in Antarctica compared to those growing out of water. He also reported inducing absence of costae and change in leaf shape in *Bryum argenteum* (Figure 115) in culture, with temperature playing a major role in inducing leaf changes; lower temperatures resulted in wider leaves. Furthermore, at 4°C the costa was absent. Clearly in some species the environment can affect how the costa develops. But what does it mean for the plant?

Figure 115. *Bryum argenteum* leaf showing well developed costa of a terrestrial form. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

In the genus *Dicranum* (Figure 116-Figure 121), the costa varies widely, with almost no differentiation in *Dicranum rhabdocarpum* (Figure 116) to phalanges along the costa in *Dicranum scoparium* (Figure 121). In other members of the *Dicranaceae*, for example *Pilopogon peruvianus*, the costa can occupy most of the leaf width (Figure 122).

Glenn Shelton (Bryonet 15 June 2012) contended that mosses tend to evolve from having multiple costae (Figure 123) to few (single or none). He and colleagues have found a number of tricostate mosses from the Early Cretaceous of Vancouver Island, B.C., Canada, some apparently pleurocarpous, as evidenced by a high degree of branching (including pinnate) and cell morphology. On the other hand, it appears that costa number is quite plastic among major moss lineages – and even within species (see above). And Ben Tan (Bryonet 30 June 2012) enters a word of caution – that folds or plicae at the leaf base can look like short costae, so one must be careful in interpreting fossil costae.

Shelton (Bryonet 15 June 2012) explains that one theory is based on the premise that the costa gives rigidity to the leaf and that multiple costae provide more rigidity. This assumes, then, that the need for this rigidity has been lost in some species. The theory also considers evolution from complex leaf structure to a simpler structure – **reduction**.

Figure 123. *Vesicularia montagnei* showing short, double costa. Photo by Tan Sze Wei, Aquamoss website <www.aquamoss.net>, with permission.

Perhaps Kürschner (2004) has the right idea for some species. He notes that the costa is often shiny (Figure 124-Figure 125) in mosses growing in xeric sites. Hence, he suggests that the costa may reflect the solar radiation and thus reduce both evaporation and heat stress. I would need

proof to see how a narrow costa could have much impact, and it seems that xeric costae are often darker than the leaf (Figure 124-Figure 125), suggesting they might absorb more heat than the lamina.

Figure 124. *Syntrichia andicola* showing shiny costa. Photo by Michael Lüth, with permission.

Figure 125. *Syntrichia andicola* showing costa of leaf. Photo by Michael Lüth, with permission.

Zander (Bryonet 25 June 2012) reminded us of the perspective of Gould (2002) that there are minimum constraints on size – a developmental wall to small size for particular organisms. He considers that the elimination of superfluous costal material might depend on size. As leaves get smaller, the costa necessarily gets smaller, and it might no longer serve the same function or advantage it did in larger leaves. Zander points out that acrocarpous mosses usually have costae, but that pleurocarpous mosses may or may not. Is this a size difference, or a difference in phylogenetic history? And perhaps costae persist, or not, because some other linked trait is affected by some selection pressure that has changed over time.

Lamellae

Lamellae (Figure 126-Figure 138) can greatly increase the surface area of a leaf. They provide numerous surfaces, exposed on both sides for absorption of light and especially CO₂ and provide capillary spaces for taking up and holding water.

Members of the family **Polytrichaceae** are defined by the presence of lamellae (Figure 126-Figure 131), but other genera in scattered families have them as well. These include *Aloina* (Figure 132), *Crossidium* (Figure 133-Figure 134), *Pterygoneurum* (Figure 135-Figure 137), and some *Syntrichia* (Figure 138).

Figure 138. *Syntrichia papillosa* leaf showing tips of lamellae. Photo by Des Callaghan, with permission.

Kürschner (2004) suggests that the lamellae facilitate water conduction as well as storing water. These roles are in addition to their photosynthetic role. But this role seems to be incorrect. The surface of cells surrounded by water presents a barrier to CO₂ absorption (Budke 2010). Instead, the waxy cuticle repels the water. The lamellae in *Polytrichum commune* (Figure 129) increase the leaf surface area 2.4 fold (Thomas *et al.* 1996). Even the lamellae margins are coated with a waxy cuticle that restricts external capillary water. Thus they serve as photosynthetic tissue rich in chlorophyll.

Proctor (2005) demonstrated that the lamellae in **Polytrichaceae** (Figure 126-Figure 131) are important for the absorption of CO₂, increasing typical uptake by six times that of the projected leaf area, whereas in unistratose leaves of most other bryophytes, CO₂ uptake is limiting. This permits the **Polytrichaceae** to take advantage of high light intensity in open areas by increasing available absorptive surface area. In a number of these species, including some of *Polytrichum* (Figure 130), the leaf margins fold over the lamellae, affording protection from excess UV light, preserving moisture, and providing space for CO₂ exchange.

Air Chambers

Air Chambers are present in some of the thallose liverworts, such as species of *Marchantia* (Figure 139-Figure 142) (Ishizaki *et al.* 2013) and others (Figure 143-Figure 148). These facilitate the exchange of gasses within the thallus (Ishizaki *et al.* 2013). The small pores at the surface of the thallus in these chambered species permit the exchange of these gasses, providing an entry for CO₂ and exit of O₂.

Keels

Most leaves are slightly concave, some are flat, and some are folded over, forming a **keel** (Figure 149). The most striking of these is the keel in several species of the aquatic moss *Fontinalis*. The keel appears to give rigidity to the leaf, but when this species occurs in flowing water the keel often is abraded, leaving the leaf in nearly two pieces.

A modification of the keel occurs in the **Fissidentaceae** (Figure 150). This unique structure forms a pocket on the apical edge of the leaf into which the succeeding leaf can partially fit. The double area of each leaf adds rigidity and provides capillary space that presumably holds water for a longer time. When the leaves overlap into the pockets, they can help to make the entire plant more rigid.

Figure 150. *Fissidens curvatus* showing pockets with succeeding leaves fitting into them in some cases. Photo by Tom Thekathyl, with permission.

Leaf Plications

Some genera are characterized by leaf plications (Figure 151-Figure 153). These are typically folded like a Japanese fan. But what is the value of these plications? In tracheophytes, they can add strength. Consider lifting something with a sheet of paper. Then consider lifting the same thing with that same paper after it is fan folded. But is that kind of strength needed by a bryophyte leaf? Does it give a thin leaf a better ability to hold a drop of water?

Figure 151. *Coscinodon cribrosus* leaf with plications. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Figure 153. *Cratoneuron decipiens* leaf with plications. Photo by Michael Lüth, with permission.

Leaf Cells

Cell shape varies considerably, from small isodiametric cells (Figure 107) to large, nearly hexagonal ones (Figure 154) to elongate ones (Figure 155). Some cells have wall invaginations or wavy walls (Figure 156). Little mention has been made of the advantages of various
