CHAPTER 12-2

TERRESTRIAL INSECTS:

HEMIMETABOLA – COLLEMBOLA

Figure 1. *Hypogastrura* sp. on *Schistidium apocarpum*. Photo by Christophe Quintin, through Creative Commons.

Meet the Collembola

These tiny creatures, the springtails, are easily overlooked until they start popping about before your eyes. Previously considered to be insects, they are currently placed in the class **Entognatha**, where the name **Collembola** has been elevated from an order to a subclass. Among the bryophytes, they blend with the dark crevices between the leaves. Numerous studies attest to their frequency among bryophytes (e.g. Bonnet *et al.* 1975; Acon & Simon 1977; Skarzynski 1994). The bryological habitat is likely to yield some surprises, even new species (Acon & Simon 1977; Skarzynski 1994).

Their diversity includes the tiny non-jumping ones to the larger ones equipped with a **furcula** (Figure 2) that permits them to spring like those metal cricket toys some of us remember (Kinchin 1992). A **collophore** (Figure 3) holds the furcula in place and ready to spring. The collophore may be used in osmoregulation, water intake, and excretion (Wikipedia 2016). By comparative body size, these 15-cm jumps are equivalent to a human jumping over the Eiffel Tower (Shockley 2011). Like other insects,

they shed their outer covering (**exuvia**; Figure 4-Figure 5) in order to grow.

Figure 2. *Arthropleona oruarangi* showing **furcula**. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Figure 3. *Isotoma* (springtail) showing **collophore** (arrow). Photo by U. Burkhardt, through Creative Commons.

Figure 5. *Dicyrtoma fusca* with **exuvia**. Photo by Jan van Duinen <www.janvanduinen.nl>, with permission.

Swan (1992) suggests that "insects" such as the primitive **Collembola** may have invaded land even before the early bryophytic land plants. Mosses are often present as a photosynthetic band at the edge of **Aeolian** (wind erosion) zones, benefitting from nutrients delivered by the winds. But these windborne nutrients were available even before mosses arrived, with organic compounds collecting along the Aeolian zone. It is not hard to imagine, then, that when mosses appeared, **Collembola** colonized them.

Moisture Needs

It is easy to imagine that bryophytes can help to maintain moisture for **Collembola** in many habitats. But in many habitats both bryophytes and **Collembola** are susceptible to desiccation stress (Verhoef & Witteveen 1980). Some **Collembola** produce a special grooming fluid (Figure 6) that keeps their heads moist (Shockley 2011). They have two inflatable tubes (Figure 6) that help them to distribute the fluid. These tubes double as "arms" if the springtail lands on its back – the tubes are used to stick to the substrate and pull the springtail over to its proper position or to attach it to the substrate to prevent it from tumbling on an incline.

Figure 6. *Sminthurus* cf. *wahlgreni* with its inflatable **adhesion tube** attached to its abdomen. Note drops of grooming fluid on the head and abdomen. Photo by Jan van Duinen, with permission.

Reproduction

Mating is a bit unusual in the springtails. Rather than depositing sperm into the female, the male produces a small packet (**spermatophore**; Figure 7-Figure 8) that he attaches on a short stalk onto a substrate (Shockley 2011). The female must then take the spermatophore into her reproductive tract. The mating itself can take many forms in an attempt to insure that a female will attain the sperm. These include

1. random deposition of spermatophores across the landscape.
2. deposition of a spermatophore followed by the male using antennae to drag the female across it.
3. locating a female and depositing multiple spermatophores; male then tries to lure the female through this "garden" of spermatophores.
4. locating a female and surrounding her with spermatophores so she must contact one or more to escape.
5. holding a male-female courtship dance [e.g. *Deuterosminthurus pallipes* (Figure 9) – a species found among mosses in the floodplain meadow of the Kargy River in Russia (Bretfeld 2010)], doing a face-to-face push and retreat ritual to establish a rhythm. As the female tries to get away, the male continues to woo her. If the female accepts, the male deposits the spermatophore directly in front of her; she picks it up

and either deposits it in her reproductive tract or – eats it.

Figure 8. *Isotominae* spermatophore. Photo by Jan van Duinen, with permission.

Figure 9. *Deuterosminthurus pallipes* courting; the female is the larger one. Photo by Jan van Duinen, with permission.

Some species, *e.g.* *Folsomia candida* (Figure 10-Figure 11) (*Isotomidae*), are **parthenogenetic** (giving birth without fertilization). This is helpful in the disconnected bryophyte patches where contact is limited.

Figure 10. *Folsomia candida* with eggs. Photo by Steve Hopkin, with permission.

Figure 11. *Folsomia candida* with young. Photo by Steve Hopkin, with permission.

Christiansen *et al.* (1992) reported a generation time of about one month for most laboratory-reared **Collembola** species. But some species are **univoltine** (one generation per year) and others are **multivoltine** (more than one generation per year) (Hopkin 1997). Mitchell (1977) provided evidence that **Collembola** communities have seasonal fluctuations in composition and numbers.

Dispersal

Data for dispersal rates for **Collembola** dwelling among the bryophytes seem to be lacking. But those living in soil and those living within the bryophyte clumps may be similar. Ojala and Huhta (2001) determined the rate for soil **Collembola** to be 0.5-1 cm per week, compared to 1-2 cm per week for cryptostigmatic mites. This of course is likely to be different if they must migrate between patches where they can hop much longer distances than the

distances travelled within the confines of the moss mat itself.

For the moisture-requiring **Collembola**, winter is often the time for dispersal, a feat often accomplished across the snow (Figure 12) (Leinaas 1981a, b, c; Hågvar 1995; Zettel 1984, 1985; Zettel & Zettel 1994).

Figure 12. **Collembola** – snow flea on snow. Photo by Bob Armstrong, with permission.

It might be useful to consider the possibility of springtails being dispersed along with the bryophytes, a phenomenon already considered for tardigrades (Janiec 1996). Although this may be a rare occurrence for larger adults, might small species or the eggs get dispersed on bryophyte fragments in the winter when bits can travel long distances across the snow and even glaciers (Miller & Howe Ambrose 1976)?

Collembola appear early in succession of new moss colonies. The first organisms to appear are rotifers and protozoa (Mukerji *et al.* 2000). These are followed by nematodes, mites, and **Collembola** once the moss has formed a detrital layer. In high altitudes, the **Collembola** abound among colonizing mosses, which also serve as their food (Mani 1962).

On the other hand, Sinclair *et al.* (2003) found that **Collembola** not only graze on bryophytes, but that mosses may be essential to their temperature maintenance in the Antarctic. When the springtail *Desoria klovstadi* (**Isotomidae**; see Figure 105) was collected while foraging on moss, it had a high **supercooling point** (point of crystallization), but when the animals were starved for 2-8 hours, the supercooling point shifted towards the low group. But acclimating them with lichen or algae for five days resulted in even higher supercooling points than if supplied with moss, while those starved (with free water or 100% relative humidity) displayed a trimodal supercooling point distribution. On the other hand, the supercooling point of this springtail was lower when they were acclimated for five days and provided with moss than when supplied with algae or lichens. Sinclair and coworkers found that other pretreatments, including cold, heat, desiccation, and slow cooling, did not induce any supercooling point shifts, suggesting that their diet of mosses, algae, and lichens may have been the controlling factors. They suggested that vertical migration might permit the springtails to escape the cooler temperatures of night. In other Antarctic locations, vertical distributions indicate distinct communities (Usher & Booth 1984).

Bryophytes as a Habitat for Springtails

Kinchin (1990) considered the **Collembola** to be one of the two most abundant groups among bryophytes, the

other being the mites. Studies from wide-ranging locations have demonstrated the importance of the bryophytes as habitats (e.g. Mexico: Varga 1989, 1991; Varga & Vargha 1992; Brazil: Abrantes *et al.* 2010; Hungary: Traser *et al.* 2006; Antarctica: Seppelt & Ochyra 2008). In Brazil, *Brachystomella agrosa* (see Figure 13), *B. contorta* (**Brachystomellidae**), *Seira melloi* (see Figure 14), *S. subannulata* (**Entomobryidae**), and *Ballistura fitchi* (**Isotomidae**) inhabit mosses (Abrantes *et al.* 2010).

Figure 14. *Seira dollfusi*, from a genus that inhabits mosses in Brazil. Photo by Andy Murray, with permission.

Božanić (2011) considered the bryophytes to be important habitats for hiding from predators and unfavorable weather, for feeding, and for laying eggs. Bryophytes absorb water rapidly, reduce substrate evaporation, and insulate against temperature and wind (Gerson 1982; Smrz 1992; Andrew *et al.* 2003). By ameliorating the habitat conditions, they permit **Collembola** to aggregate (Figure 190), thus avoiding dry conditions (Joose & Verhoef 1974; Leinaas & Sømme 1984; Usher & Booth 1984).

For those who are eager to find new species, bryophytes are a good habitat for finding such treasures. Skarzynski (1994) found two species new to the Polish flora by looking at *Sphagnum* (Figure 15) inhabitants. Their small size makes these springtails easy to overlook, and sorting through samples with a microscope is time-consuming and destructive. Because of the chambered structure of the mosses, most extraction techniques are not as effective as in other kinds of samples. (See Sampling below.)

Figure 15. *Sphagnum angustifolium*, a moss where one might find new springtail species by careful sorting. Photo by Michael Lüth, with permission.

Species and Abundance

Species numbers, abundance, and dominance in bryophyte **Collembola** communities can vary widely between locations, as can be seen in Figure 17 (Traser *et al.* 2006). Traser and coworkers collected 60 species (3,451) of **Collembola** in 18 moss species in three habitats in Hungary. The highest diversity was in the reed bed (Tómalom), accompanied by very low abundance and more evenness than the other two sites: Fertőrákos is a dry grass habitat and Sopron is a Botanic Garden, both with lower diversity and higher richness. Interestingly, the **bryobiont** (animal that occurs exclusively associated with bryophytes) *Hymaphorura dentifera* was absent, but several **bryophilic** (bryophyte-loving) species (e.g. *Xenylla boernerii*; Figure 144) were present. None of the dominant species is restricted to bryophytes. The two most abundant species were *Cryptopygus bipunctatus* (Figure 28) and *Folsomia manolachei* (Figure 29). *Sphaeridia pumilis* (Figure 53) and *Parisotoma notabilis* (Figure 187) occurred on *Calliergonella cuspidata* (Figure 16) in two locations. *Brachythecium rutabulum* (Figure 161) housed four species whereas *Hypnum cupressiforme* (Figure 18) housed 14. *Entomobrya nivalis* (Figure 86) occurred on *H. cupressiforme* in two locations. The most abundant species were different for each location (Figure 17). The dominant species primarily belong to the families **Isotomidae** and **Hypogastruridae** [followed by **Entomobryidae** and **Symphyleona** (spherical springtails)]. Moss-dwelling species included:

Hypogastruridae (Figure 1): *Hypogastrura socialis*, *Hypogastrura vernalis* (Figure 19), *Xenylla boernerii* (Figure 144), *Xenylla maritima* (Figure 82), *Xenylla brevicauda*, *Willemia virae* (see Figure 20)

Brachystomellidae: *Brachystomella parvula* (Figure 13)

Neanuridae: *Friesea truncata* (see Figure 157), *Anurida pygmaea* (Figure 21), *Neanura muscorum* (Figure 166)

Onychiuridae: *Supraphorura furcifera* (Figure 22), *Protaphorura armata* (Figure 23)

Tullbergiidae: *Doutnacia xerophila* (see Figure 24), *Mesaphorura critica*, *Mesaphorura hylophila* (Figure 25), *Tullbergia krausbaueri*, *Tullbergia macrochaeta* (Figure 26), *Metaphorura affinis* (Figure 27)

Isotomidae: *Pachytoma crassicauda*, *Cryptopygus bipunctatus* (Figure 28), *Folsomia manolachei* (Figure 29), *Folsomia penicula* (Figure 30), *Folsomia quadrioculata* (Figure 88), *Isotomiella minor* (Figure 31), *Parisotoma notabilis* (Figure 187), *Isotoma viridis* (Figure 32), *Isotoma riparia* (Figure 33), *Isotomurus* cf. *palustris* (Figure 34), *Isotomurus prasinus* (Figure 35)

Entomobryidae: *Entomobrya corticalis* (Figure 36), *Entomobrya handschini* (Figure 37), *Entomobrya multifasciata* (Figure 38), *Entomobrya nigriventris*, *Entomobrya nivalis* (Figure 86), *Lepidocyrtus cyaneus* (Figure 120), *Lepidocyrtus lanuginosus* (Figure 39), *Lepidocyrtus lignorum* (Figure 40), *Lepidocyrtus paradoxus* (Figure 41), *Lepidocyrtus peisonis*, *Lepidocyrtus violaceus* (Figure 42), *Pseudosinella alba* (Figure 43), *Pseudosinella octopunctata* (Figure 44)

Orchesellidae: *Orchesella cincta* (Figure 68), *Orchesella bifasciata* (Figure 150), *Orchesella xerothermica* (Figure 45), *Heteromurus major* (Figure 46), *Heteromurus nitidus* (Figure 47)

Tomoceridae: *Tomocerus* cf. *baudoti* (Figure 48), *Tomocerus minor* (Figure 164-Figure 165)

Cyphoderidae: *Cyphoderus albinus* (Figure 49)

Oncopoduridae: *Oncopodura crassicornis* (Figure 50)

Neelidae: *Megalothorax minimus* (Figure 51), *Neelides minutus* (Figure 52)

Sminthuridae: *Sphaeridia pumilis* (Figure 53)

Katiannidae: *Sminthurinus elegans* (Figure 54), *Sminthurinus aureus* (Figure 55)

Dicyrtomidae: *Dicyrtoma fusca* (Figure 5)

Bourletiellidae: *Deuterosminthurus bicinctus* (Figure 56), *Fasciosminthurus strigatus*, *Heterosminthurus bilineatus* (Figure 57)

The greatest numbers of bryophyte-dwelling **Collembola** seem to be those in the Antarctic. But abundance numbers seem to be rare in the literature. Matveyeva (1972) found that moss carpets in the tundra sedge-moss community of Taimyr, USSR, supported 4000 **Collembola** per square meter. That moss carpet area accumulates more snow than areas with turf and the mosses may provide a protected habitat in which the **Collembola** can move and find sufficient food without being detected.

At Spitsbergen, mites and springtails comprised 96-99% of the total arthropods, numbering 268,000 individuals m^{-2} in the wet moss tundra compared to 42,000-63,000 on lichen tundra and 518,000 on grassland there (Bengtson *et al.* 1974).

Božanić (2011) reported 1341 Collembola in individual samples from the Litovelské luhy National Nature Reserve, Czech Republic, compared to only 137 in the control samples (soil, wood, *etc.*). These numbers compared to 2946 mites and 320 isopods. Other groups exhibited lesser numbers.

In the Antarctic, mites and springtails typically dominate the bryophyte habitat. **Collembola** [especially *Parisotoma octooculata* (Figure 58) and *Cryptopygus antarcticus* (Figure 78)] ranged up to 20,540 individuals per 100 cm^2 of *Polytrichastrum alpinum* (Figure 64) (Schenker & Block 1986).

Figure 58. *Parisotoma octooculata*, a common bryophyte inhabitant in the Antarctic. Photo by Te Papa, through Creative Commons.

Food

Collembola are opportunists, feeding on fungi, detritus, and mosses (Gerson 1969; Peterson & Luxton 1982; Hodkinson *et al.* 1994; Chen *et al.* 1995; Varga *et al.* 2002a, b). Ponge (2000) demonstrated that **Collembola** living in soil of 13 Belgian beech forests had gut contents that corresponded with the available food in their immediate proximity. Nevertheless, the **Onychiuridae** (Figure 59) exhibited plasticity of food items based on depth.

Figure 59. *Onychiurus* sp., a species with adaptable food preferences. Photo by Andy Murray, through Creative Commons.

At least some **Collembola** eat bryophytes. And they have actually been seen eating mosses in Antarctica (Pryor 1962; Janetschek 1967). In addition, Pryor (1962) successfully reared them on mosses in the lab. *Gomphiocephalus* (Figure 60 - Figure 61) (**Hypogastruridae**) prefers mosses over **Cyanobacteria**, red lichens, and the mold *Penicillium* (in Gerson 1969). Gerson (1969) reported that *Isotoma* feeds extensively on mosses. *Desoria klovstadi* (see Figure 105) prefers mosses over fungi and feeds extensively on them (Pryor 1962). Nevertheless, Davis (1981) found no evidence of

Collembola feeding on bryophytes in two Antarctic terrestrial moss communities. Despite the dominance of bryophytes in the flora of Antarctica, Block (1985) similarly found that arthropods feed on epiphytic algae, micro-flora, and detritus.

Figure 61. *Gomphiocephalus* feeding on the lichen *Caloplaca setrina* growing on dead *Bryum argenteum* in the Antarctic. Photo courtesy of Rod Seppelt.

Merrifield (2000) suggested that **Collembola** may graze on some bryophytes, possibly causing the increased dependence on gemmae for reproduction. A search of the moss *Syntrichia laevipila* (Figure 62) revealed considerable grazing, but this could also have been the activity of slugs.

Figure 62. *Syntrichia laevipila* with capsules, a species that is grazed, possibly by *Collembola*. Photo by Michael Lüth, with permission.

Megaphorura arctica (Figure 63) (*Onychiuridae*) in West Spitsbergen feeds mostly on living and dead bryophytes, detritus, and sometimes algal cells (Hodkinson *et al.* 1994). The bryophytes include *Sanionia uncinata* (Figure 184-Figure 185), *Polytrichastrum alpinum* (Figure 64), and *Racomitrium lanuginosum* (Figure 65-Figure 66).

The fungi within bryophyte mats can serve as a food source for bryophyte dwellers (Varga *et al.* 2002b). McMillan and Healey (1971) found mosses in guts of the genus *Tomocerus*. But even the fungi they eat might be moss inhabitants. The springtails *Tomocerus longicornis* (Figure 67) (*Entomobryidae*) and *Orchesella cincta* (Figure 68) (*Entomobryidae*) feed on fungi living on the moss *Tortella tortuosa* (Figure 69) preferentially over other fungi (Varga *et al.* 2002b). One can recognize *T. longicornis* because when it is disturbed, it curls the ends of its antennae (Figure 67). Gut contents of these two species consisted of detritus (55 & 63%), moss particles (20 & 33%), and fungal propagules (10 & 24%), respectively. The fungal gut contents were not in the same proportion as those on the moss, indicating that the springtails were selective in their choice of fungi.

Figure 69. *Tortella tortuosa*, home of fungi that serve as food for springtails. Photo by Michael Lüth, with permission.

Many springtails that live among mosses are treated to choices of fungi that grow in the association. At least some springtails are able to use olfactory cues – scents provided by the fungi – to both locate the fungi and to distinguish those that are poisonous (Staadén *et al.* 2011).

Bengtsson *et al.* (1988) further supported this discriminatory ability in the springtail *Onychiurus armatus* (Onychiuridae; see Figure 59). This species locates **hyphomycetous** fungi (fungi in Hyphomycetes; molds) by volatile compounds released by the **mycelium** (fungal threads). However, their choice of species differs depending on whether the fungus was grown on agar or on soil.

Sarah Lloyd sent me images of a Tasmanian endemic springtail species of *Acanthanura* (Figure 70) apparently dining on the plasmodium of the slime mold *Diderma* sp. (Figure 70-Figure 71) which is growing on a moss.

Predators

Bryophytes can be safe sites for the smaller creatures such as springtails. They make movement and even striking difficult for larger predators. But when the springtails are in the open spaces (Figure 72), their best protection is their powerful spring.

Miller *et al.* (2008) found a positive correlation among the bryophytes, springtails, and spiders in the Acadian Forest of Maine, USA. However, they found no correlation between number of **Collembola** and adult spiders (Miller *et al.* 2008). They considered spiders to be potential predators on bryophyte-inhabiting **Collembola**, thus confounding the correlations. The relationship between spiders and **Collembola** was sensitive to a decline in bryophyte abundance. This relationship with spiders might influence the abundance of the Brown Creeper (*Certhia americana*; Figure 73) (Miller *et al.* 2008), a bird that feeds on spiders that feed on springtails that live among bryophytes at the bases of trees (Mariani & Manuwal 1990; Weikel & Hayes 1999).

Figure 73. *Certhia americana* (Brown Creeper), part of the food web of bryophytes, springtails, and spiders at tree bases in Maine, USA. Photo by B. J. Stacey, through Creative Commons.

In the coastal grey dunes of France, Bonte and Mertens (2003) found that dwarf spiders considered springtails to be dinner there as well. They found a positive relationship between the phenology of the preferred springtails and the **stenotopic** (tolerating a narrow range of habitats) dwarf spiders. This was especially true for the female spiders because of their dependence on their prey, usually springtails, for reproduction. The spiders and springtails likewise have similar spatial aggregations. And the springtail aggregations typically occur among mosses.

The distribution of the spider *Coelotes terrestris* (Figure 74-Figure 75) was positively related to the cover of mosses and negatively related to litter cover in a beech-dominated (*Fagus sylvatica*; Figure 76) forest floor habitat in Europe (Sereda *et al.* 2012). But Sereda and coworkers did not find an association of spiders to prey-rich areas (**Collembola**) at the scale of 100 m, based on pitfall traps. It could be that the moss dwellers were within the moss clumps and not active near the traps, but these **Collembola** did have a positive relationship to medium deadwood pieces (**Entomobryidae** except *Lepidocyrtus* spp., Figure 77).

The Antarctic herbivore *Cryptopygus antarcticus* (Figure 78) is abundant in areas with bryophytes (Block 1985). The single arthropod predator, the mite *Gamasellus racovitzai* (see Figure 79) (*Ologamasidae*), feeds primarily on *C. antarcticus*, the most abundant of the available prey. In the summer this predator is non-selective and in the winter it does little feeding. Block considers it unlikely that such a predator ever has a shortage of food in bryophyte habitats. This aggregation has a strong relationship to moss cover. However, Usher and Booth (1986) considered *Gamasellus* (Figure 79-Figure 80) to have a random distribution. It is probably more accurate to say that the aggregations are random.

Wandering Salamanders (*Aneides vagrans*, Figure 81) prey on *Collembola* in the old-growth redwood forest of western USA (Camann 2011). In the canopy the springtails and mites are the most abundant arthropods, with springtails being by far the more abundant group. The salamanders hide in humus moss mats and other more moist locations in the crown of the tree and dine on these abundant springtails.

Figure 81. *Aneides vagrans*, a predator on *Collembola* that dwell in bryophyte refuges. Photo by Todd Pierson, with permission.

Adaptations

So how does a primitive, tiny, land-invader springtail survive among the bryophytes? First, being tiny is an advantage, making it possible for it to crawl about easily amid bryophyte leaves and stems and hide from predators. Some are blind (Figure 26), but that may be an adaptation to living in soil, with bryophytes also being a suitable habitat. Salmon and Ponge (2012) suggest that blind species may have better developed chemical senses. The ability to survive winter helps too. And its need for water is coupled with the ability to survive desiccation (Leinaas & Sømme 1984), making it well attuned to the wet-dry cycling in bryophytes.

Little has been written about adaptations to living among bryophytes, but Leinaas and Sømme (1984) described adaptations for *Collembola* that live among lichens on alpine rocks. Those should apply for many bryophytes as well, although the species of *Collembola*

may be different. The springtails *Xenylla maritima* (Figure 82) (**Hypogastruridae**) and *Anurophorus laricis* (Figure 83) (**Isotomidae**) in South Norway have seasonal cold hardiness. They prevent formation of ice crystals by gut evacuation in preparation for winter and accumulate cryoprotective substances during autumn in preparation for winter cold. These activities permit them to supercool below normal expected winter temperatures. However, those springtails in unprotected areas of the rocks were killed by an exceptionally cold period, suggesting the importance of lichens (or bryophytes) as a refuge. These two species are able to survive **anaerobic** (no free oxygen) conditions, permitting them to survive when their habitat is encased in ice. Both are able to survive drought stress. Reproduction later in the season than other **Collembola** species permits the hatchlings to emerge after the driest periods of summer.

Figure 82. *Xenylla maritima*, a lichen-dwelling species with seasonal cold hardiness in Norway. Photo by Jan van Duinen < www.janvanduinen.nl>, with permission.

Figure 83. *Anurophorus laricis*, a lichen-dwelling species with seasonal cold hardiness in Norway. Photo by Jan van Duinen < www.janvanduinen.nl>, with permission.

Salmon and Ponge (2012) speculated on adaptations for living among bryophytes and other communities associated with tree bark. They considered a short furcula, dark color, stocky body, and limited number of eyes (Figure 84) to be adaptations to living in concealed environments. These are accompanied by small size and limited movement. Pigmentation provides protection from UV light.

Figure 84. *Neelus murinus* showing few eyes and spherical body typical of epiphyte dwellers. Photo by Andy Murray, through Creative Commons.

Collembola commonly form aggregations (Figure 190). Benoit *et al.* (2009) suggest that in the Antarctic, where exposure is more dangerous, the **Collembola** *Cryptopygus antarcticus* (Figure 78) and *Friesea grisea* (see Figure 157) emit chemical cues (**pheromones**) that help them to locate each other, particularly for mating.

Sampling Methods

Pitfall traps are often used for trapping insects in the soil and have also been used to trap those inhabiting bryophytes (Drozd *et al.* 2009; Sereda *et al.* 2012). Drozd and coworkers express concern that the moss clumps are too dense for ease of movement by most invertebrates. Furthermore, the patchy, random distribution of aggregations of springtails necessitates a large number of samples.

Predators are active on the surface, but they are unable to navigate the "bushy obstacle" created by the mosses. On the other hand, **bryophagous** (eating bryophytes) and **detritivorous** (eating dead organic matter – detritus) arthropods such as **Collembola** have no reason to leave the moss clump, again avoiding traps. Similar problems are encountered when using **fogging** techniques (pesticides) to collect arthropods from canopy bryophytes (Yanoviak *et al.* 2003). The bryophyte dwellers fail to drop from the moss clumps.

Shaw (2013) suggested the use of "inert" pads to collect small arthropods as a nondestructive method in areas with sensitive cover of bryophytes. Standard scouring pads are ideal because of their relatively large pore spaces that somewhat resemble moss clumps. The accumulated arthropods can then be extracted using a Tullgren funnel (see below). He found that the percent of total species of sampled **Collembola** communities were between those of soil and those of bark (Figure 85). The numbers were slightly less than those of soil. I have to wonder if the paucity of food would not greatly decrease the number potential.

Heat gradients are common methods for extracting invertebrates from soil and bryophytes (Tuf & Tvardik 2005; Božanić *et al.* 2013). Nadkarni and Longino (1990)

used a Winkler sifting apparatus to extract insects, including **Collembola**, from tropical canopy samples. Hoyle and Gilbert (2004) used a similar method with the Tullgren funnel. The Berlese funnel is a similar method (Briones 2006). Block (1982) used a gradient of temperature and moisture for six days to extract **Collembola** from bryophytes and soil, based on a method used for lichens (Goddard 1979). Brantley and Shepherd (2004) used heptane flotation to extract springtails and other invertebrates from lichens and mosses in cryptogamic crusts in the piñon-juniper woodland in New Mexico, USA. See Chapter 4-1 of this volume for more information and an illustration on heat gradients.

Figure 85. The proportion of **Collembola** collected by three different sampling techniques. Modified from Shaw 2013.

Andrew and Rodgeron (1999) found that the kerosene phase separation was especially more effective in extracting larger numbers of mites and springtails when compared to heat separation with the Tullgren funnel or sucrose flotation (Pask & Costa 1971; see Chapter 12-1 in this volume). Especially for **Collembola**, they concluded that two samples should be used and extracted as replicates, rather than a bulk sample, because of the important effect that spatial scales have on the distribution of these invertebrates.

Temperature Survival

Zettel (1999) examined the cold hardiness of alpine **Collembola**. He found that the winter-inactive hibernator *Entomobrya nivalis* (Figure 86) (**Entomobryidae**), an inhabitant of mosses on boulders, builds up cold hardiness in an anticipatory fashion, using photoperiod and temperature as cues, whereas the winter-active *Isotoma hiemalis* (**Isotomidae**) only responds to sub-zero ($<0^{\circ}\text{C}$) temperatures. Alpine populations of *E. nivalis* living among the lichens on trees hibernate through the winter in crevices under bark flakes. This was the only alpine species Zettel found to increase its low-molecular-weight antifreeze in the winter, making it more sluggish compared to its behavior at the same temperatures in summer. But when this species overwinters in Norway where the temperatures are even colder, it hibernates under the snow (Leinass 1983).

Figure 86. *Entomobrya nivalis*, a moss-dwelling species that anticipates oncoming cold based on photoperiod and temperature. Photo by Steve Hopkin, with permission.

Some alpine **Collembola** survive winter by going deeper into the soil (Zettel (1999)). Soil surfaces under the snow are typically above 0°C , despite subzero air temperatures. And deeper in the soil the temperature is typically even warmer. Spaces in the soil make such migrations to deeper locations possible.

Pigmentation provides a mechanism for absorbing heat, even at low temperatures. Zettel (1999) reported that only one snow-dwelling, winter-active collembolan in the European alpine area had a light color. All others were dark in color. This dark color simultaneously protects them from the high UV radiation present in the alpine zone.

Since **Collembola** are common among bryophytes in the Antarctic, it is easy to understand that the **Collembola** there must have special means to tolerate the low temperatures. These can include physiological adaptations that protect them against the formation of internal ice crystals, the ability to supercool, and life cycle adaptations in which they are dormant during the long, cold winters. Coulson and Birkenmoe (2000) found that the springtails *Hypogastrura tullbergi* (Figure 87) (**Hypogastruridae**) and *Folsomia quadrioculata* (Figure 88) (**Isotomidae**) survived for four years at temperatures below -22°C in soil samples in the lab.

Figure 87. *Hypogastrura tullbergi*, a species that can survive for four years at -22°C . Photo by Arne Fjellberg, through Creative Commons.

Figure 88. *Folsomia quadrioculata*, a species that can survive for four years at -22°C . Photo by Andy Murray, through Creative Commons.

One mechanism in two common Antarctic *Collembola* species is the ability to **supercool** (Block *et al.* 1978). *Cryptopygus antarcticus* (Figure 78) can supercool to -30°C . To do this, they must evacuate the gut by starvation prior to winter cold. This can protect them against internal ice crystal formation by removing water. Such behavior seems to be common among *Collembola* that must endure low temperatures. They lack freeze tolerance, so supercooling is their only physiological survival mechanism (Sømme 1981). For this to work, the gut must be empty to avoid the danger of **ice nucleation** (formation of crystals around proteins and other nucleators). Accumulation of **glycerol** or other **cryoprotectant** (substance that protects against damage by low temperatures) further helps them to survive. Glycerol is used to keep insects from drying out completely in museum collections. Could it serve a similar function for the live animal?

Cannon (1986) likewise demonstrated the importance of evacuation of the gut in preparation for cold weather. He investigated the common *Cryptopygus antarcticus* (Figure 78) (*Isotomidae*) from Signy Island in the Antarctic. If the animal has a diet of moist algae and distilled water at 5°C , it loses most of its ability to supercool. The guts of field-collected animals contain unicellular green algae, dead mosses, fungi, and mineral particles, but living mosses are absent in the gut. As winter approaches, these springtails exhibit a decline in feeding activity. Those foods containing potential **ice nucleators** (small particles such as proteins that serve as the centers for ice crystal formation; such crystals damage cell membranes) are eliminated and replaced by alcohols such as **glycerol**. The glycerol renders a **cryoprotective** (protection against cold) role and is produced in response to low temperatures.

Some Antarctic *Collembola* survive because they live among bryophytes in geothermal areas where temperatures remain warm year-round. In the heat-tolerant *Campylopus introflexus* (Figure 89), the upper 0.5 cm of the moss remains at $40\text{--}47^{\circ}\text{C}$ (Convey & Lewis Smith 2006). More *Collembola*-friendly temperatures occur in slightly cooler geothermal sites. The mosses *Anisothecium hookeri*, *Sanionia georgico-uncinata*, *Pohlia nutans* (Figure 90- Figure 91), and *Notoligotrichum trichodon* (Figure 92), and the liverworts *Cryptochila grandiflora* (Figure 93) and *Marchantia berteriana* (Figure 94) live where

temperatures are $25\text{--}35^{\circ}\text{C}$ and subsurface temperatures are $50\text{--}60^{\circ}\text{C}$.

Fertilizing Mosses

The most exciting bryological discovery this century, at least for me, has been that of arthropod fertilization of mosses. This was presented to us in a video at the biennial meeting of the International Association of Bryologists in Kuala Lumpur, Malaysia. Cronberg *et al.* (2006) found that the relationship between mosses and mites (*Scutovertex minutus*, *Scutoverticidae*) or **Collembola** (*Isotoma caerulea*, *Isotomidae*, Figure 95) can be **mutualistic** (both benefitting). In their experiments, these arthropods served as sperm vectors for the moss. This relationship permits sperm to reach females 10 cm, even 1

m, away (Milius 2006). In experiments, if the mosses were even as close as 2-4 cm, they did not reproduce unless they had one of these arthropod vectors to transfer the sperm. The springtails are more effective than the mites in making the transfer. Both seem to be attracted by something in the female moss because they visit it more often than they do the males (Figure 96 (see also Chapter 6-3 in this volume). That's good, because one visit to a male could potentially carry many sperm and thus fertilize a number of females.

Figure 94. *Marchantia berteroa* female, a thallose liverwort that provides a suitable habitat for **Collembola** in geothermal areas of the Antarctic. Photo by Clive Shirley, Hidden Forest, with permission.

Figure 95. *Isotoma caerulea* on mosses, a species that fertilizes some moss species. Photo by Andy Murray, through Creative Commons.

Figure 96. Gender preference of *Ceratodon purpureus* by springtails in Petri dishes (**left**) and olfactometer (**right**). Bars are means with error bars. *** $P < 0.0001$. From Milius 2006.

Both of the mosses *Ceratodon purpureus* (Figure 97) and *Bryum argenteum* (Figure 98-Figure 99) use springtails (*Folsomia candida*, Figure 10-Figure 11,

Figure 97) to transfer their sperm (Cronberg *et al.* 2008; Rosenstiel *et al.* 2012). It is ironic that this species that lacks sexual reproduction itself helps to accomplish it in mosses. Rosenstiel *et al.* demonstrated that springtails are attracted by volatile substances emitted from the moss *Ceratodon purpureus*. Furthermore, these volatile chemicals are sex-specific. Much as in flowering plant pollination, the springtails significantly increase moss fertilization rates (Figure 100). But unlike in pollination, water is important in springtail transfer of sperm. Rosenstiel and coworkers found that water alone and springtails alone were equally effective at fertilizing mosses, but when the two were present together, moss reproduction was more than twice as successful (Figure 100).

Figure 100. Fertilization success in *Ceratodon purpureus* and *Bryum argenteum*, measured as the fraction of microcosms that developed sporophytes. Bars are means \pm standard error. Plus and minus symbols represent the presence and absence of springtails and water spray. $n = 108$ microcosms. * $P < 0.05$. Modified from Rosenstiel *et al.* 2012.

Bisang and Hedenäs (2015) suggest that springtails, and perhaps other organisms, may be more widespread among bryophytes as agents of fertilization than we have realized. They found *Xenylla humicola* (Figure 101) in great numbers on *Tortula cernua* (Figure 101). Further examination revealed a mix of immature and mature antheridia and mature archegonia. They postulated that the mosses produce a volatile substance at this stage that

attracts the springtails. The springtails, in return, increase the fertilization success. This moss, unlike the previous examples in dioicous mosses, is **autoicous** (antheridia & archegonia in different clusters on the same plant). Hence, we have three examples in three different moss families (**Bryaceae**, **Ditrichaceae**, **Pottiaceae**) to demonstrate moss fertilization by **Collembola**. Thus far no examples are known for pleurocarpous mosses or liverworts.

Figure 101. *Xenylla humicola* on *Tortula cernua* during fertilization season for the moss. Photo courtesy of Lars Hedenäs & Irene Bisang.

There is yet another case of a member of *Xenylla* that can live in the spent antheridial cup of *Polytrichum piliferum* (Fjellberg *et al.* 2017). This species, *Xenylla maritima* (Figure 102), presents a puzzle because two individuals were curled up there when the splash cup was already producing new growth from the center, indicating that the sperm had already been dispersed much earlier. Hence, we are left to wonder what attracted them to this location, and in the right season do they facilitate dispersal of the sperm.

Figure 102. *Xenylla maritima*, an isopod, in the male splash cup of the moss *Polytrichum piliferum*. Note the new, green growth in the center of the cup. Photo by Arne Fjellberg, with permission.

Habitat Differences

Bryophytes in different habitats house different species of *Collembola*. These differences seem to be primarily the result of the habitat differences, not the bryophyte differences. In either case, moisture is an important determinant (Lek-Ang *et al.* 2007).

Bogs and Wetlands

Blackith (1974) pulled together the known literature on *Collembola* from blanket bogs in Ireland and assessed their ecological needs. He found that they are sensitive to

waterlogging, being driven from the peat in spring when the water level rises. This is time of high mortality for them, in part because they have lost their shelter. They benefit from the heat sink provided by the bog mosses, and only a small number of them have a dark color as would be typical of tundra species. This lack of dark color is more typical of tropical species. The *Collembola* are very specific in their choice of host (food) plants, essentially eliminating competition between *Collembola* species.

Many bog *Collembola* are also associated with a particular layer/depth of the peat. Krab *et al.* (2010) experimented with the parameters that determine that depth by literally turning the bog layers upside down with their *Collembola* inhabitants still in them. The responses were of two sorts. The **stayers** remained with the stratum they were in, thus remaining with the substrate of choice. The **movers** left the original position and returned to the vertical position corresponding to their original position. Presumably, the latter group sought a suitable moisture and temperature level. These *Collembola* are important in making the peat suitable for decomposers, and the behavior of the mover group suggests that if the bogs were to undergo warming, this would affect the faunal composition and decomposition rate of the bog.

In a further study of this decomposition relationship, Krab *et al.* (2013) found that in a high-latitude ecosystem, increased litter from birch (*Betula pubescens*), a predictable event from global warming, changed the feeding habits of the resident *Collembola*. Instead of their normal levels of the peat moss *Sphagnum fuscum* (Figure 103) in the diet, all species switched to a strong dietary preference (67%) for *Betula*-associated food sources instead of *Sphagnum*. This resulted in slower decomposition of the *Sphagnum* litter while the *Collembola* species composition remained the same.

Figure 103. *Sphagnum fuscum*, home of *Collembola* with non-specific feeding habits. Photo by Jutta Kapfer, with permission.

In 13 mire habitats of Norway, Fjellberg (1976) found 35 species of surface-active species of *Collembola*. He even found three species new to Norway: *Isotoma tenuicornis* (see Figure 104), *Arrhopalites cochlearifer*, and *Sminthurides pseudassimilis*. Typical mire inhabitants included *Desoria olivacea* (Figure 105), *Isotoma neglecta*, *I. tenuicornis*, *Isotomurus plumosus* (Figure 106),

Sminthurides aquaticus (Figure 107), *Arrhopalites principalis* (Figure 108), and *Heterosminthurus novemlineata* (Figure 109). As is typical with other insects, the highest species richness occurred in the transition zone between the mires and the forest.

Figure 109. *Heterosminthurus novemlineata*, a typical species in Norwegian mires. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Sławska (2000) found that even the small basin bogs of pine forests have **stenotypic** (able to live in only a narrow range of environmental conditions) species of **Collembola**. These included many typical mire species: *Ceratophysella mosquensis* (see Figure 110), *C. scotica*, *Isotomurus plumosus* (Figure 106), *Ballistura crassicauda*, *Arrhopalites principalis* (Figure 108), *Sminthurides schoetti* (Figure 111), *S. malmgreni* (Figure 112), *S. parvulus* (Figure 113), and *S. pseudassimilis*. Rare species included *Isotoma neglecta*, *I. tenuicornis*, *Desoria fennica* (Figure 114), *Folsomia bisetosa* (Figure

115), *Pseudanurophorus binoculatus* (Figure 116), *Arrhopalites spinosus*, and *Stachorutes sphagnophilus*. Seven of these species are the same as those found by Fjellberg (1976) as typical of the Norwegian mires. Slawska found that the species composition and diversity varied with the size of the peatland, mire type, water conditions, plant communities, and topography, but that the boreal-alpine species in basin bogs did not seem to relate to these parameters. Instead, geography seemed to be an important determinant of the boreal-alpine communities.

Kuznetsova (2002) found that *Vaccinium myrtillus* and green mosses serve as indicators of mesic conditions where one can find **mesophilous** (loving mid-moisture conditions) **Collembola**. The *Sphagnum* communities

typify wet sites and house **hygrophilous** (water-loving) **Collembola** communities. Saraeva *et al.* (2015) identified **continuous** and **spotty distributions** of **Collembola** in **Sphagnum** pine forests of Karelia, Russia. But these patterns are influenced little by relative humidity, mass of moss cover, and litter thickness.

Predators are important in reducing springtail numbers. Bardwell and Averill (1997) found 24 spider genera that possessed prey items in cranberry bogs in Massachusetts, USA. Among 7009 spiders, 2.7% of them possessed prey. The prey items represented 11 orders of insects; 18.6% of these were **Collembola**.

Forests

Moisture seems to be a primary driving factor in delineating differences among collembolan communities. Lek-Ang *et al.* (2007) examined the gradient from forest to peat bog in the French Pyrenees and found a total of 63 species using 48 samples in the bog and 20 in the forest. They found that the peat bog communities were always distinct from those of the forest. Variations were strongly correlated with substrate water content, **Sphagnum** (Figure 117), and grass cover. In this case, the **ecotone** (transition zone between two biological community types) between the forest and bog did not display a greater **species richness** (number of species). (Generally an ecotone has species of both communities, resulting in greater species richness).

Snider (1967) reports collecting *Bourletiella arvalis* (**Bourletiellidae**, Figure 118) from *Sphagnum* (Figure 117) in Michigan, USA, forests. *Sminthurinus quadrimaculatus* (**Katiannidae**; Figure 119) occurred in forest moss scrapings and *Lepidocyrtus cyaneus* (Figure 120) and *L. helenae* among mosses.

Figure 120. *Lepidocyrtus cyaneus*, a species from forest mosses in Michigan, USA. Photo by Steve Hopkin, with permission.

Miller *et al.* (2007) found that the abundance of most of the **Collembola** species in the Acadia Forest in Maine, USA, were correlated with the dense bryophyte cover at the base of sampled trees. Only the family **Isotomidae** (Figure

10-Figure 11) seemed to decrease in abundance as bryophyte cover increased. Instead, this family was primarily associated with the epiphytic lichen *Usnea subfloridana* (Figure 121) higher up the trees. Nevertheless, Snider (1967) listed few *Collembola* from bryophytes outside of bogs in his treatment of Michigan, USA, *Collembola*. Could it be that the human collectors have the same problem as the predators – the *Collembola* are too difficult to see or capture when they live among the bryophytes?

Figure 121. *Usnea subfloridana*, preferred home for *Isotomidae* compared to mosses. Photo by Jerzy Opiola, through Creative Commons.

Majzlan and Fedor (2003) found that springtails may "crawl" up trees, observing this activity on the trunks of *Aesculus hippocastanum* (horse chestnut) in Slovakia (but they were unable to observe downward movement). They determined that this activity might relate to their trophic preference (bryophytes, lichens, algae) or to their tolerance of soil humidity. [Davies (1928) found that the optimum humidity for *Collembola*, except *Entomobrya*, at 25°C was a saturated atmosphere.] Majzlan and Fedor (2003) documented that there were four times as many springtails in the lower (1 m) tree samples compared to the upper ones (5 m), but in autumn, this number increased to ten times as many in the lower samples.

Rodgers and Kitching (1998) examined the vertical stratification of *Collembola* in the subtropical rainforest site at Lamington National Park in southeast Queensland, Australia. They found that the vertical stratification was complex for the arthropods. The greatest homogeneity existed among samples on the forest floor and the greatest dissimilarity in the upper canopy. They considered that dispersal barriers might account for some of the observed differences, accompanied by a greater risk of extinction in the upper canopy. These two limiting factors could account for the greater heterogeneity of canopy *Collembola* species. Since Rodgers and Kitching used leaf litter as a substrate to sample the *Collembola*, suspending the samplers in canopy epiphytes, it is unclear how these differences relate to stratification of bryophyte-*Collembola* communities.

Forest Floor

Deciduous forests and conifer forests have very different ground flora. Bryophytes in deciduous forests are restricted to emergent structures such as logs, stumps, tree bases, vertical inclines, and rocks. This is because the leaf litter buries them elsewhere. These bryophytes serve as important habitats for *Collembola*.

In a boreal forest in northern Sweden, removal of mosses, such as that following fire, strongly negatively impacted both abundance and diversity of the *Collembola* (Bokhorst *et al.* 2014). On the other hand, the species diversity of the *Collembola* community gradually increased with forest decline in Tam Dao National Park, Vietnam (Vu & Nguyen 2000). A major reason for the correlation of *Collembola* with bryophytes is the need of these springtails for moisture, whether it be in the bryophyte mat or is the soil beneath them (Jucevica & Melecis 2005).

For some species, mosses are a seasonal habitat. In a spruce forest of the High Tatra Mountains, Slovakia, there is a mosaic cover of the mosses *Dicranum scoparium* (Figure 122) and *Hylocomium splendens* (Figure 123) (Čuchta *et al.* 2012). *Vertagopus cinereus* (Figure 124) lives in that moss layer in winter and in early spring, but it migrates into the soil during summer (Prat & Massoud 1982). On the other hand, Čuchta *et al.* (2012) found that in this same spruce forest, *Orchesella cincta* (Figure 68) and *Xenylla tullbergi* are far more common among bark pieces and tree mosses and lichens than in the litter layer.

Ponge *et al.* (1993) experimented with litter perturbations to see the effects on the *Collembola* community. They found that the bog species *Sminthurides schoetti* (Figure 111) and *S. parvulus* (Figure 113) increased in abundance following litter disappearance in the forest. These two species are typical of *Sphagnum* bogs (Stach 1956; Gisin 1960; Sławska 2000). Ponge (1993) concluded that vegetation does not itself directly influence the *Collembola*, but that it may affect them indirectly by humus formation.

In *Picea sitchensis* (Figure 125) plantations, succession after cutting starts with unvegetated needle litter and progresses to well-developed herb or shrub layers that then become suppressed by shade during canopy closure about 15-20 years after clear-cutting (Butterfield 1999). Depending on thinning, little ground vegetation may remain, but sparse moss cover may be present. **Collembola** densities were high in spring when the canopy was open, decreasing in summer. Under closed canopy, the opposite relationship occurred, with drying most likely accounting for the low summer densities in the open. The closed canopy also supported higher **Collembola** densities in the upper soil layer than in the drier ones under the open canopy.

The Checklist of Nordic **Collembola** notes mosses among the habitats for many **Collembola** species (Fjellberg 2007b). These include *Micranurida anophthalmica* (Neanuridae), a rare species among mosses on rotten wood; *Appendisotoma abiskoensis* (Isotomidae) among boreal forest mosses; *Pseudisotoma sensibilis* (Figure 141, common) (Isotomidae), *Orchesella spectabilis* (Entomobryidae; Figure 126), *Pogonognathellus flavescens* (Tomoceridae; Figure 127), and *Lipothrix lubbocki* (Sminthuridae; Figure 128-Figure 129) in moss and forest litter; *Orchesella cincta* (Figure 68) common in moss and dry forest litter; *Orchesella flavescens* (Figure 130) in moss and litter in damp forests, mainly conifers; *Pogonognathellus longicornis* (Figure 131) among mosses and forest litter, mainly hardwoods; *Sminthurinus aureus signatus* (Katiannidae; Figure 132) in moss and litter of damp habitats in forests; and *Gisinianus flammeolus* (Katiannidae; Figure 133) in moss and litter of rich, moist hardwood forests.

Tetrodontophora bielanensis (Onychiuridae; Figure 134) is common on the forest floor of the Bielany Hills near Kraków, Poland, where it lives among dead leaves, mushrooms, and on mosses (Klag 1982). In Hungary, *Xenylla brevisimilis* and *Tetracanthella franzi* (Isotomidae) occur in mosses and litter (Dány & Traser 2008). *Tetracanthella wahlgreni* (Figure 135) lives among xerophilous (dry-loving) mosses and lichens.

Andy Murray (2015) describes chasing *Sminthurides schoetti* (Sminthuridae; Figure 136) through a "forest of moss" in order to get its picture. It at least appears to use mosses to escape as well as being a common bog dweller. Murray describes finding *Stenacidia violacea* (Sminthuridae; Figure 137-Figure 139) among mosses. This forest species is relatively common and may even use bryophytes for mating sites (Figure 137).

Some species that live on rotten wood also take advantage of the mosses occurring there. Such is the case for *Sminthurinus bimaculatus* (Figure 140) as seen in this picture by Andy Murray. *Pseudisotoma sensibilis* (Isotomidae; Figure 141) prefers cushions on logs not far above the ground (Bauer & Christian 1993).

Entomobrya muscorum (Figure 142) has been a puzzle for me. This species has a name that suggests that it

should live among mosses. But instead, I was able to verify it as living on soil. Finally, as I was preparing the final formatting of this sub-chapter, I made one more search. A study on nematode predators on other invertebrates verified that it does indeed live among mosses as well, and it eats nematodes there (Heidemann *et al.* 2014).

Epiphytes

The epiphytic bryophytes seem like an unlikely habitat for an insect with a spring on it. But not all "springtails" have springs. Hence, they may be small and round, lack a furcula, be small, and produce a glue that helps to hold them to the tree or catch them like a tether when they fall.

Dicyrtoma fusca (Figure 5) is well adapted to living among epiphytic bryophytes by its small, globular shape (Figure 143) (Traser *et al.* 2006; Nature Spot 2015). It feeds on mold and other fungi. Dány and Traser (2008) found that *Xenylla boernerii* (Figure 144) is **corticophilous** (bark-loving), living among epiphytic mosses in Hungary; its furcula is reduced to two small warts. Fjellberg (2007b) reported *Entomobrya albocincta* (Figure 145) (**Entomobryidae**) and *Pseudachorutes boernerii* (Figure 146) (**Neanuridae**) in mosses and lichens on trees in the Nordic countries. These two genera do have well-developed furculas.

Both epiphytic bryophytes and **Collembola** are affected by gap harvesting. Wagner *et al.* (2007) found that springtails, mites, and spiders were most abundant near the tree bases in the Acadian forest of central Maine, USA. Gap harvesting reduced the abundance of all three of these groups on the bark of red maple (*Acer rubrum*; Figure 147). There was a positive correlation among these three groups. It is likely that the spiders preyed on the **Collembola** and that gap harvesting affected the spiders by affecting their prey. Miller *et al.* (2008) found that spiders tended to be where the **Collembola** were, but they also found indications of an association between six families of **Diptera** (flies) and members of the **Collembola** family **Entomobryidae**.

Figure 147. *Acer rubrum* in autumn, home of springtails, mites, and spiders among epiphytic bryophytes. Photo by Anderson & Ryser (2015), through Creative Commons.

Cutz-Pool *et al.* (2010) examined **Collembola** communities at three different heights among epiphytic mosses on trees in Mexico, where they collected 12 **Collembola** species. Both species richness and density decreased with increasing height on the tree. Height on the tree had a significantly negative effect on the densities of *Pseudachorutes subcrassus* (**Hypogastruridae**; see Figure 146), *Entomobrya* cf. *triangularis* (**Entomobryidae**), *Americabrya arida* (**Entomobryidae**; Figure 148), and *Ptenothrix marmorata* (**Dicyrtomidae**; Figure 149).

Figure 149. *Ptenothrix marmorata*, an epiphytic moss dweller. Photo by Tom Murray, with permission.

The epiphyte mats of tropical cloud forests provide important niches for a diverse microarthropod community, including the **Collembola** among the most abundant (Yanoviak & Nadkarni 2001). The bryophytes buffer the environment against the wind, retain moisture, provide foraging sites, provide shelter for egg deposition, and provide safe sites against predators (Gerson 1982; André 1983; Nadkarni 1994; Kitching *et al.* 1997; Yanoviak *et al.* 2004). Yanoviak *et al.* (2004) investigated the differences in arthropod communities in the green vegetative portion and brown humic portions of these epiphytic mats, a portion of which was comprised of bryophyte species. The dominant arthropods were mites, ants, and springtails. The green portion of the mats housed twice as many arthropod individuals and species per gram compared to the brown portion and **Collembola** were more abundant in the green portion.

In a neotropical montane forest in Costa Rica, Nadkarni and Longino (1990) found that while the relative abundance of arthropods, including **Collembola**, are essentially the same on the forest floor and in the canopy. The densities of all groups except ants are significantly higher on the ground by a factor of 2.6. Among these, mites, beetles, ants, and springtails are consistently the most abundant arthropod taxa in the mats of epiphytes and humus (Longino & Nadkarni 1990; Nadkarni & Longino 1990; Paoletti *et al.* 1991; Yanoviak & Nadkarni 2001; Yanoviak *et al.* 2003).

A number of additional species of **Collembola** live among bryophytes on both tree trunks and boulders, as discussed below.

Boulders and Rock Canyons

As in trees, some bryophytes can provide the necessary moisture for collembolans in the harsh environment of boulders and rock walls. Hence, bryophytes on boulders share many of the same **Collembola** species that live among bryophytes on tree trunks. Fjellberg (2007a) included *Vertagopus arboreus* (Figure 151) (**Isotomidae**), *Vertagopus westerlundi* (Figure 152), *Vertagopus pseudocinereus* (Figure 153), and *Pseudisotoma sensibilis* (Figure 141) (**Isotomidae**) among boulder and tree trunk mosses in Fennoscandia and Denmark. Likewise, the Nordic **Collembola** include many species common to mosses of both boulders and tree trunks (Fjellberg 2007b): *Orchesella bifasciata* (**Entomobryidae**; Figure 150), *Xenylla boernerii* (**Hypogastruridae**; Figure 144), *Tetracanthella strenzkei* (**Isotomidae**; see Figure 158), *Vertagopus arboreus* (**Isotomidae**; Figure 151), *Vertagopus westerlundi* (northern; Figure 152).

Figure 150. *Orchesella bifasciata*, a Nordic species of mosses on boulders and tree trunks. Photo by Anki Engström <www.krypnaturen.se>, with permission.

Figure 153. *Vertagopus pseudocinereus*, a species that lives among mosses on boulders and tree trunks. Photo by Jan van Duinen, with permission.

But boulders can also have unique assemblages of bryophyte-dwelling **Collembola**. In beech and spruce forests in Bohemia, Rusek (2001) found that the **Collembola** communities among mosses on boulders differed significantly from other forest communities. Forest age and microhabitat characteristics were important in determining the forest collembolan inhabitants, and some species were restricted to only one or two microhabitats. As in a number of other studies, Rusek demonstrated the importance of examining both local patch variation and broader ecosystem differences.

Onychiurus armatus (Onychiuridae; see Figure 59) lives exclusively in moss cushions on granite boulders in Australia where the microclimate is stable, taking advantage of the supercooling ability and avoiding the need to cross bare rock (Bauer & Christian 1993). *Xenylla boernerii* (Figure 144) is the dominant species when the microclimate is unstable in cushions on boulders and does not share any aversion to bare rock. The mosses may help these collembolans to survive the winter.

Wood (1967) found it difficult to categorize communities associated with moorland soils in Yorkshire, England, based on the species assemblages of 200 species of mites and springtails. However, on limestone boulders one indicator emerged – the springtail *Anurophorus laricis* (Isotomidae; Figure 83) seemed to be characteristic of the moss genus *Grimmia* (Figure 154) and lichens on these boulders.

Figure 154. *Grimmia pulvinata* on a wall where **Collembola** live among them. Photo from Botany Department Website, University of British Columbia, Canada, with permission.

In Fennoscandia and Denmark, Fjellberg (2007a) adds the rock/boulder-dwelling *Isotomurus antennalis* (Entomobryidae; Figure 155) in damp moss of rocky habitats and *Vertagopus sarekensis* (Isotomidae; Figure 156) among mosses and lichens on alpine rocks. Among the Nordic **Collembola** (Fjellberg 2007b), rock and boulder dwellers include *Friesea claviseta* (Neauridae; Figure 157), *Anurophorus fulvus* (Isotomidae) and *Anurophorus laricis* (Isotomidae; Figure 83) (common) in moss/lichen patches on rocks, *Vertagopus sarekensis* and *Vertagopus arcticus* among alpine mosses on rocks, *Megaphorura arctica* (Onychiuridae; Figure 63) common in the Arctic on rocks with moss/algae growth, *Tetracanthella arctica* (Isotomidae; Figure 158) in the Arctic among mosses and lichens on seashore rocks, and *Isotomurus antennalis* among wet mosses on rocks of seashores. In Michigan, USA, Snider (1967) reports *Isotoma nigrifrons* (Isotomidae) from mosses on a rocky bluff.

Figure 158. *Tetracanthella arctica*, a species that lives in the Arctic among mosses and lichens on seashore rocks. Photo by Arne Fjellberg, through Creative Commons.

Some boulder-dwelling **Collembola** are more specific in their locations. *Mackenziella psocoides* (Mackenziellidae) occurs in rock fissures and among mosses on sand (Fjellberg 2007b). *Folsomia*

coeruleogrisea (**Isotomidae**; Figure 159) lives among mosses on **bird cliffs** (steep cliffs with numerous small shelves that serve as nesting locations for bird colonies).

Figure 159. *Folsomia coeruleogrisea*, a species among mosses on bird cliffs. Photo by Arne Fjellberg, through Creative Commons.

Boulders can present harsh conditions for **Collembola**, particularly on a hot summer day. And some boulders are subject to frequent disturbance. Inhospitable conditions make it difficult for the tiny springtails to navigate from one moss patch to another. Hoyle and Gilbert (2004) studied the role of bryophyte corridors in movement of **Collembola** and other arthropods among bryophyte [*Homalothecium sericeum* (Figure 160), *Brachythecium rutabulum* (Figure 161), *Hypnum lacunosum* var. *lacunosum* (Figure 162)] patches on a wall habitat, a good model for boulders as well. They found 12 morphospecies of **Collembola**, including *Entomobrya nivalis* (**Entomobryidae**; Figure 86), *Orchesella villosa* (**Entomobryidae**; Figure 163), *Tomocerus minor* (**Entomobryidae**; Figure 164-Figure 165), *Neanura muscorum* (**Neanuridae**; Figure 166), *Pseudisotoma sensibilis* (**Isotomidae**; Figure 141), *Dicyrtomina minuta* (**Dicyrtomidae**; Figure 167-Figure 168), and *Lepidocyrtus curvicolis* (**Entomobryidae**; Figure 169). These were represented by 314 individuals per moss patch, on average. Numbers were positively correlated with patch weight. They found no evidence that populations of predators were more affected by fragmentation than non-predators. Hoyle and Gilbert suggested that corridors of mosses might be more important during extreme conditions.

Limestone outcrops are absent in many parts of the world. Some **Collembola** prefer living among mosses in such habitats. In Moldova, several species of *Orchesella* (Figure 150) and *Entomobrya* (Figure 86) occurred in these habitats, with *Orchesella maculosa* occurring in most of the canyons in the Moldova study, but not in other ecological conditions (Buşmachi *et al.* 2015).

Considering this problem of migrating from one patch to another, Starzomski and Srivastava (2007) examined the effect of fragmentation of moss patches and the importance of disturbance on mites and springtails – two taxa comprising more than 200 morphospecies in <20 m². The moss community covered a granite outcrop in British Columbia, Canada, and was comprised of *Polytrichum* (Figure 170) and *Bryum* (Figure 171) moss species. Starzomski and Srivastava determined that the disturbance

rate, size, and connectivity were the most important factors affecting species richness and abundance in local patches. Reductions in patch size had little effect unless there was also an absence of connectivity between patches. Repeated disturbance also caused rapid declines in both richness and abundance and caused considerable change in the community composition.

Vertical Gradients

The transition from soil to soil bryophytes to boulder bryophytes creates a gradient of moisture, light, and food sources. Bonnet *et al.* (1975) considered this gradient for 26 species of **Collembola**, but restricted the observations to the soil and aerial mosses and ignored the soil mosses. On the south faces of rocks, the habitat is dry with highly drained mosses. On the north sides of the rock the soil is deep. The gradients of **Collembola** in these locations emphasize the importance of humidity and temperature in determining the distribution of these moss-inhabiting springtails.

Mountains, Alpine, and Arctic

Fjellberg (2007b) has contributed much to our knowledge of **Collembola** among the bryophytes in alpine and Arctic areas. These records include *Folsomia binoculata* (**Isotomidae**; Figure 172) in wet mossy habitats, Arctic Islands only; *Folsomia agrelli* (**Isotomidae**; Figure 173), rare in high alpine wet moss communities; *Desoria tolya* (**Isotomidae** Figure 174) in moss and forest litter, more common in alpine rocky habitats; *Sminthurinus concolor* (**Katiannidae**; Figure 175) in damp moss on rocks of the Arctic tundra.

Figure 173. *Folsomia agrelli*, a rare species among high alpine wet mosses. Photo by Arne Fjellberg, through Creative Commons.

In the poor high mountain areas of the North Swedish Mountains, Agrell (1941) found the **Collembola** to be well represented by **stenotopic** species (able to tolerate only a restricted range of habitats or ecological conditions) with few stenotopic **Coleoptera** (beetles), but he found no characteristic bog species there.

In the Russian tundra, Bretfeld (2010) reported *Arrhopalites principalis* (Arrhopalitidae; Figure 176) in moss, *Sminthurinus alpinus* (Katiannidae; Figure 177) in moss-lichen tundra, *S. oiskiyensis* in moss on rocks along a river in a small forest with *Abies sibirica* at 1300 m altitude, and *Sminthurus cogsonzavi* (Sminthuridae) in an alpine moss-lichen tundra at 1500-1800 m altitude.

Altitudinal Gradients

Cutz-Pool *et al.* (2008) examined altitudinal gradient effects on the structure of the collembolan community among **epiphytic** (bark) mosses in a sub-humid forest in Mexico. Density was greatest at the highest altitude (3250 m asl), but species richness was highest at the lowest altitude in the study (2750 m asl). Density had a significant positive relationship with altitude. *Americabrya arida* (Figure 148) and *Willowsia mexicana* (Figure 178) (both **Entomobryidae**) were the dominant species among these epiphytic mosses.

Antarctic Bryophyte Communities

The Antarctic continent is covered with ice except for about 2% of the surface (Seppelt & Ochyra 2008). The vegetation is comprised of lichens, bryophytes, algae, Cyanobacteria, and fungi. **Collembola**, **Diptera**, and mites are the predominant arthropod fauna (Strong 1967; Tilbrook 1967), and the lichens and bryophytes provide a suitable cover (Tilbrook 1973 – Signy Island; Lewis Smith 1996). In the drier areas, the bryophytes are covered with algae and Cyanobacteria (Green & Broady 2001).

Even bryophytes with very different species can have similar trophic levels. Davis (1981) examined two moss communities on Signy Island in the Antarctic. One was a moss turf dominated by *Polytrichum juniperinum* (Figure 179) and *Chorisodontium aciphyllum* (Figure 180-Figure 181). The second was a moss carpet of *Calliergon sarmatosum* (Figure 182), *Calliergidium austrostramineum* (Figure 183), and *Sanionia uncinata* (Figure 184-Figure 185) along with the leafy liverwort *Cephaloziella varians* (Figure 186). The two communities had similar productivity levels, trophic structure, and organic matter transfer efficiencies, but the standing crops of **Collembola** and mites, turnover of mosses, and accumulation of dead matter differed.

Who Dares to Live Here?

With temperatures reaching extremes within a single day, a long, harsh winter, and elevated UV radiation, it is little wonder that the flora and fauna of the Antarctic are limited. But some *Collembola* (as well as mites and *Diptera*) are relatively common here. Bryophytes serve as important habitats for many of these arthropods, providing cover and protection and ameliorating the microclimate.

On the Schirmacher Oasis, a 25 km long and up to 3 km wide ice-free plateau with more than 100 freshwater lakes on the Antarctic continent, Mitra (1999) reported two families of *Collembola* inhabiting mosses. The springtail *Cryptopygus antarcticus* (Figure 78) is the dominant arthropod in the maritime Antarctic (Tilbrook 1967). Gressitt (1967) reports *Gomphioccephalus hodgsoni* (*Hypogastruridae*; see Figure 60), *Friezea* (*Neanuridae*; Figure 157), and *Parisotoma* (*Isotomidae*; see Figure 187) as common in moss clumps. Block (1982) reported *Friezea grisea*, *Parisotoma octooculata* (see Figure 187), and *Cryptopygus antarcticus* in the *Polytrichum-Chorisodontium* moss turf (Figure 179-Figure 181) of Signy Island, where they had a density of 49,928 individuals per m². In the *Calliargon-Calliergidium-Drepanocladus* moss carpet (Figure 182-Figure 185) *Collembola* averaged 9913 individuals m². *Cryptopygus antarcticus* was present in 99% of the moss turf samples and 100% of the moss carpet samples. This species was

significantly more abundant in *Polytrichum* (Figure 179) than in dead moss or bare peat. But this is not a bryophage – it feeds on unicellular green algae that grow on the mosses (see also Green & Broady 2001).

Figure 187. *Parisotoma notabilis*, a common species among mosses in the maritime Antarctic. Photo by Andy Murray, through Creative Commons.

On Anvers Island of the Antarctic Peninsula, *Cryptopygus antarcticus* (Figure 78) is again abundant in the moss *Dicranum* (*Chorisodontium aciphyllum*?; Figure 180-Figure 181) (Lippert 1971). These live mostly at about 5 cm depth in the moss mat, with few in the first cm. *Polytrichum* (Figure 179) had this same species, but also provided home to *Parisotoma* (*Isotomidae*; Figure 187), *Friezea* (*Neanuridae*; Figure 157), as well as several mite species. And as usual, *C. antarcticus* was the most abundant. This dominant species also occurred in wet *Sanionia uncinata* (Figure 184-Figure 185).

Species are often arranged vertically by temperature and moisture preference (Sømme 1995). These behavioral adaptations permit them to move up or down as the moisture and temperature conditions change on daily and seasonal regimes. For example, *Cryptopygus antarcticus* (Figure 78) occurs mostly in the upper 1.5 cm of moss, preferring the moisture content there. *Friezea woyciechowskii* (*Neanuridae*) is absent in that zone, but is distributed below it down to 9 cm or more. For *F. woyciechowskii*, water content of the moss seems to be of little importance.

Geothermal Areas

For several arthropods in polar regions, the **geothermal** (steam vent) areas provide cozy homes with suitable temperatures. The higher temperatures support a richer vegetation with a longer growing season (Convey & Lewis Smith 2006). These plants, largely bryophytes, support a more diverse and abundant fauna than other areas of Antarctica, including species that are non-native and unknown elsewhere on the continent (Greenslade *et al.* 2012). The bryophytes are restricted by moisture (Kennedy 1993; Convey 2001), and geothermal areas provide them with moisture coming from the warmer air arising from the soil in heated areas. This same moisture is favorable for the *Collembola* (Hogg *et al.* 2006). Greenslade *et al.* (2012) found *Proisotoma minuta* (Figure 188) and *Hypogastrura viatica* (Figure 189-Figure 190), both non-indigenous species, on heated ground where bryophytes dominate. They suggest that the moisture there may be more important than the temperature.

Habitat Suitability and Collembolan Adaptations

Water is one of the most important factors in determining the species composition of Antarctic moss-turf communities (Booth & Usher 1984). For example, *Cryptopygus antarcticus* (Figure 78) has an optimum water content, but this species has a relatively wide acceptable moisture range.

Most of the arthropods in the maritime Antarctic are concentrated in the upper layers among vegetation (Tilbrook 1967), including mostly mosses and grasses. The soil and mosses absorb the solar radiation and winter snow insulates, creating temperature regimes that are more suitable for the **Collembola** than elsewhere in the area. Gressitt (1967) found that temperatures in clumps of the moss *Polytrichum* (Figure 179) could exceed the air temperatures by as much as 13°C. Temperatures in mat-forming *Drepanocladus* s.l. (most likely *Sanionia uncinata*; Figure 184-Figure 185) had temperatures closer to ambient air temperatures.

Like so many other invertebrates, the **Collembola** exhibit differences in vertical distribution (Usher & Booth 1984). And it appears that the Collembolans use the mosses to survive winter in the Antarctic. But it is not the protection of the bryophyte cushion cover that saves them from the cold. Rather, they may eat the mosses and gain the ability to survive lower temperatures (Sømme & Block 1982). When fed moss turf homogenate, *Cryptopygus antarcticus* (Isotomidae; Figure 78) from Signy Island, Antarctica, exhibited evidence of efficient nucleators in their moss substrate. When fed purified green algae, a high proportion of low group supercooling points were retained, i.e. it required a lower temperature for tissue freezing to occur, suggesting a lack of nucleators in the algae. In *C. antarcticus* the concentrations of cryoprotective substances increase at -5°C, concurrent with lowering of the mean supercooling point. The primary substances of this cryoprotectant system were **trehalose**, **mannitol**, and **glycerol**.

Collembola can migrate vertically to achieve the best combination of conditions within the mosses. The relationship between the green zone of *Polytrichum* (Figure 179) and the **Collembola** is weak; chemical characteristics seem to be the most important influence on the distribution of the arthropods in the green zone (Booth & Usher 1984). There seems to be no relationship of the arthropod communities with the dead moss zone.

On Signy Island, 78-88% of the **Collembola** were in the top 6 cm of *Polytrichum-Chorisodontium* (Figure 179-Figure 181) turf and 96-99% were in the top 6 cm of the *Calliergon-Calliergidium-Drepanocladus* carpet (Figure 182-Figure 185) (Block 1982). *Cryptopygus antarcticus* (Figure 78) responded to seasonal changes by migrating vertically. In summer it reached as many as 94% of its individuals in the top 3 cm, but in winter this percentage dropped to as low as 48%. Some were as deep as 21 cm, but they rarely went below 6 cm in the moss carpets. The carpets have less extreme temperatures and accumulate more snow than does the turf, ranging 25 to -20°C. The **Collembola** need temperatures of -5 to +5°C to be able to move, and hence to feed. But the moss carpet presents a different problem – it periodically floods, a condition intolerable for the **Collembola** (Kühnelt *et al.* 1976).

Usher and Booth (1986) looked at the relationship of scale in the bryophyte faunal communities. The common *Cryptopygus antarcticus* (Figure 78) demonstrates different patterns at scales of 10 and 60 cm depth in the surface layer of the moss turf. *Friesea grisea* (see Figure

157), on the other hand, occurs deeper – at 5 cm – and has only a single scale of pattern. Their predator, the mite *Gamasellus* (Ologamasidae; Figure 79), is distributed randomly. The moss *Polytrichum* (Figure 179) exhibits moisture trends along transects and at smaller scales, perhaps accounting for the patterns seen in at least some of the *Collembola*.

In contrast to its abundance among mosses, *Cryptopygus antarcticus* (Figure 78) is not desiccation tolerant and is thus absent from the drier rock platform habitat (Hayward *et al.* 2004). Instead, *Friesea grisea* (Neanuridae; see Figure 157) is the only collembolan able to survive there. Nevertheless, *F. grisea* has a stronger preference for 98% relative humidity conditions than does *C. antarcticus*, suggesting that the former species can take advantage of such refuges when available.

Temperatures in the Antarctic summer can vary considerably between day and night. Some of the Antarctic *Collembola* exhibit a bimodal supercooling point (SCP) distribution (Sinclair *et al.* 2003). Mosses may play a slight role in setting the supercooling point. *Desoria klovstadi* (Isotomidae) that was foraging on mosses had high SCPs (froze at higher temperatures), but these shifted to the low group when the springtails were starved for 2-8 hours. They developed even higher SCPs when fed with lichen or algae for five days, compared to those supplied with mosses. *Friesea grisea* (Neanuridae; see Figure 157), on the other hand, had unimodal distribution of SCPs that did not vary between day and night.

Eat and Be Eaten

Suitable food is always a requirement in any habitat. In some cases, food preferences may determine where organisms live. In the Antarctic, food sources can be limiting as few organisms can survive the harsh climate. Furthermore, provision of cryoprotectants can play a role in determining suitable food sources, providing the springtails with cryoprotectants in preparation for winter or for cold events during the growing season.

Gressitt (1967) found that many *Collembola* eat fungal hyphae and lichens in the Antarctic. *Friesea* (Figure 157) lays eggs among the mosses, suggesting that the young probably find their food among the mosses, most likely eating fungal mycelia.

But larger organisms among the bryophytes also need to eat, and for the carnivores, these springtail aggregations (Figure 190) may be an ideal food source. On the Antarctic Peninsula of Antarctica, predators on *Collembola* include the mites *Rhagidia* (Rhagidiidae) and *Cyrtolaelaps* (Ologamasidae) (Strong 1967). Strong considers the live mosses to provide little nourishment for insects and mites, serving mostly as a site of shelter. Nevertheless, the mosses provide a suitable environment for other sources of food, including fungi and algae, for the *Collembola* (Figure 191). These springtails typically spend the winter in the same habitat, probably enjoying at least some insulation among the moss cushions while having adequate moisture.

Figure 191. These Antarctic *Collembola* are common on this *Bryum subrotundifolium*. Photo courtesy of Catherine Beard.

Glacier Mice – Moss Balls

One unusual habitat for arthropods is among "glacier mice." These are actually unattached moss balls that form from wind-blown mosses on the glaciers. Coulson and Midgley (2012) explored this unusual habitat on glaciers in Iceland. In this case, the moss was a species of *Racomitrium* (Figure 65-Figure 66), a common genus in Iceland. The 8-10 cm balls always contained invertebrates and housed two species of *Collembola*. *Pseudisotoma sensibilis* (Isotomidae; Figure 141) numbered 12-73 individuals per ball, with *Desoria olivacea* (Isotomidae; Figure 192) comprising far fewer inhabitants. Tardigrades numbered approximately 200 while nematodes numbered near 1000. Surprisingly, there were no mites or arachnids and no annelids.

Figure 192. *Desoria olivacea*, a springtail that can be found in glacial moss balls. Photo by Andy Murray, through Creative Commons.

Pollution

Air pollution can be harmful not only to bryophytes, but also to the fauna within, including *Collembola* (Steiner 1995). Species richness decreases as a function of increased pollution. This is especially true for mites, possibly giving the springtails a small advantage if their predators diminish in numbers. Alterations in relative humidity, substrate type, and pH can have further influence on the species richness. Nevertheless, the arthropods are less sensitive than are nematodes and tardigrades.

The subalpine mosses *Plagiobryum zierii* (Figure 193) and *Saelania glaucescens* (Figure 194) near a busy road in the Bükk Mountains of Hungary are protected species there, but they are subject to pollution from the traffic on the road (Varga 1992). They exhibit a higher lead level and poorer fauna, including *Collembola*, than mosses from an unpolluted site.

Summary

Collembola were once considered insects but are now considered a subclass instead of an order. Most species spring by a **furcula**, a structure that is absent among some of the epiphyte dwellers. These springtails most likely existed before bryophytes did and moved to inhabit them later. They are sensitive to moisture and use bryophytes to maintain it. They eat algae, detritus, fungi, and slime molds among the bryophytes, and occasionally the bryophytes themselves, depending on the springtail species. Some are parthenogenetic and others deposit the sperm in a spermatophore that the female places into her reproductive tract. Their

dispersal is slow and traversing bare rock or other non-vegetated areas brings the risk of desiccation. Bryophytes can provide safe channels for migration; *Collembola* are among the first arthropods to colonize mosses.

Bryophytes provide cover, feeding sites, and egg-laying sites. Some *Collembola* are important in transferring sperm from male to female mosses. The bryophytes are moist and may help in lowering the supercooling point and protect the *Collembola* from freezing damage when the gut is empty. Vertical migration in the bryophyte mat can also help them find the best temperature and moisture where they can aggregate, further reducing water loss. Bryophytes provide safe sites against predators, especially spiders and mites, but also some salamanders. Few true **bryobionts** exist, one being *Hymaphorura dentifera*. The dominant families seem to be *Isotomidae*, *Hypogastruridae*, and *Entomobryidae* as well as the spherical springtails (*Symphyleona*).

The *Collembola* are adapted by small size and pigmentation where they live exposed to light. Those living among bryophytes on tree bark often have short furculas, dark color, stocky body, few eyes, small size, and limited movement. Sampling is usually done by pit traps or collecting the bryophytes. Bryophytes can be placed in funnels with a heat gradient that causes the *Collembola* to drop into a preservative or by using a flotation technique. But many won't leave the bryophytes to be sampled by these techniques. The springtails may number hundreds of thousands in a square meter, especially in Arctic and Antarctic regions.

Bogs seem to be important for some species, with water content being a controlling factor. Species living among epiphytic bryophytes are often the same as those among bryophytes on boulders. In forests they are usually in moist sites such as log or soil mosses, especially in wetter areas. In the Antarctic, *Cryptopygus antarcticus* is by far the most abundant, often reaching 95-100% of the springtail community among bryophytes. Some live in mobile homes known as glacier mice – moss balls on glaciers.

Acknowledgments

I appreciate the help of Richard Snider who, many years ago, helped me identify the *Collembola* in my bryophyte collections. He and other entomologists introduced me to the willingness of experts to help with identifications. Thank you to Sarah Lloyd for sharing her interesting finds with me. Rod Seppelt and Catherine Beard kindly offered their Antarctic pictures and provided me with a sense of the habitat. My sister, Eileen Dumire, proofread an earlier version of the sub-chapter and made suggestions to improve clarity for beginners.

CHAPTER 12-3

TERRESTRIAL INSECTS: HEMIMETABOLA – ODONATA

Figure 1. *Uropetala chiltoni* naiad emerging from burrow hidden among leafy liverworts. Photo by Rod Morris, with permission.

ODONATA – DRAGONFLIES AND DAMSELFLIES

Most of the **Odonata** are discussed in Chapter 11-5 with the aquatic insects, but some are terrestrial even as naiads and are appropriately discussed here. The **Odonata** are **hemimetabolous**. That is, they have an incomplete life cycle, one in which the immature animal resembles the adult and has no **larval** or **pupal** stage. Rather, the **naiad** (Figure 2), or **nymph**, develops directly into the adult. Naiads are the aquatic nymphs and thus the term doesn't apply in the strict sense to the terrestrial species. The large eyes (Figure 3) and scoop mouth enable these to be formidable carnivores. The odonate wings develop within the wingpads of the nymphs/naiads and expand when the last nymphal skin is shed. These adults must climb upward and pump fluids into the wing veins to expand them. They are vulnerable at this time because they are not yet ready to fly. Refer to Chapter 11-5 for more detailed discussion of this order of insects.

Figure 2. *Aeshna interrupta* naiad, a species whose naiads are not tolerant to drying. Photo by Donald S. Chandler <www.discoverlife.org>, with permission.

Figure 3. *Sympetrum striolatum* head showing large eyes. Photo by Anki Engström <www.krypinauren.se>, with permission.

Both dragonflies (**Anisoptera**) and damselflies (**Zygoptera**) have members that spend their nymphal life among bryophytes on land. These habitats provide cover and help the **Odonata** retain moisture. Others deposit eggs among mosses near water bodies where it is easy for nymphs to reach water through flooding, crawling, and or dropping into the water.

Biology

The **Odonata** are voracious carnivores and are preyed upon as naiads primarily by fish in their aquatic habitat. On land, this larger predator is absent and birds and amphibians are the most likely predators for both nymphs and adults. But their larger danger as nymphs on land is drying out. Hence, enter the bryophytes.

Paulson and Buden (2003) collected **Odonata** on the Eastern Caroline Islands of Micronesia, bagging 448 specimens. These comprised 15 species, six of which were damselflies in the genus *Teinobasis* (**Coenagrionidae**), a genus with known bryophyte dwellers. *Teinobasis ponapensis* (see Figure 4) was taken only in areas with moss and fern cover, suggesting that even adults can find some advantage in association with bryophytes. On that island they found that body size increases with an increase in altitude.

Figure 4. *Teinobasis sjupp* adult. *Teinobasis ponapensis* is a species whose adults live only in areas with mosses and ferns. Photo by V. J. Kalkman, through Creative Commons.

Terrestrial Naiads

Terrestrial nymphs are known for some families of **Odonata**, and moist forests, especially montane rainforests, seem especially suited for the moisture needs of this

"aquatic" insect. Oppel (2005) reported on the **Odonata** of Papua New Guinea, where its 61 species were predominately among the **Zygoptera** (damselflies). Most were associated with moving or standing water, but one group was associated with temporary water sources or forest sites with high non-seasonal rainfall and high humidity. No **Anisoptera** (dragonflies) were among these terrestrial associations. Surprisingly to me, there was a negative correlation between the **Odonata** and mosses among this group.

Nevertheless, bryophytes can play an important role for some species. In Australia, the nymphs of *Pseudocordulia* (**Corduliidae** or **Pseudocorduliidae** – dragonflies) occur among leaf litter in the rain forests and moss forests of northern Queensland far from water (Watson 1982). Thus it should be no surprise to find **Odonata** nymphs among mosses as well, and many records of **Odonata** in litter may include mosses – soil biologists typically include mosses as part of the litter layer. *Austropetalia patricia* and *A. tonyana* (Figure 5-Figure 6) (**Austropetaliidae** – dragonflies) nymphs live on logs or among mosses in waterfalls and on streambanks (Theischinger & Hawking 2006). These alpine species are often rare due to limited habitat.

Figure 5. *Austropetalia tonyana* adult, a species whose nymphs can live among terrestrial mosses. Photo by Reiner Richter, with permission.

Figure 6. *Austropetalia tonyana* habitat where nymphs live above water among mosses. Photo by Reiner Richter, with permission.

Some **Odonata** use water-filled tree holes for their naiads. It is interesting that the rare damselfly naiads of *Podopteryx selysi* (**Megapodagrionidae** – damselflies; Figure 7) occur in such tree holes in the rainforest of north Queensland, Australia, but Watson and Dyce (1978) surmise that this species must lay its eggs on moss-covered stones or bushes. They apparently base this on finding the adults clinging to shrubs along paths and to the use of mosses for egg laying by other rainforest **Odonata**.

Figure 7. *Podopteryx selysi* adult, a species that may lay its eggs among mosses near tree holes in the rainforest. Photo by Reiner Richter, with permission.

In the Northern Sierra Madre Natural Park, Philippines, *Risicnemis elegans* (**Cordulegasteridae** – dragonflies; Figure 8) nymphs occur in shaded seepages and on the moist forest floor several meters from water (Villanueva *et al.* 2009). In these locations, the females lay eggs on moist mosses.

Figure 8. *Risicnemis cf. elegans*, a species that lays its eggs on moist mosses. Photo through Project Noah, with permission.

The genus *Gomphomacromia* (**Corduliidae** – dragonflies) also has at least semi-terrestrial nymphs. Von Ellenrieder and Garrison (2005) found nymphs under stones about 3 m from a moist, rocky area in Chile. Louten *et al.* (1996) found *G. cf. fallax* (Figure 9) on a moist, moss-covered slope along a dirt trail in Pakitza, Peru. That Beckemeyer (2002) found *Gomphomacromia fallax* laying eggs in dripping mosses on a cliffside suggests that nymphs of this species live there as well.

Figure 9. *Gomphomacromia cf. fallax* adult, a species that sometimes lays eggs in dripping mosses. Photo by Roy J. Beckemeyer, with permission.

Bryophytes can be a refuge for aquatic **Odonata** naiads when their habitat dries up. Willey and Eiler (1972) observed this in *Somatochlora semicircularis* (**Corduliidae**; Figure 10) from subalpine pools in Colorado, USA. When their pond dried up, they could be found under rocks, in moss mats, under logs, and at the bases of sedge clumps. This species dries more slowly than the dragonflies *Aeshna interrupta interna* (Figure 2, Figure 11) and *Libellula quadrimaculata* (Figure 12). It takes *S. semicircularis* twice as long to reach the same lethal state of dryness as that experienced by these two less tolerant species. This advantage seems to be incurred by a lower transpiration rate, and further protection is afforded by the early formation of snow pack over the dry pond. The mosses and other substrata are sufficient to protect the naiads from drought until the snow arrives.

Figure 12. *Libellula quadrimaculata* adult, a species with poor desiccation tolerance as a naiad. Photo by Böhringer Friedrich, through Creative Commons.

Donnelly (1990) found damselfly naiads of the dominant Fijian genus *Nesobasis* (Coenagrionidae; Figure 13) near a stream, crawling over wet mosses. As Donnelly cautiously pointed out, these may not be truly terrestrial. Rather, normally aquatic insects often climb above the water level in search of food, or perhaps to avoid excessive flow – or just because they can. In other cases, receding water levels after a rainstorm may leave them above the water surface. There is sufficient moisture for them to maintain hydration until they return to the water. But naiads must leave the water to shed their naiadal skin and emerge as adults, perhaps also explaining this above-water observation.

Figure 13. *Nesobasis* sp., a species whose naiads are known to crawl over wet mosses occasionally. Photo through Creative Commons.

Mosses may aid in the selection of burrowing sites of terrestrial dragonflies. Rod Morris (2010) shows the giant mountain dragonfly (*Uropetala chiltoni*; Figure 1, Figure 14) nymph poking its head out of its burrow in the soil and into a bed of mosses in a small wetland in New Zealand.

Figure 14. *Uropetala chiltoni* nymph emerging from burrow to a bed of mosses. Photo by Rod Morris, with permission.

Emergence

Terrestrial bryophytes can serve as emergence sites where the naiads shed their exoskeleton, leaving it behind as an **exuvia** (Figure 15-Figure 16), to become adults (Needham *et al.* 1901). These researchers found layers of shed exuviae of both *Gomphus exilis* (Figure 17) and *G. spicatus* (Gomphidae – dragonflies; Figure 18-Figure 19) among the mosses on logs at the edge of a pond. Similarly, *Somatochlora elongata* (Corduliidae – dragonflies; Figure 20; see also Figure 21-Figure 22) left exuviae on mosses at the edge of a pond. Soriano and Gutiérrez (1998) found the exuviae of *Oplonaeschna magna* (Aeshnidae – dragonflies; see Figure 23-Figure 24), a new species at the time, clinging to mosses on the vertical rock walls of a canyon in Mexico. These exuviae were 0.80-1.25 m above the water, reaching as much as 3 m on tree trunks and shrubs. Bryophytes are easy to climb, provide moisture, and permit at times a refuge or limited camouflage.

Once the dragonflies shed their naiad exoskeleton, the newly emerged adults must climb or hang in place to spread their wings and pump fluids into those veins (Figure 25). I have watched them climb *Eleocharis* to the top, then climb down and climb another, apparently in search of a minimum height where they finally stayed to emerge. In the Huron Mountains of the Upper Peninsula of Michigan, USA, Kielb *et al.* (1996) observed emergent adults of *Stylogomphus albistylus* (Gomphidae – dragonflies; Figure 26) resting on vertical moss-covered rock faces below waterfalls and on nearby trees.

But not all naiads must assume a vertical position to emerge. *Aeshna juncea* (Figure 28-Figure 29) is able to emerge in a horizontal position on *Sphagnum* (Figure 33) (Maitland 1967).

Figure 25. *Anax junius* on *Eleocharis*, where it is has emerged and is preparing to pump fluids into its wings. Photo by Richard Orr, with permission.

Perching and Mating

Although the adults are strong fliers, even they must rest at times. For some, mosses seem to be suitable sites (Figure 27), especially in bogs.

Figure 27. *Celtithemis martha tenera* adult resting on male *Polytrichum*. Photo by Richard Orr, with permission.

Figure 29. *Aeshna juncea* in flight. Photo by Jens Nielsen Buurgaard, through Creative Commons.

Adults no longer must live in the water and these strong fliers (Figure 29) can often stray far from their naiadal home. For example, members of *Enallagma* (Figure 30) occasionally travel up to 1 km to a different lake to lay eggs (McPeck 1989). But some exhibit mass annual migrations of a much greater distance, a phenomenon noted as early as 1494 in Europe! (Calvert 1893; May 2013). Matthews (2007) used a hydrogen isotope ratio to track migrations of *Anax junius* from Ontario, Canada, to Veracruz, Mexico in late August to

October. Matthews found that about 90% of the individuals moved southward for a mean distance of ca. 900 km, but exhibited a maximum of nearly 3,000 km. During these migrations they often stop to feed, mate, or lay eggs (Russell *et al.* 1998; Wikelski *et al.* 2006; Matthews 2007). Distance travelled depends on species, sex, age, size, and weather (Angelibert & Giani 2003). They may seek a particular habitat as adults that differs from that adjacent to the water, at least in part to avoid predators such as frogs while mating.

Figure 30. *Enallagma divagans* mating pair. Photo by Richard Orr, with permission.

In New Guinea, the genus *Lathanusa* (Libellulidae – dragonflies) is restricted to high elevations above 1350 m (Lieftinck 1955). *Lathanusa lamberti* occurs in the moss forests at 2800-2850 m, the highest known elevation of any Libellulidae in New Guinea. The mosses there may simply like the same atmospheric conditions and habitat as the odonates, but the presence of the moss could also provide some aspect of the habitat that makes it more suitable for these dragonflies. One such possibility could be as sites for egg deposition and nymphal development.

Beckemeyer (2002) found *Gomphomacromia fallax* (Figure 9) adult males perching on mosses beneath cliff sides where there was dripping water. Females were flitting about nearby and flicking their abdomens to deposit eggs toward the mosses. A discussion of perching and mating in bogs (Figure 31) is in Chapter 11-5 of this volume.

Oviposition

If a nymph is terrestrial, then the eggs must also be laid in a terrestrial habitat, although the converse is not necessarily true. (Hatched naiads could drop into the water from overhanging plants or crawl to the water.) Most aquatic Odonata are not moss inhabitants, but the female may nevertheless lay her eggs among mosses, providing them with a secure and hidden location for development. Such is the case for *Austroargiolestes chrysoides* (Figure 32) in Australian rainforest streams (Theischinger & Hawking 2006).

Figure 32. *Austroargiolestes chrysoides* adult, a species that lays its eggs among mosses in Australian rainforest streams. Photo from Biodiversity Centre, through Creative Commons.

Michiels and Dhondt (1990) described the selection of the oviposition site by the dragonfly *Sympetrum danae* (Libellulidae; Figure 33). This species deposits its eggs among *Sphagnum* (Figure 33), but given the choice of *Sphagnum* and *Mnium hornum* (Figure 34-Figure 35), some females will deposit eggs in the latter as well. Michiels and Dhondt attempt to explain the choice of these mosses, considering them to have similar form but distinctly different odors, at least to humans. They thus eliminate odors as determining the choice and consider moss form to be a more likely determining factor. They derived a list of advantages for depositing eggs among *Sphagnum*, based on a number of literature references:

1. Wet *Sphagnum* prevents summer drying of eggs and is likely to be submerged in the spring when eggs hatch and naiads develop.
2. Acid water associated with *Sphagnum* has fewer fish and other predator species.
3. Conditions are optimal for mycobacteria that feed Cladocera that in turn feed naiad Odonata.
4. *Sympetrum danae* (Figure 33) naiads are sprawling and need support and shelter found among *Sphagnum* (Figure 33).

Figure 33. *Sympetrum danae* male on *Sphagnum*, a suitable egg deposition site. Photo copyright by David Kitching <<http://www.brocross.com/dfly/dfly.htm>>, with permission.

Figure 35. *Mnium hornum* up close, showing that it is quite different from *Sphagnum*. Photo by Bob Klips, with permission.

These advantages would not be present in the terrestrial moss *Mnium hornum* (Figure 34-Figure 35), so the choice of *Sphagnum* for egg deposition is also dependent on its availability in the proximal habitat to that of the naiads. Nevertheless, mosses near water bodies and in rain forests do afford more limited protection from drying. One must wonder how the terrestrial nymphs are adapted for obtaining prey. The large jaws and watch and

wait behavior should still work on land, but the prey items will be different.

Egg-laying among bryophytes has been observed for a long time. Lucas (1900) noted that *Aeshna caerulea* (Aeshnidae – dragonfly) occurred on "moss-hags" around peaty tarns and laid its eggs in wet, mossy ground. A female *Aeshna juncea* (Figure 36) on the Brooks Peninsula of Vancouver Island, Canada, oviposited into the wet mosses clinging to a vertical rock surface at the edge of a drying pool (Cannings & Cannings 1983).

Wang (2000, in Reels & Dow 2006) found that *Bayadera brevicauda brevicauda* (Euphaeidae – damselflies; Figure 37) from Taiwan uses moss-covered stones or fallen leaves, often at some distance from water, as oviposition sites.

In Hawaii, the seepage damselfly *Megalagrion hawaiiense* (Coenagrionidae; Figure 38) deposits her eggs in dripping moss banks (Williams 1936). These damselflies are territorial (Moore 1983) and males guard the females while they lay eggs (Williams 1936; Polhemus 1994). The eggs hatch in about ten days.

The heaviest of all dragonflies, females of *Tetracanthagyna plagiata* (Aeshnidae; Figure 39-Figure 40), seem to prefer soft substrates (Leong & Tay 2009). One such substrate is decaying logs kept moist and soft by moss cover. Leong and Tay observed this behavior on a log next to a stream in Singapore.

Figure 39. *Tetracanthagyna plagiata* (dragonfly; Aeshnidae) adult in Malaysia. This is the heaviest of the dragonflies. Photo by Keith Wilson, through Creative Commons.

Matushkina and Klass (2011) suggest that the ovipositor of female *Phenes raptor* (Petaluridae; Figure 41) is particularly adapted for the substrate where the eggs are to be laid. This ovipositor (Figure 42) has numerous sensilla of different shapes and Matushkina and Klass suggest these may be able to detect suitable places for depositing eggs. These females choose loose substrata, including mosses, grass roots, and decaying plant matter. The ovipositor also lacks serration and the interlocking mechanism that connects the first two valves medially is reduced, both adaptations they suggest to relate to depositing eggs within soft substrata, including mosses.

Figure 40. *Tetracanthagyna plagiata* showing oviposition into soft wood. Photo by Marcus Ng, with permission.

Figure 41. *Phenes raptor* ovipositing into the soft end tissue of log. Mosses help to keep logs moist so they become soft. Photo by Eric LoPresti, with permission.

Figure 42. *Phenes raptor* female showing ovipositor. Photo by Eric LoPresti, with permission.

It would be interesting to see if the **Odonata** have preferences for growth forms of mosses. Dense cushions would seem appropriate for those adapted to a soft but solid substrate. Others that drop or "throw" the eggs to the substrate may prefer loose, thick mats, or at least be able to use them. If such correlations exist, the structure of the ovipositor may tell us the kinds of mosses or liverworts they would prefer.

Sampling

These nymphs are worth bringing home live for a closer look, but bring some smaller food items for observations of the interesting feeding. Keep them separate until you are ready to watch! Lucas (1900) suggests carrying the live specimens home in wet moss to avoid the jostling they would get in a jar. They can live this way for several hours to several days. Winstanley *et al.* (1981) were able to keep nymphs of *Uropetala carovei carovei* (**Petaluridae**; Figure 43) from New Zealand alive and rear them through emergence to adults by filling 2-liter containers with leaf mold, moss, and water.

Figure 43. *Uropetala carovei*, a species that can be reared using mosses, leaf mold, and water. Photo by Geoff Tutty, through Creative Commons.

Collection of terrestrial nymphs that live among bryophytes is a matter of collecting the bryophytes. Some may be collected by using traps, but small ones may not leave the bryophyte. Adults are usually collected with insect nets.

Life in a Thallus

Some of the **Odonata** use bryophytes as food for larvae and pupae, providing a safe, moist habitat for their survival in semiterrestrial habitats. For the dragonfly *Epiophlebia superstes* (**Epiophlebiidae**; Figure 44), an **endemic** (restricted to certain area or country) in Japan (Asahina & Eda 1982; Inoue 1983; Tabaru 1984), it appears that bryophytes also provide egg-laying substrata. This dragonfly is often confused with damselflies because

its hind wings are nearly equal to the forewings and it folds its wings over its back at rest like damselflies do. Furthermore, it lacks the jet propulsion typical of dragonflies but absent in damselflies (Tabaru 1984). But it has apparently branched from a dragonfly, then become separated from them when the Himalayas uplifted. Normally the adult lays her eggs in vegetation alongside a waterfall (Asahina & Sugimura 1981). However, in the absence of any nearby tracheophytes, females in locations in Nakamura, Kochi Prefecture, Japan, used bryophytes on the nearby rocks. The eggs were injected into the thallose tissues of the thallose liverworts *Dumortiera hirsuta* (Figure 45), *Conocephalum* (Figure 46), and *Pellia* (Figure 48). In China, *Epiophlebia diana* selects tracheophytes, and Carle (2012) considers the preferred plants of *E. superstes* there to be tracheophytes as well as the liverworts *Dumortiera*, *Conocephalum*, and *Pellia* (Asahina 1934, 1950; Asahina & Eda 1958, 1982; Asahina & Sugimura 1981; Tamiya & Miyakawa 1984; Tokunaga & Odagaki 1939).

In fact, it appears that the dragonfly *Epiophlebia superstes* (Figure 44) actually prefers the liverworts (Asahina & Eda 1958, 1982) for oviposition. Males stake out a "territory" over a patch of *Conocephalum conicum* (Figure 46), despite the presence of the usual tracheophyte egg depositories of *Petasites japonica* and *Eutrema wasabi*. Subsequently the female deposits her eggs in the tissues of this thallose liverwort (Figure 47). Upon dissection Asahina and Eda discovered that the eggs were precisely deposited in the air chambers of the thallus. Further egg deposits are also made into another thallose liverwort, *Pellia endiviifolia* (Figure 48). Because the liverwort thallus has an irregular shape compared to the symmetry of the tracheophyte leaves, the female has to keep changing her position relative to the surface, resulting in some of the eggs being laid in nearby tracheophytes.

Figure 44. *Epiophlebia superstes* (**Epiophlebiidae**) adult, a dragonfly that lays its eggs in thallose liverworts. Photo through Creative Commons.

Figure 48. *Pellia endiviifolia*, site of egg deposition for the dragonfly *Epiophlebia superstes*. Photo by Michael Lüth, with permission.

The ovipositor leaves a small "scar" on the liverwort thallus and the young nymphs later hatch through this hole. These holes permitted the researcher to identify thalli containing eggs and to count them. One thallus had 175 eggs! Others had lesser numbers of 24, 51, and 100. Development of the nymphs to become adults requires 5-8 years, perhaps setting the record for **Odonata** (Tabaru 1984). Use of the liverworts seems to vary between locations, with females in some areas seemingly avoiding the liverworts despite their suitable availability.

Asahina and Eda (1982) suggest that the related *Epiophlebia laidlawi* (**Epiophlebiidae**; Figure 49), a relict species from the Himalayas, might also use bryophytes for egg-laying. Now one can find in Wikipedia the statement that bryophytes are the preferred egg-laying substrate for that species, citing information from Silby (2001). At these high altitudes, mostly above 2000 m, the nymphs can take up to six years to develop before they emerge as adults.

Figure 49. *Epiophlebia laidlawi*, dragonfly nymph that hatches from eggs laid in thallose liverworts. Photo by Shyamal, through Creative Commons.

It appears that *Epiophlebia* (Figure 44, Figure 49), which has only four species (Wikipedia 2007) and these are restricted to Asia, may not be the only odonate that uses a bryophyte thallus for oviposition (Villareal 2009). It's not

water, but it offers similar protection from desiccation – what better place than within the tissues of a plant that is seldom eaten? In this case, the nymphs were damselflies (**Zygoptera**; Figure 50-Figure 55), but their identity remains unknown. Although *Nothoceros aenigmaticus* (Figure 53) is not a true liverwort, but rather is a hornwort, its thalloid structure is similar to that of liverworts. This species is endemic to the southern Appalachian Mountains, USA, where, sadly, it is threatened to extinction resulting from a plague of hemlock woolly adelgids (*Adelges tsugae* – Hemiptera) on the hemlocks (*Tsuga canadensis*) that make its environment suitable for the hornworts (Jacobs 2005; Hyatt 2006).

Figure 53. *Nothoceros aenigmaticus* thallus, a hornwort, with eggs that are probably those of a dragonfly or damselfly. Note that the small dark-green patches are *Nostoc* symbionts (blue-green bacteria that live in partnership with the hornwort, contributing converted atmospheric nitrogen). Dragonfly identification is by K. Tennessen. Photo courtesy of Juan Carlos Villareal.

Figure 54. Damselfly egg cases in *Nothoceros aenigmaticus*. Photo courtesy of Chris Cargill.

Figure 55. Damselfly egg case from *Nothoceros aenigmaticus*. Photo courtesy of Chris Cargill.

Juan Carlos Villareal (pers. comm. 23 December 2008) made a similar find in Mexican populations where the developing larvae were leaf miners on the thallus. The damselflies, identified by Ken Tennessen, were in the *Coenagrionidae*, possibly the genus *Argia* (Figure 56).

Figure 56. *Argia tibialis* adult, member of a genus whose nymphs may be one of those that live in hornwort thalli. Photo by Richard Orr, with permission.

I could find no observations on feeding by these thallus dwellers. How long do they remain in the thallus? What do they eat while they are there? This order of insects is highly adapted to be carnivorous. The chances that they find animal food items within the thallus seem slim.

Summary

The **Odonata** are predominately aquatic in the immature stage, but some nymphs are terrestrial, and some of these use bryophytes to protect themselves and to maintain moisture. These carnivores can find food among the bryophytes, including spiders, while hiding from their own predators – mostly amphibians and birds.

Bryophytes provide a good site for egg laying, and even aquatic species may lay eggs on streamside or poolside bryophytes. Some naiads may seek bryophytes as their water body dries up. Many more species climb to the banks of streams and lakes to

emerge from their nymphal skins, leaving behind evidence as numerous **exuviae** on the bryophytes. Others use moss hummocks as perching sites.

Live **Odonata** nymphs, including aquatic species, may be kept alive by placing wet moss in the container with them. Adults can be collected with insect nets.

A few **Odonata** actually live within the thalli of liverworts and hornworts. In particular, *Epiophlebia superstes* in Asia lays its eggs in several liverwort species and nymphs develop there. An unidentified damselfly develops within hornwort thalli; others appear to be in the genus *Argia*.

CHAPTER 12-4

TERRESTRIAL INSECTS:

HEMIMETABOLA - ORTHOPTEROIDEA

Figure 1. **Orthopteran** moss mimic, blending with surrounding bryophytes. Photo courtesy of Matt von Konrat.

The **Orthopteroidea** (Figure 1) comprise a group of insects that used to be in the order **Orthoptera**. The group has recently been split into multiple orders, one of which is still called **Orthoptera**.

ORTHOPTERA – Grasshoppers and Crickets

Most grasshoppers are big, and in fields of tall grasses and **forbs** (non-grass herbaceous plants) they seem to be everywhere (Paranjape *et al.* 1988). But do they inhabit or use bryophytes? And what can bryophytes offer them?

At least some grasshoppers eat mosses (Appelqvist 1997). Uvarov (1977) suggested that the grasshoppers might eat mosses for their water content. But some seem to subsist primarily on mosses (Hochkirch *et al.* 2007). And some have color patterns that hide them well against the patterned moss surface (Figure 2-Figure 3) (Forsman & Appelqvist 1998). Others choose bryophytes for laying eggs (Langmaack 1997), presumably providing them with some protection (concealment) from predators and decreasing the danger of desiccation.

Figure 2. Forest grasshopper of Ecuador with liverwort color patterns on its sides and a moss hanging from its head. It appears that this hopper can help in dispersal. Photo by Arthur Anker, with permission.

Figure 3. Juvenile grasshopper in Ecuador with markings that look like leafy liverworts that are so common on tropical leaves. Photo by Arthur Anker, with permission.

Any increase in niches is likely to increase insect diversity, and bryophytes can play this role for some of the **Orthoptera**. Noting that the grasshopper family **Tetrigidae** (pygmy grasshoppers) included mosses in their diet (Hochkirch *et al.* 2000), Hochkirch *et al.* (2007) experimented with members of this family to determine how **sympatric** (having overlapping geographic distribution) species might co-exist. They used the mosses *Rhytidiadelphus squarrosus* (Figure 4) and soil algae as food sources. *Tetrix ceperoi* (Figure 5) and *T. subulata* (Figure 6), both sometimes moss inhabitants, were cultured together in the lab experiments. *Tetrix ceperoi* exhibited substantial decrease in copulations with its own species when in the presence of *T. subulata*. The males attempted more mating events with females of *T. subulata*, but the females rejected them. Although none of these two-species matings was successful in the lab, they substantially reduced the success of *T. ceperoi* in field experiments. It required much denser populations to have similar depression effects on *T. subulata*. Hochkirch *et al.* (2007) surmised that to prevent such reproductive interference the species may evolve different mating signals or different habitat preferences, spatial patterns, or temporal segregation. Having bryophytes in the habitat provides differences in available niches, including moisture and food item differences (Figure 7).

Figure 7. *Tetrix ceperoi* (Figure 5) frequency of perching on moss compared to other perching sites in its habitat. Modified from Hochkirch *et al.* 2007.

Tetrigidae – Pygmy Grasshoppers

The pigmy grasshoppers (Figure 8) are common moss dwellers and moss consumers (Hancock 1902; Chopard 1951; Bastow *et al.* 2002).

Figure 8. This grasshopper appeared to have protonemata cultured on its back. At the very least, it has cryptic coloration that makes it nearly invisible among these mosses – until it jumps! Photo by Janice Glime.

Tetrix

Tetrix granulata in Oregon, USA, lives in shaded meadows with damp mossy ground and short grass (Fulton 1930). Buckell (1921) noted that *Tetrix brunneri* (Figure 9) in the Chilcotin District of British Columbia, Canada, was present only in a small area where it lived among leaf litter and mosses under birch (*Betula*) and willow (*Salix*) surrounding an upland spring. This species occurs as high as 3,300 m among boulders in Colorado, USA (Alexander 1964). But the most widespread of these moss dwellers in North America is *Tetrix subulata* (Figure 6) (Rehn & Grant 1955).

Figure 9. *Tetrix brunneri*, a species that seems to prefer mossy areas. Photo by Lynette Schimming, through Creative Commons.

Tetrix subulata (Figure 6) has the somewhat unusual character of having both **brachypterous** (short-winged) and **macropterous** (large-winged) forms (Lock *et al.* 2006). There is a tradeoff in these insects between dispersal and reproduction, with the short-winged forms reproducing faster and the long-winged ones travelling farther and colonizing new habitats. The long-winged form consumes significantly more energy and exhibits a significantly higher protein content compared to the short-winged form. Carbohydrate and lipid content do not differ. The males have higher protein content and consume more energy than females, providing males with the energy needed to search for females.

Color Morphs – Thermoregulation or Camouflage?

Many grasshoppers exhibit color morphs (Nabours 1929; Rowell 1971; Holst 1986; Forsman 1999, 2000). *Tetrix subulata* is able to exhibit a variety of morphs (Figure 6, Figure 10-Figure 11) even within a single clutch (Forsman 2000). *Tetrix subulata* occurs in damp places on the soil surface where it eats mosses, algae, and humus (Forsman 1999) and is widespread in Europe (Holst 1986). This species exhibits discontinuous color morphs that could affect body temperature or protection from predation (Forsman 1997). Forsman (1997) found that black morphs had up to 49% higher **temperature excess** (difference between ambient and body temperature) compared to white morphs in the same external conditions. Forsman (2000) found that females preferred higher body temperatures than did males. Dark morphs both attain higher temperatures and prefer higher temperatures compared to paler morphs.

Gause's Law and Bryophyte Dwellers

When multiple species in the same genus occupy the same area, one must ask what keeps the species from competing – and out-competing (**Gause's Law**)? Gause (1934) described this "law" and experiments to support it in his "Struggle for Existence." This "law" has become known as the **competitive exclusion principle**. Based on many plant experiments, Gause put forth the principle that competition begins due to the reaction when plants are spaced in such a way that the reaction of one affects the response of the other by **limiting** it. He used this base to suggest that animal experiments are needed, demonstrating that when there is growth a number of individuals of a first and a second species will compete for common food. "At a certain moment food will have been consumed, or toxic waste products will have accumulated, and as a result growth of the population will cease. Competition will take place for utilization of a certain **limited** amount of energy." I have emphasized "limited" because this part of Gause's argument is often ignored. If food and space are unlimited or in excess, competitive exclusion need not apply.

Gause built his famous law upon the work of many other ecologists. In his comprehensive treatment of competitive exclusion (Gause's Law), Gause again emphasized the importance of experiment, providing guidance on the types of experiments needed. Levin (1970) presented it somewhat differently: "No stable equilibrium can be attained in an ecological community in which some r of the components are limited by less than r limiting factors. The limiting factors are thus put forward as those aspects of the niche crucial in the determination of whether species can coexist." If each species is limited by an independent combination of predation and resource limitation, it is possible for them to coexist. "If the two have comparable threshold values, which is certainly possible, any equilibrium reached between the two will be highly variable, and no stable equilibrium situation will result."

Here is where proving the competitive exclusion principle gets messy. Two species may co-exist because the environment is constant and advantages for survival may shift as the weather shifts. As a result of this and other problems with the complex relationship, Gause's law has come under close scrutiny, with many researchers providing examples that appear to disprove it. For example, Simberloff (1982) stated that it "has not helped us to understand how nature works. It has generated predictions that are either practically untestable, by virtue of immeasurable parameters or unrealizable assumptions, or trivially true."

Simberloff (1982) recognized the inherent problems with our use of Gause's law and offered an explanation. "When species do compete with one another, effects are usually moderated by other factors (*e.g.*, weather, predators, pathogens) that keep populations below levels at which exclusion would occur, or else each competitor is favored in a different set of times and/or places and this fact combined with normal individual movements keep all species in the system."..."Chance plays a major role in many potentially competitive interactions, and there is good evidence that many species that do compete with one another do so rarely or intermittently, and at most times their population dynamics are governed by other forces."

While this explains why closely related species are able to co-exist, it does not disprove Gause's law.

But in many of the examples that seem to refute Gause's law, the requirement of competition for a limiting resource or being preyed upon by a common predator is often missing because neither population has reached a limiting state for the needed resource. Levin (1970) attempted to improve upon our understanding of the "law" by suggesting three considerations:

1. Eliminate the restriction that all species are resource-limited, a restriction persistent in the literature.
2. The results relate in general to periodic equilibria rather than to constant equilibria.
3. The nature of the proof relates to the crucial question of the behavior of trajectories near the proposed equilibrium, and provides insight into the behavior of the system when there is an insufficient number of limiting factors.

Vance (1978) added further to the explanation of seeming exceptions. He took the position that one means by which two closely related species can co-exist is by having "suitable differences in spatial refuges from the predator, differences in appearance and/or location which induce frequency-dependent predation, and a difference in energy allocation between competitive and predatory defense." Vance concluded that "Gause's Law is just as true when predators are common and important as when they are absent. Most of those prey in nature whose coexistence is known to depend on predation differ in resource use; *i.e.*, these prey appear to partition environmental resources just as is expected of coexisting species in predator-free systems. A large proportion of cases of coexistence of similar species in nature probably results not from resource partitioning alone or from predation alone but from both mechanisms operating simultaneously."

Hanski (1983) carries this argument somewhat farther to include the role of a patchy environment. He concludes that two possible outcomes of regional competition are (1) a decrease in the fraction of habitat patches occupied by the competing species and (2) an increase in the proportion of regionally rare species, some of which may ultimately go extinct. This study has implications for bryophytes as a habitat because of the often patchy nature of their distribution within a habitat. This patchiness can especially affect invertebrate species that have limited dispersal ability.

Caesar *et al.* (2010) examined the application of Gause's Law within the moss-dwelling pygmy grasshopper genus *Tetrix*. According to Gause's Law, if two species are in the same genus, then their niches are likely to be similar, but one might be expected to be better in that niche, out-competing the other. An often overlooked part of this law is the part "if any factor is limiting."

Tetrix subulata (Figure 6) not only differs within the species by differences in color pattern, but also in form, behavior, and physiology (Caesar *et al.* 2010). Caesar and coworkers tested the interactions of these factors, using the moss *Polytrichum* sp. (Figure 12) as food. Individuals climbed the moss to feed and to find the best combination of moisture, light, and temperature. Survival is higher in low density of mothers than in high density. In high

density, the intermediate color morphs survived best, but survival was independent of color diversity at low densities, presumably due to less intense competition. Mixed siblings had higher survival than mixes of non-siblings, suggesting some competitive advantage. The mosses in their natural habitat therefore provided not only food, but permitted the various morphs to find locations suitable to their temperature, moisture, and light needs as well as being the safest place for particular morphs.

Figure 12. *Polytrichum juniperinum*, an acceptable food source for *Tetrix subulata* (Figure 4). Photo by Janice Glime.

To demonstrate the advantages of certain color patterns against predators in grasshoppers, Forsman and Appelqvist (1998) likewise experimented with *Tetrix subulata* (Figure 6). By manipulating color patterns and exposing these pygmy grasshoppers to predation from domestic chickens they could determine prey advantages (Figure 13). They painted some black and others striped. The striped individuals experienced enhanced survival when reaction distance was short and jumping performance was poor, but when the reaction required a long distance jump with high performance, their survival decreased compared to those individuals painted black. The advantage to the multiple color patterns seems to differ with circumstances, resulting in each morph surviving at different times and circumstances. The differences in form, behavior, and physiology make their specific habitat needs differ, hence defining different niches.

Figure 13. Comparison of *Tetrix subulata* (Figure 6) painted solid black and with stripes to determine the success of chickens preying upon them. Modified from Forsman & Appelqvist 1998.

Discotettix

One species, *Discotettix belzebuth* (= *Tetrix belzebuth*; Figure 14), occurs on mossy tree trunks in the orient (Gen & Rahman n.d.). Rather than having its own cryptic coloration, this species is sometimes bedecked with small plants of bryophytes or algae (I was unable to independently verify this). This enables them to move about undetected while they eat the epiphytic mosses, plants, and detritus on the tree trunks. However, when I searched for a picture to demonstrate this, all representatives were clean. Nevertheless, as you can see in Figure 14, the species is well suited for culturing bryophytes and algae. Its surface has pits where they can cling and become established, and the "thorns" could even help to hold larger bryophytes in place. These same pits and thorns provide disruptive coloration that helps to camouflage the uninhabited ones.

Figure 14. *Discotettix belzebuth* showing the pits in the exoskeleton and the thorns, both of which could aid in establishment of mosses. Photo by Bernard Dupont, through Creative Commons.

Vibration Sites

It seems a bit odd that females rest on mosses, but males do not call from mosses. But there is a very sound reason for that (pun intended!). Males attract females for mating by using vibrations (Kočárek 2010). But for vibrations to be effective, the hopper must be sitting on a suitable substrate, and that is not a moss. Moss, instead, can effectively absorb sounds. Rather, the males sit on bare ground, especially when exhibiting mating behavior. Sand is especially good at transmitting the sound, especially in the hearing range of frequencies between 300 and 400 Hz. And this is a choice mating substrate for males of *Tetrix ceperoi* (Figure 5), despite the increased risk of predation compared to resting on mosses or other vegetation. These vibrations are important in mate recognition in this species (Kočárek 2010).

Elias *et al.* (2004) examined the effectiveness of sound transmission from several substrates in their study of a jumping spider, *Habronattus dosseus*. They found that both rocks and sand quickly attenuated the sound, and that leaf litter was the most effective of the three for sound transmission. Furthermore, there is great variability among rock types. But mosses are more like a sponge, whereas

leaf litter has a large, nearly flat surface that can reflect and direct sound. I would hypothesize that at least some mosses would make effective sound-proofing. And different organisms make sounds with different tones and frequencies, so more study is needed to determine if mosses are good or bad for carrying mating sounds to females of any particular species. (See *Troglophilus neglectus* below.)

Reproduction

Competition isn't the only problem for closely related species living together. Reproductive barriers are likewise needed to maintain species differences. These are especially important for **sympatric** (having overlapping distributions) species such as members of *Tetrix*. To be an effective barrier, there must be an isolating mechanism such as behavior, timing, habitat, morphology, or genetics.

Reproduction is energetically costly. It typically carries a cost in future ability to reproduce, growth, or survival (Forsman 2001). Age is important in determining **clutch** size [number of eggs deposited in single reproductive bout (Godfray 1994)], with **clutch** size decreasing progressively from the first to the third clutch (Forsman 2001). Furthermore, larger first clutches correlate with greater reduction in the size of the next clutch and increase the time to the next clutch.

Reproduction in **ectothermic** (temperature controlled by external environment) animals, including insects, can be modified by body temperature. Temperature in grasshoppers affects both activity levels and physiological performance. Forsman (2001) compared four different color morphs under two different temperatures in *Tetrix subulata* (Figure 6). Different colors absorb different amounts of heat, whereas white reflects it. Warmer females were more likely to oviposit, had earlier first clutches, produced more clutches, and had decreased intervals between clutches compared to females kept at cooler temperatures. Some color morphs produced larger clutches with fewer clutches per unit time. No differences in relative fat content existed between dark and pale individuals in either sun or shade exposures. The data suggest that the differences in color morphs were advantageous in camouflage against predators rather than providing any reproductive advantage.

Forsman (1999) examined reproductive performance in five of these morphs, noting variation in body size and reproductive life-history characteristics. These lived in an area characterized by bare rocks and boulders, with bryophytes [*Ceratodon purpureus* (Figure 15), *Pohlia nutans* (Figure 16-Figure 17), *Polytrichum commune* (Figure 18), *P. juniperinum* (Figure 12)] and some tussock sedges (*Carex* spp.) dominating the vegetation. Season played a major role, with number of females with eggs declining significantly as the season progressed from mid-May (100%) to mid-June (40%). However, seasons had no effect on body size, clutch size, or egg size. On the other hand, morphs differed from each other in body size, and these size differences accounted for differences in clutch and egg size.

Figure 18. *Polytrichum commune*, home and probably food for *Tetrix subulata* on rocks. Photo by David T. Holyoak, with permission.

The ratio of egg size to clutch size also differed among the morphs (Forsman 1999). These factors suggest that different color morphs may have different reproductive strategies. The color differences may be responsible for variation in thermoregulation, but they also most likely affect the ability to avoid predation due to cryptic coloration. This implies that predation would differ among the morphs.

Food Consumption

Most grasshoppers are not moss consumers. In Bavaria, all tested grasshoppers except *Tetrix* (Figure 1, Figure 11, Figure 30-Figure 31, Figure 34) rejected mosses, but in 80% of the fecal pellets of *Tetrix* there were leaves of the moss *Hypnum* (Figure 19) and rhizoids and protonemata of a variety of mosses (Verdcourt 1947). Kaufman (1965) likewise found that *Tetrix* sp. fed on mosses, whereas other grasshopper genera in that study fed on **forbs** (non-grass herbaceous flowering plants).

Figure 19. *Hypnum cupressiforme* with young sporophytes. Fecal pellets of *Tetrix* contained leaves from this genus. Photo by Dick Haaksma, with permission.

Tetrix ceperoi (Figure 5) is among the moss consumers in the **Tetrigidae** (Kočárek *et al.* 2008a, b). Kočárek and coworkers examined the gut of 21 males and 18 females of this species. Of the nine mosses [*Amblystegium serpens* (Figure 20), *Barbula convoluta* (Figure 21), *Brachythecium albicans* (Figure 22), *B. velutinum* (Figure 23), *Bryum argenteum* (Figure 24), *B. caespitium* (Figure 25), *Ceratodon purpureus* (Figure 15), *Funaria hygrometrica* (Figure 26), *Plagiomnium undulatum* (Figure 27)] in their sandy habitat, all nine appeared in at least one gut. The most frequent species was *Bryum argenteum* (in 81% of specimens). At least one fragment of moss occurred in 92% of the specimens, *i.e.* only 8% had not consumed mosses. **Tracheophytes** (in this case grasses) were in 20%, all females, and algae were in 25%. The average number of species of mosses per gut was three, but some contained as many as six. Hence, mosses appeared to be the preferred food, but there seemed to be only limited preference for any particular moss.

Based on the gut analysis of *Tetrix ceperoi* (Figure 5), Kočárek *et al.* (2008c) found its "favorite" to be *Bryum caespiticium* (Figure 25), but this was also the most common moss in the area with a 70% cover (Table 1). Other commonly consumed mosses included *Bryum argenteum* (Figure 24), *Ceratodon purpureus* (Figure 15), and *Barbula convoluta* (Figure 21) and/or *B. unguiculata* (Figure 28). Only the females had grasses in their diet, whereas 94% of females and 86% of males had at least one fragment of moss in the gut. Males had an average of 1.5 moss species and females had an average of 2, whereas the maximum number of species in any gut was 4 (Figure 29). It was not unusual to find three species in the crop at one time. Kočárek and coworkers offer three explanations for this behavior:

1. A mixed diet promotes better health, development, and survival for grasshoppers than a single-food diet (Chapman & Sword 1997).
2. Mosses often contain toxic secondary compounds (Zinsmeister *et al.* 1991; Becker 1994; Markham *et al.* 2006) and must thus be consumed only in small quantities.
3. The multiple species indicate that the grasshoppers move around a lot and are able to sample the high diversity of mosses present in the area.

Table 1. Frequency of moss species in guts of 39 specimens of *Tetrix ceperoi* (Figure 5). From Kočárek *et al.* 2008c.

Moss species	T. ceperoi specimens					
	♂(ind.)	♂(%)	♀(ind.)	♀(%)	Σ(ind.)	Σ(%)
Barbula sp. (B. convoluta or/and B. unguiculata)	6	31.6	6	35.3	12	33.3
Bryum argenteum	4	21.1	6	35.3	10	27.8
Bryum caespiticium	15	78.9	17	100	32	88.9
Ceratodon purpureus	6	31.6	7	41.2	13	36.1

Figure 29. Comparison of mosses in guts of one individual in males and females of *Tetrix ceperoi* (Figure 5). Modified from Kočárek *et al.* 2008c.

Like the aforementioned species of *Tetrix*, *T. bolivari* (Figure 30) eats primarily detritus and mosses (Kočárek 2011). The main mosses consumed in this European study were *Bryum caespiticium* (Figure 25) and *B. argenteum* (Figure 24), but at least eight different species were consumed. Like the other species, these were sensitive to temperature and were most active at warmer temperatures. However, their activities were negatively correlated with humidity, suggesting that mosses were most likely not important in maintaining a humid environment for them.

Figure 30. *Tetrix bolivari*, a moss eater. Photo by Petr Kočárek, with permission.

The moss eater *Tetrix undulata* (Figure 31) eats mosses throughout its life (Hodgson 1963). As it gets older, it is able to eat coarser food. Both young and old eat mosses, humus, lichens, and algae, but adults add **tracheophytes** (lignified vascular plants) such as grass to their diet.

Figure 31. *Tetrix undulata*, a moss eater on moss. Photo by Gilles San Martin, through Creative Commons.

Paranjape (1985) compared the diets of three subfamilies of the **Tetrigidae** and found that not only mosses, but also liverworts and hornworts are consumed (Figure 32).

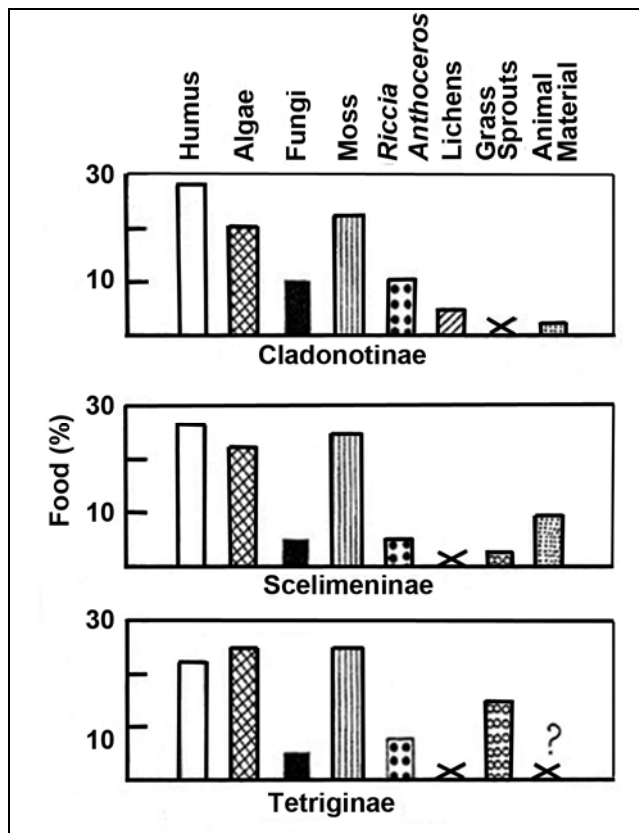

Figure 32. Diet of three subfamilies of **Tetrigidae**. Note that in addition to mosses, they consume the liverwort *Riccia* and the hornwort *Anthoceros*. Modified from Paranjape 1985.

Age and Seasonal Differences

Tough foods require strong mandibles and teeth to break through the lignin in vascular tissue. The strength can change as the nymphs age, so diets can change or expand as the organism matures. Similarly, moss tissues can change with the seasons, becoming tough when dry and soft when wet. These factors can affect the diet of the consumers.

Tetrix tenuicornis specializes on mosses and detritus (Kuřavová & Kočárek 2015). This species maintains its moss diet throughout the growing/feeding season. But the moss species change. More moss species occur in the alimentary tract in spring and summer compared to autumn. Females eat more food than males, and the diet changes with developmental stage. Furthermore, the rate of consuming detritus is affected by ambient temperature (most at 19-21°C), whereas the rate of moss consumption is primarily affected by relative humidity (lowest at 67-72%, highest at 90% or higher). Detrital consumption increases as body size increases.

These groundhoppers do not seem to specialize on any part of the mosses, consuming leaves, gemmae, and rhizoids (but apparently not stems) (Kuřavová & Kočárek 2015). Furthermore, they show little preference for moss species, consuming all of those present except *Pohlia nutans* (Figure 16-Figure 17) and *Bryoerythrophyllum recurvirostrum* (Figure 33). Nevertheless, an individual never contained more than 3 moss species, with the average being 1.9. Moss consumption was considerably less than that of detritus, with one population having 12% moss in the gut and the other only 3%. The amount of moss consumption is linearly related to the amount of moss available. Kuřavová and Kočárek suggest that keeping the moss consumption low prevents poisoning by secondary compounds produced by mosses. A reduction in moss consumption near the end of the growing season supports this hypothesis. Mosses increase their production of secondary compounds in autumn in preparation for the freezing conditions of winter (Cornelissen *et al.* 2007).

Figure 33. *Bryoerythrophyllum recurvirostrum*, a moss that seems to be avoided as food by *Tetrix*. Photo by Hermann Schachner, through Creative Commons.

It is also possible (probable?) that the choice of food is more a choice of habitat as the environmental conditions change. Low or high temperatures could drive the groundhoppers to the more stable conditions of the moss cushions. Furthermore, unfavorable conditions most likely reduce activity, resulting in lower consumption.

Mandibular Abrasion

Tetrix tenuicornis (Figure 34) avoids eating grasses, instead eating mosses [16.3%; *Barbula convoluta* (Figure 21), *Brachythecium albicans* (Figure 22), *Bryum caespitium* (Figure 25), *Campylopus introflexus* (Figure 54), and *Ceratodon purpureus* (Figure 15)] and detritus (83.7%) (Kuřavová *et al.* 2014). But it still exhibits

increased mandible abrasion with age, with females showing more age-related abrasion than males, perhaps due to greater frequency of feeding. On the other hand, Hence, even detritus and bryophytes cause wear on groundhopper mandibles.

Figure 34. *Tetrix tenuicornis*, a species whose mandibles show wear from eating bryophytes. Photo by B. J. Schoenmakers, through Creative Commons.

It is interesting that the diet of males and females may differ. Hochkirch *et al.* (2000) found that *Tetrix subulata* (Figure 6) males fed exclusively on algae and mosses, but females consumed grasses and forbs as well, perhaps accounting for the greater mandibular abrasion in females of *T. tenuicornis* observed by Kuřavová *et al.* (2014). Temperature also plays a major role in feeding, with only 1% feeding on a cool day but 24.7% feeding on the warmest day of the study (Hochkirch *et al.* 2000). When not feeding, the grasshoppers preferred sitting on the more open, warmer locations. These resting locations differed significantly from the feeding locations, which included mosses, suggesting that a color morph might be at a disadvantage in one of those locations.

Potua sabulosa

This pygmy grasshopper (Figure 35) is also a moss consumer, having mosses, especially *Funaria* (Figure 26), as its preferred food (Bhalerao *et al.* 1987). It lacks the molar dentes that are used for eating tracheophyte leaves, making it difficult to eat these foods as an alternative food source. For example, female adults fed on only "paddy" sprouts died within 5-6 days. The species overwinters as an adult. During the cold winters and hot, dry periods in summer it does not eat.

Figure 35. *Potua sabulosa*, a moss consumer that lacks polar dentes. Its roughened body helps it to blend with its surroundings. Photo by Jason Weintraub, through Creative Commons.

These tiny grasshoppers can jump 25-35 cm (Paranjape & Bhalerao 1985). In southwest India they hang out among mosses, being protected by their cryptic coloration. They also eat the mosses, as well as humus, and are capable of making an entire clump of moss disappear (Paranjape 1985). In the summer they survive the heat and drought by burrowing into soil, where they can remain for at least two months without food (Paranjape & Bhalerao 1985). When it is time for egg laying, the females dig a small burrow (~2 mm) in the soil or between the dense moss tufts, using their ovipositors. Their 23-25 eggs are laid in a loose cluster, hatching 10-12 days later at 23-25°C.

Acrididae – Grasshoppers

Akris is the Greek word for locust and is the basis for the name of the family that contains them (Acrididae 2015). More than 10,000 species comprise this family. The species are medium to large, as grasshoppers go. They are **diurnal** (day-active) and typically travel by jumping in their preferred open habitats. They often have cryptic coloration, but some are brightly colored. And many prefer "mossy" habitats.

"Three years ago there was a grasshopper 'explosion' in some central British Columbia grassland sites" (Terry McIntosh, pers. comm. 6 September 2013). "In the Gilpin Grasslands, they completely cleaned up most of the broad-leaved herbaceous plants (and ignored the grasses by the way), then started browsing on some shrubs, including, at one site, poison ivy! Later that day, I noticed a peculiar *Grimmia* on an outcrop. On closer inspection, the reason it look odd was because the whole moss face (mainly *G. ovalis*) had been grazed by the 'hoppers.' Not one plant in some 10 square meters had any leaf tips left." And the capsules were eaten too. (See discussion of other moss eaters under Food below.)

Melanoplus

Although this genus (Figure 38-Figure 44) does not exhibit the close food association exhibited by the **Tetrigidae**, at least several members prefer mossy habitats. *Melanoplus lovetti* lives in damp mossy ground, avoiding taller grasses (Fulton 1930). *Melanoplus islandicus* (Figure 38) in Michigan, USA, occurs along damp shorelines of pools where vegetation includes short grasses and sedges as well as mosses and organic debris (Bland 1989).

Melanoplus borealis (Figure 39) is well camouflaged among the mosses near Fairbanks, Alaska, USA. Kaufmann (1971) recounts seeing an adult that jumped/flew away from the approaching human. Once it landed, it became invisible among the moss-covered field where its color pattern blended with both the colors and spongy texture of the mosses. This species, like others in the genus, avoided areas of tall grass, apparently requiring areas where they could rest in the sun.

Figure 39. *Melanoplus borealis* male, a species well camouflaged among the Arctic mosses. Photo by Denis Doucet, with permission.

This genus has a variety of feeding strategies. Kaufmann (1968) found that *Melanoplus differentialis* (Figure 40) in Maryland, USA, prefers *Taraxacum officinale* (dandelion), but will also feed on grasses. They also eat dried plants, even when fresh ones are present. Kaufman found that the habitat was more important in the

choice of food (light, temperature, plant orientation) than the foods themselves. The mandibles are typical of grasshoppers that eat forbs, but the maxillae are similar to the moss feeders in the genus *Tetrix*.

Figure 40. *Melanoplus differentialis*, a grasshopper that eats mostly forbs but has maxillae similar to those of moss feeders. Photo by Rob Curtis, through Creative Commons.

Melanoplus femurrubrum (Figure 41-Figure 43), like many of the grasshoppers, has many color forms (Figure 41-Figure 43). This species has been studied to determine the effect of food absence on survival. As you may know, grasshoppers will eat their own appendages when starved for days. Bland (1981) found that nymphs survived up to 113 hours with no food. But hatchlings required food within 48 hours to insure their continued survival and growth. This species tends to eat the first suitable food it encounters, using olfactory senses to find it.

Figure 43. *Melanoplus femurrubrum* reddish form. Photo by Sheryl Pollock <www.discoverlife.org>, with permission.

It appears that members of this genus have not been tested for sensitivity to secondary compounds in mosses. In tests of compounds in tracheophytes on nymphs of *Melanoplus sanguinipes* (Figure 44), a species that does not typically eat mosses, many elicited no response, but several compounds caused a reduction in mean weight (Westcott *et al.* 1992). Saponin decreased survival and seven compounds significantly decreased both survival and mean weight. Vanillic acid significantly increased mean weight. This leaves the intriguing question of the effects of secondary compounds of bryophytes. Investigations into the chewing apparatus and digestive response to bryophytes compared to preferred foods may help us to understand why some insects choose bryophytes while others avoid them.

Figure 44. *Melanoplus sanguinipes* female, a forb feeder that benefits from vanillic acid in forbs. Photo by Lynette Schimming, through Creative Commons.

Not only do populations of *Melanoplus* (Figure 40-Figure 44) differ in coloration, but their physiology can differ as well. Fielding (2006) demonstrated **facultative diapause** (resting period that can change based on conditions) in the widely distributed *Melanoplus sanguinipes*. In an Idaho population, diapause in this species was facultative, with pre-diapause embryos averting diapause when held at 5°C for 90 days. On the other hand, this same population entered diapause in the late stage of development if held at 22°C for 30 days or more (Figure 45). The subarctic Alaskan populations had obligate diapause and entered diapause in a late stage of development. Chilling in the pre-diapause stages had no effect on diapause. These differences in life cycle strategies permit this species to occupy its wide distribution and are likely to be important for some of the moss-dwelling species as well.

Chorthippus

Langmaack (1997) found that mosses were important in the reproduction of some grasshoppers. *Chorthippus montanus* (Water-meadow Grasshopper; Figure 46) and *C. parallelus* (Figure 47) (*Acrididae*), both flightless, clearly selected moist mosses for depositing their egg pods.

Figure 45. Comparison of proportion of eggs from Alaska and Idaho populations of *Melanoplus sanguinipes* that hatched after exposure to 5°C for 90-100 days following incubation at 22°C for different times. $n > 200$ observations at each point. Modified from Fielding 2006.

Figure 47. *Chorthippus parallelus* male, a flightless grasshopper that selects moist mosses for egg deposition. Photo by Atlasroutier, through Wikimedia Commons

Chorthippus montanus (Figure 46) is a flightless wetland species and therefore it is likely to become rarer because its habitat is disappearing. Using a mark-recapture technique, Weyer *et al.* (2012) found that this species travels on average only 23.5 m, with a maximum of 104 m. This is not sufficient to permit its dispersal among widely fragmented wetland landscapes, and even the requirement to replace a drained wetland with another (somewhere else) will not solve this dispersal problem. Even if it could travel farther, it has restricted habitat requirements and is unable to traverse unsuitable habitats.

Based on fecal analyses, *Chorthippus pullus* (Figure 48) has a varied diet that includes dicotyledons, monocotyledons, and bryophytes (Steiner & Zettel 2006). The bean *Astragalus onobrychis* was the most consumed food in the Steiner and Zettel study. Moss consumption, including the moss *Dicranoweisia crispula* (Figure 49), formed a greater part of the diet in seasons and locations when other herbs were less abundant, despite having mandibles adapted for eating grasses. At one location *D. crispula* comprised 45% of the diet. Contrary to the suggestion of Uvarov (1977) that grasshoppers eat mosses for their water content, the water content of this moss was the lowest among the top four foods consumed, suggesting that the grasshoppers derived some other value from eating it.

Figure 48. *Chorthippus pullus*, a species that lays its eggs in moss **polsters** (cushions) in Austria. Photo by Gabriele Kothe-Heinrich, through Creative Commons.

Figure 49. *Dicranoweisia crispula*, a species that can form as much as 45% of the diet of *Chorthippus pullus* (Figure 48). Photo by Michael Lüth, with permission.

In the Lake Salzburg area of Austria, *Chorthippus pullus* (Figure 48) lays its eggs in June and July as an ootheca (egg case; Figure 50) in sand or moss polsters (Schwarz-Waubke 2001). This species deposits an average of 75 eggs during its lifetime. Each ootheca contains an average of 6.1 eggs. These moss polsters are especially important in rocky areas where they supply protection in an otherwise hostile environment.

Figure 50. Insect ootheca. Photo by Gilles San Martin, through Creative Commons.

Nicarchus

The genus *Nicarchus* (Figure 51) is flightless and lives on tree trunks (Rowell 2009). These grasshoppers are adapted to their habitat by having a wider thorax with reduced sternal lobes, the latter correlating with the reduced wings and flightless condition. This reduction in wing muscle provides additional space for a larger than typical crop (part of digestive system in which food is stored before digestion). Like other members of this group of tree trunk orthopterans (*Ommatolampinae*), their adaptations include cryptic coloration that mimics mosses, lichens, or bark; roughened cuticle or spines, again mimicking their substrate; strongly protuberant eyes; pronotum with bumpy projections; widely separated metasternal lobes; nodular antennae; 7 external spines on hind tibia; all but *Sciaphilacris* (Figure 52) flightless. They live on the trunks and major branches of tropical forest trees in the Amazon basin and in Central America. Among this group, only *Nicarchus* is known to feed on mosses, a habit that is probably favored by the enlarged crop.

Figure 51. *Nicarchus erinaceus*, a species that lives among mosses on tree trunks and branches in the tropical forest and feeds on mosses. Photo by Frank through What's that Bug <<http://www.whatsthatbug.com/2014/01/19/orthopteran-costa-rica/>>.

Sciaphilacris – Moss and Lichen Mimics

Sciaphilacris (Figure 52) lacks many of the modifications noted for *Nicarchus* and is the only member of *Ommatolampinae* that is not flightless (Rowell 2009). Nevertheless, despite having somewhat reduced wings, it rarely flies. Little seems to be known about it – it lives in South and Central America and most likely spends part of its time among the mosses, blending well.

Figure 52. *Sciaphilacris alata*, a good moss mimic. Photo by Arthur Anker, with permission.

Myrmeleotettix maculatus

Interactions with mosses is not always positive, and *Myrmeleotettix maculatus* (Figure 53) would most likely agree. In Europe it is a species of acidic coastal dunes. However, these dunes are being invaded by the exotic moss *Campylopus introflexus* (Figure 54). In a comparison of invaded dunes vs non-invaded dunes, Schirmel (2010) found that the mean number of captures of this species in non-invaded (native) plots was significantly higher than that in the invaded plots. Schirmel suggested that this difference may have been due to the higher proportion of grasses as food, more appropriate shelter, or more favorable microclimate in the native plots, leading to a higher mortality in the invaded plots. On the other hand, the mean number of young and older nymphs did not differ between the two habitats, suggesting that the invaded sites were suitable for oviposition but in some way detrimental to adults.

Figure 53. *Myrmeleotettix maculatus* female, a species that is disappearing in European coastal dunes due to the invasion of the moss *Campylopus introflexus* (Figure 54). Photo by Brian Eversham, with permission.

Food

Kaufman (1965) found that the feeding rate of *Acrididae* grasshoppers in Bolivia increased greatly with temperature. Feeding habits seem to correspond with mandibles and maxillary laciniae. These mouth parts can be divided into the graminivorous (grass) type, the forb-feeding type, and the moss-feeding type. Even the gastric caeca can be divided into four types based on diet preference. Nevertheless, experiments with *Euthystira brachyptera* (Figure 55) suggest that feeding on several different species, in this case of grasses, improves mortality, longevity, fecundity, and body weight.

Figure 55. *Euthystira brachyptera* female, a species that feeds on grasses but thrives best on mixed species. Photo by Gilles San Martin, through Creative Commons.

Position of the food can be important (Kaufman 1965). *Chorthippus parallelus* (Figure 47) prefers to feed on vertical grass blades. Passage time for the food in the alimentary tract differs not only in different species, but also depends on food plant, individual differences, and developmental stage. And males seem to assimilate more of the food they eat than do females.

Patterson (1984) demonstrated differences in shape and arrangement of dentes resulting in different mandibular ratios among members of the *Acrididae* with different feeding choices. Patterson (1984) and Kaufman (1965) pointed out the need for comparative studies among the moss-feeding species. Some of the species in this family are *stenophagous* (having narrow range of suitable foods) (Philippe 1991). For example, whereas *Trimerotropis saxatilis* (Figure 56-Figure 57) is specialized on eating mosses, *Boottettix punctatus* (Figure 58) specializes on *Larrea tridentata*, an evergreen shrub.

Figure 56. *Trimerotropis saxatilis* nymph well camouflaged among the grey lichens. Photo by Ted C. MacRae <beetlesinthebush.wordpress.com>, with permission.

Figure 57. *Trimerotropis saxatilis*, a specialist for eating mosses, is conspicuous here on mosses. Photo by Ted C. MacRae <beetlesinthebush.wordpress.com>, with permission.

Figure 58. *Bootettix argentatus*, a specialist on the shrub *Larrea tridentata*. Photo by Margarethe Brummermann, through Creative Commons.

In the southeastern United States lichen grasshoppers, also known as rock grasshoppers (*Trimerotropis saxatilis*; Figure 56-Figure 57), are important consumers in desert-like rock outcrops (Duke & Crossley 1975). This small species consumes 27.25 mg of the moss *Grimmia laevigata* (Figure 59), an **apparent** (conspicuous) moss, per day, totalling 391 mg m⁻² per year in this harsh habitat. This grasshopper species has a variety of color patterns that help it blend with its lichen and moss environment (Morse 1907). Although Morse says that *T. saxatilis* is restricted to bare rock surfaces, as its name implies, it has to eat somewhere, and it is a vegetarian. Do the math!

Figure 59. *Grimmia laevigata* on a rock outcrop, common habitat for *Trimerotropis saxatilis* (Figure 56-Figure 57). Photo by Michael Lüth, with permission.

Oviposition

Knowing that some grasshoppers eat mosses, it is not hard to imagine that they also lay their eggs among mosses. *Chorthippus pullus* (Figure 48), in Salzburg, Austria, is endangered in Europe (Schwarz-Waubke 2001). Despite this rarity, in the proper habitat of wild river landscape near Taugl it is a **eudominant** [>10% (Bick 1989)] among 12 other members of the **Saltatoria** (suborder of **Orthoptera**

including grasshoppers, crickets, and related forms). This species lays its eggs as an ootheca (Figure 50) in sand or moss clumps during June and July.

Some species of *Chorthippus* seem to have an inexplicable combination of oviposition habitats. For example, *C. albomarginatus* (Figure 60), *C. montanus* (Figure 46), and *C. parallelus* (Figure 47) prefer vertical plant surfaces for oviposition (Langmaack 1997). But *C. parallelus* and *C. montanus* also use moist mosses for egg deposition, a quite different type of structure. Rather than structure, it seems that height is important, with *C. albomarginatus* preferring 2-6 cm, *C. montanus* 0.5-2 cm, and *C. parallelus* 0-0.5 cm. Langmaack suggested that these preferences may indicate different requirements for moisture and temperature during development. *Chorthippus albomarginatus*, the species ovipositing at the greatest height, has the greatest desiccation resistance and highest temperature requirement for its eggs. Eggs of both *C. parallelus* and *C. montanus* have low desiccation resistance and a low temperature requirement.

Figure 60. *Chorthippus albomarginatus* female, a species that prefers higher positions of 2-6 cm above the ground for its egg deposition, including moss locations. Photo by Gilles San Martin, through Creative Commons.

Gryllidae – Crickets

The common names of the families of "crickets" have been hopelessly confused among the continents (Alexander *et al.* 1972), and me, so I will stay with only scientific names for most of these. The males are the callers in these groups, but in some the female may also call. The crickets make their well known chirps by rubbing together the leathery forewings. These chirps increase in frequency as the temperature increases. Overlapping species may have "songs" that we cannot distinguish, but they can be distinguished by instrumentation – and other crickets. Females are attracted to the calls and go to the males for mating. We know that frogs use mosses to modulate their calls, so it is appropriate to ask how grasshoppers might use them.

Alexander *et al.* (1972) report *Eunemobius melodius* singing in a *Sphagnum* bog (Figure 61) in Michigan, USA. Strang (2015) states that the sphagnum ground cricket (*Neonemobius palustris*; Figure 62-Figure 64) is not found outside of *Sphagnum* bogs. Some crickets make nests in *Sphagnum* (Vickery 1969). Crickets don't seem to be commonly known from mosses, but in captivity with

predators like frogs and lizards they will typically hide among the mosses. Does that happen in nature as well?

Rhaphidophoridae – Camel Crickets, Wetas

These **Rhaphidophoridae** like it dark, living in forests, caves, animal burrows, under stones, in wood, and in cellars (Rhaphidophoridae 2015). They occur on all seven continents, where they are usually active at night and rely on their sense of touch to identify things in their environment. Wetas are characterized by lack of wings, lack of auditory organs, long, compressed tarsi with no pads, small bodies, and long hind legs and antennae (Richards 1961). They are primarily scavengers, often eating plant debris that is washed into the cave and left stranded on the cave walls, but they also eat bryophytes.

Johns and Cook (2014) found the new genus and species *Maotoweta virescens* (Figure 65-Figure 66) hidden in a moss forest in New Zealand. This mottled green weta is inconspicuous among the mosses; *maoto* is the Maori word for fresh green. Johns and Cook reported the difficulty of finding this weta on the mossy tree trunks during their night-time activity; it required 16 person hours for them to locate only 5 individuals. The only female collected was in copulation – on a moss.

Figure 65. *Maotoweta virescens* on bryophytes, a recently described weta that is well camouflaged among bryophytes. Photo by Tony Jewell, with permission.

Figure 66. Green weta (cf. *Maotoweta virescens*) in its mossy habitat. Photo by George Gibbs, with permission.

In the caves of New Zealand, one might find *Pallidoplectron turneri* feeding on the thallose liverwort *Marchantia* that grows near the electric lights, but I cannot verify the reference and my new Zealand colleagues and I suspect it was really fern prothalli being eaten.

Troglophilus (Figure 67-Figure 69) species exhibit cryptic coloring with shades of marble brown, green, or grey (Karaman *et al.* 2011). These color patterns blend well with the forest background and the lichen and moss-covered rocks where they hide during the day.

One consideration for crickets of all kinds is the need to call in order to connect with a mate. But all calls are not equal (Stritih & Čokl 2012). The surroundings modify the calls, and mosses have a different resonance than that of grasses or bushes. The *sympatric* (occupying overlapping distributions) *Troglophilus neglectus* (Figure 67-Figure 68) and *T. cavicola* (Figure 69-Figure 70) use vibratory signalling to distinguish the opposite sex of their own species. *Troglophilus neglectus* uses abdominal vibrations, whereas this behavior is absent in *T. cavicola*. Both species use whole-body vibrations after copulation. Although they most frequently use bark for both signalling and mating, mosses are often used as well. The signalling frequency depended on the substrate. On rocks, the intensity of *T. neglectus* is below the detection range for this species and therefore could not be heard if they signal from within a cave. The frequency extends up to 600 Hz on mosses, whereas its highest frequency on stone was below 250-300 Hz. This difference explains the movement from the caves to bark, or less often moss, for mating calls, with mosses and litter providing suitable vibratory substrate (Magal *et al.* 2000; Elias *et al.* 2004).

Tettigoniidae – Katydids

Katydids can be abundant and diverse. At only three collecting sites in Loreto Province, Peru, Nickle and Castner (1995) found more than 370 species of Tettigoniidae.

Many katydid males offer a large gelatinous spermatophore to the female during mating (Del Castillo & Gwynne 2007). This is energy expensive and the larger the

reward offered, the less calling is done, another energy expensive activity. Size of the spermatophore and of the male do not seem to play any role in mate selection, but larger females seem to be favored over smaller ones.

Bogs seem to be the most common place for moss-associated katydids. The bog bush cricket *Metrioptera brachyptera* (Figure 71-Figure 72) is frequent in southern England heaths and bogs, but in northern England it is rare and in Scotland it has been found only once (Aucheninnes 2011). *Neonemobius palustris* (Figure 62-Figure 64) in Canada is rare, confined to *Sphagnum* (Figure 61) bogs (Johnstone & Vickery 1970; Kevan 1979), and feeds on the *Sphagnum* (Kevan 1979). Not only are the various *N. palustris* populations distinct genetically, but their **phenotypes** (sets of observable characteristics of individuals resulting from interaction of genes with environment) differ as well because interbreeding is rare if not non-existent between populations in different locations. Both *Neonemobius palustris* and *Allonemobius fasciatus* (Figure 73) lay their eggs on *Sphagnum* (Gerson 1969). Only these two species are considered to be characteristic peatland species in Canada (Marshall & Finnamore 1999).

Camouflage

Like the previous **Orthoptera**, katydids exhibit cryptic coloration. *Haemodiasma tessellata* (Figure 74-Figure 75), known as a moss mimic katydid, exhibits a mix of brown and green with a roughened light and dark surface (Thorman 2008) that helps it blend not only with mosses but also with leaf litter. But *Steiroxys strepens* (Figure 76), with a nearly solid green coloration, was sitting on damp mossy ground where it most likely blended better with the short grasses there (Fulton 1930).

Figure 74. This katydid (*Haemodiasma tessellata*) from Costa Rica was billed as a moss mimic katydid (Thorman 2008), but it seems to resemble a tracheophyte leaf more than it does a moss. It does have markings that would blend with epiphyllous bryophytes. Photos by Mary Thorman, permission pending.

Figure 75. *Haemodiasma tessellata* showing its cryptic coloration that could blend with leaves or bryophytes. Photo by Bernard Dupont, through Creative Commons.

Figure 76. *Steiroxys strepens* male, illustrating the solid colors typical of most katydids. Photo by Jim Johnson, with permission.

Nickle and Castner (1995) summarized the strategies used by katydids in the rainforests of northeastern Peru to protect themselves against daytime predators. These included primary defenses – camouflage, concealment within leaf parts or litter, territoriality by defending roosting sites against other katydids; secondary defenses used when making contact with predators – colorful displays by distasteful species (Figure 77), aggressive counterattacks, **aposematic** (serving to warn or repel) wasp mimicry, visual or acoustical alarm displays. They seem to return to the same daytime locations, suggesting they may be aware of their camouflage in those surroundings. Of the 378 species, 71.4% had general color patterns of green (208 spp.), brown (46 spp.), and both green and brown (19 spp.). Another 13.8% were more specific, mimicking wasps, bark, twigs, leaves, or lichens. Another 4.8% hid from view within vegetation or litter. Nickle and Castner did not distinguish any as having bryophyte camouflage, but some patterns that work well among leaf litter also work well among bryophytes (Figure 75).

Figure 77. *Acanthodis* sp. female showing startle display in Campana Highlands, Panama. Photo by Arthur Anker, with permission.

In Columbia, *Championica bicuspidata* (Figure 79) feeds on mosses and mimics them (Cardona Granda 2012). This genus has a number of moss mimics, including *C. pallida* (Figure 78-Figure 80). *Acanthodis curvidens* (see Figure 77) is also a moss mimic and rests prostrate to avoid detection (Robinson 1991). In addition to its camouflage, on Barro Colorado Island, Panama, this katydid avoids predation by bats when it is calling by maintaining a low frequency of calls (Belwood 1988). Bats locate katydids that produce frequent calls in about 26 seconds, immediately flying directly from their perch to the singing insect. In contrast, bats require nearly 34 minutes to locate the katydids (*Acanthodis curvidens*) that call less often (about once per minute), typically flying about seemingly randomly.

Figure 80. *Championica pilata* blending with a dead leaf. Photo by Arthur Anker, with permission.

Paraphidnia

Paraphidnia (Figure 81-Figure 85) is known as the moss katydid. Its markings look like leafy liverworts and lichens, making it blend well with its rainforest habitat, where it lives among and eats mosses and lichens (Ferrari 2015).

Figure 85. *Paraphidnia* sp. from Ecuador, mimicking a stick with leafy liverworts. Photo by Arthur Anker, with permission.

Balboana tibialis

Like many tropical species, little seems to be known about *Balboana tibialis* (Figure 86-Figure 87). And like many katydids, it most likely benefits from its cryptic coloration.

Figure 87. *Balboana tibialis* in Gamboa, showing camouflage markings suitable for living on bryophytes. Photo by Arthur Anker, with permission.

***Arachnacris tenuipes* – Emperor Bush Cricket**

A big thank you to Nick Garbutt for allowing me to use his image to show *Arachnacris tenuipes* (Figure 88) eating a moss. This is a species that may reach 12 cm (Hincks 1956), and it has the largest wingspan (27.4 cm) in the **Orthoptera** s.s. (Cowardine 2008). Its size is limited by temperature (Makarieva *et al.* 2005). Because of increases in metabolism with increasing temperature, the maximum length increases approximately twofold for each 10°C increase in ambient temperature. Hence, larger **poikilotherms** (those with temperature controlled by the environment) occur farther north, with smaller individuals in the tropics. *Arachnacris tenuipes* (syn. *Macrolyrstes imperator*) is known from Malaysia and Indonesia, but its distribution may be wider. This may be the first report that it eats mosses.

Figure 88. *Arachnacris tenuipes*, an emperor bush cricket (katydid) eating moss. Photo by Nick Garbutt, with permission.

"Endless forms most hidden." Thus is the title of an article by Kikuchi *et al.* (2017) in *Ecology* regarding katydids that mimic mosses. A katydid, *Adeclus* cf. *trispinosus* (Cadena-Castaneda 2011), was discovered as a short-winged adult male, presenting a wing pattern and coloration with legs and other parts that made it resemble a moss (Kikuchi *et al.* 2017). The katydid that became famous in *Ecology* uses three strategies of concealment: background matching, disruptive coloration, and masquerade. A member of the **Pleminiini**, it joins many other species that resemble mosses. Other moss mimics in the **Tettigoniidae** include *Panacanthus varius* (Figure 89) and *P. intensus* (Montealegre-Z & Morris 2004). This type of mimicry seems to have evolved multiple times in the **Orthoptera** (Mugleston *et al.* 2013).

Figure 89. *Panacanthus varius*, a moss mimic. Photo by Andreas Kay, through Creative Commons.

PHASMIDA – Walking Sticks

The common name of walking stick indicates that the **Phasmida** is a group of mimics. While looking like a stick is cool, looking like a hanging moss is awesome! And some members in the rainforests do just that (Figure 90), resembling pendent mosses in both color and appearance (Robinson 1969). The genus *Acanthoclonia* (**Pseudophasmatidae**) exhibits this moss-mimicking appearance (Gutiérrez & Bacca 2014).

Figure 90. Moss mimic walking stick. This one moves with a swaying, vibrating motion that mimics the movement of moss branches in the wind. Photo by Neil Bell, permission pending.

This kind of camouflage has been named in different ways, including **Batesian mimicry** and **crypsis**. But these terms may both be misleading conceptually (Skelhorn *et al.* 2010). Rather, the term **masquerade** has been applied to them (Figure 91). One problem in naming and understanding this phenomenon is the paucity of evolutionary studies on it, perhaps because its greatest representation is in the tropics where our level of understanding the systematics is much less than in other parts of the world. The term **masquerade** was introduced to describe those organisms that cause misidentification by other organisms.

Figure 91. A walking stick in Peru that looks like a twig with mosses growing on it. Photo by Arthur Anker, with permission.

Trychopeplus laciniatus

An incredible insect, *Trychopeplus laciniatus* (**Diapheromeridae**; Figure 92-Figure 98), is a montane Neotropical rainforest walking stick that looks like strands of mosses and leafy liverworts. Its range includes the mountainous forests of Costa Rica, Nicaragua, Panama, and Colombia. It "sways" its way through its mossy habitat, a behavior scientists have suggested resembles the moving of mosses in the wind. Regarding its presence in Monte Verde, Costa Rica, Ryan Burrows (Bryonet 14 April 2010) states that it "would be a perfect match to the habitat there." This phenomenal insect bears such resemblance to the mosses on the cloud forest tree trunks that it is virtually

undetectable to an untrained eye. It is flightless and slow moving, and has no means of defense (Simon 2015). Hence, this invisibility is its only means of protection.

Figure 98. *Trychopeplus laciniatus*, clearly masquerading as a bryophyte. Photo by Dan Doucette through Project Noah, with permission.

Another observer (Anonymous 2015) describes the mating in more detail. *Trychopeplus laciniatus* is a herbivore and uses its mossy appearance to hide among the mosses while it feeds. Instead of laying its eggs in a cluster like most mantids, it lays them singly and loosely on the trees. The eggs subsequently fall to the forest floor where the nymphs hatch and develop.

Ng (2015) reports a moss mimic stick insect that laid eggs among mosses in the Botanical Garden of the Kinabalu Park, Malaysia (film is available on website). In China, *Pericentrus* (Phasmatidae; possibly synonym of *Trychopeplus laciniatus*, **Error! Reference source not found.**-Figure 98) has coloration of green and brown that makes it look like mosses and lichens (Hennemann *et al.* 2008). It moved its body back and forth from side to side as it laid the eggs, occasionally releasing the ovipositor and re-inserting. It is likely that variants of these mimics exist in many locations in the tropics. Some may have been transported along with mosses, but their lack of wings would limit their distribution once they arrived. This kind of isolation promotes the formation of new species through the **founder principle** and **genetic drift**. For example, Belt figured one of these masqueraders in 1888 (Figure 99). But Tilgner (2002) disagrees with this explanation, suggesting instead that the multiple locations of such masquerading phasmids is the result of **convergent evolution**.

In Puerto Rico, *Lamponius nebulosus* (Pseudophasmatidae; Figure 100), a spiny green and brown mantid, represents the mimics (Nico Franz & Ines Sastre-de Jesus, Bryonet 15 April 2010). Those moss "leaves" you see are the spiny cuticle projections. This species is endemic to the cloud forest in the Luquillo Experimental Forest (Tilgner *et al.* 2000; Tilgner 2002) and has only been known for a short time. Its host plants include *Miconia* sp. and *Guzmania*, both likely to have associated mosses where it can rest undetected. In this group, activity is typically restricted to only certain times of day; when they are resting they are well camouflaged (Willig *et al.* 1993; Basset 2000; Berger 2004). But this species has two backup plans if it is discovered – it can exhibit **catalepsy** (trance state) or regurgitate fluid from its mouth.

T. Belt 1888

382 THE NATURALIST IN NICARAGUA. [Ch. XXI.

related genus (*Pterochroza*), imitate leaves in every stage of decay, some being faded-green, blotched with yellow; others, as in the species figured, resemble a brown withered leaf, the resemblance being increased by a transparent hole through both wings that looks like a piece taken out of the leaf. In many butterflies that resemble leaves on the under side of their wings, the wings being raised and closed together when at rest so as to hide the bright colours of the upper surface, there are similar transparent spots that imitate holes; and

MOSS INSECT.

others again are jagged at the edge, as if pieces had been taken out of them. Many chrysalides also have mirror-like spots that resemble holes; and one that I found hanging from the under side of a leaf had a real hole through it, formed by a horn that projected from the thorax and doubled back to the body, leaving a space between. Another insect, of which I only found two specimens, had a wonderful resemblance to a piece of moss, amongst which it concealed itself in the daytime, and was not to be distinguished except when accidentally shaken out. It is the larval stage of a species of *Phasma*.

Figure 100. *Lamponius nebulosus*, a moss mimic. Photo courtesy of Alfredo D. Colon Archilla <alfredocolon.zenfolio.com>.

Even egg shape may contribute to adaptations for living among bryophytes (see Hennemann 2008). *Parasthenobea foliculata* (Diapheromeridae) has many

irregular pale green, straw, or brown markings and speckles that give it good camouflage among lichens and mosses. *Parastheneboea exotica* (Figure 101) and *P. imponens* (Figure 102-Figure 103) have elongate, cylindrical, bullet-shaped eggs with conical polar ends. The **operculum** (lid) is surrounded by a collar of **setae** (hairs). This egg shape is usually associated with taxa having an appendicular ovipositor that is suitable for laying eggs into soil, moss, and bark crevices.

Figure 101. *Parastheneboea exotica*, a species with good camouflage among lichens and mosses. Photo by Albert Kang through Project Noah, permission pending.

Figure 102. *Parastheneboea imponens*, a moss and lichen mimic. Photo by Albert Kang through Project Noah, permission pending.

Figure 103. *Parastheneboea imponens* is blending here among the mosses. Photo by Albert Kang through Project Noah, permission pending.

In *Cnipsus rachis* (Phasmatidae; Figure 104) the thorn pads consist of a single pair (Buckley *et al.* 2010). Projections along the body resemble moss leaves. Some of the New Caledonian species prefer ferns for food, but it seems that New Zealand species do not feed on ferns.

Figure 104. Mantid *Cnipsus rachis* from Costa Rica – and New Caledonia. Photo by Louis Thouvenot, with permission.

Neoclides laceratus

Neoclides laceratus is a stick insect from Sumatra, Kalimantan, and Sarawak (Meagher 2022). In the swampy forests of Borneo it resembles creeping moss or the liverwort *Jungermannia* (Figure 106) with the insect's olive-green color and leaf-like projections.

Figure 105. *Neoclides laceratus* camouflaged perfectly among bryophytes on wood in Costa Rica. Photo by David Meagher.

Figure 106. *Jungermannia atrovirens*, in a liverwort genus that is mimicked by the stick insect *Neoclides laceratus*. Hermann Schachner, through Creative Commons.

***Antongilia laciniata* (Bacillidae)**

The moss mimic stick insect *Antongilia laciniata* (Figure 107) blends well with mosses in its aerial habitat. Although there are several images of this mimic online, there seems to be little information about its life.

Figure 107. *Antongilia laciniata* showing its moss-like camouflage in Madagascar. Photo by Frank Vassen, through Creative Commons.

***Phanocles* (Diapheromeridae)**

The genus *Phanocles* (Figure 108) is distributed in Central and South America (Gutiérrez & Bacca 2014) where it blends in with the epiphytic and epiphyllous bryophytes due to its markings and its shape like a twig.

Figure 108. *Phanocles* sp. nymph resembling a twig with adnate mosses, liverworts, and lichens in Panama. Photo by Arthur Anker, with permission.

MANTODEA – Preying Mantids

This group of mantids are predators, hence the name preying mantis, but they also look like they are praying, so you will see the name spelled both ways. I still recall seeing my first mantid as a child. I thought at first someone had dropped a pocket knife, then realized it was the largest insect I had ever seen. These insects usually are safely camouflaged while at rest (Figure 109), but when they are searching for food or attacking prey they become more visible (Figure 110). Some are able to secrete a nasty spray that can blind the predators ("Steve" on Fellowship of the Minds 6 May 2013).

Figure 109. Mantid moss mimic among mosses on tree trunk. Photo by Nick Garbutt <www.nickgarbutt.com>, with permission.

Figure 110. *Polytrichum strictum* capsules with a mantid. Photo by Michael Lüth, with permission.

But they are not all so large – Zborowski (1993), in *Animals in Disguise*, illustrates mantids from Borneo that are no more than a cm long. Coyne (2013) discusses *Pogonogaster tristani* (Thespidae; Figure 111-Figure 112), described in 1918 but reported only a few times since. Others in this genus are present in Colombia (Gutiérrez & Bacca 2014). This is one of the minute preying mantids that mimics mosses.

Figure 111. *Pogonogaster tristani*, one of the many moss mimics in this genus. Photo by Oscar Blanco, through Creative Commons.

Figure 112. Mantid that resembles mosses. Photo by Evelyne Lennette.

Not all camouflage involves morphology of the insect. Some mantids carry their own flora around with them. Two species of the shield mantis, *Choeradodis rhombicollis* (Figure 113) and *C. rhomboidea* (Figure 114-Figure 115) (Mantidae) in Costa Rica have **epizoic** (growing on animals) leafy liverworts and lichens growing on them (Lücking *et al.* 2010). Of the 84 individuals Lücking and coworkers examined in the lowland rainforests, 60 of them had epizootes, comprised of five liverwort species, 23 lichen species, and several unidentified fungi (Figure 116). These epizootes grew mainly on the enlarged pronotum, but some also grew on the forewings. The liverworts were all in the family

Lejeuneaceae and were all species typical as **epiphylls** on leaves, especially *Leptolejeunea elliptica* (Figure 117). These pronotal inhabitants were more pronounced in *C. rhombicollis* than in *C. rhomboidea*, and more in females than in males (Figure 116). One female of *C. rhombicollis* also had the leafy liverworts *Diplasiolejeunea brunnea* (Figure 118), *Cololejeunea gracilis* (Figure 119), *C. camillii* (Figure 121), and *Colura tortifolia* (Figure 120). The researchers suggested that the longer life span of females may account for the greater development of liverworts there. This camouflage permits these large mantids to rest undetected among the leaves with their own flora of "epiphylls."

Liturgusidae

Members of the genus *Majangella* can even resemble liverworts – a common group of bryophytes in the tropics. *Majangella moultoni* (Figure 122) has a green and brown patterned coloration with various protuberances that give it good camouflage when it is among mosses and liverworts. This species is tropical southeast Asian from Borneo, Indonesia, Malaysia, and Sumatra where it is inconspicuous in its rainforest habitat (Svenson & Vollmer 2014).

Figure 122. *Majangella moultoni* closely resembling the bryophytes beneath it. Photo by Hee Jenn Wei, with permission.

Mating

The mantids are well known for their mating behavior (Figure 123). The male is smaller than the female, and the female needs to be well fed before producing her egg case with eggs (Figure 124). Perhaps this is why the katydid males have evolved to offer a gelatinous spermatophore before mating. In short, it isn't safe to be the male mantid – you might get eaten! The predatory females see the smaller males as food (Figure 125), so males must make their moves carefully.

BLATTODEA – Cockroaches and Termites

You would most likely prefer not to think of cockroaches and termites as moss dwellers. If so, it may please you to know that the Australian wood-boring cockroach *Panesthia australis* (Blaberidae; Figure 126) prefers odors of individual tracheophyte species over the odor-neutral *Sphagnum* (Figure 61) (Billingham *et al.* 2009).

Figure 126. *Panesthia australis*, a cockroach that avoids mosses as a food item. Photo by Toby Hudson, through Creative Commons.

But the tables can be turned. Bernard Dupont photographed the ootheca (Figure 127) of a cockroach that was deposited on bryophytes and that had leafy liverworts growing up onto the ootheca. And Chatervedi sent me a picture of a cockroach that was hiding under the thallose liverwort *Dumortiera hirsuta* (Figure 129).

ISOPTERA – Termites

Termites have lost their status as an order and are now included as an infraorder within the **Blattodea**. Termites have a division of labor much like that of the ants.

There are some bizarre habitats occupied by bryophytes, and these include termite mounds (Figure 131-Figure 133). One of these is the preferential occurrence of four species of *Fissidens* (*F. gymnostomus*, *F. hornschurchii*, *F. scariosus*, and *F. subulatus*) on termite structures in the Amazon (Reese & Pursell 2002). In one case, *F. allionii* co-occurred with *F. subulatus* on mounds in Amazonian Brazil. In another *F. pellucidus* var. *pellucidus* (Figure 130) and *F. prionodes* both occurred on one mound.

Figure 130. *Fissidens pellucidus* var. *pellucidus*, a termite mound colonizer. Photo by Scott Zona, with permission.

Figure 131. Termite mounds in the Bungle Bungle Range in Western Australia. Photo by Ouderkraal, through Creative Commons.

Figure 132. *Nasutitermes triodiae* in Northern Territory, Australia. Photo by J. Brew, through Creative Commons.

These organically enriched structures may benefit from the mosses through erosion control, while the mosses benefit from enrichment by feces, saliva, and other substances (Reese & Pursell 2002). The raised mounds serve in the same way as tree roots and soil banks by elevating the substrate above the leaf litter accumulation. Nevertheless, few other mosses and liverworts seem able to live in this habitat.

It appears that *Fissidens* may actually help the termites (Reese & Pursell 2002). One can observe fishbone-like patterns on some kinds of termite nests, and *Fissidens* provides such a pattern on nests it occupies. This pattern most likely facilitates drainage of rainfall. Furthermore, the mosses can serve to bind the particles that comprise the nest as well as softening the blow as raindrops strike.

Fissidens termitarum in Bolivia and Brazil occurs almost exclusively on termite structures (Reese & Pursell 2002). In the Amazon Churchill (1998) recorded 13 of the

38 *Fissidens* taxa on termite structures, but none were found there exclusively. In Rondônia, Brazil, Lisboa (1993) found 7 of the 15 *Fissidens* taxa associated with termite nests.

Figure 133. Termite mound with mosses at base. Photo by Izuchukwu Ezukanma, with permission.

Fissidens is also known from termite mounds in Africa (Potier de la Varde 1928, 1936; Bizot & Pócs 1979; Bizot *et al.* 1990; Bruggeman-Nannenga 1993). Likewise, Catcheside and Stone (1988) reported this genus from termite mounds in northern Australia. Even Mitten (1869) referred to *Fissidens pellucidus* (Figure 130) on "ant mounds," but Reese and Pursell (2002) considered that these were most likely termite mounds.

Other species of mosses are rare on the termite structures. Reese (2001) reported several species of *Calymperaceae* on termite structures. Churchill (1998) has the largest number of collections noted, including *Calymperaceae*: *Syrrhopodon cryptocarpus* (Figure 138), *S. ligulatus*, *S. xanthophyllus*; *Pilotrichaceae*: *Brymela parkeriana*; *Stereophyllaceae*: *Pilosium chlorophyllum*. Reese and Pursell (2002) found *Phyllocladus falcifolium* (*Phyllocladaceae*) with *Fissidens* on one termite structure in the Amazon. Nevertheless, none of these non-*Fissidens* species seems to frequent the nests. Ezukanma (in prep) found 5 species (none included above) on termite nests in the Eastern Nigeria highlands: *Campylopus savannarum* (Figure 134), *Daltonia angustifolia* var. *angustifolia* (Figure 135), *Philonotis hastata* (Figure 136), *Rhachitheciopsis tisserantii*, and *Sematophyllum brachytheciiforme*.

Termites are generally unable to digest mosses (Bush 2015). Their guts have protozoa that facilitate their digestion of cellulose and lignin, hence their ability to eat wooden houses. Some people have considered termites to actually be a deterrent to mosses. Bush (2015) refers to a study in Ontario, Canada, that compared various types of

mulch on termite mortality. When used as the only source of food, peat moss starved the termites to death. Another study showed that subterranean termites tended to avoid travelling through peat, but only if the peat was moist. Dry peat seemed to have no effect.

Nevertheless, *Hospitalitermes umbrinus* (Termitidae; Figure 137) has "food balls" that contain bryophytes, but it prefers lichens (Collins 1979). This species forms foraging parties of roughly 500,000 soldiers and workers that leave the nest in the evening and return in the morning carrying these food balls.

Figure 137. *Hospitalitermes umbrinus*, a species that makes food balls containing bryophytes. Photo by Budak, through Creative Commons.

Termite mounds are an interesting ecosystem engineering feat. The termites actually benefit the ecosystem. The structure of these mounds cause more water to be absorbed into the soil and thus provide oases where green plants are able to subsist, preventing desertification (Bonachela *et al.* 2015; Hance 2015).

Figure 138. *Syrrhopodon* sp. Several species in this genus are known from termite mounds. Photo by Blanka Shaw, with permission.

EMBIOPTERA - Webspinners

This is a little-known order of tropical and subtropical net spinners. The name *embio* refers to the fluttery wings (*ptera*) of the first one described (Meyer 2009). One must wonder why one net spinner was collected from a moss cushion in Israel (Gerson 1982), but the image (Figure 139) below from Brazil supports it.

Figure 139. **Embioptera** from Brazil with net on mosses. Photo by Arthur Anker, with permission.

Summary

The **Orthopteroidea** include grasshoppers, pygmy grasshoppers, crickets, wetas, katydids, walking sticks, preying mantids, cockroaches, ice crawlers, and **Embioptera**. Among this group are many forms of camouflage and mimicry, and some of these are adaptations to living among bryophytes.

The pygmy grasshoppers (**Tetrigidae**) include many species that live among bryophytes and eat them. Some species have multiple morphs, permitting the species to occupy a variety of habitats. Many in this family also lay eggs there, as do many members of the **Acrididae**, a family that also includes bryophyte feeders. *Discotettix beelzebuth* has bryophytes growing on it, providing camouflage.

Mosses contribute a variety of patchy habitats that enable grasshoppers to remain separated spatially, supporting **Gause's** law by coexisting in the same environment but failing to compete due to the spatial separation.

Gryllidae (crickets) are rare among bryophytes, with bogs being the primary bryophyte habitat for them. Wetas are often found with bryophytes in caves or among them on tree trunks.

Rhaphidophoridae (camel crickets and wetas) include cave dwellers and other species that have color patterns blending with bryophytes. Some of the cave crickets also eat bryophytes.

Tettigoniidae (katydids) are good leaf mimics and some blend well with bryophytes by having a more broken color pattern. Some feed on *Sphagnum* and some lay their eggs there.

Walking sticks (**Phasmida**) are the master of disguise, mimicking pendent mosses in their rainforest homes. This type of mimicry, in which the insect can be mistaken for a hanging moss, may more

appropriately be termed **masquerading**. This type of mimicry has recently been termed masquerading. Some of these seem to have egg shapes adapted for oviposition among bryophytes.

The mantids (**Mantodea**) can have bryophyte camouflage and blend well, but their broad bodies prevent them from being mimics of pendent bryophytes. However, some do an excellent job of mimicking leaves with epiphylls living on them, including liverwort epiphylls, by having their own garden of bryophytic epizoots.

Cockroaches (**Blattodea**) seem to avoid mossy habitats, but one image shows the **ootheca** on bryophytes with liverworts growing onto the ootheca. Termites, formerly **Isoptera**, are members of the **Blattodea**. They often build mounds, especially in Australia, Africa, and the Amazon. These mounds are suitable habitats for a number of species of *Fissidens*, some of which seem to prefer that habitat. Few other bryophyte species occupy the mounds.

The **Embioptera** are probably not moss dwellers, although they were reported among mosses once.

Acknowledgments

Pavel Drozd helped me obtain some of the grasshopper photos. Heino Lepp and Judith Curnow introduced me to the tiny moss-mimicking mantids from Borneo. Jessica Beever, Thomas Buckley, and Sven Bradler helped me to get the identity of *Trychopeplus laciniatus*. Ryan Burrows helped me find web sites with information and the scientific name of the walking stick, *Trychopeplus laciniatus*. Louis Thouvenot sent me the image of another mantid mimic, *Cnipsus rachis*. Rob Gradstein provided me with the story of liverworts on *Choeradodis* (Mantidae). Matt Renner provided the reference on using the term masquerade. Thank you to all the photographers who gave me permission to use their images or placed them in Creative Commons. Three professional photographers gave me permission to use their images in this chapter – thank you to Nick Garbutt for the mantis moss mimic, Tony Jewell for his picture of *Maotoweta virescens*, and Alfredo D. Colon Archilla for his picture of *Lamponius nebulosus*. Tomás Pócs took pictures of Lejeuneaceae just for use in this chapter. Allan Fife helped me make contacts to try to understand the role of bryophytes for cave wetas. Petr Kočárek kindly sent me images of *Tetrix* spp. and *Discotettix beelzebuth* on mosses. Izuchukwu Ezukanma showed me an advance copy of his manuscript that documented termites on Eastern Nigerian highlands mosses on termite mounds.

CHAPTER 12-5

TERRESTRIAL INSECTS:

HEMIMETABOLA – NOTOPTERA AND PSOCOPTERA

Figure 1. Example of **Mantophasmatodea**, a subgroup of the **Notoptera**. Photo by Michael F. Schöntzer through Creative Commons.

NOTOPTERA

The order **Notoptera** perhaps deserves its own chapter simply because the smallest chapter is appropriate for the smallest order (<30 species) of insects (Ando & Machida 1987). But alas, for practical reasons, I have included the **Psocoptera** here as well, a much larger order but rare among bryophytes. The order **Notoptera** is poorly known and has limited, but widespread, distribution. Nevertheless, it is important in our understanding of insect evolution (Vrsansky *et al.* 2001). And mosses seem to play a role for at least some of their lives.

The order **Notoptera** is **relict** (survived from an earlier time period) (Vrsansky *et al.* 2001; Schoville & Kim 2011) and in addition to the two living families, it is known from fossils in middle Eocene (Lutetian) Baltic amber (Arillo & Engel 2006) and the Lower Permian (Aristov 2004), suggesting that it has been widespread in time and space. The living **Notoptera** are known only from Canada (Walker 1914), western United States (Caudell & King 1924; Kamp 1963, 1970), Russia (Bey-Bienko 1951; Kevan 1979), Korea (Storozhenko & Park 2002; Kim &

Lee 2007), China (Wang 1987), and northern Japan (Schoville 2010). Genetic isolation in parts of Asia may have resulted from geologic events in which islands fragmented and collided, causing mountain uplifts in Japan (Schoville *et al.* 2013). The remaining taxa appear to be a "poorly dispersing, cold-adapted terrestrial insect lineage" that occupies Japan, Korea, and Russia. The island fragmentation events have created a number of endemic species. In the western US, several *Grylloblattidae* and *Gryllacrididae* returned to the devastated Mt. St. Helens within three years after its eruption in 1980 (Sugg & Edwards 1998), suggestion that it has some means of dispersal.

The order **Notoptera** was named in 1915 but was largely overlooked (Wikipedia 2016a). More recently, it was somewhat resurrected and joined with the *Grylloblattodea*, placing both of them in the order **Notoptera**.

These insects resemble mantids, but never have wings (Ando & Machida 1987). They live under stones and in

caves in the alpine areas (Schoville & Kim 2011). They are well adapted to cold conditions (Pritchard & Scholefield 1978; Kevan 1979; Jarvis & Whiting 2006). Many retreat deep below the surface to escape surface temperatures ranging -35 to +45°C (Kevan 1979).

Grylloblattodea – Ice Crawlers

The **Grylloblattodea** are predominately nocturnal and feed on detritus (Wikipedia 2015). They are wingless and have either reduced eyes or no eyes (Figure 2). There is only one family and it is comprised of only 5 genera and 34 species that live mostly in leaf litter and under stones of extremely cold environments of higher elevations.

Figure 2. Member of **Grylloblattidae** on snow, a small family that may lay eggs in mosses. Photo by Alex Wild through Creative Commons.

When temperatures are cold enough for ice crystals to form in the body, the **Grylloblattidae** retreat under the snow pack near the soil (Grimaldi & Engel 2005). They feed mostly on arthropod carcasses, but if these are insufficient they rely on plant material (Wikipedia 2015). At least one member deposits its eggs among mosses (Richards & Davies 1977).

Grylloblattidae – Ice Crawlers

The North American ice crawlers are known for their adaptations to cold, whereas the Asian members are the most diverse (Jarvis 2005; Jarvis & Whiting 2006). They are rarely encountered, but this may be due to their seclusive habit of going underground or hiding among mosses. Bai *et al.* (2010) suggested that they lost their wings and became adapted to living under rocks or hidden in mosses in cold areas.

Most members of this family are carrion feeders, but they will also eat plant material, fungi, and detritus (Bai *et al.* 2010).

The modern (extant) members of this family are 14-34 mm long, pale, wingless, and avoid light (nocturnal or living in caves) (Bai *et al.* 2010).

Galloisiana

Galloisiana nipponensis (Figure 3) was first described by Caudell and King in 1924 from Japan. This was the introduction of a new genus and new family, the **Grylloblattidae**. This species occurs on the ground under stones and in moss (Memim Encyclopedia 2015). To date, no eggs have been found among mosses in **G. nipponensis** (Rentz & Ingrisch 2009).

Figure 3. **Galloisiana nipponensis**, an extant member of the **Notoptera** in northern Japan. Photo by Obsidian Soul through Creative Commons, with modified background.

Three quarters of a century later, **Galloisiana olgae** is a recently described species occurring in a small area on the banks of the Vasilkovka River in southeastern Russia (Vrsansky *et al.* 2001). The genus has also spread to Korea (Schoville & Kim 2011) and China (Wang 1987). It inhabits wet soil and is found under rocks that are covered with mosses. This raises an interesting question. What is the importance of the mosses on those rocks. I venture a guess. This and all members of the order are omnivores, often feeding on carcasses of other arthropods (Wikipedia 2015). Rocks with mosses provide easy access for these wingless insects to hunt for food among the mosses at night (or whenever they feed).

Grylloblatta

In North America, 13 species of **Grylloblatta** (Figure 4) have been described, but Schoville and Graening (2013) considered that another 16 are awaiting description and publication. Its known distribution in western North America (Caudell & King 1924) includes California, USA (Caudell 1923; Schoville & Roderick 2010; Schoville 2012), to British Columbia, Canada (Gregson 1938; Kamp 1979; Huggard & Klenner 2003). This is a genus with high endemism and small species ranges.

Bai *et al.* (2010) considered temperature to be the primary limiting factors in their distributions. This does not bode well for them in the face of global warming. A species of **Grylloblatta** (Figure 4) on Mt. Rainier, Washington, USA, is active on the snow in summer, where it forages at night (Edwards 1982). But they have behavioral strategies that enable them to avoid freezing, as seen in this **Grylloblatta**. This species lacks the usual means to survive freezing (cryoprotectants, supercooling) and dies at a mere -6.5°C (Edwards 1987). On the other hand, it experiences heat convulsions at temperatures of 14°C. Morrissey and Edwards (1979) similarly found that the Mt. Rainier species suffers lethal heat convulsions at 15-20°C and speculated that unsaturated fatty acids might be important in their low-temperature adaptations. Could it

be that arachidonic acid, a polyunsaturated fatty acid in mosses, might contribute to this cold tolerance? Nevertheless, it migrates downward to overwinter among the rocks under deep snow where it is assured of temperatures above its -6.5°C lethal temperature (Edwards 1987). Henson (1957) was able to maintain nymphs of *Grylloblatta campodeiformis* (Figure 4) at 4.5°C for six months.

Figure 4. *Grylloblatta campodeiformis*, a cold climate species that lays eggs on mosses. Photo through NSF public domain.

Huggard and Klenner (2003) collected 147 specimens of *Grylloblatta campodeiformis* (Figure 4) in British Columbia, Canada, in pitfall traps in the subalpine spruce-fir forest and lower elevation cedar-hemlock forest. Many were associated with mossy old-growth forests. They suggested that the moss layer was important for this species and that forest management practices might be reducing suitable habitat by affecting microclimate and snow accumulation – and moss cover.

When the female is about one year old, she will deposit black eggs singly among mosses or in soil (Kamp 1963, 1970; Ramel 2015). These eggs require another year to incubate, and the nymphal instars require about 5 years (8 instars) to become adults.

Grylloblatta campodeiformis (Figure 4) is a predaceous species that feeds on other arthropods (Pritchard & Scholefield 1978). Pritchard and Scholefield collected this species in the Rocky Mountains in Alberta, Canada at 1300 asl. Beamer (1933) found *G. campodeiformis* var. *occidentalis* in Mt. Baker in Washington.

The gut contents contained arthropods and little else, with a crane fly in the Tipulidae being the most common food. Both the *Grylloblatta campodeiformis* (Figure 4) and the tipulid are typical of cold, montane habitats. The *G. campodeiformis* eat only live or recently killed animal prey and both larvae and adults fail to develop or grow without animal food. To detect their prey, they use their antennae. Both the antennae and palpi (mouth parts) have sensitive hairs that most likely help in prey identification. The prey are seized by the mandibles.

I would expect to find some of them living among mosses or going there to feed because there are several species of crane fly larvae that live among the mosses. It could explain their association with the moss layer in old-growth forests. One cannot expect a wingless species to travel very far for food.

Members of *Grylloblatta* (Figure 4) possess **sensilla** (McIver & Sutcliffe 1982), a series of branched hairs protected by cuticle near the tip of the mandibles. Baker (1982) suggests they may be used to sense the pressure being exerted on the mandible tips, perhaps avoiding damage to the muscles.

Grylloblattella

Grylloblattella cheni was described as the second species in this genus, occurring in China (Bai *et al.* 2010). It is known from only one specimen, collected in the primary boreal coniferous forest near a lake. It was under the bark of a log near the summer snow line. This and other extant species have a shorter meso- and metathorax than prothorax, the opposite of the fossil species where the prothorax is shorter. They suggest this may be due to the loss of wings in the extant species.

PSOCOPTERA – Booklice, Barklice, Barkflies

This order is considered the most primitive of hemipteroids (Wikipedia 2016b). These are small insects (1-10 mm long). The barklice are harmless to the trees where they live, eating mostly algae and lichens. Their small size apparently makes scraping their food somewhat hazardous; their chewing mandibles are accompanied by a slender rod modified from the central lobe of the maxilla. This modified rod is used to brace them while they scrape their food with their mandibles. Some can spin silk, covering large areas of the bark (Hoell *et al.* 1998).

Most of the **Psocoptera** feed on detritus, epiphytes, fungi, and some on leaves (Baz 2008). They have a thin cuticle and thus are susceptible to desiccation. They are able to take up moisture from the atmosphere and obtain some of their water from food, but rarely by drinking.

Bryopsocus (**Bryopsocidae**) is associated with trees and mosses in wet forests (New & Lienhard 2007). This genus is endemic to New Zealand. Only two species occur there, both associated with mosses: *Bryopsocus angulatus* and *B. townsendi*, ranging 2-3 mm long (Bess & Johnson 2009). Likewise in New Zealand, *Echmepteryx madagascariensis* (**Lepidopsocidae**; Figure 5) lives on mosses that grow on the horizontal trunks of *Metrosideros* (Figure 6) (Smithers 1973). Smithers (1974) also collected *Spilopsocus avius* (**Elipsocidae**) from mosses in the subAntarctic islands of New Zealand.

Figure 5. *Echmepteryx madagascariensis*, a species that lives among mosses on horizontal trunks of *Metrosideros*. Photo by Sean McCann through Creative Commons.

Figure 6. *Metrosideros umbellata* (rata) showing horizontal trunks with mosses where one might find *Echmepteryx madagascariensis*. Photo by John Barkla, with permission.

Evidence of members of **Psocoptera** eating bryophytes is limited. Valle *et al.* (1977) reported one that feeds on mosses and lichens growing on citrus in Cuba.

Lucking (2000) pointed out that the **Psocoptera** are among the insects that feed on epiphyllous bryophytes, as well as other organisms (algae, fungi, lichens) that grow on the leaves. Unlike the **Lepidoptera** feeding there, the **Psocoptera** are generalists, eating whatever is available on the leaf. They typically lay their eggs on the lower leaf surfaces. The young juveniles are protected by their mothers. Lucking concluded that although they did considerable damage to the leaf habitat, they positively influenced the diversity of the lichen and bryophyte community.

Schmidt and New (2008) recorded other **Psocoptera** in association with mosses in Tasmania. *Lepinotus patruelis* (**Trogiidae**; Figure 7) was among mosses on a log; *Liposcelis* (**Liposcelidae**; Figure 8) occurs among mosses on logs and living trees.

Figure 7. *Lepinotus patruelis*, a moss dweller on logs and trees in Tasmania. Photo from <www.aphotofauna.com>, with permission.

Figure 8. *Liposcelis* sp. hiding under bark. Photo by Peter J. Bryant, with permission.

Some members of this order are known from mossy forests, but the role of the mosses is unclear. García Aldrete (2009) reported several species from this habitat in Argentina: *Polypsocus jujuyensis*, *Polypsocus selenius* (**Amphisocidae**), *Lachesilla dividiproctus*, *Lachesilla peckorum*, and *Lachesilla cuala* (**Lachesillidae**). On the other hand, Thornton (1985) found that the numbers and diversity of **Psocoptera** decreased on mountain tops with wet conditions and epiphytic mosses in many areas of the Pacific.

Some **Psocoptera** are restricted to caves. The **neotenous** (retaining juvenile characteristics in adults) *Cyptophania pakaratii* (Figure 9) seems to be limited to the fern-moss "gardens" in the cave entrances (Figure 10) in the Pacific basin (Mockford & Wynne 2013). These habitats serve as relict habitats of the last glacial maximum, supporting species that are restricted to the conditions they offer (Benedict 1979; Northup & Welbourn 1997; Wynne 2013; Wynne *et al.* 2014).

Figure 9. *Cyptophania pakaratii*, a species apparently restricted to the fern-moss patches in cave entrances. Photo by Jut Wynne, with permission.

Summary

The **Notoptera** is a small order of relict insects, due in part to absence of wings and dispersal limitations. The **Grylloblattodea** (ice crawlers) are mostly nocturnal detritus feeders. Some can use mosses for oviposition. Members of **Grylloblattidae** may live under mosses in cold regions. **Grylloblatta campodeiformis** is often associated with mossy old-growth forests and deposits her eggs on the mosses.

Few species of **Psocoptera** are moss inhabitants, but their small size permits some of them to live there. The genus **Bryopsocus** is known only from mossy habitats in New Zealand. Some may feed on bryophytes, including epiphyllous bryophytes. Some are restricted to cave entrances where they live among mosses and ferns.

CHAPTER 12-6

TERRESTRIAL INSECTS:

HEMIMETABOLA – HEMIPTERA

(HETEROPTERA)

Figure 1. Lacebug (**Tingidae**) with moss *Tortula papillosa* and lichen *Candelaria concolor*. Photo by Robert Klips, with permission.

HEMIPTERA – True Bugs

While many people call all insects bugs, there is only one order that officially carries that name. Their scientific name of **Hemiptera** revealed their most unique character, wings that are "half" membranous and "half" chitinized. But recent classification has added other groups to the **Hemiptera** that do not have this character, and some have no wings at all. The order is now divided, including the traditional "bugs" in the suborder **Heteroptera**. The **Hemiptera** are **hemimetabolous**, having a life cycle of eggs, nymphs, and adults. The overwintering stage depends on the species and may be spent among mosses.

Although most bugs feed on tracheophyte (mostly flowering plant) leaves, often specializing on one species, for many the bryophytes are important alternate hosts when the tracheophyte leaves are no longer available or no longer hospitable. But Rédei *et al.* (2003) considered the ground fauna to be under-sampled relative to the pest species that

occurred above ground on plants. Using Berlese funnels for extraction (without specifying sample size) they found that the assemblages of **Hemiptera** from mosses were similar to those from soil and could occur "in great numbers" (Table 1). In fact, moss samples had higher numbers per sample than soil samples, although it is hard to know the appropriate base (weight, area, volume, *etc.*) on which to compare them. To sample **Hemiptera** among bryophytes, Marie-Claude Larivière uses a sieve technique (Figure 2).

As an example of moss hemipteran diversity, the communities among various moss species in Hungary differ little from each other, with the exception of those on *Sphagnum* (Figure 3; Table 1) (Rédei *et al.* 2003). On the other hand, the **Hemiptera** communities on bryophytes differ significantly ($p < 0.05$) from those of tussocks and those of soil, leaf litter, and debris (Figure 4). An important factor among the bryophyte habitats is the moisture level. Mosses on the ground retain water longer

than those on tree trunks, with those on rocks retaining the least water and providing the driest habitats. Consequently, **Hemiptera** species preferring humid conditions are common among bryophytes on the ground and some tree trunk conditions but do not occur among the drier rock dwellers.

Table 1. Comparison of Hemiptera in bryological samples and non-bryological samples on the ground. From Rédei *et al.* 2003.

substrate	number of samples	number of specimens	number per sample
mosses on tree trunks	225	725	3.2
mosses on stones and rocks	292	1240	4.2
mosses on ground	259	520	2.0
other mosses	117	221	1.9
<i>Sphagnum</i>	94	107	1.1
soil	390	159	0.4
leaf litter, debris	795	586	0.7
tussocks, tufts of sedges	287	209	0.7

Figure 3. *Sphagnum* becoming established on *Potentilla fruticosa* as a fen becomes more moist and acidified. The fen and bog locations typically have both flowering plants and mosses, providing the two alternative hosts needed by many **Hemiptera** species. Photo by Janice Glime.

Figure 4. Similarity pattern of communities associated with the four major substrata groupings of Hungarian hemipteran ground fauna. Redrawn from Rédei *et al.* 2003.

True bugs are affected by the nutrients available to mosses. Richardson *et al.* (2002) found that moss-feeding true bugs in fertilized plots in Scandinavia diminished in number to as little as 6% of those in the unfertilized controls. The **Homoptera** on grasses, on the other hand, were more than 400% more abundant, indicating that fertilization was detrimental to the moss communities. Such a reduction could be the result of nutritional changes in the mosses or a reduction in mosses, reducing both food and cover for bryophyte-adapted bugs.

Adaptations

Most of the bugs that live among bryophytes are tiny, often only 1-2 mm in length. Their biggest adaptation is that many of the moss dwellers are able to eat mosses. This ability not only may involve differences in mouthparts, but at least sometimes requires the presence of **endosymbiotic** bacteria to help in digestion (Kuechler *et al.* 2013). But it seems that few other adaptations exist. Their coloration is often brown, and I find that the common moss-dwelling lace bugs often resemble seeds, not mosses. That's not a bad appearance if you are hiding from carnivores, but it doesn't make you invisible. Instead, the coloration of most species is adaptive for the primary host. On the other hand, mosses provide a habitat where behavior is important. Many species are able to migrate vertically within the moss mat to find suitable temperature and humidity (Marie-Claude Larivière, pers. comm. 1 September 2015).

Nutrients

Among the factors that limit **Hemiptera**, nutrients in the plants can play an important role. This can be especially important for some adapted to Arctic and sub-Arctic habitats where nutrient turnover is slow. In a dwarf shrub heath community, Richardson *et al.* (2002) manipulated nutrients and temperatures to determine responses. Nutrient addition had a strong effect on the subordinate mosses and resulting changes in the abundance of the insect herbivores. These changes had a greater impact on the insect herbivore community than those of the shrub layer. Those **Hemiptera** (**Heteroptera**) on the fertilized plots reached an abundance only 6% that of the unfertilized controls. **Homoptera** (former classification),

on the other hand, were more than 400% more abundant. The grass-eating **Delphacidae** (plant hoppers) were only present in fertilized plots.

Habitats

Forests

Forests offer a variety of habitats for bryophyte-dwelling **Hemiptera** (Lattin & Moldenke 1990). In the woodland habitats of Hungary, Rédei *et al.* (2004) found *Acalypta carinata* (2.5 mm; **Tingidae**; Figure 5) among the *Sphagnum* (Figure 3) and the moss *Abietinella abietina* (Figure 6), living on tree trunks or the ground. This lace bug prefers humid, shady woodland habitats. *Acalypta musci* (2.5-2.8 mm; Figure 7) is typically a moss dweller, but it also occurs on fungi on tree trunks and among mosses at tree bases.

Figure 6. *Abietinella abietina*, a woodland home for *Acalypta carinata*. Photo by Janice Glime.

Figure 7. *Acalypta musci*, a species named for its association with mosses. Photo by Boris Loboda, with permission.

The mossy forests of the temperate and Antarctic rainforests of New Zealand (Figure 8) are home to the tiny **Peloridiidae** (2-4 mm) (Burckhardt 2010; Burckhardt *et al.* 2011; Harris 2011, 2014). The **Peloridiidae** also occur in temperate forests in Australia (Grozeva *et al.* 2014). The genus *Xenophyes* (2.18-3.23 mm; Figure 9), a member of **Peloridiidae**, is common in the rainforests throughout the southern hemisphere, including Chile, Argentina, New Zealand, New Caledonia, and Australia (Burckhardt *et al.* 2011). *Pelordium hammoniorum* (3.9-4.3 mm), the only member of the family with both winged and flightless forms, was recently described as a new species from Chilean secondary forests, living among mosses, primarily on *Polytrichadelphus magellanicus* (Figure 10) (Shcherbakov 2014).

Figure 8. Wet Rimu (*Dacrydium*) forest in New Zealand where **Heteroptera** live among mosses. Photo by Marie-Claude Larivière, with permission.

Figure 10. *Polytrichadelphus magellanicus*, home of *Peloridium hammoniorum*. Photo by Juan Larrain, with permission.

Dikraneura aridella (5.6-6 mm; **Cicadellidae**; Figure 11) lives in moss-covered coniferous European forests, where it feeds on grasses (Söderman 2007). *Aguriahana pictilis* (~5 mm; **Cicadellidae**; Figure 12) likewise lives in moss-covered forests, but it feeds on blueberry (*Vaccinium myrtillus*) leaves. The importance of the mosses for these two species is unclear. Elsewhere, *Macrocixius emeljani* (0.51-0.64 mm; **Cixiidae**) and *M. oropilus* (0.69-0.70mm) live in high mountain mossy forests in Taiwan and Nepal (Orosz 2013). *Melanocoryphus albomaculatus* (~9 mm; **Lygaeidae**; Figure 13-Figure 14),

a critically endangered species in the Czech Republic, lives under lichens, moss, dry leaves, stones, etc. (Kment *et al.* 2013a). Its bright orange and black color patterns seem left over from some prior host of its relatives because they do not seem adaptive to mosses or to some of its host plants like *Senecio* (Chateau Moorhen 2015). And, oddly for a moss dweller, in France it likes hot, dry places!

Figure 11. *Dikraneura aridella*, a species that prefers moss-covered coniferous forests in Europe. Photo by Marko Mutanen, through Creative Commons.

Larivière *et al.* (2011) reported *Oiophysa ablusa* (Peloridiidae; Figure 15) from montane *Nothofagus* forests in New Zealand where they lived among wet mosses and leaf litter. *Oiophysa cumberi* (Figure 16) is a more lowland species, living in broadleaf-podocarp and *Nothofagus* forests among both mosses and liverworts on the ground and on trees. *Oiophysa distincta* is likewise in the lowland to montane podocarp and *Nothofagus* forests where it lives among mosses on the ground and on trees as well as in litter. This species also occurs on the pendulous moss *Weymouthia* sp. (Figure 17).

Figure 15. *Oiophysa ablusa* on leafy liverwort. Photo by E. Wachmann through M.-C. Larivière, with permission.

Epiphytes

Tree-trunk bryophytes are typically drier than those growing on the ground and some species of *Lygaeidae* prefer to live among mosses in this habitat (Rédei *et al.* 2003). Members of *Peloridiidae* (Bechly & Szvedo 2007) and *Rhyparochromidae* (Rédei *et al.* 2003) are common on tree trunk mosses in Europe. Furthermore, the genus *Acalypta* (*Tingidae*) is represented there by a number of species, and *Piesma maculatum* (2-3 mm.; *Peismatidae*; Figure 18), *Myrmedobia exilis* (1.3-2.2 mm; *Microphysidae*; Figure 19), *Cryptostemma* (2.5-2.8 mm; *Dipsocoridae*; Figure 20), and *Ceratocombus coleoptratus* (1.5-2.0 mm; *Ceratocombidae*; Figure 21) also prefer this tree trunk habitat, as well as ground and other substrata.

Rédei *et al.* consider many terrestrial *Hebrus* (*Hebridae*; Figure 36-Figure 38) species, including young nymphal stages, to prefer moss on tree trunks, ground, and other surfaces. In Tasmania, *Xenophyes cascus* (2.48-3.10; *Peloridiidae*; Figure 22) occurs among bark mosses (Burckhardt *et al.* 2011).

The **Saldidae** (shore bugs; Figure 24-Figure 23) include a range of habitats from the intertidal zone to terrestrial habitats. Among these habitats is the moss on the trunks of rainforest trees (Polhemus & Chapman (1979). *Lampracanthia crassicornis* (1 mm; Figure 23) and *Salda anthracina* (Figure 24) lay their eggs between the leaves of mosses (Hungerford 1918). *Salda anthracina* is much like the preying mantis in its mating behavior. But unlike the preying mantis, the male initially follows the female around, keeping a safe distance (Hungerford 1919). When he decides to mate (or the opportunity is right), he pounces upon her. He exits quickly at completion lest he too, like the preying mantis male, be eaten by his mate. And sometimes he is eaten.

Sand Dunes

In dunes, bryophytes can offer respite from the dry sand. Spungis (2005) found that **Hemiptera** density was limited by available cover of mosses and lichens. Sand dunes are dry and inhospitable for insects that do not have desiccation protection. For some, that protection comes in surface waxes, hard chitin, and a reduced physiological need for water. For others, behavior is the most important adaptation, allowing the hemipterans to move to mosses when host plants become inhospitable. Spungis (2005) found that mosses provided a refuge for bugs in the coastal grey dunes (Figure 25) of Latvia. The number of species of **epigeic** (active at the soil surface) **Hemiptera** correlated with the moss-lichen cover in the dunes ($p < 0.01$). The density of ground-dwelling species was low and both population density and species diversity were limited by available cover of lichens and mosses. *Nysius thymi* (3.5-4.5 mm; **Lygaeidae**; Figure 26) and members of **Miridae** (jumping tree bugs; Figure 118-Figure 123) had high population densities and were dominant compared to the grass-dwelling hemipterans. *Sciocoris cursitans* (4.5-6.0 mm; Figure 27) in the **Pentatomidae** dominated the soil dwellers (41%), with a high correlation ($r = 0.81$; $p < 0.01$) with moss and lichen cover.

Figure 25. Coastal grey dunes in The Netherlands. Similar sites in Latvia have limited **Hemiptera**-moss associations, including mostly **Miridae**. Photo by Bas Kers, through Creative Commons.

In Hungary, Rédei *et al.* (2004) found that *Acalypta gracilis* (2-2.8 mm; **Tingidae**; Figure 28) preferred the Pannonic dune open grassland patches (Figure 29) over the dune-slack (Figure 30) purple moor grass meadow. *Acalypta marginata* (2.0-3.0 mm; Figure 31-Figure 32) was present equally in the Pannonic dune open grassland and the Pannonic sand puszta patches (Figure 33), but likewise avoided the dune-slack purple moor grass meadow. Both species are moss dwellers.

Figure 33. Pannonic sand puszta with draw well in Hungary. Photo by Andreas Poeschek, through Creative Commons.

Streamside and Wet Habitats

This habitat group includes bugs with high moisture requirements, but that are not truly aquatic. For example, *Macrovelia hornii* (4.2 mm; **Macroveliidae**; Figure 34) nymphs and adults live among mosses at the water's edge but are unable to live in the water or on its surface (Usinger 1974).

Figure 34. *Macrovelia hornii*, a moss inhabitant at water's edge. Photo by Jerry Wilson, with permission.

Hebrus concinnus (2.25-2.5 mm; **Hebridae**; Figure 35), from a genus that is dominant among **Hemiptera** in bogs and fens (see Chapter on aquatic Hemiptera in this volume), lays its eggs where they are partially concealed between moss leaves (Usinger 1974). Schuh and Slater (1995) described them as living deep in moss mats, with *Hebrus ruficeps* (1.3-3.7 mm; Figure 36) overwintering frozen in ice among *Sphagnum* (Figure 37). *Hebrus pusillus* (1.6-2.1 mm; Figure 38) is associated with *Sphagnum* and other mosses (Howe 2004) and also reproduces among mosses at the edge of water (Münch 2013). Hebrids also often lay their eggs among mosses, suggesting that early instars may develop there.

Figure 38. *Hebrus pusillus*, among the dominant *Hebrus* species in bogs and fens. Photo by Joseph Botting, with permission.

Micracanthia schuhi (2.64-3.35; **Saldidae**; see Figure 39) is a moss dweller in Oregon, USA, where it lives beside a small stream on Mt. Hood among moist mosses (Lattin 1968, 1997). It moves up and down within the moss mat to achieve the best temperature level (Lattin 1968).

Figure 39. *Micracanthia marginalis*. *Micracanthia schuhi* lives among mosses on Mt. Hood, Oregon, USA. Photo by Jürgen Deckert, with permission.

Cryptostemma waltli (1.2-1.5 mm; **Dipsocoridae**; Figure 20) lives in shaded wet habitats where it inhabits the mosses *Sphagnum* (Figure 37), *Hypnum* (Figure 40), *Brachythecium* (Figure 41), and *Cratoneuron* (Figure 42) (Kment *et al.* 2013b).

Peatlands

Peatlands are borderline between aquatic and terrestrial habitats. I have already discussed the more aquatic-leaning taxa in the chapter on Aquatic Insects, especially those living in bog pools. Here I will treat the species that use other (non-bryophyte) plants that live in the bogs, perhaps also using the mosses, but that require or benefit from the peatland habitat.

Rédei *et al.* (2003) found that the **Hemiptera** tussock community and species living among *Sphagnum* (Figure 3) species were comprised primarily of ubiquitous species that were able to occupy most kinds of mossy substrata. Like many other invertebrates, many of the species of **Hemiptera** are not restricted to bogs and tend to be widespread (Holzinger & Schlosser 2013).

Holzinger and Schlosser (2013) conducted a survey of the **Hemiptera** fauna of Austrian peat bogs in the Bohemian Forest. They found that the **Auchenorrhyncha** formed a considerable fauna, with 93 species among 7465 specimens in these bogs, making them one of the most abundant animal groups in peatlands (see also Holzinger 1995, 2000; Holzinger & Novotny 1998). Eleven of these species were either **tyrphobiontic** (peat bog specialist; restricted to bogs) or **tyrrophilous** (common in bogs but not restricted to them). Tyrphobiontic species in these bogs include *Sorhoanus xanthoneurus* (3.1-3.4 mm; **Cicadellidae**; Figure 43) and *Stroggylocephalus livens* (5-6.5 mm; **Cicadellidae**; Figure 44), *Kelisia vittipennis* (3-3.6 mm; **Delphacidae**; Figure 45), and *Cixius similis* (5 mm; **Cixiidae**; Figure 46) (see also Trivellone 2010). *Cixius similis* migrates from mosses to shrubs to feed and mate, then returns to the moss-covered ground to oviposit (Söderman 2007). Tyrrophilous species include the **Cicadellidae** *Sorhoanus assimilis* (often the most frequent hemipteran; 2-2.9 mm; Figure 47), *Cicadula saturata* (4-5.5 mm; Figure 48), and *Macrosteles ossiannilssoni* (Figure 49), and the **Delphacidae** *Paradelphacodes paludosa* (2.8-3 mm; Figure 50), *Kelisia ribauti* (3-4.5 mm; Figure 51), and *Oncodelphax pullula* (2-4 mm; Figure 52) (Holzinger & Schlosser 2013).

Figure 51. *Kelisia ribauti*, a species that is common in bogs but that is not restricted to them. Photo by Gernot Kunz, with permission.

Figure 53. *Conomelus lorifer*, a bog dweller in Europe. Photo by Gernot Kunz, with permission.

Figure 52. *Oncodelphax pullula* on Cyanobacteria, a species that is common in bogs but not restricted to them. Photo by Joe Botting, with permission.

Figure 54. *Conomelus lorifer* adult, a bog dweller. Photo by Gernot Kunz, with permission.

Conomelus lorifer (Delphacidae; Figure 53-Figure 54) occurs in *Sphagnum-Carex* associations in Switzerland (Trivellone 2010) at higher altitudes (Ökteam 2012). *Conomelus anceps* (4 mm; Figure 55-Figure 56) is a lower altitude species and comprised 17% of the individuals in the Austrian peat bogs and was the most common species there (Holzinger & Schlosser 2013). This species was followed by *Muellerianella extrusa* (3.6-4.2 mm; Delphacidae; Figure 57) (9.2%), *Sorhoanus xanthoneurus* (Cicadellidae; Figure 43) (7.6%), *Jassargus pseudocellaris* (Cicadellidae; Figure 58) (5.5%), and *Macustus grisescens* (5-6 mm; Cicadellidae; Figure 59) (5.2%). Most of these species are **stenoeicous** (having a narrow habitat range) and specialize not only on the habitat, but also on their host plants (Nickel *et al.* 2002; Nickel 2003). The bogs have more **univoltine** (having one brood of offspring per year) **Auchenorrhyncha** species compared to other habitats in Austria and likewise more of their species in the bogs hibernate during their nymphal stage (Holzinger & Schlosser 2013). Densities of adults are low in spring (10-60 individuals per m²), rising to a high of 180 individuals per m² in July.

Figure 59. *Macustus griseus*, a *Sphagnum* associate in Europe. Photo by Tristan Bantock, with permission.

In Austrian peatlands, life cycle stages of the **Auchenorrhyncha** represent different proportions than in the whole of the Austrian fauna (Figure 60) (Holzinger & Schlosser 2013). The number of generations tends to be fewer in peatlands than in the general fauna (Figure 60).

Figure 60. Comparison of generation stages and numbers of generations per year for species of **Auchenorrhyncha** in Bohemian forest peat bogs compared to those of the whole Austrian **Auchenorrhyncha** fauna. Redrawn from Holzinger & Schlosser 2013.

SUBORDER HETEROPTERA

(true, typical bugs)

PENTATOMOMORPHA – STINK BUGS, FLAT BUGS, AND SEED BUGS

Thyreocoridae – Ebony Bugs

One member of this family was collected among mosses of the Cheviot Hills, UK – *Corimelaena scarabaeoides* was common among mosses (Champion 1871). *Thyreocoris scarabaeoides* (Figure 61-Figure 63) is a common moss inhabitant, measuring only 3-4 mm (British Bugs 2015a). Its black color as an adult makes it difficult to notice in the depths of the moss. (I can't find confirmation of the nomenclature for *Corimelaena scarabaeoides*, so it may be a synonym of *Thyreocoris scarabaeoides*.)

Figure 62. *Thyreocoris scarabaeoides* late-instar nymph. Photo by Tristan Bantock, with permission.

Figure 63. *Thyreocoris scarabaeoides* adult. Photo by Tristan Bantock, with permission.

Cydnidae – Burrowing Bugs, Shield Bugs

Burrowing bugs don't normally inhabit bryophytes, but there are some exceptions. These include the somewhat larger *Canthophorus impressus* (6-7 mm; Figure 64), a rare species (British Bugs 2015b) that hibernates in groups under mosses and leaves in winter (eImageSite.net 2013). Records for *Canthophorus dubius* (7mm; Figure 65) are often actually *C. impressus*, requiring dissection for certain identification (British Bugs 2015b).

Figure 69. *Rhacognathus punctatus* adult, a moss dweller. Photo by James K. Lindsey, with permission.

Pentatomidae – Stink Bugs and Shield Bugs

In Hungary this family is represented in great numbers in moss mats (Rédei *et al.* 2003). In the UK Champion (1871) reported *Rhacognathus punctatus* (7-9 mm; Figure 68-Figure 69) among mosses in heath (Figure 70) and *Zicrona caerulea* (5-7 mm; Figure 71-Figure 72) as a common bug among mosses on the chalk downs (Figure 73). *Sciocoris cursitans* (4.5-6 mm; Figure 27) dominated the epigeic Hemiptera at the coastal gray dunes in Latvia (Spungis 2005) and demonstrated a significant positive correlation with the amount of moss-lichen cover. This family seems to prefer mosses for cover in relatively exposed and dry habitats. Despite the statement by Rédei *et al.* (2003) that they occur in great numbers in moss mats, there seems to be little published about the role of these relationships.

Berytidae – Stilt Bugs

The **Berytidae** are comprised of about 100 species (Encyclopædia Britannica 2015). They are delicate looking, with slender bodies, and despite their long legs they are slow moving. They are somewhat larger (5-9 mm) than most moss dwellers, but their brown color helps them to blend somewhat with at least some mosses. All members of the family are plant feeders and they

sometimes damage crop plants. A few are known moss dwellers.

Berytinus signoreti (4.5-6 mm; Figure 74-Figure 75), *Berytinus minor* (Figure 76), and *Neides tipularius* (10-11.5 mm; Figure 77) are all moss dwellers in the UK (Champion 1871). Woodroffe (1959) reported *Berytinus signoreti* occurring under the flower *Lotus corniculatus*, but also noted "scattered individuals" among mosses. *Berytinus minor* is common among mosses and grass roots in the UK (Douglas & Scott 1865). In Dorset, England, members of *Cymus* (2.5-5 mm; Figure 78-Figure 79) live in meadows and heathlands on rushes, but in winter this genus overwinters under moss or bark (Recording Dorset 2011).

Figure 78. *Cymus glandicolor* nymph, a moss dweller. Photo by Tristan Bantock, with permission.

Figure 79. *Cymus glandicolor*, a species that overwinters under mosses or bark. Photo by Tristan Bantock, with permission.

Lygaeidae – Seed Bugs and Milkweed Bugs

Most of the members of this family are ill-suited for living among bryophytes. They typically feed on seeds, but

some are predatory, some feed on sap, and some feed on blood (TrekNature 2011). They often exhibit bright colors (Figure 80) and are too large to move easily among most kinds of mosses.

Figure 80. *Lygaeus creticus* on *Atrichum*, exhibiting a size and sharp color contrast that does not make this a safe environment. Photo by Dragiša Savić, with permission.

In Eastern Europe, Kment *et al.* (2013a) found *Melanocoryphus albomaculatus* (7-9.5 mm; Figure 13-Figure 14), a colorful bug, under lichens, mosses, dry leaves, and stones. They preferred sunny rocky hillsides and clearings. Perhaps its red and black warning colors are enough to scare away would-be predators, or it simply isn't seen when under the moss. *Taphropeltus hamulatus* (2.9-3.4 mm; Figure 81) lives in well-drained base-rich sites, particularly among the mosses in areas with loose rocks (Alexander 2008). At least its colors are less conspicuous. *Lamproplax picea* (4.0-5.0 mm; Figure 82) is a moss dweller in the UK and has similar dark coloration (Hallett 1916).

Figure 81. *Taphropeltus hamulatus*, a moss dweller in well-drained, base-rich sites. Photo by Tristan Bantock, with permission.

Figure 82. *Lamproplax picea*, a moss dweller in the UK. Photo by Joe Botting, with permission.

Piesmatidae – Ash-Grey Leaf Bugs

This is a small family of plant-eating bugs. Using the Berlese funnel to extract bugs from various substrata, Rédei *et al.* (2003) found that *Piesma maculatum* (2-3 mm; Figure 83) preferred to live among mosses on tree trunks, ground, and other substrata. Alexander (2008) likewise found it in moss litter in the UK. I have not found any other records for this family among bryophytes.

Figure 83. *Piesma maculatum*, a species that "prefers" living among mosses. Photo by Joe Botting, with permission.

Rhyparochromidae – Seed Bugs

I discovered a record of this family by accident as I was searching for harvestman pictures. Naturalist Graeme Lyons (2011) of Sussex, UK, reported "beating" a clump of *Thuidium tamariscinum* (Figure 84) to find invertebrates. With this activity, he was able to add a new species of **Hemiptera** to his list of finds: *Peritrechus nubilus* (5-6 mm; Figure 85). In New Zealand, this family occurs among mosses in the forest (Figure 86).

Figure 84. *Thuidium tamariscinum* with capsules, home to *Peritrechus nubilus*. Photo by Michael Lüth, with permission.

Figure 85. *Peritrechus nubilus*, a species found in the moss *Thuidium tamariscinum*. Photo by Tristan Bantock, with permission.

Figure 86. **Rhyparochromidae** habitat under moss in Arthur's Pass, NZ. Photo by Marie-Claude Larivière, with permission.

Early reports of bryophyte dwellers in this family date as far back as 1871 (Champion 1871). A species of *Peritrechus lundii* (4-5 mm; Figure 87) along with two *Drymus* (Figure 97-Figure 98) species, *Trapezonotus arenarius* (4-4.5 mm; Figure 88-Figure 89), and *Stygnocoris sabulosus* (2.5-3 mm; Figure 90-Figure 91), were most common among mosses in alder (*Alnus*) woods.

Figure 87. *Peritrechus lundii*, a moss dweller. Photo by Tristan Bantock, with permission.

Figure 88. *Trapezonotus arenarius* nymph, a common species among UK mosses in alder woods. Photo by Tristan Bantock, with permission.

Figure 90. *Stygnocoris sabulosus*, a moss dweller. Photo by Tristan Bantock, with permission.

Figure 91. *Stygnocoris sabulosus* adult at Crowle Moors, UK. Photo by Brian Eversham, with permission.

Alexander (2008) reported that *Trapezonotus desertus* (4-5 mm; Figure 92) nymphs occurred among dry mosses and lichens. *Peritrechus geniculatus* (5-6 mm; Figure 93-Figure 94) is also known from mosses and leaves on light sandy and chalky soils in Dorset, England (Alexander 2008; Recording Dorset 2011). This species overwinters as an adult, protected by the mosses. *Eremocoris abietus* (6-7.5 mm; Figure 95) and *Stygnocoris rusticus* (3-4 mm; Figure 96) likewise occur among mosses elsewhere in the UK (Champion 1871).

Figure 92. *Trapezonotus desertus*, a species whose nymphs live among dry mosses and lichens. Photo by Tristan Bantock, with permission.

Figure 96. *Stygnocoris rusticus*, a species that lives among mosses in the UK. Photo by Tristan Bantock, with permission.

Drymus sylvaticus (Figure 97), *D. brunneus* (Figure 98), *Stygnocoris sabulosus* in a UK study occurred primarily among mosses in the alder woods. *Canthophorus dubius* (Cynidae; Figure 65) was more rare, overwintering among mosses under junipers of the chalk downs, a habitat where *Zicrona coerulea* (Pentatomidae; Figure 71-Figure 72) was common. *Drymus brunneus* (4-5 mm) occurs among mosses in damp, shady places; it is widespread and common (Stenhouse 2007) despite preferring damper soils than other species of *Drymus* (Alexander 2008). *Drymus sylvaticus* (4-5 mm) is one of the most common of the British ground bugs, often occurring among mosses on dry soil (Alexander 2008; Bury Wildlife 2014). This species becomes active at night, feeding on mosses and fungal hyphae (Southwood & Leston 1959; Alexander 2008). Champion (1871) reported both of these species from mosses near Cheviot Hills, UK. *Recording Dorset* (2011) reports *D. sylvaticus* as common, occurring in most dry habitats that have mosses. In the UK, the rare *Drymus pilicornis* (3.9 mm) lives mostly in moss clumps among grasses on calcareous or base-rich grassland (Alexander (2008). In France, the rare *Drymus pilipes* (~2 mm) lives among mosses and litter (Péricart 1999).

Figure 97. *Drymus sylvaticus* adult, a moss dweller on dry soil in the UK. Photo by Tristan Bantock, with permission.

Figure 98. *Drymus brunneus*, a moss dweller in damp, shady places in Europe. Photo by Tristan Bantock, with permission.

Pterotmetus staphyliniformis (5-5.5 mm; Figure 99) is a rare species in the UK, living on moss-covered boulders on cliffs (Alexander 2008). Both *Megalonotus praetextatus* (4-5 mm; Figure 100) and *M. sabulicola* (4.5-5.5 mm; Figure 101) live in dry areas, the former where it is warm and sunny, especially in dunes and quarries, but it also lives on cliffs with mosses on partly vegetated ledges and gentle slopes. *Megalonotus sabulicola* is mainly coastal and is a ground-dwelling species that is most easily found among mosses. *Megalonotus chiragra* attaches its eggs to moss stems (Southwood & Leston 1959; Gerson 1982).

Figure 99. *Pterotmetus staphyliniformis*, a rare species that lives on moss-covered boulders on cliffs. Photo by Gernot Kunz, with permission.

The *Recording Dorset* (2011) website notes that the tiny *Tropistethus holosericus* (2mm) (Figure 102) lives among the low vegetation and mosses over sand and chalk, overwintering there as adults.

Figure 102. *Tropistethus holosericus*, a species of low vegetation and mosses. Photo by Michael Münch <www.insekten-sachsen.de> through GBIF, with permission.

Rédei *et al.* (2003) found this family "in great numbers" in moss mats in Hungary. Abundant species included *Plinthisus pusillus* (1.8 mm; Figure 103) and *Rhyparochromus vulgaris* (7-8 mm; Figure 104). Adult members of *Rhyparochromidae* preferred mosses on tree trunks, ground, and other substrata. The seed eaters in this family search mostly on the ground, where they live among the mosses. In Hungary Rédei *et al.* (2003) found that *Stygnocorini* young nymphs (a tribe in the *Rhyparochromidae*) preferred moss mats on rocks. Other members of the family *Rhyparochromidae* seemed to prefer mosses on tree trunks, ground, and other surfaces. Within these, humidity conditions typically determined the preference.

Figure 103. *Plinthisus pusillus*, an abundant species in moss mats in Hungary. Photo from Zoologische Staatssammlung Muenchen, SNSB, through Creative Commons.

Figure 104. *Rhyparochromus vulgaris* on moss, an abundant species there in Hungary. Photo by Tristan Bantock, with permission.

In Dorset, England, one can find *Scolopostethus puberulus* (4 mm; Figure 105) among mosses that reside with taller vegetation, especially at cliff bases and in marshy places (Champion 1871; Recording Dorset 2011). Alexander (2008) likewise found this species in damp, mossy places. The adults hibernate in mosses (Champion 1871). Other moss-dwelling members of this genus include overwintering *S. thomsoni* (3.5-4 mm; Figure 106) and commonly *S. affinis* (3.5-4.5 mm; Figure 107) (Torre-Bueon 1917).

Figure 105. *Scolopostethus puberulus*, an inhabitant of mosses at cliff bases and other mossy places. Photo by Michael Münch <www.insekten-sachsen.de> through GBIF, with permission.

Figure 107. *Scolopostethus affinis*, a common species among mosses. Photo by Tristan Bantock, with permission.

Englund (2003) found several new species of **Rhyparochromidae** in the Austral Islands. These were mostly located by fogging mosses in the rata (*Metrosideros*) forest (Figure 108). Englund commented that his habitat had been largely overlooked.

Figure 108. Rata (*Metrosideros*) forest near stream, home for Austral **Rhyparochromidae** in mosses. Photo by Marie-Claude Larivière, with permission.

Scutelleridae – Jewel Bugs

The **Scutelleridae** are rarely reported from mosses. Alexander (2008) reported the coastal species *Odontoscelis lineola* (4-5 mm; Figure 109), a warmth-loving species, on fairly stable sandy substrates, often with growth of mosses. This species is an active burrower. But the mosses may simply have been indicative of the habitat.

Figure 109. *Odontoscelis lineola*, a burrowing species that often occurs with mosses in coastal regions. Photo by Tristan Bantock, with permission.

CIMICOMORPHA – BED BUGS, BAT BUGS, ASSASSIN BUGS, AND PIRATE BUGS

Anthocoridae – Minute Pirate Bugs or Flower Bugs

These are predaceous bugs that suck fluids from their prey by cutting a hole in the prey, injecting enzymes, and drinking the contents (Wikipedia 2016). In Hungary Rédei *et al.* (2003) found the **Anthocoridae** (among others) represented in great numbers in moss mats by using Berlese funnel extraction, but it is possible he was referring to those previous members of the family treated herein as **Microphysidae**.

Nevertheless, *Anthocoris nemorum* (3-4 mm; Figure 110) builds a **hibernaculum** (winter shelter for dormant animal) in sheltered places under bark, in leaf litter, or among mosses (Hill 1957). *Temnostethus pusillus* (2.5-3.1 mm; Figure 111) often occurs on branches and trunks that are overgrown with mosses (Graff 2015). Fauvel (1999) suggests that mosses and lichens on trees may help members of the **Anthocoridae** to colonize that habitat.

Figure 110. *Anthocoris nemorum*, a species that uses mosses for its winter hibernaculum. Photo by Joe Botting, with permission.

Figure 111. *Temnostethus pusillus*, a species that lives on branches and tree trunks overgrown with mosses. Photo by Tuomo Vainio, through Creative Commons.

Microphysidae – Minute Bladder Bugs

This is a family of tiny insects (0.5-2.4 mm long) that emit a repugnant liquid to defend themselves (Watson & Dallwitz 2003). The family **Microphysidae** (Figure 112- Figure 113) finds its food among the bryophytes (Howe 2004). They feed on booklice, aphids, and other small creatures under bark and among those lichens and mosses growing on trees.

Figure 112. *Loricula* sp. female, member of the family **Microphysidae**. This predominately terrestrial family feeds on organisms living among mosses. Photo by Sarefo, through Creative Commons.

Figure 113. *Loricula* sp. male, a predator on moss-dwelling organisms. Photo by Sarefo, through Creative Commons.

Loricula ruficeps (lichen bugs) (1.5-1.6 mm; see Figure 112-Figure 113) in Hungary is numerous in moss mats (Rédei *et al.* 2003). *Myrmedobia exilis* (3 mm; Figure 19) lives among mosses on tree trunks, ground, and other substrata. It is often associated with *Polytrichum commune* (Figure 138) or *Rhytidiadelphus triquetrus* (Figure 114) (EOL 2015). The good news is that it is a predator on *Adelges* (see *Adelgidae* in next sub-chapter on Hemiptera). Nymphs of *Myrmedobia exilis* live among mosses in open clearings on acid or sandy soils, but the adult females move to conifers to feed on aphids (Alexander 2008). *Myrmedobia coleoptrata* (0.5 mm; Figure 115) usually grows beneath the bark of various trees, especially *Picea*, but it occasionally occurs in tufts of mosses at the tree base (Alexander 2008), as well as being associated with *Rhytidiadelphus triquetrus* and *Polytrichum commune* (EOL 2015). Douglas (1861) considered it a rare species that lives with ants. Moisture is important in determining which species occur in which locations (Rédei *et al.* 2003).

Figure 115. *Myrmedobia coleoptrata* with moss, a species that occasionally lives among mosses at tree bases. Photo by Rob Ryan, with permission.

Nabidae – Damsel Bugs

In Hungary Rédei *et al.* (2003) found the **Nabidae** (among others) represented in great numbers in moss mats by using Berlese funnel extraction. The **Nabidae** were mostly 5-10 mm long. *Nabis ferus* (8-8.5 mm; Figure 116) lives on mossy outcrops in the relict dry acid grassland of the UK (Alexander 2008).

Figure 116. *Nabis ferus*, a species living on mossy outcrops in dry acid grasslands in Europe. Photo by Joe Botting, with permission.

Miridae – Jumping Tree Bugs

Wheeler (2001) stated that mosses have been undocumented hosts for **Miridae** until recently. Using the Berlese funnel method, Rédei *et al.* (2003) found the **Miridae** (among others) represented in great numbers in moss mats. Humidity was important in determining locations and substrata.

Spungis (2005) found this family to have high population densities in the coastal grey dunes (Figure 25) of Latvia, dominating over grass-dwelling **Hemiptera**. These habitats suggest that these hemipterans may do best in somewhat dry habitats, but that they require the protective cover of mosses to survive there.

The predominantly North American genus *Bothynotus* (Figure 117) is relatively small (2.4-4.7 mm), typically brown, and densely pilose (Henry 1979), making it somewhat inconspicuous on soil or among mosses. Mosses may serve as the main habitat for the predatory *Bothynotus pilosus* (Figure 117) in Great Britain (Southwood & Leston 1959; Wheeler 2001). Bedwell (1930) found this species among *Sphagnum* and other mosses in Scotland. Later, Scudder (1995) found that it has a Nearctic distribution as well, occurring on the ground (probably among mosses) in the Yukon and British Columbia, Canada, and now it is known in China (Qi & Huo 2007). Henry (1979) considered that its association with conifers may actually be an association with the mosses that grow there, with few collectors actually finding them on the conifers. Nevertheless, the importance of bryophytes to this genus remains unknown, but ground level trapping records suggest that mosses may be an important habitat for it.

Figure 117. *Bothynotus pilosus*, a ground dweller that might live among mosses. Photo by Petri Parkko, through Creative Commons.

In another study in Great Britain, *Plagiognathus chrysanthemi* (Figure 118-Figure 120) and *Amblytulus delicatus* (see Figure 121) occurred among mosses (Woodroffe 1959).

Figure 121. *Amblytulus nasutus* adult; *A. delicatus* is a moss dweller in Great Britain. Photo by Ruth Ahlburg, with permission.

In Hawaii, the endemic species *Kamehameha lunalilo* (Figure 122) occurs on the mosses and ferns that cover trunks and branches of a number of tree species (Zimmerman 1948). Few of the moss dwellers have long legs and antennae like this species.

Figure 122. *Kamehameha lunalilo*, a moss dweller in Hawaii. Photo from American Museum of Natural History, through Public Domain.

Pseudoclerada (Figure 123), an endemic genus with only two species currently, is another Hawaiian **Miridae** (Asquith 1997). This genus lives in mid-elevation wet gulches and mid- to high-elevation mesic to wet forests. The species are usually solitary and live among the mosses covering tree branches.

Tingidae – Lace Bugs

This is a family of small to mid-sized bugs (2-10 mm) with lacy wings. The **Tingidae** are primarily associated with flowering plants, but *Acalypta* (Figure 124-Figure 125, Figure 133-Figure 136, Figure 139, Figure 146, Figure 149)

is most frequently collected from mosses (Froeschner 1976). In fact, it appears that mosses offer an alternative habitat housing a number of species.

The evolutionary history of *Acalypta* (Figure 124-Figure 125, Figure 133-Figure 136, Figure 139, Figure 146, Figure 149) is reflected in its occasional use of seed plants (Froeschner 1976). This seems to occur most commonly when the mosses are not in a favorable condition for lace bug development. Predictably, the genus is absent in the dry desert and plains states of the United States, but its absence along the Mississippi River is more difficult to explain. Its **brachypterous** (short) wings and recent geological history of the Mississippi flood plain may account for its continued absence there – it is dispersal limited.

Many species in *Acalypta* (Figure 124-Figure 125, Figure 133-Figure 136, Figure 139, Figure 146, Figure 149) live among the bryophytes (Michael Münch pers. comm. 30 October 2014). The bryophyte-dwelling members of the genus are tiny (~2 mm long) and have short (brachypterous) wings (British Bugs 2011). Some species, such as the widespread *Acalypta parvula* (~2 mm; Figure 124-Figure 125) (Hallett 1916), also have frequent macropterous (large or normal winged) forms. This species, the smallest of the *Acalypta* species, is common in the UK among short mosses, especially where soils are dry. It overwinters as an adult.

Figure 125. *Acalypta parvula* amid mosses and soil. Photo by Tristan Bantock, with permission.

In the United Kingdom, five species of *Acalypta* feed on both capsules and vegetative parts of mosses (Howe 2004). Bailey (1951) likewise observed members of *Acalypta* feeding on the capsules of *Climacium* (Figure 126-Figure 128) after the calyptrae had fallen.

Figure 126. *Climacium dendroides* individuals, a species whose capsules and leaves are eaten by *Acalypta*. Photo by Michael Lüth, with permission.

Figure 128. Capsules of *Climacium americanum* that have shed their calyptrae and are suitable food for species of *Acalypta*. Photo by Janice Glime.

The substrate under the moss helps to determine which *Acalypta* species will occur there (Rédei *et al.* 2003). *Acalypta musci* (2.5-2.8 mm; Figure 7) prefers mosses on stones and rocks, along with most nymphs in the *Acalypta* genus. In addition to living among *Abietinella abietina* (Figure 6), often a rock dweller, *A. musci* also lives on typical soil moss species such as *Plagiomnium cuspidatum* (Figure 129) and *P. undulatum* (Figure 130) (Roshko 1969; Putshkov 1974; Rédei *et al.* 2004), and frequently occurs among mosses growing at the bases of trees (Singer 1952; Jordan 1963; Wagner 1967; Rédei *et al.* 2004). In the Bükk Mountains of Hungary, Varga (1992) found *Acalypta musci* and *A. gracilis* (Figure 28) living among the protected subalpine moss species *Plagiobryum zieri* (Figure 131) and *Saelania glaucescens* (Figure 132). Nearby road traffic polluted these mosses with lead, causing a poor bryofauna, and those invertebrates living there, including the two *Acalypta* species, contained high concentrations of lead. *Acalypta gracilis flaventis* occurs in the eastern and central Palearctic among mosses under *Ephedra* (Golub 1998). *Acalypta susanae* has been observed feeding on mosses (Allen *et al.* 1988). Whereas its typical habitat is among mosses, *Acalypta* can also occur on fungi growing on tree trunks (Rédei *et al.* 2004).

Tree trunk mosses, ground, and other surfaces are preferred by *Acalypta carinata* (2.5 mm; Figure 5) and *A. platycheila* (Figure 133). *Acalypta carinata* occurs among *Sphagnum* (Figure 37), but also can be found in the drier habitat of the moss *Abietinella abietina* (Figure 6) in Hungary (Rédei *et al.* 2004). In southeast England, Kondorosy *et al.* (2010) found *Acalypta platycheila* feeding on mosses in apple orchards (Figure 134). The typical habitat of this species is humid, shady woodland.

Figure 133. *Acalypta platycheila*, a tree-trunk moss dweller. Photo by Boris Loboda, with permission.

Figure 134. Apple orchards at Leavenheath, UK. Photo by Jonathan Billinger, through Creative Commons.

Moss mats house numerous *Acalypta marginata* (Figure 31) in Eurosiberia and *A. platycheila* (Figure 133) in Hungary (Rédei *et al.* 2003). *Acalypta marginata* occurs in mosses such as *Rhytidiadelphus* sp. (Figure 135) as well as among tracheophytes (Roshko 1969; Rédei *et al.* 2004). In these habitats it occurs throughout the year, oviposits in the mosses and litter, and overwinters as adults or older larvae (Putshkov 1974; Rédei *et al.* 2004). *Acalypta platycheila* and *A. carinata* (Figure 5) also live among mosses in the *Dryopteridi-Alnetum* (ferns and alders) (Rédei *et al.* 2004), but Alexander (2008) considered them to have a preference for mosses on rotting logs in the UK. *Acalypta brunnea* is most likely to occur among mosses at tree bases or on decaying stumps (Alexander 2008). These substrate preferences of both the mosses and the species of *Acalypta* can be explained by differences in humidity.

Figure 135. *Rhytidiadelphus loreus*, home to *Acalypta marginata*. Photo by David T. Holyoak, with permission.

In Scotland, Corbet (2006) reported *Acalypta nigrina* (Figure 136) among mosses. Moss form may play a role in the choice of habitat by some hemipterans, but for *Acalypta nigrina* the selected mosses have diverse forms, including the horizontal-growing (pleurocarpous) *Hylocomium splendens* (Figure 137) and upright (acrocarpous)

Polytrichum sp. (Figure 138) among its Hungarian habitats (Rédei *et al.* 2004). However, both moss species form deep "mats" that provide a relatively wide moisture and light range that would permit the lace bug to seek the most suitable humidity level and temperature.

Acalypta saundersi (Figure 139) does seem to have a moss form preference, selecting loose-growing bryophyte forms on fallen logs (Lattin 1997). It lives only in old-

growth western USA coniferous forests and its flightlessness, like that of other members of the genus, seems to correlate with its requirement for old growth (Lattin & Moldenke 1990), probably due to limited dispersal that causes a long colonization time. To find the lace bugs in this habitat, Lattin (1997) suggests gathering quantities of mosses and using a Tullgren funnel with heat and light to drive the bugs out of the moss. Sadly, this method is highly destructive if one wants to make a quantitative study and some slow-moving taxa simply die in place.

Figure 139. *Acalypta saundersi*, a species among loose-growing mosses on logs. Photo by BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

In Hungary, Rédei *et al.* (2004) found only *A. marginata* (Figure 31) and *A. gracilis* (Figure 28) among the mosses of Kiskunság National Park, both in great numbers. *Acalypta gracilis* occurs in typical boreal forest mosses such as *Pleurozium schreberi* (Figure 140) and *Ptilium crista-castrensis* (Figure 141), as well as in the dry habitat of exposed sites among *Syntrichia ruralis* (Figure 142-Figure 143) (Péricart & Golub 1996).

Figure 143. *Syntrichia ruralis* wet, home for *Acalypta gracilis*. Photo by Janice Glime.

Although most of the species of *Acalypta* occur in relatively moist habitats, in the Upper Columbia River Basin, western North America, *Acalypta cooleyi* (Figure 144) lives at the bases of sagebrush (Figure 145) and other shrubs (Lattin 1995). There it finds refuge among the mosses, which it also eats.

Figure 144. *Acalypta cooleyi*, a species that finds refuge among mosses and eats them in sagebrush habitats. Photo by Bio Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Figure 145. Sagebrush and moss, home for *Acalypta cooleyi* in western North America. Photo courtesy of Roger Rosentreter.

Acalypta barberi (1-2 mm; Figure 146) and *A. saundersi* (Figure 139) both feed and breed among the mosses (Drake & Lattin 1963). Interestingly, *A. barberi* feeds on mosses until they dry up. Then it shifts to hops (*Humulus lupulus*). Both adults and nymphs of *A. barberi* occurred on *Eurhynchium oregonum* (Figure 147) in Oregon and Washington, USA (Russell 1979). In the lab it subsisted for several weeks on this species. This widespread lace bug caused a shipment of nursery stock from Japan to be halted at quarantine in New York because of the danger of importing it among the mosses and introducing it where it can damage crops (Drake & Lattin 1963). In Arkansas, *A. susanae* (1.9 mm) was described as a new species from a log where it lived with mosses and slime molds (Allen *et al.* 1988). This species also eats mosses.

Figure 146. *Acalypta barberi*, a species that feeds on and breeds among mosses. Photo by Gary Griswold, with permission.

Figure 147. *Eurhynchium oregonum*, home and food for *Acalypta barberi*. Photo by Matt Goff, with permission.

Bryophytes are often used as packing material for house plants and garden plants. Froeschner (1991) suggested that the new species *Acalypta laurae* (2 mm) was almost introduced to the United States from Mexico in the mosses used for packing the house plant *Tillandsia inoantha* (Figure 148).

Figure 148. *Tillandsia ionantha*, a species that is packed in mosses for shipment. These mosses could introduce *Acalypta laurae* from Mexico to the US. Photo by Cliff, through Creative Commons.

Wheeler and Reeves (2004) searched for members of *Acalypta* in the southeastern United States. In North

Carolina they found one nymph and one adult of *Acalypta duryi* (Figure 149) associated with the moss *Dicranum scoparium* (an acrocarpous moss; Figure 150). In Tennessee they found both nymphs and one adult of this species associated with *Hylocomiastrum umbratum* (a pleurocarpous moss; Figure 151) and adults from *Anomodon rostratus* (a pleurocarpous moss; Figure 152). *Acalypta lillianis* (~2.2 mm; Figure 153) occurred with *Polytrichum commune* (acrocarpous; Figure 138) and *P. juniperinum* (Figure 154) in the southeastern states, including new records for Alabama and South Carolina. Bailey (1951) observed *A. lillianis* feeding on mosses. These tiny insects are hard to find and require destructive collecting techniques to be thorough. Both *Acalypta lillianis* and *A. mera* are bryophagous in northwestern USA.

But other genera of **Tingidae** do occur among mosses. Alexander (2008) described the habitat of *Campylosteira verna* (Figure 155) in the UK as one among mosses on hot, dry slopes, usually in calcareous grassland. *Campylosteira* and *Acalypta* (Figure 124-Figure 125, Figure 133-Figure 136, Figure 139, Figure 146, Figure 149) are **phytophagous** (plant-eating) bugs and subsist mostly on moss mats or stems of various herbaceous plants (Rédei *et al.* 2003). In their Hungarian study, Rédei *et al.* (2003) found more *Acalypta* species on mosses than on any other substrate. But for *Campylosteira verna*, only 16.2% were collected on moss, whereas 61.6% were collected among leaf litter. Based on their studies in Hungary, Rédei *et al.* considered members of *Acalypta* to be **musculicolous** (growing best among mosses). The other **Tingidae** genera found among mosses seem to have wider preferences.

Figure 155. *Campylosteira verna*, a species that lives among mosses and elsewhere in hot, dry, calcareous grassland in the UK, often eating the mosses. Photo by Boris Loboda, with permission.

In West Virginia, USA, Torres-Miller (1995) found a different representative of this family. She was able to extract *Leptoypha mutica* (2.7-3.0 mm; Figure 156-Figure 157) from mosses with a Berlese funnel. *Derephysia foliacea* (foliaceous lace bug) (3-3.5 mm; Figure 158) hibernates as adults among mosses in the Ukraine

(Putshkov 1974; Lattin 2009). Thomas (1938) found that the uncommon species *Catoplatus fabricii* (3.8-4.5 mm; Figure 159) was located more easily among mosses, where it could even be abundant; Woodroffe (1959) reaffirmed that it was most frequently collected among mosses.

Figure 158. *Derephysia foliacea*, a foliaceous lace bug that hibernates among mosses in winter in the Ukraine. Photo by Tristan Bantock, with permission.

Drake and Buhoff (1959) reported a moss-feeding member of the **Tingidae** from Mexico. Lis (2000b) recently described *Paraphatnomella tamasi* (2.35 mm) as a new genus and species from India, likewise a moss dweller.

Figure 159. *Catoplatus fabricii* adult, a species found mostly among mosses in Great Britain. Photo by Boris Loboda, with permission.

Cantacaderidae

This family is a segregate of the **Tingidae**. And like some **Tingidae**, some members of **Cantacaderidae** are bryophyte eaters. Moir and Brennan (2007) point out that the more primitive bug families like these two feed on fungi, lichens, mosses, and underground roots. In Australia, *Carldrakeana tingalei* feeds on mosses and lichens (Hacker 1928). More recently, Lis (2000a) described a new Australian species, *C. pallida* (2.04-2.52 mm), also a moss feeder.

Reduviidae

There's always one! A beetle, a lizard, a mantid, and now a bug! These are all animals that cultivate bryophytes on their exterior. These are not just idle passengers using free transportation. The bryophytes actually grow on these animals. But unlike the other bryophyte gardeners, nymphs of *Reduvius personatus* (masked bug; Figure 160) actually place soil and various objects, sometimes including bryophytes (Figure 160), on their bodies as camouflage (Harz 1952; Weirauch 2006). Members of the genus *Reduvius* are only 9-14 mm in length (Wygodzinsky & Usinger 1964), so the kinds of plants that can grow on them are limited to those no bigger than bryophytes – small bryophytes.

Figure 160. *Reduvius personatus* with liverwort and insect camouflage. Photo compliments of Kurt (Hock Ping Guek) <orionmystery.blogspot.com>.

Reduvius personatus (Figure 160) builds two layers of camouflage. The first layer is made from soil, often called a **dust coat** (Brandt & Mahsberg 2002) or **natural camouflaging** (Figure 161) (Ambrose 1999). This was originally thought to be a product of dust in the habitat, but instead it is accumulated by an active process of kicking it there with the hind legs (Weber 1930; Immel 1955), using the **tarsal fan** (Weirauch 2006). This dust layer is present in all the reduviids that use this form of camouflage.

Figure 161. *Reduvius personatus* nymph with only the first layer of cover, the dust coat. Note the flatness typical of the nymph in spring. Photo by Whitney Cranshaw, through Creative Commons.

The second layer is more variable among the individuals. It typically contains coarser particles, including such objects as corpses of insects the reduviid nymph has eaten (Figure 161). This habit has earned this layer the name of **corpse camouflaging** (Ambrose 1999) or **backpack** (Brandt & Mahsberg 2002). It is this layer that sometimes has bryophytes in it (Figure 161). The question remains whether these bryophytes were placed there deliberately, or if they arrived as spores or fragments and grew there. I have seen pictures with protonemata growing on the soil layer. This entire camouflage apparatus must be replaced each time the insect molts. Nevertheless, I have seen pictures of liverworts with branches fully developed. Javahery (2013) reported that third instars were dormant during the first winter and the fifth instar was dormant during the second winter, with the life cycle being completed in two years. With the right climate and timing, this could permit the observed growth from a spore.

Reduvius personatus has multiple means of holding the soil particles there. Short setae help trap the dust and hold the first layer in place (Weirauch 2006). There are short-projection trichomes and long-projection trichomes that help to hold the outer layer. At least in some species, short-projection trichomes appear to be responsible for the fastening of the camouflaging layer close to the integument, whereas long-projection trichomes may hold the outer layer of camouflaging material in place. Both short-projection trichomes and long-projection trichomes, as well as grouped trichomes, secrete a sticky substance that helps to affix such items as smooth-bodied insect carcasses (Weirauch 2006; Javahery 2013).

The nymph becomes engorged before entering winter dormancy and does not eat during the entire winter (Readio 1931). By the time warm weather returns, the body is thin

and flat (Figure 161). Nevertheless, it has enough energy remaining to once again eat and be active. This dormancy behavior appears to be due to a biological clock and is not altered when the insect is maintained over winter in a warm environment with a supply of its normal food.

Other members of the **Reduviidae** in West Africa likewise adorn themselves with soil and the "backpack" materials. *Paredocla* and *Acanthaspis* (Figure 162) species add larger objects to the second layer, including prey corpses and plant parts (Brandt & Mahsberg 2002). In these species, the dust covering masks the chemical and tactile cues that are recognized by the worker ants that they often eat, making it easier for the reduviid nymphs to hunt. On the other hand, the second layer, the backpack, seems to play only a minor role in deterring the ants from approaching and being caught.

The predators on West African *Paredocla* and *Acanthaspis* (Figure 162) species include spiders, geckos, and centipedes (Brandt & Mahsberg 2002). In experiments using these three predators, the bug nymphs were more likely to survive with full camouflage than were the ones denuded of their covering. Not only did the backpack layer confuse the visually oriented predators, it also could be shed to distract the enemy while the reduviid nymph ran away, working much like the detached lizard's tail. In a different set of experiments in East Africa, Jackson and Pollard (2007) demonstrated that three species of the spider family **Salticidae** (*Hyllus* sp., *Plexippus* sp., and *Thyene* sp.) responded as predators to the naked *Acanthaspis petax* (Figure 162) (back packs removed) significantly more often than they responded to the masked bugs.

DIPSOCOMORPHA

Dipsocoridae

Cryptostemma (Figure 20) in Hungary seems to prefer living among mosses on tree trunks, ground, and other surfaces (Rédei *et al.* 2003).

Ceratocombidae

Rédei *et al.* (2003) used Berlese funnels to assess the **epigeic** (ground-living) Hemiptera in Hungary. The

Ceratocombidae are not common among mosses, with only one species represented. *Ceratocombus coleoptratus* (1.5-2 mm; Figure 21) prefers mosses on tree trunks, ground, and other substrata as well as mosses in swampy meadows (Alexander 2008; Münch 2012). Edwards (1874) considered it to be rare in Norfolk, UK.

Ceratocombus vagans (3.8-4.5; Figure 163) is predaceous, eating such small arthropods as oribatid mites and springtails that frequently occur among bryophytes (Lattin 1997). In northern Michigan, USA, it lays its eggs at the end of the summer, inserting them into the tissues of *Sphagnum* (Figure 37) with its well-developed ovipositor.

Figure 163. *Ceratocombus vagans* nymph, a species that preys on small organisms among bryophytes and lays its eggs among *Sphagnum*. Photo by Jim McClarin, with permission.

Schizopteridae – Jumping Soil Bugs

This is a relatively small, mostly tropical family, but it has bryophyte dwellers among its species. Members of the family are suitable for moss-dwelling by their small size (0.5-2 mm). They eat small invertebrates, so bryophytes should provide suitable hunting grounds.

In New Zealand, *Hypselosoma acantheen* (Figure 164) lives mostly in forests among litter and mosses (Hill 1999). In New Caledonia, one can find *Hypselosoma rembaiensis*, another recently described species, among mosses (Hill 2013). In Australia, new species of *Kaimon* were described from mosses (*K. polysperes*, *K. thorntonensis*, *K. webbensis*) (Hill 2004).

Figure 164. *Hypselosoma acantheen*, an inhabitant of forest mosses and litter. Photo by Marie-Claude Lariviere, through Landare Research, with permission.

India likewise has newly discovered moss dwellers in this family. Rédei (2008) described *Kikeshia stysi* from sifted mosses in West Bengal.

GERROMORPHA – SEMIAQUATIC BUGS OR SHORE-INHABITING BUGS

Hydrometridae

A few weeks ago I received an email from Eugenia Ron with an image of a strange object attached to the capsule of one (Figure 165) and seta of another (Figure 166) *Funaria hygrometrica* (Figure 167). This alien was unknown to both of us and was clearly not of bryophyte origin. We considered fungi, slime molds, and insects, so Eugenia sent the images to specialists in these groups. The fungal and slime mold experts said it wasn't one of theirs. Today Eugenia sent me an answer to the mystery.

Figure 165. *Hydrometra stagnorum* eggs on *Funaria hygrometrica* capsule courtesy of Tomas Sobota and Eugenia Ron.

Figure 166. *Hydrometra stagnorum* eggs on *Funaria hygrometrica* seta. Photo courtesy of Tomas Sobota and Eugenia Ron.

Figure 167. *Funaria hygrometrica* with maturing capsules. Photo by Jiří Kameníček (BioLib, Obázek), with permission.

Dr. Hernández de Miguel (Universidad Complutense, Madrid, Spain) identified it as the eggs of *Hydrometra stagnorum* (Figure 168), (Hemiptera, family Hydrometridae). Eugenia Ron has found additional eggs on both acrocarpous and pleurocarpous mosses and on leafy liverworts. The environments are always very humid near a river. This species uses its body like a kayak, rowing over the water surface of quiet streams or ponds to find food.

Mesoveliidae – Water Treaders

Although most of these species live on floating plants, some live in forest leaf litter and damp moss (DiTerlizzi 2004).

Gerridae

"Aquatic insects" are only aquatic for part of their lives, so many of the species discussed earlier as aquatic insects may also appear here as terrestrial insects. Among the amphibious species is *Gerris lacustris* (Figure 169). It skates on the water and does not live among mosses in the water, but when it hibernates it may seek out the protection and moisture of terrestrial mosses near its pond (Butler 1886).

Figure 169. *Gerris lacustris* adult in its aquatic, surface-dwelling stage. It may seek mosses on land to spend the winter. Photo by Jakub Rom, through EOL Public Domain.

NEPOMORPHA

Aphelocheiridae

I found only one record of this family associated with mosses. Alexander (2008) reported *Aphelocheirus aestivalis* (8.5-10.5 mm; Figure 170) among the UK fauna, living where there is overhanging vegetation or on moss-covered rocks.

Figure 170. *Aphelocheirus aestivalis*, a species one can find on moss-covered rocks. Photo by Niels Sloth, with permission.

Summary

Several orders of insects have been lumped into the current order **Hemiptera**. The suborder **Heteroptera** contains those members that were traditionally **Hemiptera**. Among these are a number of moss dwellers. The Hemiptera have a life cycle of egg – nymph – adult.

Some members of **Hemiptera** use bryophytes as a habitat, an egg-laying site, a food source, an overwintering site, and a hunting site. Most of the faithful species are tiny but seem to lack any special resemblance to bryophytes. They benefit from the moisture and protection while often finding food there among algae, slime molds, fungi, bryophyte leaves, and invertebrate fauna.

The most common habitats of moss dwellers include forest floor and epiphytic bryophytes, sand dunes, streamside and other wet mosses, and peatlands. Some aquatic bugs leave the water to spend the winter under mosses.

The most primitive **Hemiptera** are typically moss dwellers, especially the **Tingidae** and closely related families. Members of the genus *Acalypta* are typically moss dwellers, eat mosses, and have many species among mosses. Many of the species have limited distribution.

The **Miridae** most likely have bryophyte dwellers that are yet to be discovered, with evidence suggested by ground traps. In some parts of the world, **Rhyparochromidae** are common among mosses. A number of families have lesser representation than those just mentioned.

Some members of the **Reduviidae** include bryophytes among the camouflage items they carry on their backs. Such "back packs" are known to discourage would-be predators.

Acknowledgments

Thank you to Marie-Claude Larivière for her encouragement and help in providing images and making suggestions, and reviewing the chapter. Images available

CHAPTER 12-7

TERRESTRIAL INSECTS:

HEMIMETABOLA – HEMIPTERA (NON-HETEROPTERA) AND THYSANOPTERA

Figure 1. *Brachythecium buchananii* with capsules, overwintering home of *Schlechtendalia chinensis*, a gall aphid. Photo by Ivanov, with permission.

SUBORDER AUCHENORRHYNCHA

(Cicadas, Leafhoppers, Treehoppers, Planthoppers, and Spittlebugs)

Holzinger and Schlosser (2013) identified 93 species of **Auchenorrhyncha** fauna in Austrian peat bogs in the Bohemian Forest, indicating how common this group of **Hemiptera** is in bogs. Disturbance increases the number of species and densities in this group, but the number of species and densities of peatland specialists (**tyrphobionts**) decreases with disturbance.

CICADOMORPHA

Cicadellidae – Leaf Hoppers

Megophthalmus scanicus (3-4 mm; Figure 2) is among the few European **Cicadellidae** with a bryophyte association (Edwards 1874). This species overwinters among mosses. *Sorhoanus xanthoneurus* (3.1-3.4 mm; Figure 3), *Sorhoanus assimilis* (often the most frequent hemipteran; 2-2.9 mm; Figure 4), and *Stroggylocephalus livens* (5-6.5 mm; Figure 5) associate with *Sphagnum* (Figure 6) in bogs in Austria and seem to be true **tyrphobionts** (Holzinger & Schlosser 2013). Another

moderately common member of the family associated with *Sphagnum* is *Macustus grisescens* (5-6 mm; Figure 7).

Jassargus dentatus (Figure 8) occurs in association with *Sphagnum* in Slovenia and the Piedmont of Italy (Trivellone 2010). *Jassargus pseudocellaris* (Figure 9) is among the abundant hemipterans in Austrian bogs (Holzinger & Schlosser 2013).

Figure 9. *Jassargus pseudocellaris*, a bog inhabitant in Austria. Photo by Tristan Bantock, with permission.

Paracephaleus curtus (Figure 10) lives on grass tufts of *Chionochloa rubra* (Figure 11) and mats of short plants, including mosses (Larivière *et al.* 2010).

Figure 10. *Paracephaleus curtus*, a species that sometimes lives among mosses. Photo by Marie-Claude Larivière, with permission.

Figure 11. *Chionochloa rubra* in New Zealand, home for *Paracephaleus curtus*. Photo by Ulrich Lange, through Creative Commons.

Spittlebugs are so-named for their production of a frothy medium that resembles human spit. This "spittle" provides them a place to hide from would-be predators, but it not only hides them, it has an acrid taste that deters the predators (Wikipedia 2015). It is good insulation against heat and cold, much like hiding in water, but with air spaces that make it an even better insulator. And it provides moisture, protecting the soft-bodied nymphs from dehydration. The nymphs are plant suckers, and it appears that bryophytes, at least *Polytrichum juniperinum*, are on the menu (Figure 12-Figure 13), as well as many tracheophyte species.

Figure 12. Spittlebug on *Polytrichum juniperinum*. Photo courtesy of Timea Deakova, with permission.

FULGOROMORPHA - PLANTHOPPERS

Delphacidae – Delphacid Planthoppers

The **Delphacidae** is a family of herbivores with a worldwide distribution. A sweep net revealed *Euconomelus lepidus* (1.8-3 mm; Figure 14) from mosses beside a lake in Scotland (Bratton 2012). This is one of the few species that seems to be associated with bryophytes.

Figure 14. *Euconomelus lepidus* lives in association with mosses near a lake in Scotland. Photo by Tristan Bantock, with permission.

Javesella opaca (see Figure 15, Figure 16) is a planthopper that feeds on mosses in the eastern United States (Wheeler 2003). Nymphs live on the upright leafy gametophytes of *Polytrichum commune* (Figure 17) and *Polytrichastrum alpinum* (Figure 18) where these mosses grow over flatrock areas. In South Carolina, USA, the late instars overwinter among *Polytrichum commune*, with adults developing by mid- to late March. Most of the adults are **brachypterous** (having short wings). It is interesting that these insects feed on the thick stems of the mosses, whereas in our experiments with pillbugs the stems were avoided in *Polytrichum* and only leaves were eaten. In Russia, *Javesella discolor* (Figure 19) lives in moss bogs, moist forests, and swamp meadows (Emeljanov 1988), where mosses play an important role in creating a suitable microclimate.

Figure 19. *Javesella discolor*, a species that lives in mossy bogs and other mossy habitats. Photo by Joe Botting, with permission.

Muellerianella extrusa (2.1-3.1 mm; Figure 20) occurs in association with *Sphagnum* in Austria (Holzinger & Schlosser 2013).

Figure 20. *Muellerianella extrusa*, a *Sphagnum* associate in Austria. Photo by Gernot Kunz, with permission.

Richardson *et al.* (2002) found that changes in subordinate plant species had a greater impact on the herbivorous insect community than on those living on the dominant dwarf shrubs. Moss-feeding bugs were reduced to as little as 65% of the controls when their plots were fertilized, whereas grass-feeding insect species showed a 400% increase. This benefitted the **Delphacidae**, a **graminivorous** (grass-eating) family, suggesting that for most of the species the mosses were not important.

Derbidae – Planthoppers

Wilson and Wheeler (2015) attempted to learn more about the life history of this little known family. They were able to rear *Cedusa hedusa* (Figure 21) successfully from fifth instars to adults. These were collected from populations of the moss *Polytrichum commune* (Figure 17) in Alabama, USA. Nevertheless, food of the nymphs remains unknown, as well as oviposition sites and food preferences of the adults.

Figure 21. *Cedusa hedusa*, a species that lives on the moss *Polytrichum commune* in Alabama, USA. Photo from CNC-BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Issidae – Planthoppers

Issus coleoptratus (3-4 mm; Figure 22-Figure 23) seems to spend most of its nymphal time among mosses (undocumented comment from Flickr). *Issus muscaeformis* (1.9-3.6 mm; Figure 24) has a name that suggests it has some relationship with mosses, but I can find no reference that places it in such a habitat. Consulted references include those that describe mosses as habitats for other insects.

Figure 23. *Issus coleoptratus* adult, a moss-dwelling species. Photo by Sarefo, through Creative Commons.

Figure 24. *Issus muscaeformis* adult, a likely moss dweller. Photo by Roger S. Key, with permission.

The genus *Issus* (Figure 22-Figure 25) has an unusual means of locomotion (Burrows & Sutton 2013). It uses gears that intermesh, rotating like mechanical gears (Figure 25). These are located on the hind legs at the trochanter and rub together to propel the insect when it jumps. They insure that both legs have the same velocities and are synchronized. But as strange and unique as these are, they exist only in the nymphs, disappearing at the last molt. The adults must move like other insects.

SUBORDER STERNORRHYNCHA

(aphids, whiteflies, and scale insects)

Anyone who has kept a greenhouse will probably cringe at the mention of these insects. All are pests in that environment. And you might just introduce some of them with mosses you bring in.

Eriococcidae – Scale Insects

One of these greenhouse horrors is the scale insect (Figure 26). These seem like unlikely moss inhabitants, but Henderson (2007) considered mosses and ferns to be the most likely candidates as host plants for *Affeldococcus kathrinae* (0.4-0.65 mm). This very tiny species lacks a specific host tree, but lives in the high canopy epiphyte mat of the rata (*Metrosideros* spp.; Figure 27) in New Zealand. This led Henderson to conclude the epiphytic bryophytes and/or ferns might be the hosts.

Figure 27. Rata forest (*Metrosideros umbellata*), Enderby Island, New Zealand. These forests have mostly mosses and ferns as ground cover and provide a suitable home for *Affeldococcus kathrinae*. Photo by John Barkla, with permission.

Aphididae (including Pemphigidae) - Aphids

Although incidences of **bryophagy** (eating bryophytes) are not well known among aphids, there are actually species that specialize on bryophytes, and others that eat them for special purposes (Hille Ris Lambers 1954; Müller 1973; Smith & Knowlton 1975; Stekol'Shchikov & Shaposhnikov 1994). Moss aphids pierce the cells, then

suck the contents from the cells (Thomas & Lombard 1991; Longton 1992). Aphids are common enough among mosses that there is a whole group known as the moss aphids (Müller 1973; Smith & Knowlton 1975).

Aphids are not common moss inhabitants, with the exception of the gall aphids, but perhaps we aren't looking in the right places. Recently Robin Stevenson found *Sphagnum* forming sleeves around young saplings of *Pinus sylvestris* and *Betula* spp. (Stevenson & Masson 2015). He pursued these strange sleeves, determining that they were formed by ants (*Lasius platythorax*). But why? Upon tearing them apart, he found lots of aphids (*Symydobius oblongus*; Figure 28-Figure 29) were running about. Ants are well known for tending aphids, using the "honey dew" excreted from two tubercles at the ends of the alimentary (digestive) canals (Figure 28). See Chapter 12-10 on Hymenoptera for more details on this relationship.

Figure 28. *Symydobius oblongus* nymph, a species that lives in *Sphagnum* sleeves created by ants on young birch and pine saplings in bogs. Note the two tiny white tubercles near the end of the abdomen where ants are able to harvest honey dew. Photo from <www.influentialpoints.com>, through Creative Commons.

Gall Aphids

Some moss aphids form galls (Figure 85-Figure 86), but not on the mosses. Instead, the mosses act as alternate hosts (Chiuh 1976). One of the few remaining agricultural uses of mosses is the culturing of mosses as the winter host for Chinese gall aphids (Li *et al.* 1988, 1999; Liu & Li 1992, 1993; Liu *et al.* 1994). This has led to studies on the effects of temperature and water content on the vitality of these host mosses in winter (Liu *et al.* 1994) and on the physioecology of these mosses (Liu 2000).

Liu and coworkers (Liu 2000; Liu *et al.* 2000) studied the hosts *Plagiomnium acutum* (Figure 30), *P. maximoviczii* (Figure 41), *Thuidium cymbifolium* (Figure 31), and *Chrysocladium retrorsum* (Figure 32), hoping to cultivate them at optimal conditions. These mosses are able to maintain a net photosynthetic gain at temperatures as low as -15 to -10°C. The optimum temperatures for *T. cymbifolium* and *C. retrorsum* were in the range of 25-36°C in spring, dropping to 20-30°C in winter.

Figure 30. *Plagiomnium acutum*, overwintering host for gall aphids in China. Photo through Creative Commons.

Figure 31. *Thuidium cymbifolium* with capsules, a host plant for gall aphids, including *Schlechtendalia elongallis*. Photo by Li Zhang, with permission.

Figure 32. *Chrysocladium retrorsum*, a host plant for gall aphids. Photo by Yao Kuiyu, through Creative Commons.

Li *et al.* (1999) compared photosynthetic capacity in the two gall aphid hosts *Plagiomnium acutum* and *Herpetineuron toccoeae*. *Plagiomnium acutum* had lower photosynthesis on sunny days and higher on cloudy and rainy days compared to that of *H. toccoeae*. Consistent with its preferred bright days, *H. toccoeae* also had lower transpiration rates than did *P. acutum*, permitting the former to tolerate high temperatures and dry environments.

There are at least 24 known species of moss hosts in China, and their cultivation is critical to the production of the gall nuts (Li 1990). In China, the gall aphid species are generally highly specialized on only a few winter moss hosts (Chiuh 1976; Li *et al.* 1988). Among those used are *Mnium lycopodioides* (Figure 33), *M. thomsonii* (Figure 34), *Orthomnion dilatatum*, *Plagiomnium rhynchophorum*, *Brachythecium albicans* (Figure 35), *B. buchananii* (Figure 1), *B. velutinum* (Figure 36), *B. rutabulum* (Figure 37), *Homalothecium leucodonticaule* (Figure 38), *Hypnum callichroum* (Figure 39), and *Erythrodontium julaceum* (Figure 40). The first four of these are winter hosts of the Chinese gall aphid *Schlechtendalia chinensis* (Aphididae; Figure 42). The virus-carrying *Melaphidini* (Pemphigidae, a segregate from Aphididae) species shift their habitat between *Rhus* (sumac; Figure 85) and bryophytes (Eastop 1977).

Figure 40. *Erythrodontium julaceum*, an alternate host for gall aphids in China. Photo by Michael Lüth, with permission.

Plagiomnium maximoviczii (Figure 41) is also a common species that serves as the winter host for the Chinese gall aphids (Horikawa 1947; Tang 1976; Lao *et al.* 1984; Li *et al.* 1988). The aphids *Schlechtendalia chinensis* (Pemphigidae; Figure 42), *Nurudea shiraii*, and *Nurudea yanoniella* (Pemphigidae) are important commercially in China because of the galls they make on the sumac (*Rhus*) tree (Tang 1976; Min & Longton 1993). These galls are highly prized for medicines (expectorant; treatment of cankers and wounds) and the chemical industry (black dyes for dyers and tanners; ink) (Fagan 1918). The aphids migrate to the mosses for the winter, using them for both shelter and food (Chiu 1976; Tang 1976; Lai *et al.* 1990).

Figure 41. *Plagiomnium maximoviczii*, a winter host for Chinese gall aphids. Photo from Hiroshima University Digital Museum of Natural History, with permission.

Schlechtendalia

Schlechtendalia chinensis (Figure 42) makes its galls on *Rhus chinensis*. It uses *Plagiomnium maximoviczii* (Figure 41), *P. cuspidatum* (Figure 43), and *P. vesicatum* (Figure 44) for its winter shelter (Chiu 1976). When the galls burst open at maturity, the aphids emerge and migrate to their moss hosts. There they produce 20-30 nymphs that will develop into spring migrants. The newly emerged nymphs move to the moss stalks near the ground and cover their bodies with a waxy secretion in preparation for winter. In early spring they develop into the winged females that give live birth. These females are spring

migrants that move to the *Rhus chinensis* (sumac; Figure 45) where they will feed. Their offspring will be wingless. These become wingless adults and will be ready to mate in 4-8 days.

Figure 44. *Plagiomnium vesicatum* (formerly included in *Mnium*), a winter host for the Chinese gallnut *Schlechtendalia chinensis* (Figure 42). Photo from the Digital Museum, University of Hiroshima, with permission.

Figure 45. *Rhus chinensis*, host of the Chinese gall aphid *Schlechtendalia chinensis* (Figure 42). Photo from Kinmen National Park Digital Archives, through Creative Commons.

The females lay their eggs on the mosses (Lai *et al.* 1990). Because the host tree, the sumac, grows on dry slopes and the mosses tend to grow on more humid stream banks, there are few places where the mosses are sufficiently close to the trees for the relationship to work for the aphids (Zhang, pers. comm.). Hence, it is desirable to create more suitable habitats, possibly by cultivating mosses, placing them near the sumac at the appropriate season, then culturing the mosses through the winter in a favorable environment.

In addition to the *Plagiomnium* species, *Schlechtendalia* (Figure 42) also uses *Homomallium* (Figure 46), *Palamocladium* (Figure 47) (Liu & Li 1994), and *Herpetineuron toccoe* (Figure 48) (Li *et al.* 1999).

Figure 46. *Homomallium incurvatum*, member of a genus that provides a winter host for *Schlechtendalia chinensis* (Figure 42) in China. Photo by Hermann Schachner, through Creative Commons.

Kaburagia

Another gall-making aphid, *Kaburagia rhusicola* (1.3-1.5 mm), likewise uses mosses for winter hosts in China (Lai & Zhang 1994). These mosses include *Brachythecium* spp. (Figure 35-Figure 37), *Entodon* (Figure 49), and *Oxyrrhynchus* (= *Eurhynchium*?; Figure 94). In northern China, this aphid species moves from galls in late summer, and hibernates in an immature stage on the secondary host, the moss *Eurohypnum leptothallum* (Figure 50) (Chinese Academy of Forestry Science Institute

of Resource Insects 2014; The Aphids 2015). This institution has patented the procedure for growing the aphids on *E. leptothallum*. *Kaburagia ensigallis* (perhaps the same species as *K. rhusicola*) uses *Brachythecium buchananii* (Figure 1) as a host plant (Lou & Chen 2000).

Figure 50. *Eurohypnum leptothallum*, where *Kaburagia rhusicola* migrates in late summer in China and hibernates for the winter. Photo from <prologue.blog.naver.com>, through Creative Commons.

Muscaphis

But China does not have a corner on the gall aphid/moss association. Among the moss inhabitants is *Muscaphis escherichi* (1.7-2.7 mm; Figure 51), a bryophagous species on *Sorbus*, but when it is seasonally unavailable as a suitable habitat, they live primarily on the moss *Rhytidiadelphus loreus* (Figure 52) in the state of Washington, USA (Russell 1979). In Europe *M. escherichi* is common on many species of mosses, but researchers have had poor success in rearing it on any species but *Plagiothecium laetum* (Figure 53) and males have never been found on mosses (Stekolshchikov & Shaposhnikov 1993). *Muscaphis cuspidata* (0.9-1.3 mm) lives on *Calliergonella cuspidata* (Figure 54) and *Drepanocladus aduncus* (Figure 55), either close to the water or just below the water level. *Muscaphis mexicana* (1.7-2.1 mm) migrates to unidentified mosses, where wingless yellow or yellowish green aphids (0.6-0.8 mm) are produced (The Aphids 2015). The species *Muscaphis musci* (1.1-1.5 mm; Figure 56) occurs on many species of mosses, including those in *Amblystegium* (Figure 57), *Atrichum* (Figure 58), *Barbula* (s.l.; Figure 59), *Brachythecium* (Figure 37), *Bryum* (Figure 60), *Calliergonella*, *Eurhynchium* (Figure 94), *Hylocomium* (Figure 61), *Mnium* (probably *Plagiomnium*) (Figure 33-Figure 44), *Polytrichum* (s.l.) (Figure 17), *Pseudoscleropodium* (Figure 62), and *Tortula* (s.l.; Figure 63). In Denmark, Wilkaniec & Borowiak-Sobkowiak (2009) report *Muscaphis musci* from *Calliergonella cuspidata*, *Brachythecium rutabulum* (Figure 37), *Atrichum undulatum* (Figure 58), and *Plagiomnium undulatum* (Figure 64). *Muscaphis utahensis* (0.7-1.1 mm; Figure 65) occurs on mosses in the western USA and is thus far known only from the moss *Cratoneuron filicinum* (Figure 66) (Stekolshchikov & Shaposhnikov 1993). In most of the *Muscaphis* species, the bryophytes serve as alternate hosts and oviposition sites.

Myzodium

Another moss-dwelling aphid is the genus *Myzodium* (0.9-1.9 mm; Figure 67), one of the few genera of aphids that builds nests among *Sphagnum* (Figure 6) (Gerson 1969), and at least some of them eat mosses.

Aphids tap into the phloem of vascular plants to obtain nutrients. Clever researchers have used this behavior as a means to determine what substances are travelling in the phloem. Thomas and Lombard (1991; Thomas 1993) have used these tiny moss-dwelling aphids on *Polytrichum commune* (Figure 17) to obtain similar information on this moss. Their impact is sufficient to reduce the flow of labelled materials to other individuals that share rhizomes with the infested individuals. *Myzodium* sp. (~1.5-1.9 mm; Figure 67-Figure 68) not only diverts the nutrients from the **leptoids** (moss food-conducting cells) but also alters the normal source-to-sink flow within the moss turf.

Russell (pers. comm.) found many nymphs of *Myzodium modestum* (1.2-1.9 mm; Figure 67-Figure 68), a **bryophagous** species (eats bryophytes) (Müller 1973), overwintering on *Polytrichum* sp. (Figure 17) in early September at Waldo Lake, Oregon, USA. This species lives on other mosses as well, including *Dicranella crispa* (Figure 69), *Dicranum* sp. (Figure 113), *Oligotrichum aligerum* (Figure 70), *Pleurozium schreberi* (Figure 114), *Pogonatum dentatum* (Figure 71), *Polytrichastrum alpinum* (Figure 72), *Polytrichastrum formosum* (Figure 73), *Polytrichastrum longisetum* (Figure 74), *Polytrichum commune* (Figure 17), *Polytrichum juniperinum* (Figure 75), *Racomitrium* sp. (Figure 76), *Roellia roellii* (Figure 77), *Sanionia uncinata* (Figure 78), and *Sphagnum rubellum* (Figure 79) (Pike *et al.* 2010). This list attests to a wide variety of habitats including bogs, alpine, forest, boreal, and others as well as a wide range of bryophyte families from primitive to advanced, and it includes both acrocarpous and pleurocarpous mosses. *Polytrichum juniperinum* seems to have the most collection records. Unlike many species on tracheophytes, *Myzodium modestum* is not attended by ants.

Melaphis

The sumac gall aphid *Melaphis rhois* (Pemphigidae; Figure 85-Figure 89) is one of these moss aphids in the USA, alternating between mosses and sumac [*Rhus glabra* (Figure 90) and *R. typhina* (Figure 91)] (Moran 1989; Hebert *et al.* 1991; Pike *et al.* 2012).

Figure 89. *Melaphis rhois* adult, a species that lives on sumac and uses mosses as alternate hosts for winter and egg laying. Photo by Claude Pilon, with permission.

Moran (1992), an avid aphidologist, was walking in the Santa Catalina Mountains, Arizona, USA, when she discovered 5-cm galls (Figure 85-Figure 86) on a stand of smooth sumac (*Rhus glabra*; Figure 90). Further inspection revealed the sumac gall aphid, *Melaphis rhois* (0.8-1.2 mm; Figure 85-Figure 89). Upon further research, she discovered that this aphid was known from New York and that A. C. Baker had suspected that the tiny aphids he found among mosses in West Virginia, USA, might be the unknown spring migrant stage of *Melaphis rhois*. A return trip to the mountains enabled Moran to gather mosses and find that they indeed were inhabited by tiny aphids. She also transferred aphids from the sumac to the mosses and these produced morphs exactly matching those identified by Baker in West Virginia. After spending the summer inside the gall, where the single female reproduces asexually to make daughters, and they in turn her granddaughters, the granddaughters leave the gall in autumn as the sumac leaves begin dying and winter approaches. The granddaughters must find appropriate mosses where they deposit tiny aphid offspring. There the tiny daughters (great grandchildren of the original gall-maker) feed, develop, and reproduce. Their own waxy secretions protect them from desiccation. In spring of the first – or the second – year these females produce not only females but also males. Within a week they mate, females

deposit their eggs once more on the sumac, and the mating generation dies.

This species depends on the mosses for food (Baker 1919; Heie 1980; Moran 1989; Hebert *et al.* 1991). Pike *et al.* (2012) list a number of mosses that serve as hosts for *M. rhois*: *Rhytidiadelphus loreus* (Figure 52), *Leucolepis acanthoneura* (Figure 92), *Claopodium crispifolium* (Figure 93), *Eurhynchium praelongum* (Figure 94), and *Dicranum scoparium* (Figure 113).

Clydesmithia (Pemphigidae)

Clydesmithia canadensis (1.5-2.7 mm; Figure 95) includes a number of species among its moss hosts and is associated with mosses in Alaska (Pike *et al.* 2012). These moss alternate hosts are summarized in a table in Pike *et al.* (2012) and include such species as *Climacium dendroides* (Figure 96) and *Rhizomnium magnifolium* (Figure 97) that have not been mentioned here for other aphids.

***Pemphigus* (Pemphigidae)**

There seem to be few reports of European gall makers that use mosses as alternate hosts. In the UK, *Pemphigus trehernei* (1.3-2.4; see Figure 98-Figure 100) reproduces only by **parthenogenesis** (reproduction from an unfertilized egg), using roots of grasses and moss mats for oviposition (Alexander 2008). Norzikulov (1964) reported *Pemphigus hydrophilus* (1.9-2.2 mm) from *Cratoneuron filicinum* (Figure 101) and possibly also *Hygrohypnum luridum* (Figure 102) in Russia.

Other Aphididae that Live Among Mosses

Decorosiphon corynothrix (1.4-1.9 mm; Aphididae; Figure 103) lives on basal parts of *Polytrichum* spp. (Figure 17) growing in damp, shady situations and on *Atrichum undulatum* (Figure 104) (The Aphids 2015).

Figure 103. *Decorosiphon corynothrix*, a species that lives on the basal parts of *Polytrichum* spp. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Figure 105. *Jacksonia papillata*, an aphid that often spends time among mosses. Photo through BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Jacksonia papillata (Aphididae; Figure 105) often occurs among mosses (Müller 1973). This is consistent with the mossy habitats of its primary hosts. Müller suspects that it sometimes feeds on mosses. *Pachypappa rosettei* (0.84-1.41 mm; Aphididae or Pemphigidae; Figure 106), *Pachypappa sacculi* (Figure 107), *Prociphilus*

xylostei (~3 mm; Aphididae; Figure 108-Figure 109), and *Thecabius populimonilis* (only once; Aphididae; Figure 110-Figure 111) also occur on mosses (Pike *et al.* 2012). *Prociphilus xylostei* is a strange-looking insect that secretes copious wax to cover and camouflage itself, making it look more like a fungus than an insect.

Figure 106. *Pachypappa rosettei*, a moss inhabitant. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Figure 110. *Thecabius populimonilis*, a moss inhabitant. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Pseudacaudella rubida (0.7-1.0 mm; Figure 111- Figure 112) lives on the moss genera *Calliergonella* (Figure 54), *Climacium* (Figure 96), *Dicranum* (Figure 113), *Hylocomium* (Figure 61), *Mnium* (probably *Plagiomnium*; Figure 33-Figure 34, Figure 43-Figure 44), *Pleurozium* (Figure 114), *Polytrichum* (Figure 17), *Pseudoscleropodium* (Figure 62), and *Thuidium* (Figure 31) (The Aphids 2015).

Attractants?

Do aphids help mosses attract more aphids? *Nurudea shiraii* (Aphididae) uses *Hypnum plumaeforme* (Figure 115) as a food plant (Lou & Chen 2000). *Thuidium cymbifolium* (Figure 31) is the host plant of *Schlechtendalia elongallis* (Pemphigidae). Lou and Chen found that these two mosses and the host moss *Brachythecium buchananii* (Figure 1) produce such aliphatic compounds as alcohols, aldehydes, ketones, and esters. They suggested that production of these compounds might be induced by the damage caused by their inhabiting aphids. They further suggested that these compounds might help the aphids locate their host plants. This sounds like an interesting hypothesis in need of testing.

Figure 115. *Hypnum plumaeforme*, food for *Nurudea shiraii*, produces aliphatic compounds that might help aphids to locate these mosses. Photo by Janice Glime.

Why Alternate Hosts?

Moran (1989) speculated on the evolutionary pressures that would cause such a host alternation as mosses and woody plants to evolve. Since this strategy is present in both the Chinese species and the North American ones, she postulated that both had their origins in Alaska and were separated when forced southward before the land bridge across the Bering Strait separated. Moran (1989) had already found fossil evidence of a 48-million-year-old aphid (*Melaphis rhois*; Figure 85-Figure 88) – host plant association with a similar moss/sumac alternation in

Alaska, apparently established prior to the southward retreat of sumac. Unlike the alternation seen in China and North America, in England and Scandinavia the aphid has lost its alternate host behavior and lives entirely on mosses, but has sacrificed all sexual behavior. This type of response is also known in the whitefly parasitoid *Encarsia formosa* (Hymenoptera) (Birkett *et al.* 2003), but both the production of aliphatic compounds by the moss and the insect response to these need to be verified as a consequence of moss herbivory.

Adelgidae – Woolly Conifer Aphids

The Adelgidae made their claim to fame by destroying forests, especially in the Appalachian Mountains, USA. Their connection with bryophytes is indirect, but can be strong. The woolly adelgids (*Adelges tsugae*; 1.5-mm; Figure 116-Figure 118) have had a major impact on the eastern hemlock (*Tsuga canadensis*; Figure 119-Figure 120) in the Appalachian Mountains, as far south as the Smoky Mountains (Jackson & Bellemare 2014). This disturbance has caused a decline in the leafy liverwort *Bazzania trilobata* (Figure 121) because the dying hemlocks open the canopy and the habitat becomes drier. This is accompanied by more deciduous litter (resulting from invasion of black birch – *Betula lenta*), greater light exposure, and higher temperatures.

Figure 121. *Bazzania trilobata*, a leafy liverwort that is disappearing where hemlocks have been killed by *Adelges tsugae*. Photo by Janice Glime.

Quite the opposite story can be told about one moss in the southern Appalachian Mountains of North Carolina. There, in high elevation locations, the moss *Leptodontium viticulosoides* (Figure 122-Figure 123) had become rather rare (Zander 1980). But prior to 1980 it began spreading. This spread is attributed to *Adelges piceae bouvieri* (Figure 124, Figure 125, Figure 128). In this case, the adelgid aphid causes the bark of the **endemic** (growing in a limited area) Fraser fir (*Abies fraseri*; Figure 126-Figure 128) tree to peel, creating habitat suitable for the moss.

Figure 122. *Leptodontium viticulosoides*, a moss that is spreading in areas where bark of Fraser fir (*Abies fraseri*) is peeling due to infestations of *Adelges piceae*. Photo courtesy of Claudio Delgadillo Moya.

Figure 128. *Adelges piceae* on *Abies fraseri*. Photo by William M. Ciesla, Forest Health Management International, <Bugwood.org>, through Creative Commons.

In the Southern Appalachian Mountains, the hornwort *Megaceros aenigmaticus* suffered a decrease in sexual reproduction. Although this was partly due to its rarity and lack of contact between males and females, Villareal (2009) suggested that its survival is further threatened by habitat degradation due to the adelgid plague on the hemlocks that created its habitat.

SUBORDER COLEORRHYNCHA

(moss bugs or beetle bugs)

The **Coleorrhyncha**, with only one exception, are flightless. They have an extremely reduced **pharyngeal ring** muscle layer (muscles surrounding the pharynx, which is the first part of the foregut) (Spangenberg *et al.* 2013). Spangenberg and coworkers suggest that this reduction prevented any secondary shift in diet (these are bryophyte eaters), preventing them from using a broad range of food sources and consequently preventing radiation of the species into new locations and new species.

Peloriidiidae – Moss Bugs

The **Peloriidiidae** are cryptic species that frequent wet mosses, liverworts, and leaf litter (Spangenberg *et al.* 2013). They are small (2-4 mm), flattened, and cryptically-colored relict **Hemiptera** in the Southern Hemisphere (Evans 1982; Burckhardt 2009), resulting in their remaining undiscovered in Australia until 1932, although they were known elsewhere in the area (Monteith 2015). Cranston (2010) cites this family as one living among *Sphagnum* and liverworts (Austin *et al.* 2004; Cranston 2009). Evans (1941) considered the presence of moss in a habitat that is moist all year round to be a necessity.

One adaptation of bryophyte fauna that is often forgotten is vibration frequency of the "call." Hoch *et al.* (2006) considered the small size of the **Peloriidiidae** to necessitate vibrational signals for mates to locate each other. The low frequency of the signals suggests that they may be adapted to calling from their host of soft mosses. This signal is effective at short range and would therefore be effective to initiate courtship or signal disturbance.

The history of the **Peloriidiidae** is an interesting one. *Peloriidum* (Figure 129) had been collected from Tierra del Fuego in 1892, *Xenophyes* (Figure 131) from New Zealand in 1920, and *Hemiodoecus* (Figure 135) from Tasmania in 1904 (Monteith 2015). But in total, only six specimens had been collected to represent these three genera! All came from dripping wet *Nothofagus* forests (Figure 130). In 1932, Hacker described *Hemiodoecus veitchi* from the Antarctic Beech forest of Lamington National Park, Queensland, Australia. This name was later changed to honor both Hacker and his mentor – *Hackeriella veitchi*. In 1971, a further discovery by Bob Taylor resulted in the description of *Rhacophysa taylori* (Burckhardt 2009) from dripping mosses near Cairns, Queensland, a wet area receiving 8 m of rainfall per year.

Figure 129. *Pemphigus bursarius*, member of a moss-dwelling genus. Photo from Pest and Diseases Image Library, Bugwood.org, through Creative Commons.

Despite having only 21 species known in 1982 (Evans 1982), the **Peloriidiidae** have been reported from bryophytes many times compared to other **Hemiptera**. These frequent reports, nevertheless, most likely grossly under-represent their presence because of their cryptic habits and small size (Burckhardt *et al.* 2011). Adequate sampling requires sifting of the mosses and forest litter with a sieve. They also tend to occur in remote locations that are hard to reach.

Moss bugs are known from fossils, occurring on mosses in the wet, cool *Nothofagus* (beech) forests (Figure 130) in the Southern Hemisphere (Bechly & Szewo 2007). Today they are most common in the *Nothofagus* forests of southern South America, Australia, Tasmania, New Caledonia, Lord Howe Island, and New Zealand, where they live in damp mosses on decaying mossy trunks and twigs of the *Nothofagus*. In addition to eating the leafy mosses, they may feed on moss rhizoids, wood-decaying fungi, or lichens.

Figure 130. *Nothofagus* beech forest with a dense bryophyte ground cover, Eglinton Valley, NZ. Photo from Department of Conservation of NZ, through Creative Commons.

Drake and Salmon (1948) first reported *Xenophyes cascus* (2.48-3.10 mm; Figure 131) from New Zealand in 1948, identifying it from damp moss. *Xenophyes cascus* is currently distributed in temperate forests and fens in the Southern Hemisphere (Australia, New Zealand, New Caledonia, Chile, Argentina) (Grozeva *et al.* 2014). They also occur on the moss *Notoligotrichum crispulum* (Figure 132) in heavily forested areas where *Weinmannia racemosa* (Figure 133) is dominant (Carter 1950). These are both moss dwellers and moss feeders. Burckhardt *et al.* (2011) reported New Zealand moss dwellers to include *Xenophyes cascus* from moss on an old log, the broadleaf-taraire dominant *Xenophyes adelphus* (2.35-2.63 mm) by sifting mosses from cloud forests and the mosses and liverworts on tree trunks and branches, *Xenophyes goniomus* (2.68-3.10 mm) and *Xenophyes kinlochensis* (2.80-3.23 mm) from mosses, *Xenophyes metoponcus* (2.35-2.55 mm) from mosses in mixed podocarp/broadleaf forest, and *Xenophyes rhachilophus* (2.18-2.95 mm; Figure 134) from mosses under beech trees, sifted mosses, and mosses on a wet bank.

Figure 140. *Oiophysa ablusa*, a New Zealand bryophyte dweller on a leafy liverwort. Photo by E. Wachmann through M.-C. Larivière, with permission.

The genera *Oiophysa* (2.19-2.98 mm; Figure 140) and *Xenophysella* (2.34-3.00 mm) are among the moss dwellers in New Zealand (Larivière *et al.* 2011). These include *Oiophysa ablusa* (3 mm; Figure 140), *O. cumberi* (2.5 mm; Figure 141), *O. distincta* (2.6 mm), *O. pendergrasti* (2.5 mm), *Xenophysella greensladeae* (2.48-3.0 mm), and *X. stewartensis* (2.34-2.63 mm; Figure 142). *Xenophysella greensladeae* has two 3-lobed **bacteriomes** where bacteria are maintained. Larivière and coworkers presumed that as environmental conditions become drier the **Peloriidiidae** would move deeper into the moss layers where there is greater humidity, remaining there until the surface becomes more suitable.

Figure 142. *Xenophysella stewartensis*, a New Zealand moss dweller. Photo by Birgit E. Rhodes in Larivière *et al.* 2011, with permission.

Oiophysa distincta (2.44-2.98 mm) is considered a living fossil relict in native New Zealand forests, where it lives among wet mosses in the temperate and Antarctic rainforests (Figure 143) (Harris 2011; Grozeva *et al.* 2014). Today other *Peloridiidae* likewise occur in damp mosses, frequenting the decaying mossy trunks and branches of *Nothofagus* (Figure 130), where they feed on wood-decaying fungi, lichens, and moss rhizoids (Bechly & Szwedo 2007).

Figure 143. Rainforest, Fiordland National Park, New Zealand, mossy home for *Oiophysa distincta*. Photo by Christiaan Briggs, through Creative Commons.

On Lord Howe Island, *Howeria kingsmilli* (3.0-3.1 mm) occurs on the long pendent moss *Spiridens vieillardii* (Figure 144) and on the leafy liverwort *Porella elegantula* (Figure 145-Figure 146) (Evans 1967).

In Australia, *Hemiodoecellus fidelis*, like *Hemiodoecus leai* (Figure 135) in New Zealand, lives in

damp moss where its movement is limited by its short legs and limited space for movement (Robinson 2003).

In Australia, *Hackeriella veitchi* (3.0-3.3 mm; Figure 147) inhabits the pendent moss *Papillaria crocea* (Figure 148) (Helmsing & China 1937; Carter 1950; Spangenberg *et al.* 2013). On the other hand, a much later visit to the area failed to reveal any individuals of this species on the *P. crocea* (Spangenberg *et al.* 2013). Nevertheless, new locations have been found, making this the most readily available member of the family. *Hackeriella veitchi* is unique among the **Peloridiidae** in being able to jump. This is accomplished without any apparent morphological adaptation, but rather by suddenly rotating the hind **femora** (third segments of legs) on the **coxae** (bases of legs) (Burrows *et al.* 2007).

Figure 147. *Hackeriella veitchi*, an inhabitant of a pendent moss in Australia. Photo by J. Deckert, with permission.

Burkhardt and Agosti (1991) reported *Peloridora kuscheli* (2.8-3.3 mm; Figure 149), *P. minuta* (~2.6 mm), and *P. holdgatei* (~2.6 mm) from mosses in the *Nothofagus* forests (Figure 130) in Chile. Other Chilean moss dwellers include *Pantinia darwini* (3.2-3.9 mm; Figure 150) and *Pantinia* sp. and several unidentified early instar nymphs.

Shcherbakov (2014) found that some of the **Peloridiidae** are restricted to one or only a few bryophyte species (**mono-** or **oligophagous**). For example, *Peloridium hammoniorum* (3.8-5.2 mm; Figure 151) in Fuegia in Southern Patagonia was found only on *Pohlia cruda* (Figure 152) (China 1962; Cekalovic 1986), *Polytrichum strictum* (Figure 153) (Estévez & Remes Lenicov 1990), and *Polytrichadelphus magellanicus* (Figure 154) (Shcherbakov 2014), and it is known to eat mosses (Larivière *et al.* 2011; Shcherbakov 2014). [The host *Polytrichum strictum* was not reported previously from that region (Larrain 2007) and may be a misidentification.] The recently described species *Peloridium pomponorum* (3.4-4.1 mm) is only known from *Sphagnum magellanicum* (Figure 156) and *S. cf. recurvum* (Figure 157), both in open areas (Shcherbakov 2014).

Symbiotic Bacteria

One of the factors that may permit the **Peloridiidae** to eat mosses is their associated symbiotic bacteria. The **Coleorrhyncha**, including the **Peloridiidae**, is one of the oldest lineages of **Hemiptera**. Kuechler *et al.* (2013) analyzed **Peloridiidae** bacterial symbionts from 15 representatives from South America, Australia, Tasmania, and New Zealand. These proved to be an unknown group of **Gammaproteobacteria**, which they named *Candidatus Evansia muelleri*. These bacteria develop at the posterior pole of a developing oocyte and thus are transmitted from parent to offspring before birth. A second bacterium was usually associated with the Malpighian tubules, an endosymbiont in the genus *Rickettsia* (Figure 158).

ORDER THYSANOPTERA – Thrips

The thrips are tiny, slender insects with fringed wings (Greek *thysanos* = fringe) (Thrips 2015). They feed by sucking cell contents of plants or animals. Their tiny size (<1mm) gives them an ideal fit among bryophytes, but only one sub-tribe among the 6,000 species lives there (Mound

1989). Curiously, the word "thrips" is both singular and plural.

Although an insect most people do not often notice, these insects (**Thysanoptera**) can be associated with mosses (Mound 1989). Bhatti (1979) found two new species in a new genus of thrips (**Thripidae**) living among mosses in West Africa. Mound (1970) reported *Nesothrips lativentris* from this family among mosses on the Solomon Islands.

The Old World genera of *Bournierothrips* and *Muscithrips* are bryophyte dwellers. In fact, *Bournierothrips* seems to be restricted to mosses (Bournier 1979). A recent new genus, *Solanithrips*, was described from Mexico as an inhabitant of *Solanum* (Johansen 1997). This genus is closely related to the two Old World bryophyte-dwelling genera, so it is possible that it too may just use bryophytes when the *Solanum* is seasonally unavailable. Other members of **Thysanoptera** are known from bryophytes (and lichens) in Mexico (Mojica Guzman & Johansen 1990).

In their study of New Zealand **Thysanoptera**, Mound and Walker (1982) found records of a number of species of **Thripidae** in association with mosses: *Anaphothrips obscurus* (1.5 mm), *Anaphothrips woodi*, *Aptinothrips rufus* (1.5mm; Figure 159-Figure 160), *Aptinothrips stylifer* (~1.5 mm; Figure 161), *Ceratohrips frici* (Figure 162), *Lomatohrips paryphis*, *Pseudanaphothrips achaetus*, *Thrips australis*, *T. nigropilosus*, *T. obscuratus*, *T. tabaci* (Figure 163). At least some species, including *Ceratohrips frici*, are attracted to their primary hosts by colors (Teulon & Penman 1992). *Ceratohrips frici* is attracted to white and yellow traps. The associations of all these thrips with a number of flowering plants suggest that the mosses were most likely a refuge and not a food source (Mound & Walker 1982).

Johansen *et al.* (1983) discussed the New World (Eastern Mexico and Costa Rica) *Wegenerithrips* (0.738–1.16 mm; **Thripidae**), a genus with nine species at the time, as a bryophyte feeder. This is a genus thus far known only from females (Taylor 2013). Most likely more of these bryophyte feeders remain unknown.

Mound (1989) reported that only one sub-tribe within **Thysanoptera** feeds on mosses, the **Williamsiella** (family **Phlaeothripidae**). This sub-tribe is comprised of two genera, *Lissothrips* and *Williamsiella*. These are mostly New World species. In addition to their small size, these genera seem further adapted to moss dwelling by

being wingless. And their ability to feed on mosses seems to be a highly derived character. One even bears the name *Lissothrips muscorum* (1.17 mm), a wingless female found among mosses in Illinois, USA, and only known from mosses (Rhode 1955). Chiasson (1986) reported it from *Sphagnum* and moss litter, and it feeds on mosses. An early record of **Phlaeothripidae** among mosses is that of *Liothrips ocellatus* (Figure 164) in Illinois, USA (Hood 1908).

Figure 164. *Liothrips ocellatus*, one of the early known moss dwellers among the thrips. Photo through Creative Commons of Snipeview.

But it may not always be the moss that gives them their nutrition. In Australia and New Zealand species of these two genera have a blue-green gut, suggesting they may eat the associated **Cyanobacteria** (Mound & Tree 2015). The fact that these genera are understudied is indicated by the new finds: two species of *Lissothrips* were recorded from Australia for the first time in 2015, as well as six new species; *Williamsiella* was recorded from Australia for the first time with a new species.

Bryophytes may actually play an important role for leaf-inhabiting thrips. When the weather becomes cool and wet, these leaf dwellers seem to disappear from the landscape (Mound & Walker 1982). But if one uses a Berlese funnel to extract them from leaf litter and ground mosses, many will appear. The mosses serve as a refuge when leaves become inhospitable. Further evidence of bryophytes as a refuge comes from *Iridothrips mariae* (**Thripidae**). In Hungary, this species seeks mosses in the fall as a place to spend the winter (Jenser 2013).

Peck and Moldenke (1999) have been concerned with the invertebrates, especially insects, that are collected with harvestable mosses. Not only does this disturb the communities of origin, in some cases depriving birds, lizards, and other predators of a food source, but also it introduces these creatures to a new ecosystem where they may have no or few natural predators. They could easily become crop pests in some receiving ecosystems. Peck and Moldenke reported that the number of individuals of **Thysanoptera** per gram were greater in those moss samples collected at the bases of shrubs than in those from the tips of branches. They recommended prohibiting the harvesting of mosses from the shrub bases due to their importance in housing insect diversity.

Summary

Several previous orders have been combined into the **Hemiptera**, including leaf hoppers, plant hoppers, aphids, and moss bugs.

Some of the **Cicadellidae** are true **tyrphobionts** (bog dwellers). The **Delphacidae** includes moss eaters, especially on **Polytrichaceae**; few seem to be bog dwellers.

Other important moss-dwelling aphids include members of **Myzodium** and **Muscaphis**, both of which typically use mosses for overwintering and seasonal food. **Derbidae** and **Issidae** have moss dwellers, but little seems to be known about their habits. The latter uses a pair of gears to aid jumping in nymphs. Even less is known about **Eriococcidae** that live among mosses.

This classification includes several kinds of gall makers in the **Aphididae** that depend on bryophytes, especially **Mniaceae**, for part of the life cycle and winter food. For the Chinese gall maker *Schlechtendalia chinensis* and others, and even some North American gall makers, the bryophytes serve as an essential winter host, serving for both food and shelter and often oviposition sites. In the **Aphididae**, a family with a stylet for sucking plant juices, moss specialists have been used to trace the movement of fluids in the leptoids of mosses in the **Polytrichaceae**. Some of these moss inhabitants may respond to aliphatic compounds in the moss, but direct relationships remain to be tested.

Members of the genus *Adelges* (**Adelgidae**) have destroyed habitat for the leafy liverwort *Bazzania trilobata* and in other cases have opened new habitat for the moss *Leptodontium viticulosoides*.

The family **Peloriidiidae** is so common among mosses that the common name of "moss bugs" is applied. They seem to require that constantly moist environment, probably burrowing deeper as the moss dries. At least some members of the family may have bacteria that help in their digestion of the mosses.

Information on thrips (**Thysanoptera**) is limited, but several genera are represented among bryophytes, with the sub-tribe **Williamsiellina** feeding on mosses.

Acknowledgments

Thank you to Chen Peipei for providing a list of references on the gall aphids that use mosses as alternate hosts. John Steel alerted me to the discovery of *Hemiodocus leai* among mosses in New Zealand. Thank you to Marie-Claude Larivière for her encouragement and help in providing images, making suggestions, and reviewing the chapter. Thank you to Robin Stevenson for interesting discussion and followup on the ants that make *Sphagnum* collars to house aphids. Thank you to Andi Cairns for the article on the history of Peloriidiidae by Monteith. Thank you to Timea Deakova for sharing the story and images of the spittlebug on *Polytrichum*. Thank you also to Sean Haughian for sending me the Moran (1989) paper on evolutionary implications of gall aphids.

CHAPTER 12-8

TERRESTRIAL INSECTS:

HOLOMETABOLA – MEGALOPTERA

AND NEUROPTERA

Figure 1. *Chauliodes pectinicornis* adult, a species that spends its pupal stage among mosses. Dorothy Pugh <www.dpughphoto.com>, with permission.

MEGALOPTERA – Alderflies, Dobsonflies and Fishflies

This is a small order and most are aquatic as larvae. Nevertheless, some members of the **Corydalidae** (dobsonflies) pupate under mosses, a stage lasting about two weeks (Needham *et al.* 1901). These species include *Chauliodes pectinicornis* (Figure 1-Figure 2), *C. rastricornis* (Figure 3-Figure 4), and *Nigronia serricornis* (Figure 5-Figure 6).

Figure 6. *Nigronia serricornis* adult, a species that pupates under mosses. Photo by Richard Orr <www.marylandinsects.com>, with permission.

Barnard (1931) reported pupae of alderflies (**Sialidae**) from *Sphagnum* and other wet or aquatic mosses that grew near or in streams and waterfalls in South Africa. These alderflies required that the mosses be wet.

NEUROPTERA – Lacewings

Not many members of Neuroptera use bryophytes, but Richards and Davies (1977) reported that lacewing larvae search for prey in mosses.

Osmylidae

The larvae of *Osmylus* (Figure 7) live in the mosses on the banks of woodland streams (Elliott 1996). Even the adults are typically found near these small streams that have mossy banks suitable for larval development. In Great Britain, the larvae can be found in these mosses throughout the year. In the winter they migrate deep into the moss rhizoids where they hibernate.

The female *Osmylus fulvicephalus* (Figure 7) lays about 30 eggs 2-3 days after mating (Elliott 1996). These often are laid in small groups. When deposited on mosses they are laid singly or in pairs on the undersides of leaves and near the water (Lestage 1920; David 1936; Ward 1965). The eggs are cylindrical and slightly flattened. These white eggs darken to brown within a few days, making them less obvious than the white version. Eggs hatch in 4-22 days, depending on the temperature (Withycombe 1923; David 1936; Ward 1965).

Figure 7. *Osmylus fulvicephalus* larva, a moss dweller near woodland streams. Photo by Walter Pfliegler, with permission.

When the larvae of the giant lacewing, *Osmylus fulvicephalus* (Figure 7), emerge, they burrow into the mosses (Elliott *et al.* 1996) and live among damp mosses in the splash zones of river banks and streams (Plant 1994; Roper 2001). These larvae are only 5 mm when they hatch, but reach 15 mm by the third (final) instar from which they develop into pupae (Elliott 1996).

In this moss habitat *Osmylus fulvicephalus* (Figure 7) larvae are able to eat small arthropods (Elliott *et al.* 1996). They strike at movement and inject enzymes that paralyze the prey. When they hatch, the first instar larvae eat mites and **Collembola**, but second and third instars switch to

eating larvae of small **Diptera**. The common **Chironomidae** (midges) are paralyzed in 10 seconds by the enzymes. They then suck the contents out of the prey. The larvae may dive into the water to find prey, but if they are forced to remain submersed they die within 8-28 days (Ward 1965).

The third (and final) larval instar overwinters in **diapause** and is able to withstand total immersion during flooding (Elliott *et al.* 1996). When spring arrives, the larvae make a cocoon, incorporating some of the moss in the cocoon, then pupate for 10-14 days before cutting their way out with their mandibles. They then emerge as adults (Figure 8) without further feeding. The adults fly about over the water surfaces in their woodland homes in the evening (**crepuscular**) (Elliott 1996).

Figure 8. *Osmylus fulvicephalus* adult, a species that lays its eggs on moss leaves. Photo from <www.invertebradosdehuesca.com>, through Creative Commons.

Chrysopidae

The modern **Chrysopidae** are not known to live among bryophytes, but they sometimes wear them. The larvae attach various pieces of debris, including bits of mosses and lichens, on their backs (Figure 9) (Skorepa & Sharp 1971; Slocum & Lawrey 1976; Eisner *et al.* 2002; Pérez-de la Fuente *et al.* 2012; Anonymous 2015; Newman *et al.* 2015). This cloak provides camouflage that hides them from both predators and prey.

Figure 9. **Chrysopidae** larva with cloak of debris and lichens. Note the head and large jaws at right. Photo by David Illig, through Creative Commons.

Larvae of the green lacewing *Leucochrysa pavid*a (Figure 10-Figure 13) (Slocum & Lawrey 1976) and the brown lacewing (Anonymous 2015) take their camouflage with them. They make packets of lichen fragments, bark, pollen grains, fungal spores, and moss fragments that they attach to spines on their backs (Slocum & Lawrey 1976). Likewise, immature brown lacewings use lichen and moss coverings to camouflage and protect them from predators and to disguise themselves from their prey (Insects 2014).

Figure 10. *Leucochrysa pavid*a larva with lichen back pack. This species also uses mosses. Photo by Jim McCormac, with permission.

Figure 11. *Leucochrysa pavid*a larva with lichen back pack, ventral view. Photo by Jim McCormac, with permission.

Figure 13. *Leucochrysa pavidula* larva with lichen back pack, mandibles ready. Photo by Jim McCormac, with permission.

Hallucinochrysa diogenesi (Figure 14) is a fossil lacewing that attached plant fibers, bark, leaves, algae, mosses, snail shells, and corpses of its food prey on its back (Pérez-de la Fuente *et al.* 2012). These were held in place by the bristles on the backs of the larvae.

Figure 14. *Hallucinochrysa diogenesi*, representation of the fossil that attached mosses and other substances to its back. Photo by Jose Antonio Penas, through Creative Commons.

Fossil evidence suggests that some larvae of the **Chrysopidae** have been associated with liverworts (Liu *et al.* 2018). *Phyllochrysa huangi* larvae (Figure 15, Figure 16) from Burmese amber (Upper Cretaceous ~100 million years old) exhibit "distinctive foliate lobes" on the thorax and abdomen. This mimicry permits individuals to hide from prey (Figure 16) or to be ambush predators because the larvae are hard to distinguish from their background vegetation.

Figure 15. Chrysopid larvae, *Phyllochrysa huangi*, in Burmese amber. Image from Liu *et al.* 2018, with permission.

The shape of this larva is similar to that of bryophytes (Figure 16, Figure 17). Furthermore, its head is small and concealed under the anterior thoracic lobe (Figure 16) (PPI 2018). Antennae are extremely long with enlarged ends. The researchers found several amber fossil bryophyte species with similar morphologies (Figure 17), including size, leaf shape and arrangement, leaf folds, and lines.

Figure 16. Models of *Phyllochrysa huangi* larvae and hypothetical liverworts. Image from Liu *et al.* 2018, with permission.

Figure 17. Burmese mosses (B, E, & G) and liverworts in amber – potential hosts for *Phyllochrysa huangi* larvae. Image from Liu *et al.* 2018 and PPI 2018, with permission.

Summary

The **Megaloptera** and **Neuroptera** are small orders. Hence there are few bryophyte dwellers. Some members of **Megaloptera** pupate under mosses. In the **Neuroptera**, the best known bryophyte-dwelling genus is *Osmylus*. *Leucochrysa pavidia* makes packets of camouflage that include moss fragments among other objects.

Acknowledgments

Bernard Goffinet alerted me to the story on fossil *Phyllochrysa huangi* larvae that mimicked liverworts. Thank you to all the photographers who placed their images online with Creative Commons permission and to those who gave me permission to use their images.

CHAPTER 12-9a

TERRESTRIAL INSECTS:

HOLOMETABOLA – COLEOPTERA

BIOLOGY AND ECOLOGY

Figure 1. *Ptychomitrium* in the Neotropics with beetle navigating within the mat. Photo by Michael Lüth, with permission.

COLEOPTERA – BEETLES

I opened my email one morning to see one subject labelled "Catching Beetles." Upon investigation, I found this was an advertisement for a new book, 320 pages, all directed toward the various methods for catching beetles in the myriad of habitats they occupy and the families you might encounter (Julio 2011). This large book attests to the huge number of species, sizes, and wide range of habitats of beetles. The picture of a car with large fine-mesh funnel nets on the top and sides struck me as a symbol of their **ubiquitous** (found everywhere) nature.

It seemed like every time I looked up information on a beetle species, I found three more beetle species that inhabited mosses during part of the life cycle. At some point I had to stop and ignore or this volume would never get past the beetle chapter. Hence, I know there are more records that are out there, but these are adequate to show the wide range of families, uses, habitats, and adaptations.

Among the insects, the **Coleoptera**, those hard-winged insects known as beetles, are the largest group of organisms on the planet, and are likewise abundant within the shelter of bryophytes. A renowned biochemist and friend of the entomologist E. O. Wilson, J. B. S. Haldane, when asked by a theologian what the natural world had taught him about the Creator, replied that he has "an inordinate fondness for beetles." It is unclear whether Haldane is the one who coined the phrase because many variants of it appear in the literature (Farrell 1998).

With such large numbers, it is not surprising that we find some of them among mosses. For example, **Parnidae** and **Elmidae** are common in *Sphagnum* peatlands (Figure 2) (Leng 1913). That means that they can become unwitting passengers on harvested mosses, travelling around the world with them (Reich 1974; Peck & Moldenke 1999).

Figure 2. *Sphagnum* lawn, home for some members of **Parnidae** and **Elmidae**. Photo from Creative Commons.

Moss-dwelling beetles have been known for a long time (for example, Douglas 1871; Waterhouse 1871). Ferguson (1901) enumerated many species of beetles among mosses in the Clyde area of the British Isles, listing the most in the families **Curculionidae** (weevils) and **Staphylinidae** (rove beetles). Day (1907) reported several species from mosses in Cumberland, England. Brown (1972) considered that some seek mosses to maintain their moisture.

Des Callaghan (pers. comm. 3 February 2012) relayed to me his experience with grubs he thought might be beetle larvae. He had saved a sample of *Micromitrium tenerum* (Figure 3) for photography, but when he was ready for the photography all he found was soil covered by capsules! He later observed the grubs eating the leaves of the moss.

Figure 3. *Macromitrium tenerum*, a species for which clumps can be completely devoured by beetle grubs. Photo by Jan-Peter Frahm, with permission.

Bryophagids – Eating and Being Eaten

As seen above, a surprising number of beetles feed on mosses. A variety of small beetles eat mosses and use them as their homes (Drozd *et al.* 2007).

A number of genera in the **Byrrhidae** occur among mosses, use them for egg laying, or eat them. *Exomella pleuralis* (Figure 4) can be found in *Racomitrium heterostichum* (Figure 5), and adults both feed and oviposit on *Eurhynchium oreganum* (Figure 6) (Russell 1979). *Curimopsis albonotata* (Figure 7) and *C. brevicollis* are limited to higher elevations in the Pacific Northwest; *C.*

brevicollis from northern Idaho had moss in its gut. *Lioligus nitidus* (Figure 8) and *L. striolatus* feed on a variety of mosses in the lab: *Eurhynchium oreganum*, *Hylocomium splendens* (Figure 9), *Hypnum circinale* (Figure 10), *Plagiothecium undulatum* (Figure 11), *Racomitrium heterostichum*, *Rhytidiadelphus loreus* (Figure 12), and *R. triquetrus* (Figure 13). One specimen was reared from an egg to an adult on the leafy liverworts *Diplophyllum plicatum* (Figure 14) and *Scapania bolanderi* (Figure 15). On the other hand, adults refused to eat *S. bolanderi* and other liverworts or *Metaneckera menziesii* (Figure 16).

Adults of *Lioon puncticeps* and *L. simplicipes* (Figure 17) live among many kinds of mosses (Russell 1979). In the laboratory, *Lioon puncticeps* adults and larvae both feed on *Dicranum fuscescens* (Figure 18), *Rhytidiadelphus loreus* (Figure 12), *Antitrichia curtipendula* (Figure 19), *Eurhynchium oreganum* (Figure 6), and *Plagiothecium undulatum* (Figure 11). On *Polytrichum commune* (Figure 20), they eat only lamellae and leaf tips while avoiding the tougher parts.

Listemus acuminatus (Figure 21) and *L. formosus* grow among mosses on soil, rocks, and logs, but not among epiphytes (Russell 1979). In the lab they feed on *Eurhynchium oregonum* (Figure 6), *Hypnum circinale* (Figure 10), and *Plagiothecium undulatum* (Figure 11). Larvae occur in mats of the leafy liverworts *Gyrothya underwoodiana* (Figure 22) and *Nardia scalaris* (Figure 23), but they may only feed on associated mosses.

Figure 21. *Listemus acuminatus*, a species that lives among mosses on soil, rocks, and logs, but does not venture up the boles of trees. Photo from CNC-BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Byrrhus americanus (Figure 24), *B. concolor* (Figure 25), and *B. kirbyi* (Figure 26) have been found with mosses in their guts (Russell 1979). Hradílek and Boukal (2003) reported *Polytrichaceae* cells from the gut of *Byrrhus luniger*. These were lamellae with papillae on the terminal cells (Figure 28, Figure 30), suggesting either *Pogonatum urnigerum* (Figure 27-Figure 28) or *Polytrichastrum alpinum* (Figure 29-Figure 30).

It appears that all North American species of the *Artematopodidae* might be bryophagids (Russell 1979). Adults of *Macropogon* (Figure 31) and larvae of *Eurypogon* (Figure 32) in western Washington and Oregon usually occur on trees or shrubs near moss-covered rocks, but some larvae have been collected under the moss *Ceratodon purpureus* (Figure 33).

Figure 31. *Macropogon testaceipennis* adult, a North American bryophagid. Photo by Joyce Gross, with permission.

A beetle in the family **Lagriidae** in the Afromontane forest of South Africa feeds on both living and dead parts of the moss *Braunia secunda* (**Hedwigiaceae**; Figure 34–Figure 35), as evidenced by gut analysis (Chown 1993), but whether it is specific to this food is not known. Among the weevils (**Curculionidae**) in the sub-Antarctic Prince Edward Islands, *Antarctonesiotes elongatus*, *Bothrometopus randi*, *Ectomnorrhinus marioni*, *Mesembriorrhinus brevis*, and *Palirhoeus eatoni*

(**Brachyceridae**) all feed on cryptogams, including bryophytes (Chown & Scholtz 1989a). Similar relationships are known from Marion Island in the Antarctic (Smith 1977), where *Mesembriorrhinus brevis* and *Ectomnorrhinus marioni* prefer bryophytes over flowering plants (Chown & Scholtz 1989a). *Ectomnorrhinus similis*, a weevil (**Curculionidae**), consumed 1.67 mg per day of *Brachythecium rutabulum* (Figure 36) on an Antarctic island. On the other hand, mosses and lichens consumed by microfauna in two other Antarctic moss communities were less than 0.2 g m⁻² yr⁻¹.

Lazarenko *et al.* (1960) reported the use of mosses as food for flax flea beetles (**Chrysomelidae**). Wallin *et al.* (1999) examined the food habits of beetles inhabiting *Sphagnum* (Figure 2) mosses as a possible cause of mandibular wear. The species that exhibited the greatest mandibular wear was not the one with the highest consumption of mosses. Rather, they found that mandibular wear in the carabid beetles *Chlaenius costulatus* (Figure 37) and *C. sulcicollis* (Figure 38) appeared to be caused by their activities in biting and burrowing into *Sphagnum*-hummocks.

Figure 37. *Chlaenius costulatus* adult, an inhabitant of a protected bog in Sweden. Photo by Tim Faasen, with permission.

Chown (1990) found that even in the presence of the abundant grass *Agrostis magellanica* (see Figure 39), some larvae of the weevil *Ectemnorhinus* (see Figure 40) in the sub-Antarctic feed on bryophytes, primarily the leafy liverwort *Blepharidophyllum densifolium*. The smaller of the two species found by Chown and Scholtz (1989b), *E. marioni*, lives among the mosses, feeding on them at all stages and having a generation time of one year or less. By contrast, the larger species, *E. similis*, feeds on detritus as larvae and flowering plants as adults. It has a generation time of more than one year and has more instars. The advantage to *E. marioni* of a bryophyte diet appears to be that the bryophytes are both abundant and available year-round. Furthermore, they contrast with the flowering plants in their seasonal N distribution. The seed plants have the highest concentrations in spring, whereas the mire bryophytes have the highest concentrations in autumn. It is

interesting that the bryophytes have high concentrations of polyphenolic lignin-like compounds that interfere with digestion, whereas the flowering plants lack these.

On Heard Island, Chown and Klok (2001) found that the weevil species complex of *Ectemnorhinus viridis* feed on both tracheophytes and bryophytes. Cryptogams, including both lichens and bryophytes, serve as a primary source of energy and nutrients for 5 of the 6 species of weevils on the sub-Antarctic Marion Island (Crafford & Chown 1991).

Carabid beetles also seem to find bryophytes, particularly in peat bogs, to be suitable habitats. Främbs (1994) found that the Swedish *Agonum ericeti* (Figure 41) and *Pterostichus rhaeticus* (Figure 42) use the damp lawns in the summer and migrate to drier hummocks for overwintering. Therefore, larger populations were restricted to areas with distinct hummock-hollow complexes (Figure 43).

Beetles in geothermal areas seek refuge from the heat of the soil by inhabiting the cooler bryophytes (Elmarsdottir *et al.* 2003). In turn, bears may eat the beetles, as suggested by their piles of feces (Figure 44) in the area (personal observation).

Figure 44. Bear dung at Ponponyama, Japan. Many beetles are present in this dung. The moss in the foreground is *Campylopus japonicus*. Photo by Janice Glime.

Epichorius longulus and *E. aucklandiae* (Byrrhidae) live in the coastal rata (*Metrosideros*) forest (Figure 45) of Auckland Island, New Zealand (Farrell 1974). *Epichorius longulus* lives in the ground layer, whereas *E. aucklandiae* lives in the canopy. The former species was abundant in the liverwort *Riccardia* spp., but rarely occurred among *Bazzania adnexa* (Figure 46). When larvae were reared on the *Riccardia* (Figure 47), they gained more weight than on *Bazzania adnexa*. The adults of *E. longulus* sought shelter under the leaf litter in the daytime but moved about to feed on bryophytes at night.

Some bryophytes apparently are eaten unintentionally by animals searching for food, including the beetle fauna. The carnivorous salamander *Phaeognathus hubrichti* (Red Hills Salamander; Figure 48) typically has a diet that is nearly 70% arthropods, including beetles (Gunzburger 1999). But also in the gut and feces one can find moss fragments, most likely consumed as the salamanders forage for arthropods among the mosses.

Figure 48. *Phaeognathus hubrichti*, a salamander that eats insects among mosses. Photo by Danté B. Fenolio, with permission.

Sampling

Most researchers have used the same sampling methods for bryophytes as they use for leaf litter. But bryophytes provide small spaces, and some insects never leave those small spaces. This behavior impacts the suitability of trapping methods.

Nelson and Hauser (2012) used both Berlese funnels and water sampling for bryophyte fauna, accounting for many small invertebrates that are usually not found in these associations. Nevertheless, small insects, including tiny beetles, might not have crawled out of the moist moss and into the funnels. The bias of sampling methods is demonstrated by the near absence of overlap between the two sampling methods.

Beetles (Coleoptera) are so common among the *Sphagnum* plants (Figure 2) (Brink 1983; Runtz & Peck

1994) that sifting through squeezed mosses can be the best method of collecting (Leiler 1983). Boháč and Bezděk (2004) once again emphasized the role of sampling method in determining the bryophyte fauna. This may be especially true for beetles, where a number of species are wingless and do little moving around. In the Mrtvy Luh peat bog they found that of 38 species in their traps, only 3 were found in both pitfall and light traps.

Boháč and Bezděk (2004) found that the light traps in the Czech Republic peat bog had more species, but many were accidental species that were not typical bog inhabitants. Among these the dominant species were species that are good fliers. Based on these findings, Boháč and Bezděk (2004) recommended that sifting and **trampling** (pressing the moss down to create a pool of water and causing the beetles to float) be included in the sampling strategies. But be aware that sifting and hand grabs are destructive and should be avoided in fragile systems or where repeated sampling is planned.

Leiler (1983) was particularly successful in finding beetle fauna by sifting squeezed wet *Sphagnum*. Wallin *et al.* (1999) used pitfall traps that were connected with a gutter and embedded into large *Sphagnum* hummocks. Lindroth (1974) considered the ordinary insect sieve to be indispensable for sampling in leaf litter and "not too wet" moss, especially for hibernating insects. He suggested that litter samples could also be put under water to force the insects to the surface. For pitfall traps, he suggested adding a few drops of detergent to the formalin to break the surface tension.

Based on the differences seen among these methods, I once again recommend hand picking using a dissecting microscope if an unbiased, quantitative sampling is desired. Some insects move too slowly to get away from a heat source before they die. Some may burrow deep into the mat without vacating it. In any case, not all insects will enter traps equally.

Habitat Relations

The bryophytes are different in different habitats, and so are the beetles. But the correlations are likely to be secondary, with both of them correlating with moisture and bryophytes also with light and suitable substrate availability.

Forests

Pavel *et al.* (2007) found the **Coleoptera** to be the most abundant of the insect taxa in a forest study in the Czech Republic. Pitfall traps were used in three sites to compare those in *Polytrichum* cushions (Figure 49) with those at least 10 m away with no moss. Of the 56 species found, ~25% were found only among the mosses. These, combined with those also found in other parts of the forest floor, demonstrated a higher species richness among the mosses. Nevertheless, only one of these species (*Symplocaria* sp., **Byrrhidae**) was a **bryophage** (one that eats bryophytes). Monte-Carlo permutation tests suggest that the beetles are correlated with moisture and the mosses just happen to provide the right moisture conditions. Those beetle species in dry habitats tend to be restricted to moss cushions, making them strict **bryobionts** (living only on bryophytes).

Figure 49. *Polytrichum* cushions that form habitat islands for *Cytillus sericeus* and other beetles, providing moisture in exposed areas. Photo by James K. Lindsey, with permission.

Nelson and Hauser (2012) surveyed the epiphytic bryophyte communities at the Tryon Creek State Natural Area in Oregon, USA. Among the five phyla represented, insects were among the top five taxonomic sub-groups (except for the recently ousted *Collembola*). In addition to the five more dominant insect taxa, **Diptera** and **Coleoptera** were present. Hence, beetles were not represented in proportion to their prominence among species numbers on Earth.

Hitch-hikers

Peck and Moldenke (1999) were concerned about the export of potential pest insects in commercial harvests of bryophytes in Oregon, USA. They likewise used the Berlese funnel extraction for arthropods on 200 samples of harvestable mosses. They compared the invertebrate populations at the bases and tips of shrubs of the vine maple (*Acer circinatum*; Figure 50). The base mosses had substantially higher species richness and total abundance overall. For **Coleoptera**, the bases had greater numbers of individuals than did the tips of the shrubs. Mites were the most common arthropods at the base, whereas spiders (*Micryphantidae*) and *Sminthurus* (*Collembola*) were the predominant taxa in mosses at the tips.

Figure 50. *Acer circinatum*, home for **Coleoptera** in mosses at base and on branches. Photo by Ken Gilliland, through Creative Commons.

Forest Disturbance and Recovery

The carabid beetle *Agonum fuliginosum* (Figure 51) in Europe seems to have a generalist approach to canopy closure, but it does depend on the presence of *Sphagnum* (Figure 2) mires in the forest (Koivula 2002a, b; Koivula & Niemela 2002; Koivula *et al.* 2002). Even small islands of *Sphagnum* within a clear-cut forest will permit it to remain, presumably providing needed moisture. *Patrobis assimilis* (*Carabidae*; Figure 52) likewise requires the presence of *Sphagnum* to survive in forests (Koivula 2002b). On the other hand, *Agonum mannerheimii*, despite being a mire specialist, is unable to survive in remaining mires if the forest is clearcut (Niemelä *et al.* 1993a, b). It can take 50-60 years for a spruce mire (Figure 53) to recover its forest cover after clearcutting, but it takes longer if there is serious disturbance of the ground layer (Koivula *et al.* 2002).

Figure 51. *Agonum fuliginosum*, a species that seems to depend on *Sphagnum* for moisture in exposed or disturbed forest sites. Photo by Trevor and Dilys Pendleton <www.eakingbirds.com>, with permission.

Figure 52. *Patrobis assimilis*, a species that requires mosses to survive in forests. Photo by Roy Anderson ©Roy Anderson <www.habitas.org.uk>, with permission.

Figure 53. *Picea mariana* forest in Northern Alberta, Canada, with *Pleurozium schreberi* and *Hylocomium splendens*. Photo by Richard Caners, with permission.

Species of beetles in old-growth forests (Figure 54) are especially affected by logging (Figure 55) (Niemelä 1997). Microhabitats such as coarse woody debris, large deciduous trees, and patches of wet swamp forest and mires may disappear or be greatly reduced. These disturbances tend to cause the old-growth specialists to disappear, including those of beetles. Instead, species richness may increase as generalists remain and numerous open-habitat species invade. This trend is especially true for the ground beetles, which include moss dwellers.

Figure 54. Old Growth in Cathedral Grove, British Columbia, Canada, showing moss-covered logs (dead wood) and low-light plants. Photo by Sang Trinh, through Creative Commons.

Figure 55. Clearcut forest patches at Lewis and Clark River, Oregon, USA. Photo by Walter Siegmund, through Creative Commons.

Niemelä *et al.* (1993b) concluded that retaining habitat diversification on a regional scale was the best management strategy for retaining diversity of ground-dwelling arthropods, including beetles. Hence, retaining moss corridors for those species like the flightless *Agonum mannerheimii* may be necessary to permit these species to disperse and to retain the original species richness in the stand (Hoyle & Gilbert 2004). On the other hand, Jonsson and Jonsell (1999) showed that the occurrences of bryophytes are not good predictors for the species richness of beetles. Djupström *et al.* (2010) found only a weak positive correlation between beetles and bryophytes in Swedish boreal forests, and none between beetles and lichens. Like Jonsson and Jonsell, they found that the tested taxa did not provide reliable surrogates. On the other hand, dead wood diversity (Figure 54) represented both **saproxyllic** (those that eat dead wood) beetles and bryophytes better than did random samples.

Effects of Beetles on Forest Bryophytes

Clear cutting (Figure 55) removes shade, changes the temperature, and eliminates many kinds of microhabitats. But bark beetles can also have an impact on the forest, removing cover and permitting the sun to raise the temperature. Nevertheless, a bark beetle outbreak in the Central European mountain spruce forests did not have the devastating effect on bryophytes that was experienced under clear cutting (Jonášová & Prach 2008). The latter causes a loss of forest floor bryophytes and the invasion of open habitat pioneers. The beetle outbreak left standing dead (Figure 56) that permitted the bryophytes to remain. Instead of promoting pioneer invasions, the beetle attack left the forest in a state that was more likely to avoid the pioneer stage and to promote a direct forest recovery, including the bryophytes.

Figure 56. Spruce bark beetle damage to the spruce forest in Rio Grande National Forest, USA. Standing dead spruce trees still provide shade, permitting bryophytes to survive. Photo from US Forest Service, through Public Domain.

Dunes

Following habitat restoration of dry dunes (Figure 57) on the Belgian coast, several dune-living ground beetles increased in population size (Maelfait *et al.* 2007). The researchers concluded that the rapid development of the ground vegetation, including both bare sand and moss patches, contributed to the rapid improvement of the insect fauna.

Figure 57. Sand dune in Belgium, where the invasive *Campylopus introflexus* is becoming a problem. Photo through Creative Commons.

Heathland

Beetles seem to prefer some mosses and to avoid others. In the *Empetrum* heathlands (Figure 58), beetles avoid the moss *Pleurozium schreberi* (Figure 59), but in the *Calluna* heath (Figure 60), with different bryophytes, the beetles were much more common (Barkman 1979, p. 138, in van Tooren 1990).

Figure 58. Dune heath with *Calluna* and *Empetrum*. In *Empetrum* heaths, beetles avoid the *Pleurozium schreberi*. In the *Calluna* heaths, beetles live among the different moss species there. Photo by Pat Doody, National Coastal Consultants, UK, with permission.

Figure 60. Heath with *Calluna vulgaris* (pink flowers) and *Ulex europaea* (yellow flowers), where bryophytes seem to be an important part of the habitat for beetles. Photo by Magnus Manske, through Creative Commons.

In a wet heathland in Scotland, the heather beetle *Lochmaea suturalis* (Chrysomelidae; Figure 61) is a herbivore on *Calluna* (Figure 62) (Scandrett & Gimingham 1991). The result of this herbivory is that cover decreases and the mosses *Sphagnum plumulosum* (Figure 63) and *Hypnum jutlandicum* (Figure 64) increase. The increases in these mosses is concurrent with the decline of *Sphagnum compactum* (Figure 65) and *Pleurozium schreberi* (Figure 59), thus improving the habitat for bryophyte-dwelling beetles. The *Calluna* regenerates mostly by layering, with only limited restoration through seedlings that germinate in the moist *Sphagnum*.

In the *Racomitrium lanuginosum* heaths (Figure 66), the Dotterel *Charadrius morinellus* (Figure 67) adults eat a large number of beetles (Galbraith *et al.* 1993). Both chicks and adults prefer habitats where both montane bogs and *Racomitrium lanuginosum* heaths are available to

meet the feeding requirements of both adults and chicks. Overgrazing by sheep has endangered these suitable habitats.

Bogs and Wetlands

Boháč and Bezděk (2004) found that in the Mrtvy Luh, Czech Republic, peat bog the species of **Staphylinidae** differed significantly between the bog margin and the center. Only 1 **tyrphophilous** (bog affiliate) species occurred in the marginal peat, whereas there were no **tyrphobionts** (species living only in bogs) or **tyrphophiles** (bog affiliates, breeding in bogs and elsewhere) in the center. Rather, the center of the bog was home to *Drusilla canaliculata* (Figure 68), a staphylinid that eats ants.

Figure 68. *Drusilla canaliculata* adult male, a bog dweller that eats ants. Photo by Christoph Benisch <www.kerbtier.de>, with permission.

Likewise, Bordoni (1972) found 179 species of Coleoptera, representing 25 families) in a Tuscan fen. Many were generalists and few were bryophilous. On the other hand, the Staphylinidae were the best represented and are moss feeders (Mani 1962). And *Cretinis punctatostrata* (Hydrophilidae) spends its entire life cycle in *Sphagnum*, making it a true **bryobiont** (Matthey 1977). Its eggs are deposited in the *Sphagnum* and its pupation cell is constructed from bryophytes. On the other hand, many of the **bryophilous** mosses do not feed on the mosses, but rather feed on the epiphytic algae (LeSage & Harper 1976).

Using yellow pan traps and emergence traps, Runtz and Peck (1994) found 5734 beetles, representing 30 families, in a mature spruce-*Sphagnum* bog (fen?) (Figure 69) in Algonquin Park, Ontario, Canada. Among these, members of the **Ptiliidae** were the most abundant and **Staphylinidae** was the most taxonomically diverse family. The **Carabidae** were also important, ranking second in diversity and third in abundance. But, as in many other studies, there are few beetle species specific to the bog. Most of the species in the bog are from adjacent habitats.

Figure 69. Boreal forest fen with spruce (*Picea mariana*) and *Sphagnum fuscum*, home for many **Ptiliidae** and **Staphylinidae**. Photo by Richard Caners, with permission.

Kvamme (1976) found similar relationships to these in mires at Eidskog, Norway. He trapped (pitfall) 18 species of **Carabidae** and 4 of **Curculionidae** in thirteen mire habitats there. Only *Agonum ericeti* (Figure 41) seemed to

be a true **tyrphobiont** (restricted to bog and mire habitats). Six species of **Carabidae** were **tyrphophiles** (typical in bogs and mires but not restricted to them). The greatest number of species occurred in the transition zone between the mire and the forest.

On the other hand, bogs are habitats where rare species occur. Wallin *et al.* (1999) found the rare carabid *Chlaenius costulatus* (Figure 37) in a protected bog in central Sweden. Wallin *et al.* (2000) likewise found the rare *Chlaenius sulcicollis* (Figure 38). *Chlaenius costulatus* overwinters in the bog; larvae (Figure 70) and newly emerged adult beetles appeared in pitfall traps, suggesting that they have surface activity during all developmental stages.

Figure 70. *Chlaenius* sp. larva, a rare bog dweller. Photo by Tom Murray, through Creative Commons.

Carabid beetles have specific requirements within the bog that determine their distribution. The development of that fauna is closely related to the presence of a mosaic of hummocks and hollows (Främbis 1994). On the Swedish Ryggmossen *Agonum ericeti* (Figure 41) and *Pterostichus rhaeticus* (Figure 42) use damp *Sphagnum* lawns (Figure 2) for summer activities but migrate to drier hummocks for overwintering, accounting for the need for the mosaic. The rare carabid *Chlaenius sulcicollis* (Figure 38) was discovered in Sweden in a bog dominated by large *Sphagnum* hummocks (Wallin *et al.* 1999, 2000). Severe mandible wear in this beetle could be caused by intensive biting and burrowing needed to navigate the *Sphagnum* hummocks.

Hydroporus morio (Figure 71) has a similar topography requirement (Jackson 1956). This member of the **Dytiscidae** lives in bog pools, but when the pools dry out in summer it bores small, round holes in the deep *Sphagnum*. There it **aestivates** (spends hot or dry period in prolonged state of torpor or dormancy) until the rain returns.

Figure 71. *Hydroporus morio* adult, a species that bores into *Sphagnum* when the bog pools dry out. Photo by Niels Sloth <www.biopix.dk>, with permission.

The genus *Sphaerius*, a member of the family **Sphaeriidae**, has members that live among mosses in bogs (Wikipedia 2015). The bog dwellers are able to store air under the **elytra** (hardened outer wings). *Sphaerius acaroides* is a minute scavenger beetle that occurs in moss and plant litter at the edge of slumping cliff seepages (Boyce 2002). Other scattered records exist from sites throughout England, including other wetland habitats such as fens.

It appears that some carrion beetles may be specific to peatlands (Beninger & Peck 1992). *Nicrophorus* carrion beetles (Coleoptera: Silphidae; Figure 72-Figure 73) utilize small mammal carcasses; some are able to spend their entire lives in the bog, using the bog carrion for reproduction, whereas others migrate to the nearby forest to reproduce (Beninger & Peck 1992). In the genus *Nicrophorus* (Coleoptera: Silphidae), the proportion of dead mice (*Mus musculus* – house mouse; Figure 74) utilized in the peatland as a resource did not differ from that of the nearby forest. *Nicrophorus* buries its carrion under mosses and leaf litter (Eggert & Müller 1997). However, *N. vespilloides* (Figure 72) reproduced exclusively in the *Sphagnum*, whereas *N. defodiens* (Figure 73) reproduced exclusively in the nearby mixed forest. Furthermore, three other species in the genus rarely occurred on bog carrion but were common on forest carrion. In other cases, it is the larvae of the beetles that live among the mosses (LeSage 1983).

Figure 74. *Mus musculus*, a mouse that provides small carrion for reproduction of some species of *Nicrophorus*. Photo by Ozwildlife, through Creative Commons.

Parthenogenesis (reproduction from an egg without fertilization) is common in bogs, and *Ptiliopycna moerens* is one such species in the beetle family **Ptiliidae** (Dybas 1978). These featherwing beetles live mostly in *Sphagnum* bogs and similar habitats in swamp forests in eastern North America. In addition, *Acrotrichis* (Figure 75), *Bythinopsis tychoides*, and *Ptinella mekura* are all small beetles in these bogs and all are parthenogenetic there.

Antarctica and Antarctic Islands

Beetles are one of the groups of organisms that are able to survive in the harsh conditions of the Antarctic (Figure 76). On this icy continent, the **Curculionidae** exhibit two feeding groups – those that feed on flowering plants and those that feed on cryptogams (algae, lichens, and bryophytes). These feeding constraints result in habitat constraints. For example, on Heard Island, *Ectemnorhinus viridis* lives from sea level to 600 m, where it feeds on tracheophytes and bryophytes (Chown & Klok 2001). *Candonopsis sericeus* likewise feeds on these two plant groups, but in a narrower altitudinal range. Further details of Antarctic feeding habits in this family are discussed in the sub-chapter on Coleoptera Families.

Home for Rare Species

Bryophytes can often hold surprises, species that have been considered rare or were previously unknown. Such was the case when a group of British entomologists were forced to abandon collecting due to very cold, wet weather on the Isle of Wight (Appleton 1986). In a last furtive effort to make the trip worthwhile, the entomologists grabbed handfuls of moss to sample at home. As they sieved through them, they found three individuals of *Baris analis* (Curculionidae; Figure 77), unknown for a century, from mosses that had grown on low cliffs. Shepard and Barr (1991) were able to describe the larva of *Atractelmis* (Elmidae; Figure 78) from a bryophyte habitat. In Sweden, several red-listed *Chlaenius* (Carabidae; Figure 38) species inhabited the mosses (Wallin *et al.* 2000).

Figure 77. *Baris analis* adults mating, a rare species known from mosses. Photo by Roger Key, with permission.

Some moss beetles have been even more elusive. Duckett *et al.* (2006) described *Ivalia korakundah* (Chrysomelidae) as a new species from the Doddabetta Valley, India, where it inhabits mosses. On rocks, adults of this species occur among the branches of the moss *Isopterygium* sp. (Figure 79). Both adults and larvae were found by sifting mosses from large pine tree trunks.

Figure 78. *Atractelmis* larva, a bryophyte inhabitant. Photo by Joseph Fortier, through Creative Commons

Figure 79. *Isopterygium elegans*, home for *Ivalia korakundah* on rocks. Photo by Kristian Peters, with permission.

In addition to rare species, new species are likely to be lurking among the mosses, and until more collecting is done in these habitats, these will seem rare. For example, Konstantinov and Duckett (2005) found a new member of Chrysomelidae – *Clavicornaltica dali* (Figure 80) – in Asia. Its type locality is in Yunnan, China, where it was found under a moss. This is a tiny, rounded beetle (1.13–1.24 mm) and the only known species of *Clavicornaltica* that has wingless males – a possible adaptation for moss-dwelling that can reserve more space and energy for developing the gut or other structure. In the same collection in China they found a new species of *Benedictus* together with *Clavicornaltica dali* (Konstantinov & Lourdes Chamorro-Lacayo 2006). No moss-inhabiting weevils were known from the New World until 2006 when these same researchers found the new genus *Kiskeya* (Chrysomelidae; Figure 81) and named two new species in the Dominican Republic.

Invasive Bryophytes

We know that *Curimopsis* (Byrrhidae; Figure 7) eats the invasive moss *Campylopus introflexus* (Figure 82) (Brian Eversham, pers. comm.). On the other hand, Schirmel *et al.* (2011) found that the invasion of *Campylopus introflexus* into acidic coastal dunes (grey dunes; Figure 83) at the southern Baltic Sea shore coincided with a reduction among plant-eating beetles in **Carabidae** compared to those in native dune habitat. They considered this reduction to be the result of reduced food supply of arthropod food items in areas with dense carpets of this invasive moss. This is concerning because the dunes are home to many endangered species of arthropods.

Figure 82. *Campylopus introflexus*, an invasive moss in Europe that is food for *Curimopsis*. Photo by Michael Becker, through Creative Commons.

Figure 83. *Campylopus introflexus* invading sand dunes. Photo from BIOSOS, permission pending.

Campylopus introflexus (Figure 82) forms dense carpets in these acidic coastal dunes, replacing native vegetation. Using pitfall traps, Schirmel and Buchholz (2013) compared trait composition of beetles and spiders. They found that this invasive moss caused body size and feeding preference of the **Carabidae** to shift. The species examined were smaller in the native habitats, perhaps because percentages of web-building spiders decreased in the sites of moss invasion. But the plant-eating beetles were reduced as well. Hence, the functional diversity of the **Carabidae** was likewise reduced. The functional diversity of spiders increased in the invaded dunes, but that of the carabid beetles decreased.

On South Georgia Island, introduced reindeer reduced the native grass vegetation of *Poa flabellata* (Christie 2010). This grass, home of *Hydromedion sparsatum* (Perimylopidae; Figure 84-Figure 87), was replaced by short grass *Poa annua*, moss carpets, bare soil, and other unsuitable substrata for *Hydromedion sparsatum*. As a result, this abundant beetle was reduced from more than 33% of the invertebrate fauna to 7-9%.

Summary

Beetles comprise the largest order of insects and live in almost every imaginable habitat. Their membranous wings are protected by the outer hardened **elytra**, but many of the bryophyte dwellers are flightless. The greatest numbers among bryophytes are **Curculionidae** and **Staphylinidae**, both very large families, but some, like the **Byrrhidae**, are moss specialists, living mostly in bryophytes and eating them.

The moss-dwelling beetles are typically tiny and rounded. Some are able to play dead (**Byrrhidae**) and can retract their legs into grooves on the lower surface. This family, and others, lay their eggs among the mosses. Some live in water as larvae and adults, but come to land to pupate among the mosses. Some migrate up and down in *Sphagnum* hummocks to adjust to changing moisture conditions or to overwinter.

Many beetles not only live among mosses, but also eat them. A wide range of mosses seem to be suitable for food, but some are refused. Few beetles, however, seem to eat liverworts. In geothermal areas, the mosses provide a moist and warm refuge in these polar climates.

In forests, bryophytes provide a more moist refuge following a disturbance that opens the canopy. In other cases, the beetles may attack the forest canopy, exposing the bryophytes and causing species changes. Many forest species are likely to be transported around the world as hitch-hikers among horticultural mosses.

In dunes, the invasion of the moss *Campylopus introflexus* is changing the kinds of species of beetles occurring there, reducing the beetle functional diversity. Different kinds of heathlands differ in kinds of bryophytes and their beetle fauna.

Bogs are often home to rare beetle species, and some are tiny, wingless, and parthenogenetic, hence poorly dispersed. Here, and elsewhere, sampling bias can miss these tiny, immobile beetles. Hand sorting is the only reliable, albeit time-consuming, method for finding all the species.

On one hand, bryophytes often harbor rare or unknown species. On the other hand, invasive bryophytes can cause reductions in the number of beetle species or their abundance due to replacing food plants.

Acknowledgments

I appreciate all the photographers who have given me permission or placed their images on the web with a Creative Commons license. As usual, Bryonettors have helped me find images when I was unable to find ones I needed. Thank you to Gerhard Winter for helping me find that tramling was meant to be trampling, getting an explanation from the second author, A. Bezděk.

CHAPTER 12-9b

TERRESTRIAL INSECTS:

HOLOMETABOLA – COLEOPTERA

FAMILIES

Figure 1. *Elaphrus* sp. on moss, a genus known to live on and among bryophytes. Photo by Bob Armstrong, with permission.

The **Coleoptera** are divided into the **Adephaga** and **Polyphaga**. This chapter has used this division and within the larger group **Polyphaga**, superfamily groupings are used. However, the order if these superfamilies and the families within them is alphabetical.

ADEPHAGA

Whereas five families of **Adephaga** are among the aquatic bryophyte-dwelling beetles, I know of only one family (**Carabidae**) with bryophyte dwellers among the terrestrial beetles. Nevertheless, there are a number of species among the terrestrial members of this family that live among bryophytes.

Carabidae – Ground Beetles

The **Carabidae** have many genera and species represented among bryophytes and were among the early reported bryophyte dwellers. For example, Westwood (1839) reported *Carabus coriaceus* (Figure 2) larvae living under mosses. Several species of *Carabus* have been

photographed on mosses, perhaps only traversing them or getting a bit of remoistening (Figure 3-Figure 5).

Figure 2. *Carabus coriaceus* adult, a species that seeks refuge among mosses. Photo by Rotatebot, through Creative Commons.

Figure 3. *Carabus cancellatus* adult on moss. Photo by Ladislav Tábi, with permission.

Figure 4. *Carabus glabratus* adult on moss. Photo by Ladislav Tábi, with permission.

Figure 5. *Carabus nemoralis* adult on moss. Photo by Ladislav Tábi, with permission.

Waterhouse (1871) reported *Bradycellus collaris* (Figure 6) from mosses. Later, Lindroth (1974) reported that *Bradycellus sharpi* (Figure 7) lives under leaves and mosses in shady places, usually near water. Luff (1998) noted that *Bradycellus csikii* (Figure 8) occurs on mosses and other substrata in Central Europe.

Figure 6. *Bradycellus collaris* adult on *Sphagnum*. Photo ©Roy Anderson <habitas.org.uk>, with permission.

Figure 7. *Bradycellus sharpi* adult with moss where it dwells near water. Photo ©Roy Anderson <habitas.org.uk>, with permission.

Figure 8. *Bradycellus csikii* adult, a moss dweller in Central Europe. Photo through Creative Commons.

In Japan, Bates (1883) reported *Leistus subaeneus* living under forest mosses at high elevations and *Leistus obtusicollis* occurs in mosses on the trunks of *Cryptomeria*. In Europe, *Leistus rufomarginatus* (Figure 9) and *L. ferrugineus* (Figure 10) occur among mosses (Lindroth 1974).

Figure 9. *Leistus rufomarginatus*, a moss dweller in Europe. Photo by Niels Sloth <www.biopix.com>, with permission.

Figure 10. *Leistus ferrugineus*, a moss dweller in Europe. Photo by František Šaržik, through Public Domain.

This family has 40,000 species worldwide and are among the 10 largest families of animals worldwide (Wikipedia 2015a). Common habitats are under the bark of trees, under logs, or among rocks or sand by the edge of ponds and rivers. Most species are active nocturnal carnivores. Some are able to run swiftly to catch prey, up to 9 km h⁻¹ (Friedlander 1998). They are larger than most moss-dwelling beetles and most don't seem to have any camouflage adaptations. Rather, these most likely visit the mosses to find food organisms and to replenish moisture.

Many members of the family overwinter under mosses (Anonymous 1879). This habit of overwintering under mosses serves for *Elaphrus fuliginosus* (Figure 11) and *E. clairvillei* (Figure 12) in low woodlands (Kilman 1889).

Figure 11. *Elaphrus fuliginosus*, a species that overwinters under mosses. Photo by Yves Bousquet, through Creative Commons.

Figure 12. *Elaphrus clairvillei* adult, a species that hibernates under mosses in winter. Photo by Gimenez de Cordoba, Beatriz through Creative Commons.

Unlike the many tiny beetles with limited distribution, many of these species are widespread. *Pterostichus diligens* (5-7 mm; Figure 13) is numerous among mosses, widespread (Eurasian Boreo-temperate), and common in wet heath, mire, and grass tussocks (Stenhouse 2007). *Pterostichus strenuus* (Figure 14) stays in shady places, especially damp deciduous forests on clayish soil, where it lives among mosses and leaf litter (Lindroth 1974). *Ocys harpaloides* (4-6 mm; Figure 15) is widespread among mosses in the UK (Stenhouse 2007) and along the European and African Atlantic coast (Anderson *et al.* 2000).

Figure 13. *Pterostichus diligens* adult, a species that is numerous among mosses in mires in the UK. Photo by Trevor and Dilys Pendleton <www.eakringbirds.com>, with permission.

Figure 14. *Pterostichus strenuus* adult, a species of shady places, especially damp deciduous forests on clayish soil, where it lives among mosses and leaf litter. Photo ©Roy Anderson <habitas.org.uk>, with permission.

Figure 15. *Ocys harpaloides* adult on moss, a widespread moss-dweller in the UK. Photo by Trevor and Dilys Pendleton <www.eakringbirds.com>, with permission.

One of the more comprehensive treatments of the **Carabidae** is that of Lindroth (1974). He cited many species that live among mosses in the British Isles. These include *Notiophilus germinyi* (Figure 16) among mosses in the open; *Blethisa multipunctata* (Figure 17) with mosses and *Carex*; *Elaphrus lapponicus* (Figure 18) on wet mosses near wells and streams and in bogs; *Asaphidion pallipes* (Figure 19) on fine, slightly moist sand with patches of "tiny moss;" *Miscodera arctica* (Figure 20) on fine, dry sand with fine mosses; *Platyderus depressus* (Figure 21) in open country among leaves and mosses; *Amara communis* (Figure 22) under mosses and dry leaves in a wide range of open habitats and forests with light shade; *Amara lunicollis* (Figure 23) in similar shade situations on peaty soil and under moss carpets of rocks; *Harpalus pimalicus* (see Figure 24) among mosses and leaves under bushes and trees on gravel moraines; *Badister unipustulatus* (Figure 25) among leaves and mosses on moist, shaded places, typically near pools; and *Syntomus obscuroguttatus* (Figure 26) in moist habitats on heavy soil among mosses.

Figure 16. *Notiophilus germinyi* adult on *Sphagnum*. Photo ©Roy Anderson <habitas.org.uk>, with permission.

Figure 25. *Badister unipustulatus* adult, a species that lives among leaves and mosses near pools. Photo by Gábor Keresztes (xespok.net), with permission.

Figure 26. *Syntomus obscuroguttatus* adult, a species that lives among mosses in moist habitats. Photo by Brian Eversham, with permission.

Such widespread species as *Notiophilus biguttatus* (Figure 27) will traverse mosses in some of their habitats as they travel across the terrain. They may find cover there from the sun, search for food, gain moisture, or even take a drink, but they do not necessarily live there.

Figure 27. *Notiophilus biguttatus* adult on moss. Photo by Ladislav Tábi, with permission.

Trechus rivularis (Figure 28) occurs among mosses in lowland fens and upland mires of northern and eastern Europe (Luff 1998). *Patrobus septentrionis* (Figure 29) lives near water as well, living among mosses in the UK, but at lower elevations in other parts of its circumpolar distribution. Its widespread distribution is most likely facilitated by its ability to fly.

Figure 28. *Trechus rivularis* adult, an inhabitant of lowland fen mosses and upland mires. Photo ©Roy Anderson <habitas.org.uk>, with permission.

Figure 29. *Patrobus septentrionis*, a species that lives among mosses near water. Photo ©Roy Anderson <habitas.org.uk>, with permission.

The genus *Agonum* has a number of bryophyte-dwelling species (Lindroth 1974), occurring in the Holarctic and Mediterranean regions to a southern limit in Central Asia (Wikipedia 2015b). These beetles are small to mid-sized and often have a metallic sheen. *Agonum obscurum* (Figure 30) lives among leaves and mosses in

damp deciduous forests and densely vegetated marshes (Lindroth 1974). The very **hygrophilous** (water-loving) *A. livens* (Figure 31) lives in marshy deciduous forests among leaves and *Sphagnum*. *Agonum versutum* (Figure 32) lives at the margin of fresh water where it keeps sufficiently moist among mounds of the sedge *Carex* and mosses. *Agonum fuliginosum* (Figure 51) lives among mosses and leaves in moist, shady places under bushes and forest trees. *Agonum gracile* (Figure 33) likewise lives in very damp, shady places such as quagmires with *Sphagnum* (Figure 35-Figure 36) and mossy lake shores. *Agonum sexpunctatum* (Figure 34) lives in wet peatlands in Europe (Wikipedia 2015c). It also occurs on moist, mossy ground near water where low, mossy vegetation occurs, including damp patches in otherwise sandy heathland in Europe (Luff 1998).

Figure 30. *Agonum obscurum* adult, a species typical of leaves and mosses in damp deciduous forests and densely vegetated marshes. Photo by Brian Eversham, with permission.

Figure 34. *Agonum sexpunctatum* adult on mosses, a species that seems to be tied to bryophytes in its habitat. Photo by Christoph Benisch <www.kerbtier.de>, with permission.

In comparing *Sphagnum* bog habitats (Figure 35) on several continents, Främbs (1994) considers the open *Sphagnum* mat to be an extreme habitat with only a few carabid species. Furthermore, the behavior of *Agonum ericeti* (Figure 36) and *Pterostichus rhaeticus* (Figure 37) indicates that the carabids may only use the damp *Sphagnum* lawn habitats in the summer, moving to drier hummocks (Figure 38) to overwinter. In fact, these two species of ground beetles are scarce in bog areas in which there is no clear pattern of hummocks and hollows to allow them to escape the water.

Figure 35. *Sphagnum* in Turbal in Valle de Andorra in the east Pyrenees. Photo through Creative Commons.

Figure 38. *Sphagnum papillosum* and *Sphagnum capillifolium* forming a hummock where Carabidae can spend the winter. Photo by Janice Glime.

The carabid species *Carabus menetriesi* (Carabidae) is associated with *Sphagnum* (Figure 35) in northern Europe and northern Russia (Barbara Knoflach-Thaler, pers. comm. 9 June 2011). It is an **FFH-species** (endangered all over Europe) and needs *Sphagnum* for overwintering; otherwise it would disappear. *Carabus arvensis* (Figure 39) hibernates under mosses as well as tree stumps (Lindroth 1985). *Carabus glabratus* (Figure 40), a widespread species of central and northern Europe, is day active and prefers damp areas such as peat hummocks (Figure 38) and other mosses (Weiss-Roessler 2015).

Figure 39. *Carabus arvensis*, a species that hibernates under mosses. Photo by Christoph Benisch <www.kerbtier.de>, with permission.

Figure 40. *Carabus glabratus* adult on moss, a species that prefers damp areas such as peat hummocks and other mosses. Photo by Stanislav Krejčík, through Creative Commons.

Carabus clathratus (23-24 mm; Figure 41), a widespread Palaearctic species, is day active and lives an amphibious life style, including under mosses (Obydov 2006), diving under water to search for food. Its larvae develop in the summer and it overwinters as an adult to breed in early to late summer (Wallin *et al.* 1999). This overwintering can be far from water where it hibernates on drier land.

Figure 41. *Carabus clathratus* adult on *Sphagnum*. Photo ©Roy Anderson <habitas.org.uk>, with permission.

In Finland, several species of **Carabidae** live in *Sphagnum* habitats (Figure 41) (Ljungberg 1999; Wallin *et al.* 1999). Among these is *Chlaenius costulatus* (striped velvet runner, hairy ground beetle; Figure 42; Figure 43). This species is a 13-14 mm predator. In other European mires, with mosses like *Drepanocladus* (Figure 44), one can find *Chlaenius sulcicollis* (swamp velvet runner; Figure 45). In Sweden, *Chlaenius sulcicollis*, a species of Europe and Asia north to the Arctic Circle, is a critically endangered species that lives among *Sphagnum* in bogs (Wallin *et al.* 2000). *Chlaenius nigricornis* (Figure 46) lives in sheets of mosses in damp places (Bates 1843). *Chlaenius nitidulus* (Figure 47) lives among grasses and mosses in silty and damp places along the coast (Lindroth 1974).

Figure 47. *Chlaenius nitidulus* adult, a coastal species that lives among grasses and mosses in silty and damp places. Photo by Gernot Kunz, with permission.

In other European mires with mosses like *Drepanocladus* (Figure 44), one can find *Panagaeus cruxmajor* (great cross runner; 8-10 mm; Figure 48). The Wikipedia author for this family recounted this from Charles Darwin (1846), regarding his attempted capture of *Panagaeus cruxmajor*:

"I must tell you what happened to me on the banks of the Cam in my early entomological days; under a piece of bark I found two carabi (I forget which) and caught one in each hand, when lo and behold I saw a sacred *Panagaeus crux major*; I could not bear to give up either of my carabi, and to lose *Panagaeus* was out of the question, so that in despair I gently seized one of the carabi between my teeth, when to my unspeakable disgust and pain the little inconsiderate beast squirted his acid down my throat and I lost both carabi and *Panagaeus*!"

In European mires with mosses like *Drepanocladus* (Figure 44), one can find *Agonum hypocrita* (lacquer runner; Figure 49). In Finnish boreal forests, *Sphagnum* (Figure 41) is a refuge for some carabids following cutting of the forests (Figure 50) (Koivula 2001). *Agonum fuliginosum* (Figure 51), *Amara brunnea* (Figure 52), *Carabus glabratus* (Figure 53), *Carabus hortensis* (Figure 54), *Cychrus caraboides* (Figure 55), and *Pterostichus niger* (Figure 56) were almost exclusively in the *Sphagnum* mires after cutting. On the other hand, *Calathus micropterus* (Figure 57) did not inhabit the mires and diminished in numbers after cutting, presumably due to

increased exposure. *Platynus mannerheimii* (Figure 58) likewise disappeared after clearcutting, but distribution of *Agonum fuliginosum* is not affected by canopy cover, permitting it to survive in the more open *Sphagnum* mires. Hence, the *Sphagnum* provides a refugium that can permit at least some of the **Carabidae** to re-inhabit the forest when it regrows.

It is unusual for any invertebrate to show host specificity among the bryophytes, although some bryophytes are certainly avoided by many bryophagous species. However, the carabid beetle *Acupalpus dubius* (Figure 59) seems to be restricted to the wetland moss *Drepanocladus aduncus* (Figure 44), at least in one study in the Czech Republic (Kopecký 2001). On the other hand, *A. brunnipes* (Figure 60) and *A. flavicollis* (Figure 61) seem to lack such specificity (Luff 1998). *Acupalpus brunnipes* occurs in both mosses and litter on mud near water in northern and western Europe, Greece, and North Africa. *Acupalpus flavicollis* sometimes occurs in bogs, but it is more common on river banks and in gravel pits in fine silt-covered sand where there is sparse vegetation and some mosses.

Cold temperatures seem to preclude most **Carabidae**. In the geothermal areas of Iceland, some of the geothermal areas are covered by the mosses *Archidium alternifolium* (Figure 62) and *Campylopus introflexus* (Figure 94) and the leafy liverwort *Gymnocolea inflata* (Figure 63) (Elmarsdottir *et al.* 2003). In some of these hotter areas, the carabids *Bembidion bipunctatum* (Figure 64) and *Nebria rufescens* (Figure 65) could survive, whereas they were not present in the colder, non-geothermal areas. Lindroth (1974) reported *Nebria brevicollis* (Figure 66)

among mosses in UK forests and Barry (2014) found it under moss in a flower bed.

Figure 66. *Nebria brevicollis* adult with moss, a species known to occur under mosses. Photo by Fritz Geller-Grimm, through Creative Commons.

Elsewhere, in the UK, *Bembidion gilvipes*, *B. biguttatum*, and *B. mannerheimii* live among mosses (Lindroth 1974). The first two of these live in forests. *Bembidion mannerheimii* lives in forests and fens. All three species also live among leaf litter and other substrata as well. Darwin even reported the genus from a nest of mosses (Smith & Freeman 1987).

The **Carabidae** are generalist feeders, suggesting they should be able to find food among any of the bryophytes, including fungi, bacteria, detritus, and various invertebrates (König *et al.* 2011). Thus far there seems to be no evidence that they eat the bryophytes.

POLYPHAGA

Artemotopoidea

Artematopidae – Soft-bodied Plant Beetles

Larvae and adults of beetles often live in different places. And if they are both in the same aquatic habitat, the pupae are typically on land. Even among the terrestrial bryophytes, the physiology and morphology differ sufficiently that many prefer different habitats. On the other hand, many are flightless, restricting their ability to move around.

Such habitat difference seems to be the case for members of *Macropogon*. Adults of *Macropogon testaceipennis* (Figure 67) and *M. piceus* (Figure 68) in western Washington and Oregon, USA, usually live on trees and shrubs near moss-covered boulders or rock outcrops (Loren Russell, pers. comm.). *Macropogon* larvae, on the other hand, can be found under mosses such as *Ceratodon purpureus* (Figure 69) and others growing on sandy loam of a stream bank in Viento State Park, Oregon.

Figure 67. *Macropogon testaceipennis* adult, a species that seems to prefer trees and shrubs with moss-covered rocks nearby. Photo by Joyce Gross, with permission.

Larvae of another member of this family, *Eurypogon* cf. *californicus* (Figure 70), occur under mosses growing on exposed rocks of road cuts at Mary's Peak, Oregon, and near the Alsea River (Loren Russell, pers. comm.).

Figure 70. *Eurypogon californicus*, species that lives under mosses on exposed rocks. Photo from Museum of Comparative Zoology, Harvard, through Creative Commons.

Byrrhoidea

Byrrhidae – Pill Beetles

The **Byrrhidae** are known for their habit of living among mosses. Not only do they live there, but the mosses serve as their food source in most cases (pers. comm. Loren Russell & Paul Johnson, 21 March 2012). A few actually feed on liverworts, and some on **tracheophytes** (lignified vascular plants, including flowering plants). In the Pacific Northwest, USA, the genus *Amphicyrta* (Figure 71) is the only member of the family known to feed on tracheophytes and no bryophytes, becoming a pest in lily fields. But generally, members of this family are adapted to living in transitional **ruderal** (wasteland) microhabitats where mosses dominate (Majka & Langor 2011), including such open habitat mosses as *Ceratodon purpureus* (Figure 69), *Polytrichum juniperinum* (Figure 72), and *P. piliferum* (Figure 73) growing on moist, thin or scarified soil (Johnson 2002).

Figure 71. *Amphicyrta* sp. adult, an unusual member of **Byrrhidae** not known to eat bryophytes. Photo by Joyce Gross, with permission.

Figure 72. *Polytrichum juniperinum* with males, common home for **Byrrhidae**. Photo by Dale Vitt, with permission.

Figure 73. *Polytrichum piliferum*, common home for **Byrrhidae**. Photo by Thomas Brown, through Creative Commons.

Several of the byrrhid characteristics suit them for the moss habitat. Their small size (1-10 mm) (Johnson 2002) and convex, compact shape, and retractile appendages (Johnson 2013) permit ease of movement among the moss maze and make them inconspicuous to most predators. When detected, they have the ability to play dead by retracting their legs and antennae into grooves on the lower surface (Figure 74-Figure 75), remaining motionless (Lindquist & Ingram 1968). This motionless behavior along with their shape has earned them the common name of pill beetles. Their ability to subsist on mosses suggests that they may have special digestive adaptations as well.

The **Byrrhidae** are common farther north and at higher altitudes than most of the insects. Majka and Langor (2011) suggest that this may be possible due to their ability to eat bryophytes. The bryophyte species diversity changes little with latitude (Shaw *et al.* 2005), whereas tracheophyte diversity diminishes. Furthermore, most bryophytes have longer growing seasons than most tracheophytes and are available immediately upon snow melt as a source of food. We know that bryophytes produce **arachidonic acid** (a fatty acid) (Shinmen *et al.* 1991; Kajikawa *et al.* 2008) and it would be interesting to explore whether the arachidonic acid in bryophytes may help to keep membranes of bryophyte consumers more fluid at cold temperatures. Furthermore, it may be helpful in promoting larval growth (Fraenkel & Blewett 1947), permitting these beetles to complete their life cycles in the short growing season of cold ecosystems.

Figure 74. *Byrrhus* sp playing dead in Scotland. Photo by Roger S. Key, with permission.

Figure 75. **Byrrhidae** feigning death. Note how the legs fit into grooves on the underside. Photo by Barbara Thaler-Knoflach, with permission.

Members of the **Byrrhidae** (*Cytilus sericeus*, *Byrrhus fasciatus*, *Byrrhus pilula*, *Byrrhus glabratus*) often travel some distances from the mosses where they sleep, preferring acrocarpous mosses to pleurocarpous ones (Pyszko *et al.* in prep). Their guts contain considerably higher moss species richness than that in their immediate microhabitats.

Although several authors have considered that the direct evidence for associations of Byrrhidae with mosses is still rare (Reichenbach 1844; Watt 1971; LeSage 1983; Johnson 1986; Hradilek & Boukal 2003), that family is better known among terrestrial bryophyte inhabitants than other groups. *Cytilus sericeus* has been reported from *Sphagnum* spp. (Mateleshko, 2009), *Tortula muralis* (Reichenbach 1844) and *Amblystegium varium* (Pristinskaya 2003). *Byrrhus fasciatus* is known from *Aulacomnium* spp. (Böcher 1988), *Andreaea* spp., *Brachythecium velutinum*, *Bryum* spp., *Myurella* spp. (Pristinskaya 2003), *Philonotis tomentella* (Lindroth 1931), and *Racomitrium* spp. (Janetschek 1949); *Byrrhus pilula* occurs with *Sphagnum* spp. and *Polytrichum* spp. (Pristinskaya 2003; Sushko 2007); and *Byrrhus glabratus* with *Plagiomnium cuspidatum* and *Rhizomnium punctatum* (Reichenbach 1844).

The slow or incomplete digestion of bryophytes permits identification from the guts of bryophagous insects (Haines & Renwick 2009; Kočárek *et al.* 2008).

Amphicyrta

This genus (Figure 71), restricted to California and Oregon, USA, is the exception among the **Byrrhidae**. Larvae and adults of this genus are not bryophyte feeders (Johnson 2013). Rather, they feed on succulent leaves and stems of forest and meadow herbs and on deciduous shrubs.

Byrrhus

Byrrhus (Figure 76) ranges from tiny to small (1-10 mm) (Johnson 2013). All the adults in this genus that feed on bryophytes are surface grazers. In addition to bryophytes they may occasionally feed on conifer seedlings, grasses, and clover in the moist areas that have abundant mosses. The larvae, on the other hand, burrow through the bryophyte layers and feed at the tunnel entrance by extending part of the body out to graze on bryophyte leaves and shoots.

Figure 76. *Byrrhus fasciatus* on moss in UK, showing underside with legs tucked into grooves while it plays dead. Photo by Roger S. Key, with permission.

Byrrhus luniger eats its own home. In Štramberk, a small town in the Moravian-Silesian Region of the Czech Republic, these beetles spend at least part of their lives among **Polytrichaceae**. Gut analysis reveals cells of these mosses in the gut (Hradílek & Boukal 2003). Papillae on the terminal lamina cells suggest that the mosses were either *Pogonatum urnigerum* (Figure 77) or *Polytrichastrum alpinum* (Figure 78).

In northwestern United States, Loren Russell and Paul Johnson (pers. comm. 21 March 2012) found different species of ***Byrrhus*** as moss dwellers: ***Byrrhus americanus*** (Figure 80), ***B. concolor*** (Figure 81), and ***Byrrhus kirbyi*** (~6.5 mm; Figure 82). Gut analysis of museum specimens of all three species revealed that mosses had served as food items. Not surprisingly, these beetles have seldom been collected, perhaps because the tiny creatures seldom venture out of their cozy cushions to fall into pitfall traps.

Figure 78. *Polytrichastrum alpinum*, likely food for *Byrrhus luniger*. Photo by David T. Holyoak, with permission.

Some records of this genus among mosses are old. Ferguson (1901) reported ***Byrrhus pilula*** (Figure 79) from mosses in the Clyde Area of the British Isles.

Figure 79. *Byrrhus pilula*, a moss dweller in the British Isles. Photo by Petr Kočárek and Pavel Drozd, with permission.

Chaetophora

Yes, *Chaetophora* is also a genus of green algae. Neither group of nomenclatural taxonomists has created a rule to prevent using the same name in another kingdom. The byrrhid *Chaetophora* is a native of Eurasia, but it is adventive in northeastern USA (McLeod 2006). It lives in areas with sparse vegetation, but with mosses.

Chaetophora spinosa (Figure 83) appears to be invasive in North America as a European immigrant (Johnson 1990). On Prince Edward Island, Canada, *Chaetophora spinosa* occurs on the moss *Mnium hornum*

(Figure 84) and the nearby bare mud. In Idaho, USA, adults can be found in large numbers with the mosses *Pohlia atropurpurea*, *Dicranella varia* (Figure 85), and *Aloina brevirostris* (Figure 86), but *A. brevirostris* has not been confirmed as a host for food (Johnson 1990). The beetles also consume the Cyanobacterium *Nostoc* (Figure 87) and it would be interesting to know if the occurrence of *Nostoc* on mosses might serve as an attractant and food source there.

Chalciosphaerium

This moss-dwelling genus (Figure 88-Figure 90) was not known from South Georgia until 2009 when Roger S.

Key (2009) found it with larvae (Figure 88) and pupae (Figure 89) that might be the same species. The species was later determined to be *Chalciosphaerium solox* (Figure 90), a species known from the Falklands (Roger S. Key, pers. comm. 4 December 2015). DNA confirmation is pending. If it is indeed that species, it is likely that it arrived with human traffic. Its apparent absence in other relatively nearby locations (indicated by searches for it) further support this interpretation. The location was a few hundred meters from the dis-embarkation site for many tourists and other visitors. Its small size would make it easy to be a hitchhiker on boots or other clothing or backpacks.

This species occurred with *Polytrichum* that was mixed with grasses (Roger S. Key, pers. comm. 4 December 2015). The researchers were unable to find it among nearby grasses that had no moss associates. More were, however, among other patches of the nearby mosses.

Curimopsis

Some of our photographers make great observations! Both my sister and I have been surprised on occasion to find an insect in our pictures when we enlarge them on the computer screen, but we never saw it when we were taking the picture. So I admire and envy these astute photographers who note the interesting behavior of these tiny inhabitants.

One such photographer is Brian Eversham. He shared with me his observations on *Curimopsis* (Figure 95-Figure 98) in Great Britain (Brian Eversham, pers. comm. 21 March 2012). He studied this genus for several years and found that it seems to prefer *Dicranella* [*D. heteromalla* (Figure 91) and *D. cerviculata* (Figure 92)] for shelter and food among the mosses in its habitat. It also eats *Pohlia nutans* (which is common there too; Figure 93) and even the invasive *Campylopus introflexus* (Figure 94).

Figure 91. *Dicranella heteromalla*, home and food for *Curimopsis*. Photo by Janice Glime.

In peat areas, the peat dries out in the summer in Thorne and Hatfield Moors, UK, due to the low rainfall (Brian Eversham, pers. comm. 21 March 2012). When this occurs, the females construct burrows down to 4 cm deep in the peat. These are usually close to the *Dicranella* (Figure 91-Figure 92) species. To build their burrows they collect moss leaves, one at a time, and like ants they carry them in their jaws. These are carried underground to line the burrows in a spiral arrangement around the walls. This "wallpaper" serves to feed the young larvae.

Johnson (1986) found *Curimopsis moosilauke* (Figure 95) to be a characteristic species above the **krummholz ecotone** (transition to stunted windblown trees growing near the tree line on mountains). These beetles often occurred between rocks and boulders where fine, moist, matted mosses grew on the sandy soils.

Figure 95. *Curimopsis moosilauke* adult, a moss associate above the krummholz. Photo by Kirill V. Makarov <www.zin.ru>, through public domain.

Curimopsis nigrita (mire pill beetle, bog-hog; Figure 96-Figure 97) is a tiny beetle only about 1.2 mm long. It burrows in peat and under mosses, lining these burrows with moss leaves (Roger S. Key, pers. comm. 31 October 2014). Perhaps this is the species seen by Brian Eversham, both in the UK.

Figure 96. *Curimopsis nigrita*, on Hatfield Moors, South Yorkshire. Photo by Brian Eversham, with permission.

Figure 97. *Curimopsis nigrita* (mire pill beetle), uncovered from its burrow under mosses. Note how well it blends with its surroundings. Photo by Roger S. Key, with permission.

On Mt. Hood, Oregon, USA, *Curimopsis albonotata* (Figure 98) lives at higher elevations (Loren Russell & Paul Johnson, pers. comm. 21 March 2012). Similarly, *C. brevicollis* lives at high elevations on Mt. Rainier, Washington, USA. The latter, collected in northern Idaho, had mosses in its gut. Both of these species seem to be limited to higher elevations.

Cytilus

In the Atlantic region of Canada, larvae of the boreal *Cytilus alternatus* (Figure 99-Figure 100) live in thick layers of *Sphagnum* (Figure 35) (LeSage 1983; Majka & Langor 2011). *Cytilus* species, unlike those of most **Byrrhidae**, do not burrow and instead feed at the surface as larvae (Johnson 2013). And unlike most of the **Byrrhidae**, members of *Cytilus* are active in open mossy areas in sunlight (Figure 103) (Johnson 2002). The guts of these larvae contain dead leaves, dead wood of Ericaceae (heaths), mosses, liverworts, and other vegetable matter, suggesting that this species is a detritivore. Both adults and larvae include mosses in their diet.

Figure 100. *Cytilus alternatus* eating moss. Note that the tip of the larger *Plagiomnium* at the right has been eaten. Photo by Alex Wild, free for educational use.

In the northwestern United States, *Cytilus alternatus* (Figure 99-Figure 100) is a widely distributed boreal insect of open rocky sites, often near seepages or waterfalls (Loren Russell & Paul Johnson, pers. comm. 21 March 2012). *Cytilus sericeus* (Figure 101-Figure 102) lives among the **Polytrichaceae** (Figure 103), where it feeds on mosses. These are in the typical open habitats known for this genus (Figure 50).

Epichorius

Epichorius hails from the other end of the Earth from Auckland Island, New Zealand (Wahedi *et al.* 1974). Here one can find larvae of *E. longulus* and *E. aucklandiae* among bryophytes in the coastal rata forest (Figure 104-Figure 105). *Epichorius longulus* larvae can be found among bryophytes on the ground, abundantly occupying species of the thallose liverwort *Riccardia* (Figure 106) and rarely in mats of the leafy liverwort *Bazzania adnexa* (Figure 107). This difference may be one of nutrition. Larvae that fed on *Riccardia* thalli gained more weight than those fed on the leafy liverwort *Bazzania adnexa*. The larvae were absent on bare ground and among tree roots. But the larvae were not immobile. They sought shelter under leaf litter during the day and appeared on the liverworts at night to feed.

Figure 107. *Bazzania adnexa*, home for *Epichorius longulus* larvae. Photo by Niels Klazenga, with permission.

Exomella

This genus is restricted to mesic coniferous forests in the Pacific Northwest, USA. *Exomella pleuralis* (Figure 108) inhabits *Racomitrium heterostichum* (Figure 109) (Johnson & Russell 1978). In the lab they both ate and oviposited on *Eurhynchium oreganum* (Figure 110).

Lioligus

Both *Lioligus nitidus* (Figure 111) and *L. striolatus* occur in mossy sites of the coastal mesic coniferous forests in the Pacific Northwest, USA (Loren Russell & Paul Johnson, pers. comm. 21 March 2012). *Lioligus striolatus* is more northern, living in northwest Washington, whereas *L. nitidus* is more common in western Oregon. Russell and Johnson suggest that they may be two forms of the same species. Laboratory experiments indicate that both have broad food choices in both larval and adult stages. In the lab, their foods included the mosses *Eurhynchium oregonum* (Figure 110), *Hylocomium splendens* (Figure 112), *Hypnum circinale* (Figure 113), *Plagiothecium undulatum* (Figure 114), *Racomitrium heterostichum* (Figure 109), *Rhytidiadelphus loreus* (Figure 115), and *R. triquetris* (Figure 116). The moss *Metaneckera menziesii* (Figure 117) was refused. In the lab, Russell and Johnson found that one specimen of *L. striolatus* survived from egg to adult with only leafy liverworts [*Diplophyllum plicatum* (Figure 118) and *Scapania bolanderi* (Figure 119)] to eat. However, this was an isolated success – other adult members of *Lioligus* would not feed on *Scapania* or other liverworts in cultures.

Lioon

Lioon puncticeps and *L. simplicipes* (Figure 120) are closely related species in the coastal coniferous forests of western USA (Loren Russell & Paul Johnson, pers. comm. 21 March 2012). Larvae and adults have a wide range of mossy habitats, ranging from wet, boggy soil to dry epiphytes. Like *Lioligus* (Figure 111), they accept a wide range of host mosses, including *Antitrichia curtipendula* (Figure 121), *Dicranum fuscescens* (Figure 122), *Eurhynchium oreganum* (Figure 110), *Plagiothecium*

undulatum (Figure 114), and *Rhytidiadelphus loreus* (Figure 115) for *L. puncticeps*. They also eat leaf tips and leaf lamellae of *Polytrichum commune* (Figure 123), but they leave the tougher parts such as the stems.

Figure 120. *Lioon simplicipes* adult, a species that lives among mosses in a wide range of habitats in western USA. Photo by Joyce Gross, with permission.

Listemus

Listemus is a small genus with three species in northwestern North America. These include *L. acuminatus* (Figure 124) and *L. formosus* (Russell 1979; Loren Russell & Paul Johnson, pers. comm. 21 March 2012). They are restricted to mesic coniferous forests of the Pacific Northwest, USA, but differ from *Lioligus* (Figure 111) and *Lioon* (Figure 120) in being restricted to mosses on soil, rocks, or logs and are not known from epiphytic bryophytes. In the lab both adults and larvae of *Listemus acuminatus* can survive on *Eurhynchium oregonum* (Figure 110), *Hypnum circinale* (Figure 113), and *Plagiothecium undulatum* (Figure 114). In the field one can find larvae of *L. acuminatus* in nearly pure mats of the leafy liverworts *Gyrothya underwoodiana* (Figure 125) and *Nardia scalaris* (Figure 126), but there is no evidence that these beetles feed on them. It is possible that they feed on the occasional mosses that grow with the liverworts.

Figure 124. *Listemus acuminatus* adult, a species among mosses on the ground, rocks, or logs. Photo by Joyce Gross, with permission.

Nothochaetes

Nothochaetes howensis (see Figure 127), a new genus and species, lives among mosses on trees in Australia (Lawrence *et al.* 2013).

Figure 127. *Nothochaetes fasciculatus* adult. *Nothochaetes howensis* lives among mosses on Australian trees. Photo by Lynne Forster, with permission.

Notolioon

Lawrence *et al.* (2013) described six new genera from the **Byrrhidae** in Australia (Figure 128-Figure 129) and made nomenclatural changes in how some of the existing species are classified. This study suggests that many more **Byrrhidae** might be found around the world if more bryophytes are searched.

Notolioon nodipennis (Figure 128-Figure 129), a member of the most water-loving of the Australian **Byrrhinae**, occurs in the wet forests of southeastern Australia and Tasmania (Lawrence *et al.* (2013). Both adults and larvae appear to be adapted to feeding on mosses and liverworts, based on their lack of digging legs in the adult and the occurrence in the larvae of a well-sclerotized dorsal cuticle that has defensive glands.

Figure 129. *Notolioon nodipennis* among mosses, demonstrating its ability to play dead by pulling its legs against its body. Photo by Kristi Ellingsen, Insects of Tasmania, with permission.

Simplocaria

In western Europe one can find *Simplocaria metallica* (Figure 130) in the lower part of the alpine zone. In this alpine area it lives among mosses in sandy places, often close to water courses or lakes, attesting to the importance of water in its habitat. It also occurs in the sub-alpine region, but it is rarely found in conifer forests (Böcher 1988). In Greenland, it is typically associated with the mosses *Polytrichum commune* (Figure 123) and *Aulacomnium* sp. (Figure 131), but also with the lichen *Peltigera* sp. (Figure 132) and the flowering plant *Cerastium alpinum* (Figure 133). Johnson (1990) found it with different mosses (*Bryum*?; Figure 134) on sandy gravel in boulder fields. These larvae, like those of *Byrrhus* (Figure 74, Figure 76-Figure 81), burrow into the moss mats (Böcher 1988).

Figure 134. *Bryum algovicum*, in a genus that can serve as host for *Simplocaria metallica*. Photo by David T. Holyoak, with permission.

Simplocaria semistriata (Figure 135) is a native of Europe, but it has become widespread in North America (McClarín 2006). It grazes on the pioneer moss *Dicranella heteromalla* (Figure 85) and in Scotland on *Mnium hornum* (Figure 84) (Johnson 1990). Like *Chaetophora spinosa* (Figure 83), *Simplocaria semistriata* appears to be an invasive species in North America (Johnson 1990). Here it feeds, mates, and oviposits on mats of *Dicranella heteromalla*. At the same time, both larvae and adults avoid feeding on intermixed *Atrichum angustatum* (Figure 136) in both the field and laboratory. Since *Mnium hornum* is abundant in North America, but in more moist sites than those of *D. heteromalla*, it is likely that *Simplocaria semistriata* will be found on that host in North America as well. Nate Schoonover (BugGuide 2015) reports that this species plays dead when disturbed. His 3 mm adults appeared in his terrarium among "cushion mosses" collected in Dover, New Hampshire, USA.

Chelonariidae – Turtle Beetles

This family, mostly tropical (Harpootlian 2006), was presumed to be aquatic, but Spangler (1980) discovered that it included a number of terrestrial larvae in *Chelonarium* (Figure 137). The adults are larger than most moss dwelling beetles (2.5-10 mm) and have the oval shape and somewhat flattened body typical of swimming beetles. But these lack gills and in the tropics they are associated with roots of a number of species of orchids and a few other epiphytes. Although the larvae have been reported from aquatic habitats, Brown (1972) suggested that these larvae might have been living on damp mosses near the streams and occasionally were washed into streams.

Figure 137. *Chelonarium lecontei* adult. Some members of this genus that have terrestrial larvae associated with mosses near water. Photo by Mike Quinn, through Creative Commons.

Limnichidae – Minute Marsh-loving Beetles

This is a relatively small family (~400 spp.), as beetles go, but it nevertheless has worldwide distribution (Harpootlian 2005). It is small (~2 mm) and rounded and, in the word of Harpootlian, otherwise "unremarkable" (Figure 138). This family is primarily riparian, living streamside, on emergent plants, on wood, or in windrows of debris. The larvae live in damp soil near water. Little is known about their food – they are presumed to be herbivorous.

Figure 138. *Eulimnichus* adult showing the nondescript appearance of the **Limnichidae**. Photo by Tom Murray, through Creative Commons.

Although little is known about the biology of the **Limnichidae**, some are known to feed on algae and mosses (Pütz 1998). Jim McClarin (pers. comm. 30 August 2014) finds **Limnichidae** with bryophytes in the cloud forest zone of eastern Ecuador.

Pütz (1998) reported on members of this family in China. There one can find *Cephalobyrrhus sichuanensis* on algae and mosses of sandy river banks. Champion (1925) earlier reported *Cephalobyrrhus gibbicollis* running over wet mosses on river banks in India.

Summary

The **Carabidae** are the only members of **Adephaga** I have found to associate with bryophytes. The **Carabidae** among bryophytes lack any special adaptations for that habitat. Some are there to feed, including fungi, bacteria, detritus, and various invertebrates. Bryophytes themselves do not seem to serve as a food source for them. Nevertheless, the diversity of **Carabidae** among bryophytes is large. Some use the mosses as a summer refuge where they can find moisture or a place to spend the winter. Some, often rare species, inhabit bogs. *Sphagnum* mires in forests serve as a refuge for carabid species following cutting.

Some members of **Artematopidae** live among bryophytes as larvae.

The **Byrrhidae** are well known as moss-dwelling beetles. They are typically tiny and rounded. Some are able to play dead when disturbed and can retract their legs into grooves on the lower surface. Most of them also eat bryophytes, including a wide range of species, and some are known to eat liverworts. Some burrow into *Sphagnum*. The ability of these beetles to survive at high altitudes and latitudes may be due to the **arachidonic acid** from their bryophyte diet. The family is ancient and worldwide. Because of the difficulty of sampling these tiny moss inhabitants, and their inability to disperse far, one is likely to encounter new species if venturing into an unexplored region. Other species are invasive as passengers with their moss habitat when it is used commercially.

Other moss-dwelling members of **Byrrhoidea** include some species in the **Chelonariidae** and **Limnichidae**.

Acknowledgments

Manju Nair was helpful in providing me with publications on moss beetles. Thank you to Jiří Váňa for providing me with a translation of the critical information in the paper by Hradílek and Boukal. Thank you also to John Steel and John Barkla for tracking down and providing me with a suitable image of the rata forest. I greatly appreciate the help of Roger S. Key for his information about *Chalciosphaerium* on South Georgia. Thank you to Roy Anderson and Tim Faasen for giving me blanket permission, allowing me to use many of their images in this chapter. And thank you to all the others who have given permission for images or placed them in Creative Commons where I could use them.

CHAPTER 12-9c

TERRESTRIAL INSECTS:

HOLOMETABOLA – COLEOPTERA

FAMILY

Figure 1. *Curculionidae* on moss and litter in Ecuador. Photo by Andreas Kay, through Creative Commons.

POLYPHAGA cont.

Chrysomeloidea

Chrysomelidae – Flea Beetles, Leaf Beetles

This family of 35,000 species ranges 1-18 mm in length (Wikipedia 2015c). They are distributed everywhere except the high Arctic and the Antarctic (Benisch 2015a). All the species have wings, although some are slightly shortened so that the tip of the abdomen is visible (Wikipedia 2015c). And most are serious agricultural pests. But some are moss dwellers.

Among the earliest records of the *Chrysomelidae* from mosses is *Plateumaris sericea* (*Donaciinae*; Figure 2). Beare (1899) found several of these in his collecting in Surrey, UK.

Figure 2. *Plateumaris sericea* mating, a species that lives among mosses in the UK. Photo by Hedwig Storch, through Creative Commons.

One of the most frequently reported bryobionts is *Mniophila muscorum* (Figure 3), the moss flea beetle (Champion 1871; Kühnelt 1976; Cox 1997; Konstantinov & Lourdes Chamorro-Lacayo 2006). Its name says it all – a moss-loving moss dweller. It is a true **bryobiont**, living among the "litter" and feeding on mosses (Kühnelt 1976). And it has the typical small size of a moss dweller (1.1-1.6 mm for the genus), is globose, and has reduced hind wings (Nadein 2009). A shiny black elytra is common among small moss-dwelling beetles and is likewise characteristic of these. These characters are shared by *Mniophilosoma*, *Apteropeda* (Figure 4), *Minota* (Figure 5), *Clavicornaltica* (Figure 6), and *Kiskeya* (Figure 40).

Figure 3. *Mniophila muscorum*, the common moss dweller known as the moss flea beetle. Photo by Udo Schmidt, with permission.

Figure 5. *Minota obesa*, a shiny black and minute moss dweller. Photo by Udo Schmidt, with permission.

Figure 6. *Clavicornaltica dali*, a common moss dweller. Image by Sasha Konstantinov, with permission.

Unlike many members of the family, *Mniophila muscorum* (Figure 3) is not a leaf miner (Cox 1997). Instead, both larvae and adults occur on mosses, the latter including *Rhytidiadelphus loreus* (Figure 7), *R. triquetrus* (Figure 8), and *Eurhynchium striatum* (Figure 9), all of which grow in a variety of habitats and on a variety of substrates (log stumps, fallen trees, tree branches, rocks, walls, and chalky slopes). They are also known from a number of other bryophyte species of both ground, boulders, and tree boles, including liverworts (Nadein 2009). Their substrate preference seems to depend on elevation. Those on vertical surfaces are usually restricted to thicker mats and cushions. And at least the first instar larvae are surface feeders on mosses. Nadein (2009) described the new species *Mniophila taurica*, *M. transcaucasica*, and *M. caucasica* from mosses in the Crimean Mountains. *Mniophila taurica* is known from the

mooses *Brachythecium glareosum* (Figure 10), *Homalothecium philippeanum* (Figure 11), and *Plagiomnium rostratum* (Figure 12). The genus *Mniophila* seems to prefer fresh mosses – not dry or sopping wet. The beetles may be on the surface or within the moss colony.

Figure 12. *Plagiomnium rostratum*, home to some *Mniophila taurica*. Photo by Michael Lüth, with permission.

Let's return to those look-alikes for *Mniophila* (Figure 3). Gillerfors (1986) described *Mniophilosoma obscurum* from *Sphagnum* (Figure 13) and other substrata in the Azores. *Mniophilosoma laeve* occurs among mosses and other substrata in Europe (Wollaston 1857). Despite the generic name, which translates to moss-loving body, this

genus often lives under bark. *Apteropeda orbiculata* (Figure 14-Figure 15) and *A. globosa* (Figure 4) both occur on mosses (Tomlin 1913). Tomlin also described *Phaedon tumidulus* (Figure 16-Figure 17), which occurs among mosses in Great Britain (Tomlin 1913). *Cassida viridis* (Figure 18-Figure 19) occasionally overwinters among mosses.

Figure 13. *Sphagnum russowii*, a potential home for many species of beetles. Photo by Andrew Hodgson, with permission.

Figure 14. *Apteropeda orbiculata* larva, a moss dweller. Photo by Willem Ellis, with permission.

Figure 16. *Phaedon tumidulus* larva, a resident among mosses at times. Photo by Keith Edkins, through Creative Commons.

Figure 17. *Phaedon tumidulus* adult, a sometimes moss resident. Photo by Keith Edkins, through Creative Commons.

Figure 18. *Cassida viridis* larva, a species that occasionally overwinters among mosses. Note the shed exuvia that the larva is carrying on its back. This is an unusual habit that may have a role in avoiding predation. Photo by James K. Lindsey, with permission.

Figure 19. *Cassida viridis* adult, a species that occasionally overwinters among mosses. Photo by Roger S. Key, with permission.

The adult of *Minota* (Figure 5) occurs among mosses or litter in northern Eurasia (Medvedev 1997). But *Minota nigropicea* feeds on the ferns *Dryopteris erythrosora* (Figure 20), *Pteridium aquilinum* (Figure 21), and *Cyrtomium fortunei* (Figure 22) (Kimoto 1984; Kato 1991). Thus, being tiny, globose, shiny black, and having reduced hind wings adapts these flea beetles for not only mosses, but also for life on ferns and under bark.

Figure 20. *Dryopteris erythrosora*, food for *Minota nigropicea*. Photo by Megan Hansen, through Creative Commons.

Figure 22. *Cyrtomium fortunei*, food for *Minota nigropicea*. Photo by Harum.Koh, through Creative Commons.

In a Cornish *Calluna* heath (Figure 23), Brown (1991) noted that the young larval stages of the heather beetle, *Lochmaea suturalis* (Figure 24), are dependent on the moisture of the moss layer. They are only found in older *Calluna* heaths, where *Pleurozium schreberi* (Figure 25) has had time to develop. When there is no moss layer present, these larvae have a density of about 0.4 per sample compared to 25 per sample when a moss layer is present. The mosses are essential to the larvae (Garvey 2011). Adults are destructive of the *Calluna*. This destruction initiates a complex series of events (Scandrett & Gimmingham 1991). The *Sphagnum plumulosum* (Figure 26) and *Hypnum jutlandicum* (Figure 27) increase, while *Sphagnum compactum* (Figure 28) and *Pleurozium schreberi* decrease. The *Calluna* is able to regenerate through layering, no doubt facilitated by the moisture-holding mosses, and by seedling development, especially in the *Sphagnum*.

Figure 23. Heathland, home of the heather beetle, *Lochmaea suturalis*, where the beetle larva lives among the moss *Pleurozium schreberi*. Photo by Willow, through Creative Commons.

Figure 24. *Lochmaea suturalis* adult, a species whose larvae require the moisture of moss mats. Photo by Niels Sloth <www.biopix.dk>, through Creative Commons.

Figure 25. *Pleurozium schreberi*, home for *Lochmaea suturalis* in heathlands. Photo by J. C. Schou <www.biopix.com/>, with permission.

Figure 26. *Sphagnum subnitens*, a species that increases when *Lochmaea suturalis* damages the *Calluna* and increases light penetration. Photo by Michael Lüth, with permission.

Figure 27. *Hypnum jutlandicum*, a species that increases when *Lochmaea suturalis* damages the *Calluna* and increases light penetration. Photo by Janice Glime.

Figure 28. *Sphagnum compactum*, a species that decreases when *Lochmaea suturalis* damages the *Calluna* and increases light penetration. Photo by Michael Lüth, with permission.

In the heathland, *Lochmaea suturalis* (Figure 24) oviposits at the base of the *Calluna* (Figure 23), usually among *Sphagnum* (Beagan 2015). The larvae crawl up the *Calluna* to eat the leaves, developing to as much as 2 cm in length. The mature larvae return to the mosses, where they spend 4 weeks to pupate. Then adults return to eat the *Calluna* leaves again, but once more return to ground level to spend the winter.

Recently, Sasha Konstantinov and associates have entered the picture, specializing in the tiny tribe of **Alticini**, among which are many previously ignored moss dwellers. The tiny size and time-consuming process of separating these beetles from their moss cushions seems to have discouraged most coleopterists. After all, this is the largest order of insects, and there were many much easier beetles to study.

The elusive *Phaelota* beetles living among mosses are typically small, with lengths about 2-3 mm, and are flightless (Prathapan & Konstantinov 2009). Among collections of six new species in the genus *Phaelota* from India, three were from mosses and a fourth moss dweller (*P. semifasciata*) was not new but was longer (up to 5 mm). The new moss-dwelling species include *Phaelota saluki* (Figure 29) from the moss *Forsstroemia thomsonii*, *P. maculipennis* (Figure 30), and *P. viridipennis* (Figure 31) from moss on tree trunks and rocks. The two groups of species are separated by their ability to fly – those living on ferns are capable of flight, but the moss-dwelling species are flightless. This flight restriction may be an adaptation to protect them from the windy mountain habitat (> 1470 m) where they reside in Southern India. In India they occur in the humid tropical evergreen forests of the Western Gats at 1000-2600 m asl (Konstantinov *et al.* 2013). *Phaelota kerzhneri* (Figure 32) from Borneo, like other flightless members of *Phaelota*, is probably also an inhabitant of moss (Prathapan & Konstantinov 2008).

Figure 32. *Phaelota kerzhneri* adult, a probable moss dweller from Borneo. Image by Sasha Konstantinov, with permission.

Both Indian species in the genus *Ivalia* are moss dwelling, but their selection of host plants is not related to a loss of flight – their flightlessness apparently evolved before their choice of mosses for food (Prathapan & Konstantinov 2009). Recently, Duckett *et al.* (2006) found both adults and larvae of the new species *Ivalia korakundah* (Figure 33) on mosses in southern India by sifting mosses from the trunks of large pine trees. *Ivalia korakundah* also feeds on mosses. In one case, adults were found on the moss *Isopterygium* sp. (Figure 34). This genus seems to prefer more humid environments of the tropical evergreen forests, especially at altitudes of 1000 to 2600 m asl in the Western Ghats (Konstantinov *et al.* (2013).

Figure 34. *Isopterygium elegans*, potential home, and probably food, for *Ivalia korakundah*. Photo by Robin Bovey, with permission from Dale Vitt.

In China, Konstantinov *et al.* (2013) described the new genus and species *Cangshanaltica nigra* (Figure 35-Figure 36) from the moss cushions of *Hypnum* (Figure 27). Unlike findings in most of the studies on such tiny beetles, Konstantinov and coworkers were able to find *Hypnum* in the guts of these beetles. These likewise are among the smallest leaf beetles; they have round bodies with robust appendages, reduced hind wings, highly simplified and shortened meso- and metathorax, and their antennae have "more or less" enlarged apical antennomeres.

Figure 35. *Cangshanaltica nigra* adult, a species that lives among *Hypnum* in China. Image courtesy of Sasha Konstantinov.

Figure 36. *Cangshanaltica nigra* habitat. Photo courtesy of Sasha Konstantinov.

Figure 37. *Hypnum cupressiforme*, a genus that provides homes for *Cangshanaltica nigra* in China. Photo by Michael Becker, through Creative Commons.

The members of *Cangshanaltica* (Figure 35) are small (0.8.-2 mm) and rounded (Konstantinov & Duckett 2005). The elytra covers the abdomen, but the bodies are fragile and easily broken. The genus is distinctive in having **clavate** antennae (thicker at apex, like a club).

The additions of moss-dwelling species continue. Damaška and Konstantinov (2016) added another species of *Cangshanaltica* *siamensis* (Figure 38) from Thailand. In this case, the beetles are able to survive the dry season in the moss cushions.

Figure 38. *Cangshanaltica siamensis*, a moss dweller from Thailand. Photo by Sasha Konstantinov, with permission

Konstantinov and Duckett (2005) found *Clavicornaltica dali* (Figure 39) at 3300 m in China under mosses. The tiny *Clavicornaltica* are distributed in Sri Lanka, Vietnam, and Thailand, despite their wingless males and mostly wingless females. This new species is among the first known for the genus in China and raises the question of dispersal mechanisms. Could they be distributed with the mosses they inhabit?

Figure 39. *Clavicornaltica dali*, an Asian species that lives under mosses. Image by Alexander Konstantinov, with permission.

Benedictus (Figure 53), a moss inhabitant in Asia, is not present (or hasn't been discovered) in the New World (Sprecher-Uebersax *et al.* 2009). In fact, it seems that the Eastern and Western Hemispheres have distinct genera.

As is common for the **Alticini** bryophyte dwellers, new species and even genera are lurking in these neglected habitats, and this seems especially true for the Western Hemisphere. Konstantinov and Lourdes Chamorro-Lacayo (2006) sieved moss samples in forests of the Dominican Republic and were able to describe the new genus ***Kiskeya*** (Figure 40), small, rounded beetles at 1.06-1.10 mm long, with two species, ***K. baorucae*** (Figure 40) and ***K. neibae***. ***Kiskeya baorucae*** was collected from mosses in forests where they were growing on rocks, dangling as pendent mosses, and growing on the boles of trees. ***Kiskeya neibae*** was collected in forests from mosses growing on rocks, tree stumps, boles, and branches (Figure 41). Using a Berlese funnel, the researchers also extracted ***Aedmon*** sp. (**Alticini**; Figure 42) from the mosses.

Figure 40. ***Kiskeya baorucae***, a species that lives on mosses in forests – on rocks, tree boles, and pendent mosses. Photo by Alexander Konstantinov, with permission.

Figure 41. ***Kiskeya neibae*** habitat. Photo courtesy of Sasha Konstantinov.

Figure 42. ***Aedmon ferruginea*** adult, a moss dweller in the Dominican Republic. Photo by Celeigher Piñango, through Creative Commons.

Again in 2011, Konstantinov and Konstantinova found a new genus (***Borinken***) and three new species of moss dwellers in Puerto Rico by sifting mosses. ***Borinken elyunque*** (Figure 43) is a tiny (1.08-1.18 mm) beetle from the forest, living in mosses on rocks, tree stumps, tree boles, and branches. ***Kiskeya elyunque*** (Figure 44), an even smaller species (0.81-0.92 mm), lives in similar habitats. By comparison, ***Ulrica eltoro*** (Figure 45) is much larger (1.94-2.16 mm) and likewise lives among mosses in similar locations, whereas ***Ulrica iviei*** (Figure 46), also a new species, is thus far known only from leaf litter.

Figure 43. ***Borinken elyunque***, a moss dweller in Puerto Rico. Photo courtesy of Sasha Konstantinov.

Figure 45. *Ulrica eltoro* adult, a moss dweller in Puerto Rico. Photo courtesy of Sasha Konstantinov.

Figure 46. *Ulrica iviei* adult, a litter species in the Dominican Republic. Photo by Sasha Konstantinov, with permission.

The moss-inhabiting *Kiskeya* (Figure 40, Figure 44) is known elsewhere in the Neotropics. There are three species in the West Indies, two in the Dominican Republic, and one in Puerto Rico (Konstantinov & Konstantinova 2011).

Konstantinov *et al.* (2013) described *Cangshanaltica nigra* from Yunnan Province in China.

Konstantinov *et al.* (2015) have recently added five new species of *Monotalla* in the West Indies. Of these, *Monotalla maierae* is a new species that occurs in mosses and litter and *M. viridis* is a new species from epiphytic mosses.

Figure 47. *Monotalla maierae* adult, a moss dweller in the West Indies. Photo by Sasha Konstantinov, with permission.

Figure 48. *Monotalla viridis* adult, a species from epiphytic mosses in the West Indies. Photo by Sasha Konstantinov, with permission.

As is clear by these examples, the Western Hemisphere moss inhabitants have remained almost unexplored. Konstantinov *et al.* (2009) found another new genus in Nicaragua. *Nicaltica selvanegra* (Figure 49), a species similar to *Kiskeya*, likewise lives among mosses there. In Bolivia, Konstantinov *et al.* (2014) discovered another new genus of moss and litter dwellers; *Stevenaltica normi* (Figure 50) and *S. erroris* (Figure 51) both include mosses as well as leaf litter as their habitats.

Distigmoptera borealis (Figure 52) eats mosses in North America (Konstantinov, pers. comm. 26 June 2016). And that's it! Other records for North America are lacking. This species is known from North Dakota (Fauske 2014) and Oklahoma (Palmer 2016).

Figure 52. *Distigmoptera borealis*, the only moss-dwelling genus known in North America. Photo from BIO Photography group, Biodiversity Institute of Ontario, through Creative Commons.

As of 2013, of the 14 known genera of moss-dwelling **Alticini**, only six were true **bryobionts** [*Kiskeya* (Figure 40), *Borinken* (Figure 43), *Cangshanaltica* (Figure 35), *Mniophila* (Figure 3), *Nicaltica* (Figure 49), and *Ulrica* (Figure 45)] (Konstantinov *et al.* 2013). The remaining eight are **bryophiles** [*Benedictus* (Figure 53), *Clavicornaltica* (Figure 39), *Ivalia* (Figure 33), *Monotalla* (Figure 47-Figure 48), *Minota* (Figure 5), *Paraminota* (Figure 54), *Paraminotella* (Figure 55), and *Phaelota* (Figure 29-Figure 32)]. By 2016, the number of known moss-inhabiting **Alticini** genera in the world grew to 15 and the number of species to 30 (Damaška & Konstantinov 2016).

There is good reason why so many new beetle species remain to be found among bryophytes. Many of these bryophyte dwellers are flightless. Furthermore, their moisture requirements are somewhat specific. Many are mountain-dwellers, living only above certain elevations. This combination makes it difficult for the beetles on one mountain to mix with those on another. When one or a few do disperse to a new mountain, both the **founder principle** (small population arrives in a new area and does not represent the genetic frequencies of its parent population) and **genetic drift** (random changes in gene frequencies that are common in small populations) are likely to play a role. As time passes, original and new populations diverge genetically, and over geologic time – or less – they can become separate species. When a single individual arrives in a new location, perhaps carrying fertilized eggs or for some beetles being **parthenogenetic** (reproducing from an unfertilized egg), this individual does not represent the middle of the curve of variation and produces offspring that are recognizably different from most of the individuals at the source. Do they pass the test of reproductive isolation? As long as they are separated by a valley, yes. Could they interbreed if they were joined? That remains to be tested.

Cucujoidea

Latridiidae – Minute Brown Scavenger Beetles

These small (0.8-3 mm) beetles number 1000 species (McClarin 2005). Most are associated with leaf litter, but around habitation they associate with other rotting vegetable matter. They are elongate with sculptured thorax and outer wings. Aside from their small size, they are not well adapted for bryophytes, although their coloration is usually dull and may be mottled. The sculpturing may also help to disguise them.

Some **Latridiidae** (Figure 58) take advantage of moss inhabitants for food. This family of beetles feeds on **Myxomycetes** (slime molds; Figure 56-Figure 57) (Dudka & Romanenko 2006), and these are often found among bryophytes. Decaying logs provide good habitats for slime molds and for mosses. And the slime molds often invade the space of the bryophytes. The mosses may also improve the habitat for the slime molds by increasing the moisture retention. Hence, the bryophytes on these logs provide protected sites where the **Latridiidae** can feed on the slime molds.

Dudka and Romanenko (2006) found 13 species of slime molds on 9 species of mosses and 3 of liverworts at the Crimean Nature Reserve. Most of these slime molds occur on non-bryophyte substrates as well, but some, like **Physarum cinereum** (Figure 56-Figure 57), occur predominantly on bryophyte substrates. Dudka and Romanenko (2006) found that **Enicmus** (Figure 58) and **Dienerella** (Figure 59) were the most common **Latridiidae** on moss-dwelling slime molds. The beetles not only use the slime molds for food, but also for oviposition and cover.

Curculionoidea

Atelabidae – Leaf-rolling Weevils

This family got its name because the female lays her eggs in leaves, then rolls the leaf around them. It is unlikely that these are regular moss dwellers. It is more likely that these are one of many of the beetles that traverse mosses simply because they are there. Although the mosses can provide moisture and a home for prey items, many species of beetles may arrive there without actually choosing to be in a mossy habitat. Such may be the case for the atelabid *Eugnamptus angustatus* (Figure 60), a 4.8 mm beetle Stephen Cresswell found walking on a moss in West Virginia, USA. Or it may have been searching there for food or replenishing body moisture. Behavioral studies on beetles associated with bryophytes are greatly needed.

Figure 60. *Eugnamptus angustatus* on moss – does it live there, or is it just visiting? Photo by Stephen Cresswell, with permission.

Curculionidae – Weevils

These are the cute little beetles with long "snouts" (Figure 61), somewhat resembling a miniature aardvark. A number of species have been discovered on bryophytes, eat them [Chown (1993) reported records of 35 species eating bryophytes], and some weevils even carry mosses around as camouflage.

Figure 61. *Cionus hortulanus* adult showing long snout with antennae on it. Photo by Lukas Jonaitis, through Creative Commons.

It seems that most beetles treat mosses as if they were litter, much like many soil biologists do. *Ceutorhynchus erysimi* (Figure 62), a species of Europe and invasive in the US, lives among mosses and forest litter around rhododendrons (in The Netherlands) (USDA 1950). *Cryptorhynchus lapathi* (Figure 63) lays its 1 mm long eggs mostly at stem bases, but also high in the crowns of large trees, under soil, or in the moss layer (Broberg 1997).

I have been finding the best records of bryophyte-dwelling insects among those of the UK, especially the old records. For example, Moncreaff (1871) reported *Baridius lepidii*, *Phytobius waltoni* (= *Pelonomus waltoni*; Figure 64), and *Litodactylus leucogaster* (= *Phytobius leucogaster*) from mosses in Portsea, British Isles. *Bagous laticollis* was abundant in mosses. Tomlin (1913) was able to find *Liosoma ovatum* among mosses in Glamorgan, Wales, year round.

Figure 64. *Phytobius waltoni* adult, a moss dweller in the British Isles. Photo by Stefan Schmidt, through Creative Commons.

Dyer and Nijholt (2016) reported finding adults of *Pseudohylesinus sericeus* (Figure 65) and *P. grandis* (Figure 66), both pests on conifers in the western part of North America (USDA 2016), hibernating in thick mosses that grew on the trunks of oak trees in Oregon, USA. But in British Columbia, *P. granulatus* (Figure 67) instead penetrated the mosses on the amabilis fir and once there bored into the bark.

Some beetles only use bryophytes in part of their life cycle. Larvae of the weevil *Palirhoeus eatoni* (syn. = *Mesembriorrhinus eatoni*) develop in tufts of algae (Doyen 1976). But when it is time for pupation, the larvae in Antarctic waters move above the high water line to pupate in clumps of the moss *Grimmia amblyophylla*. Mosses are often a safe haven for Antarctic arthropods in winter.

On the Austral Islands of the South Pacific, a number of new, hence **endemic**, species of *Miocalles* (Figure 68) were located by fogging mosses in the rata forest (Englund 2003). These included *M. albolineatus*, *M. akao*, *M. carinatus*, *M. hemata*, *M. cf irregularis*, *M. perau/maii*, *M. pusillus*, *M. setifer*, *M. cf silvestris*, *M. nr varians*, *M. nr sanctijohni*.

The weevils are among the unique fauna of the Antarctic region. The genus *Bothrometopus* has several members that live among rocks on Marion Island, including *B. randi*, *B. parvulus*, and *B. elongatus* (Van der Merwe *et al.* 1997). All three of these species occur on rock surfaces, in crevices, and within the rock-dwelling bryophytes. On Heard Island, *Bothrometopus brevis* and *B. gracilipes* both feed on cryptogams (Chown & Klok 2001).

Bryophagy and Evolution

Bryophagy is known in at least 35 species of **Curculionidae** from the sub-Antarctic (Kuschel 1964, 1971; Chown & Scholtz 1989a). Chown and Scholtz (1989a) suggest that a specialized moss herbivory, rare among **Curculionidae**, may have evolved in response to the adverse conditions during Pleistocene glaciations when bryophyte species were more likely to survive than their tracheophyte counterparts. Let's examine a few examples and then return to the evolution of this bryophyte-curculionid herbivory relationship.

Dichotrachelus stierlini (Figure 69) is a moss-eating weevil, known from 3350 m in the Alps (Thaler 1999). It is easily collected in alpine regions by sieving mosses (Barbara Thaler-Knoflach, pers. comm. 9 June 2011). As seen in Figure 69, this weevil has numerous protuberances that give it texture similar to that of a moss. A shiny weevil would be much more obvious among the mosses.

Figure 69. *Dichotrachelus stierlini*, a curculionid beetle (weevil). Note how this highly textured beetle would blend with the similarly highly textured bryophytes. Photo by Barbara Thaler-Knoflach, with permission.

Smith (1977) examined the consumption of *Ectemnorhinus similis* (formerly *Dusmoecetes similis*) adults on sub-Antarctic Marion Island. These weevils reached densities up to 220 m⁻², representing a biomass of about 1 g m⁻². Their diet included 14% of their body weight per day of *Acaena magellanica* (flowering plant in Rosaceae; Figure 70) and 37% per day of the moss

Brachythecium rutabulum (Figure 71). In fact, it appears that nearly all members of the tribe **Ectemnorhinini** are cryptogam feeders, especially on bryophytes (Chown & Scholtz 1989a). This is unusual in the **Curculionidae**, a family that predominantly feeds on tracheophytes.

Figure 70. *Acaena magellanica*, part of the diet of *Ectemnorhinus similis*. Photo by El Grafo, through Creative Commons.

Figure 71. *Brachythecium rutabulum*, home and food for *Ectemnorhinus similis*. Photo by J. C. Schou <www.biopix.com>, with permission.

Chown (1989) suggests that the near absence of flowering-plant feeders in the **Ectemnorhinini** is due to the previous climatic conditions, claiming that they would preclude flowering plant herbivory. What we know about the habitat use, diet, and species morphology supports this view (Table 1; see also Chown & Klok 2001). Using *Ectemnorhinus* (see Figure 72) in the sub-Antarctic as an example (Chown & Scholtz 1989b; Chown 1990), Chown and Scholtz showed feeding and morphological differences between the larger species, *E. similis*, that feeds on angiosperms [but also on bryophytes (Grobler *et al.* 2006)], as adults and detritus as larvae, and the smaller species, *E. marioni*, that feeds on bryophytes in all its life cycle stages. Both of these species are found on *Azorella selago* (see Figure 74), but *E. marioni* feeds exclusively on the epiphytic bryophytes, whereas *E. similis* only eats bryophytes when the quality of the tracheophytes deteriorates (Chown & Scholtz 1989b).

Table 1. Feeding strategies of the tribe **Ectemnorhinini** of **Curculionidae** from sub-Antarctic Marion and Prince Edward Islands. % of cryptogams (**crypt**) and bryophytes (**bryo**) represent the percentage of individuals examined that fed on each of these groups. Note that bryophytes are included in cryptogams. Data were gathered from field observations and gut analyses. The bryophyte associations are defined by Gerson (1982) with **bryobionts** occurring exclusively in association with bryophytes, **bryophiles** usually living on bryophytes but also occurring elsewhere, **bryoxenes** regularly spending part of their life cycle on bryophytes, and **occasionals** spending part of their time on bryophytes but not dependent on them. n = number in sample. Modified from Chown and Scholtz 1989a.

Species	Stage	n	food		bryo assn
			% crypt	% bryo	
<i>Palirhoeus eatoni</i>	larvae	17	100	6	bryoxene
	adults	40	100	0	occasional
<i>Bothrometopus randi</i>	larvae	38	100	16	bryoxene
	adults	46	100	2	occasional
<i>Antarctonesiotes elongatus</i>	larvae	28	100	18	bryoxene
	adults	62	100	7	occasional
<i>Mesembriorrhinus brevis</i>	larvae	50	100	61	bryophile
	adults	116	98	21	bryoxene
<i>Ectemnorhinus marioni</i>	larvae	67	97	97	bryobiont
	adults	1314	88	88	bryobiont
<i>Ectemnorhinus similis</i>	larvae	82	9	9	occasional
	adults	1037	38	38	bryoxene

Figure 73. *Ectemnorhinus vanhoeffianus*. Photo by Alex Pozyr, with permission.

In a later publication, Crafford and Chown (1991) cast doubt on the thesis that a colder climate would preclude these weevils from feeding on flowering plants due to energy constraints. Although five of the six species of weevils in the **Ectemnorhinini** on the sub-Antarctic Marion Island feed on cryptogams, temperature does not seem to be involved. They tested the consumption rate and approximate digestibility for the two native species of *Ectemnorhinus* (Figure 72) and found that the digestibility of the leafy liverwort *Blepharidophyllum densifolium* and dry mass differed little between 5°C and 10°C. Similar results were present for *E. similis* adults fed *Azorella selago* (see Figure 74). On the other hand, the performance ratios for *E. similis* feeding on *Azorella selago* was greater at 5°C than that for *E. marioni* feeding on bryophytes at either temperature. Crafford and Chown (1991) modified their interpretation to suggest that moss feeding more likely evolved in response to an absence of angiosperms during glacial periods, rather than because of a nutritional advantage associated with bryophagy at low temperatures. This is supported by studies on these beetles on islands. These feeding habits constrain species in their habitat distributions in the South Indian Ocean Province Islands where they seem to have been a result of climatic forcing (Chown 1994).

Figure 74. *Azorella compacta* from Tierra del Fuego, a flowering plant that resembles a moss. *Azorella selago* serves as food for *Ectemnorhinus similis* and *E. marioni*. Photo by Heretiq, through Creative Commons.

In *Agrostis* (Figure 75) mires the genus *Ectemnorhinus* (Figure 72) feeds exclusively on bryophytes, mostly the leafy liverwort *Blepharidophyllum densifolium*, even in the presence of the grass *Agrostis magellanica*. Chown (1990) considers the bryophytes to be a relatively poor food source, but they have the advantage of being available year-round. Another factor is that flowering plants have their highest nitrogen concentrations in the spring, whereas the bryophytes have their highest in autumn. Only the bryophytes have secondary compounds that serve as dietary inhibitors, resulting in the bryophyte feeders being smaller than the flowering-plant feeders. In fact, Chown suggests that the differences in feeding strategies lead to both size differences in the beetles and spatial separations between the two feeding groups. These differences keep the species groups from interbreeding.

Figure 75. *Agrostis*, a common genus in mires, but *Ectemnorhinus* species there feed mostly on leafy liverworts. Photo by Malcolm Storey <www.discoverlife.org>, through Creative Commons.

Bryophytes are well known for their insecticidal properties. Abay *et al.* (2012) demonstrated that extractions of the cosmopolitan moss *Hypnum cupressiforme* (Figure 76) had high levels of contact activity against the granary weevil *Sitophilus granarius*. This research was expanded to include the mosses *Dicranum scoparium* (Figure 77), *Polytrichastrum formosum* (Figure 78), *Homalothecium lutescens* (Figure 79), and the thallose liverwort *Conocephalum conicum* (Figure 80) (Abay *et al.* 2013). Using *Sitophilus granarius* in their bioassays, Abay and coworkers determined that hexane extracts of *Polytrichastrum formosum* exhibited the highest insecticidal activity (70.3%). Mortality was highest (53.34%) from the fatty acid **myristic acid**. **Palmitic acid** resulted in 17.75% mortality and **lauric acid** 4.32%. Abay and coworkers consider liverworts to be preferred foods nutritionally because of the presence of oil bodies (Kang *et al.* 2007; Abay *et al.* 2013). Yet there seem to be few reports of insects feeding on liverworts.

Wahedi *et al.* (2013) expanded on the research on the effects of bryophyte compounds with *Sitophilus zeamais*. They tested powders from *Calymperes afzelli* (Figure 81), *Thuidium gratum*, *Bryum coronatum* (Figure 82), and *Semibarbula lambarenensis*. All four species were effective in reducing oviposition and F_1 progeny emergence rate, prolongation of pre-adult duration, and having toxicity. The order of efficacy in toxic effects was *B. coronatum* > *T. gratum* > *C. afzelli* > *S. lambarenensis*, although the symptomatic effects were different among these. The bryophyte powders were so effective that the authors suggested using them as insecticides against the weevils in maize.

New compounds are constantly being discovered in the bryophytes (You *et al.* 2007; Jockovic *et al.* 2008). Many of these are phenolic acids, often unique with the bryophytes. Others are flavonoids or unique or scarce fatty acids. The research on the effects of these compounds on herbivory are limited, especially for mosses. And we don't know if any of these are inducible or if they are always present at similar levels. Likewise, we don't know how they are affected by seasons. Understanding these phenomena could help to explain some of the seasonal food choices of part-time bryophages.

Impacts on Ecosystems

The weevils can play important roles in *Sphagnum* (Figure 13, Figure 83, Figure 128) habitats. For example, warming trends have an interesting way of increasing spruce bark beetles in *Sphagnum* fens (Figure 84), ultimately resulting in more frequent fires. Beetles in the Kenai Peninsula of Alaska typically take two years to develop in their *Sphagnum* habitat, but during recent warming the fen increased in temperature (Berg 2008). These longer, warmer summers reduced the life cycle to one year and caused exponential growth in the spruce bark beetle. The beetles declined ultimately as a result of destruction of their food source. At the same time, the warmer summers dried the fens and reduced their role as firebreaks, causing invasion of woody shrubs and white spruce. Instead of being fire breaks, the spruce and woody shrubs became fuel bridges. A 400-600-year fire interval was reduced by the beetles to one of 50 years. The warming and beetle invasion makes the lowland areas more vulnerable to fire, whereas the upland areas are likely to change toward grasslands and hardwoods with lower fire potential.

Figure 83. Spruce, Denali National Park, showing an advancing front of bark beetle damage (right and distance). Photo from National Park Service, through public domain.

Figure 84. Spruce beetle damage, Denali National Forest, Alaska. Photo by Davyd Betchkal, NPS, through public domain.

Another example of the role of these beetles, albeit indirect, is the role of bark beetles following logging (Jonášová & Prach 2008). In the Central European mountain spruce forests (*Picea abies*; Figure 85), logging had a greater impact on the bryophyte cover than did forest damage by bark beetles. Rather, the mountain spruce forests will recover from a bark beetle outbreak without intervention.

Figure 85. *Picea abies* forest, trees that provide cover for bryophytes even when damaged by bark beetles, but not when logging occurs. Photo by Crusier, through Creative Commons.

Camouflage

What better way to look like a bryophyte than to grow them on your back! Weevils of the moss forests of New Guinea "cultivate" the mosses (Gressitt *et al.* 1965, 1968; Gerson & Seaward 1977) and one liverwort species (Gerson 1969) as camouflage. The large moss forest weevils may even have special secretions that encourage the growth of the mosses on their backs (Gressitt *et al.* 1965).

Gressitt *et al.* (1968) reported mosses growing on a *Gymnopholus* weevil (Figure 86). These moss garden weevils seem to be restricted to high moss forest ridges and moist summits of New Guinea. Two of the involved genera are endemic there. These garden transporters include not only *Gymnopholus*, but *Pantorhytes* (Figure 87) and some of the cryptorhynchine weevils. The weevils provide a favorable environment for the mosses and the mosses provide a protective cover and possibly a chemical predator deterrent for the weevils.

Figure 86. The moss *Daltonia angustifolia* living epizootically on the weevil *Gymnopholus reticulatus*. Photo courtesy of Rob Gradstein.

Figure 87. *Pantorhytes* adult with epizootic lichens. Photo by Alex Riedel, with permission.

The leaf-eating weevils *Gymnopholus* (Figure 86) and *Pantorhytes* (Figure 87) have pits in their carapaces and these pits are colonized by algae, lichens, liverworts, and mosses (Gressitt *et al.* 1965, 1968; Gressitt & Sedlacek 1967). Some weevil species (e.g. *Gymnopholus reticulatus*, Figure 86) seem to be moss specialists, especially the moss *Daltonia angustifolia* (Figure 86) (Gradstein *et al.* 1984), and others are lichen specialists. Tiny mites live among these epizootic mosses and may serve as moss dispersal agents to new hosts. The epizootic mosses take advantage of the soft substrate of the beetle. The small branches of montane rainforest trees seem to provide the sources for the mosses and the humidity keeps the garden growing. *Daltonia angustifolia* (see Figure 88) matures quickly, further supporting its suitability for its mobile, short-lived habitat.

Figure 88. *Daltonia* cf. *longifolia* from the Neotropics. Photo by Michael Lüth, with permission.

It appears that the weevils have gained sufficient benefit from their gardens that their evolution has preserved characters that encourage the camouflage growth. In addition to secretions mentioned earlier (Gressitt *et al.* 1965), the genus *Gymnopholus* (Figure 86) provides depressions and grooves on its outer wings, along with specialized scales and hairs (Gressitt 1966). The bryophytes grow on the fused **elytra**, but often also grow on the pronotum. *Symbiopholus* likewise is modified to encourage cryptogamic growth. It has depressions, pits, and grooves. The dorsal surface is rough and may have specially modified hairs or scales. It likewise has secretions that seem to encourage growth of its garden. It appears that the hairs and scales are modified in ways that encourage growth of the flora, and these are the locations where the bryophytes and lichens begin their growth (Gressitt & Sedlacek 1970). The species of *Gymnopholus* that do not have plant associations have normal, flat scales or have a smooth, hairless body surface.

The latest member of this family to be described with attached bryophytes is *Lithinus rufopenicillatus* (Figure 89) from Madagascar. Paul Bertner and his associates are studying this unusual weevil, so look for more information in the future.

Figure 89. *Lithinus rufopenicillatus* with liverworts and mosses in its "backpack." Photo by Paul Bertner, with permission.

But do these gardens help the beetles? Using a reduviid bug, Jackson and Pollard (2007) demonstrated that carrying natural objects such as moss bits or dead ants does indeed reduce predation on the camouflaged bugs. However, such experiments remain to be performed on the camouflaged weevils.

Travelling Ecosystems

Some of these elytral moss gardens are moving microecosystems. Aoki (1966) found an epizootic symbiosis in which the oribatid mite *Symbioribates papuensis* lived on lichens on the backs of weevils in Papua, New Guinea. Gressitt (1970) likewise found epizootic mites in the plant growth on three members of the weevil genus *Gymnopholus* (Figure 86), a genus that lives on leaves of woody plants in moss forests and on alpine shrubs (Gressitt 1966).

Not only were mites part of this travelling ecosystem, but also lichens, fungi, rotifers, nematodes, diatoms, and other microorganisms (Gressitt 1966; Gressitt & Sedlacek 1967). Psocopterans even feed on the plants growing on the weevils. One individual of *Gymnopholus acarifer* had 60 oribatid mites among the resident fungi. The absence of flight in *Gymnopholus* (Figure 86) has resulted in different species evolving on different ridges in New Guinea. This mountain-valley system of geographic separation has resulted in 47 such specialists recognized in *Gymnopholus* in New Guinea (Gressitt & Sedlacek 1967).

Of the 850 *Symbiopholus* specimens examined, 675 had plant growth on their backs (Gressitt 1966). These included the liverworts *Metzgeria* (Figure 90) and members of the epiphytic/epiphyllous family *Lejeuneaceae* (Figure 91). Mites, only 0.2 mm long, were abundant among the fungal growth on the *Symbiopholus*. The mites are able to spread to other weevils when the weevils mate, and the spores of the fungi may likewise spread that way as well as being carried on the bodies of the mites. The mites are absent from three of the weevil species that have hairy-sided, flat-bottomed pits.

Elateroidea

Lampyridae – Fireflies

This family was one of those nice surprises one can find while browsing the internet. I was searching for images on insects on mosses when I found one of eggs of the Japanese firefly on mosses. The eggs of *Luciola cruciata* (Figure 92) were nestled among the apical portions of mosses, and one video image shows a tiny larva crawling about. Another short video shows the emerging larva getting its first view of its larval moss home <<http://www.gettyimages.com/detail/video/closeup-shot-moment-of-firefly-hatch-stock-video-footage/505766040>>. But does the larva stay there and eat the mosses?

Figure 92. *Luciola cruciata* larva, a species that can lay eggs on mosses in Japan. Photo by Keisotyo, through Creative Commons.

This species flashes, using luciferase to activate the light (Tatsumi *et al.* 1989). The frequency of the light is dependent on temperature, with more frequent flashes at lower temperatures (Iguchi 2010).

Lycidae – Net-winged Beetles

The **Lycidae** are larger beetles, 10-15 mm long (Wikipedia 2015d). They are protected from predators by their toxicity. The larvae live under bark or in leaf litter and are predaceous.

This family is unusual in that the females are **neotenous**, whereas the males go through full metamorphosis of larvae, pupae, and adults (Masek & Bocak 2014). **Neotenous** refers to reaching sexual maturity at an immature morphological stage. In this case, the females are sexually mature as mature larvae and never change into pupae and adults.

Platerodrilus paradoxus (syn. = *Duliticola paradoxa*) (trilobite beetle; Figure 93) seems to be an exception to the carnivorous habit, but perhaps it is just hunting for prey. Nevertheless, the prey must be small.

Figure 93. *Platerodrilus paradoxus* (larval trilobite beetle) foraging on moss from Borneo. Note the tiny head protruding from the triangular prothorax at the bottom of the picture. Photo by Nick Garbutt, with permission.

Platerodrilus paradoxus (Figure 93) has only been observed in copulation twice, but that proves that mating does occur. Crew (2014) described the mating process of *Platerodrilus ruficollis* (syn. = *Platerodrilus hoiseni*), based on research by Wong (1998). One can only guess if it is similar in *P. paradoxus*. The female of *Platerodrilus ruficollis* arches her abdomen upward to expose her gonopore. The male, which is much smaller (about 10% the size of the female) climbs onto the female and attaches to the gonopore. About three hours after copulation is completed, the male drops dead. The female incubates the eggs for about three days, then places them among leaf litter. Then she too dies a few weeks later.

Bupestroidea

Bupestriidae – Jewel Beetles

Trachys troglodytes (Figure 94-Figure 95) is a species that likes high humidity. It is widespread and lives in damp, grassy places and *Sphagnum* bogs (Smith & Freeman 1987). As an adult, it hibernates among *Sphagnum*.

Figure 94. *Trachys troglodytes* larva, a species that occurs in *Sphagnum* bogs. Photo by Steve Wullaert, through Creative Commons.

Figure 95. *Trachys troglodytes* adult, a hibernator in *Sphagnum* bogs. Photo by Boris Loboda, through Creative Commons.

Hydrophiloidea

Helophoridae – Water Scavenger Beetles

This is a family of small insects (2-9 mm) with only one genus. They are mostly **Holarctic** (zoogeographical region comprising Nearctic and Palaearctic regions combined), but a few occur in the tropics. *Helophorus brevipalpis* (2-3.5 mm; Figure 96) is ubiquitous and common, often occurring far from water in mosses (Stenhouse 2007).

Figure 96. *Helophorus brevipalpis* adult, a member of an aquatic family, but it can live far from water among mosses. Photo by James K. Lindsey, with permission.

Some members of the genus are flightless, but *Helophorus brevipalpis* (Figure 96) always has functioning flight "apparatus" (Landin 1980). This flight ability permits this mostly aquatic species to travel great distances. It is interesting that it rarely has food in its gut when it is flying, suggesting that mosses may provide it with moisture but probably do not provide food.

Hydrophilidae – Water Scavenger Beetles

This family, widespread in Europe, is generally considered to be aquatic. Some of these beetles are amphibious, but require a very moist environment. For

example, *Chaetarthria simillima* (Figure 97) is a tiny water beetle, but it has been found among mosses growing beside a lake in the Outer Hebrides (Bratton 2012).

Figure 97. *Chaetarthria seminulum* adult, an aquatic beetle that can live among mosses near water on land. Photo from Naturalis, Biodiversity Centre, through Creative Commons.

Crenitis punctatostratus (Figure 98) is a true bryobiont. It spends its entire life among *Sphagnum* (Matthey 1977).

Figure 98. *Crenitis punctatostratus* adult, a *Sphagnum* dweller. Photo from SNSB, Zoologische Staatssammlung Muenchen, through Creative Commons.

Scaraboidea

Scarabaeidae

Darwin reported *Pinotus torulosa* from mosses (Smith & Freeman 1987). This name has apparently been superseded and I can't find its current name or any further information.

Staphylinoidea

Leiodidae – Round Fungus Beetles

This worldwide family (1.2-7 mm long) seems to have dropped off the radar in recent studies. However, Sharp (1865) found *Agathidium varians* (Figure 99) to be abundant among mosses in Great Britain. Most are fungal

feeders (Wikipedia 2015b), a food frequently available among mosses. Most of the members of this genus are known as slime mold beetles (Miller & Wheeler 2005) and their association with slime molds may explain the association of this species with mosses, often the substrate for slime molds.

Figure 99. *Agathidium varians* adult on moss, a once-abundant moss dweller in Great Britain. Photo by Tim Faasen, with permission.

Darwin reported several members of this family from mosses, including *Nargus anisotomoides* (Figure 100), *N. wilkini* (Figure 101), *Ptomaphagus medius* (Figure 102), and *Choleva angustata* (Figure 103), but none of these were bryobionts, having not only mosses but also dead leaves and other substrata among their choices (Smith & Freeman 1987).

Pselaphidae – Short-winged Mold Beetles

This is a worldwide family, but it reaches its greatest diversity in the tropics (Benisch 2015b). More than 9000 species are known. Most prefer moist habitats such as the edges of bogs and marshes, under bark of dead trees, and especially in leaf litter and rotten wood. Like the **Staphylinidae**, they have a short elytra, leaving most of the abdomen exposed (Figure 104-Figure 105).

Ferguson (1901) reported three genera in this family living among mosses in the Clyde area of the British Isles: *Bythinus* (Figure 104), *Bryaxis* (Figure 105), and *Pselaphus* (Figure 106).

Figure 106. *Pselaphus heisei* adult, a British moss dweller. Photo by Rudolf Macek, with permission.

Ptiliidae – Featherwing Beetles

Bogs provide another set of isolated habitats, and they seem to have more than their share of parthenogenetic females. For example, *Ptiliopycna moerens* is a minute (<1.0 mm) featherwing beetle in the northeastern USA and adjacent Canada (Dybas 1978). This moss dweller lives primarily in *Sphagnum* (Figure 84) bogs/poor fens and swamp forests. In most of its range, only females are known, thus making these populations parthenogenetic. Males are known only from the northern part of the range. Other parthenogenetic small beetles in bogs include species of *Pteryx* (Figure 107), *Acrotrichis* (Figure 108), and *Ptinella* (Figure 109) – all in Ptiliidae. Dybas surmised that the incidence of parthenogenesis in small beetles in relict bogs is unusually high. This is advantageous because it means they can remain in the safety of the mosses without having to venture farther and expend a lot of energy to find a mate, often unsuccessfully.

Staphylinidae – Rove Beetles

This is a family of 58,000 species and thousands of genera, a family even larger than the **Carabidae**. They don't look like most of the other beetles because their hard, outer wings do not cover the abdomen, leaving more than half the abdomen exposed (Figure 110-Figure 111). Their size range is large (<1-35 mm). Even on mosses, the range is large. Like the **Carabidae**, these beetles are elongate and seem to lack morphological adaptations to a bryophyte habitat. They live in every imaginable habitat, including submersion at high tide (Frank & Ahn 2011), and eat almost anything, depending on the species.

The earliest records of occurrences of the **Staphylinidae** among mosses seem to be those of Champion (1871) and Waterhouse (1871). Waterhouse reported *Anthophagus alpinus* (Figure 110) from mosses in Scotland. Champion reported *Syntomium aeneum* (Figure 111) and *Atheta tibialis* (Figure 113) from mosses and *Corticaria fuscula* (see Figure 112) in peat mosses. Klimaszewski *et al.* (2015) found *Atheta graminicola* (Figure 114) in Saskatchewan and Newfoundland, Canada, where mosses near water provided a home for some adults.

Early records from the UK show that *Gymnusa brevicollis* (Figure 115) was a moss inhabitant (Beare 1899). Widespread and common species *Atrecus affinis* (Figure 116), *Phloeocharis subtilissima* (Figure 117), and *Tachyporus obtusus* (Figure 118) occur in mosses in the UK (Stenhouse 2007). *Bythinus burrelli* (Figure 119) occurs in mosses on the ground and on tree stumps (Stenhouse 2007). Others that have been found in mosses at least once include *Aleochara funebris* (female), *Aleochara verna* (female; Figure 120), *Geostiba circellaris* (female; Figure 121), *Gyrophypnus fracticornis* (Figure 122), *Othius subuliformis* (Figure 123), *Oxypoda elongatula* (female; Figure 124), *Quedius nitipennis* (female; Figure 125), and *Stenus impressus* (Figure 126).

Figure 122. *Gyrohypnus fracticornis*, a species that is at least an occasional visitor to mosses. Photo by Trevor and Dilys Pendleton <eakringbirds.com>, with permission.

Figure 123. *Othius subuliformis*, a species that is at least an occasional visitor to mosses. Photo by Trevor and Dilys Pendleton <eakringbirds.com>, with permission.

Figure 126. *Stenus impressus*, a species that is at least an occasional visitor to mosses. Photo by Trevor and Dilys Pendleton <eakringbirds.com>, with permission.

Stenus (Figure 126-Figure 127), a moss visitor, has an unusual adult behavior. These species are predators on small invertebrates, including *Collembola* (Piper 2007). To catch their prey, they shoot out the **labium** using blood pressure. This narrow structure ends in a pad of bristles and hooks. Between the bristles are small pores that exude an adhesive that sticks to the prey.

Like some **Carabidae**, some of the **Staphylinidae** obtain their moisture from wet mosses. For example, *Stenus kiesenwetteri* (Figure 127) is a rare species living among very wet *Sphagnum* (Figure 128); *Dianous coerulescens* (Figure 129) lives where water trickles over mosses and liverworts (Butler 1886). And some are aquatic, as discussed in the **Coleoptera** subchapter on Aquatic Insect interactions.

Figure 127. *Stenus kiesenwetteri*, a species that uses terrestrial mosses to create an aquatic habitat (limnoterrestrial). Photo by Udo Schmidt, with permission.

Figure 129. *Dianous coerulescens* adult on leafy liverworts. This is a species that uses terrestrial bryophytes to create an aquatic habitat. Photo by Malcolm Storey, through Creative Commons.

In Great Britain, *Achenium humile* (Figure 130) is widespread. This species is predatory and lives in broad-leaved woodlands, fields, sand dunes, coastal marshes, and alluvial flats (Hyman & Parsons 1994). It takes advantage of habitats under bark on dead wood, under stones, among mosses, at roots of grasses, muddy dykes, and clay banks. *Bryophacis crassicornis* (Figure 131) is more restricted, living in dry mixed woodlands among leaves, moss, and rotting fungi, but also in heathlands among the *Calluna* litter (Lindgren & Palm 2011).

Figure 130. *Achenium humile* adult on mosses, a widespread species with a wide range of habitats, including mosses. Photo by Tim Faasen, with permission.

Figure 131. *Bryophacis crassicornis* adult male, a species that includes mosses among its homes. Photo by Christoph Benisch <kerbtier.de>, with permission.

Philonthus nigrita (Figure 132) lives in high and transitional moors. It is most common in the ecotone between water bodies and peat "bogs," living in the partly submerged *Sphagnum* layer (Figure 133) (Burakowski *et al.* 1980; Koch 1989; Staniec & Pietrykowska-Tudruj 2008).

Figure 132. *Philonthus nigrita* adult on *Sphagnum*. Photo by Christoph Benisch <kerbtier.de>, with permission.

Figure 133. Peatland in Alaska showing the wet *Sphagnum* that borders peatland pools, a potential habitat for *Philonthus nigrita*. Photo by Vita Plasek, with permission.

There is little information regarding the specific eating habits of the moss dwellers among the *Staphylinidae*, but Mani (1962) reported that some staphylinids are moss feeders in high alpine areas.

In Canada, *Trichiusa* (Figure 134) species live in forest leaf litter and mosses, especially at the edges of streams and pools (Klimaszewski *et al.* 2015).

Figure 134. *Trichiusa immigrata* adult, member of a genus that sometimes lives among mosses. Photo by Veli-Matti Mukkala, in Public Domain.

Scydmaenidae – Ant-like Stone Beetles

This worldwide family (Figure 135) lives in moist forests where they often take advantage of the moisture they can find among mosses (O'keefe 2001, 2005). They feed primarily on mites (Wikipedia 2015a), perhaps contributing to their presence on bryophytes, where mites are common. They are closely related to the *Staphylinidae* and Grebennikov and Newton (2009) have proposed their inclusion in that family.

Figure 135. *Microscydus nanus* (Scydmaenidae) adult among mosses. Photo by Tim Faasen, with permission.

The *Scydmaenidae* are frequently associated with ants. And they even resemble ants by having constrictions between the head and thorax and between the thorax and abdomen. O'Keefe (2000) reviewed all the published relationships between ants and these beetles. He suggested that they may occur in the same locations because of a common preferred food. If so, then we should expect some of these associations to be among mosses. Ants are common among a number of kinds of mossy locations, as will be seen in the chapter on *Hymenoptera*. It would be interesting to know just why there are so many members of this family associated with ants and what they gain from the relationship.

Tenebrionoidea

Perimylopidae (=Promecheilidae)

The Antarctic has beetle species that take advantage of the insulation and moisture available when living within the moss clumps. The *Perimylopidae* contribute some of these species. *Perimylops antarcticus* (Figure 136-Figure 137) seems to be well adapted by eating bryophytes (Worland *et al.* 1993) and has cold-adapted low-temperature respiration activation rates (Sømme *et al.* 1989). It lives among the moss *Polytrichastrum alpinum* (Figure 138) and lichens. Worland and coworkers tested **ice nucleation** in these insects – a process that causes ice crystals to form, expand, and ultimately damage cell membranes. They found that the gut freezes at 1°C lower than does the adult insect. The fecal material experiences ice nucleation at temperatures as high as -2°C and the insects themselves nucleate -3°C. The mosses nucleate at -4 to -5°C. They suggest that bacteria may be responsible for the nucleation proteins, since this food has a lower nucleation temperature than does the beetle.

Figure 137. *Perimylops antarcticus* adult on South Georgia, a species that eats mosses. Photo by Roger S. Key, with permission.

Figure 138. *Polytrichastrum alpinum*, home for *Perimylops antarcticus*. Photo by Michael Lüth, with permission.

Lagriidae – Long-jointed Beetles

The **Lagriidae** (Figure 139) are medium-sized (Benisch 2015c). They are worldwide, but are concentrated in the tropics. Typical habitats are trees, shrubs, and herbaceous plants, with larvae in decaying wood or leaf litter. Chown (1993) found that **Lagriidae** from the Afromontane forest in South Africa fed on both live and dead parts of the moss *Braunia secunda* (Figure 140), based on both field observations and gut analysis. This unknown species is the only record of bryophagy in the family.

Figure 139. *Lagria* from a West Java mountain rainforest; at least one member of this family eats mosses. Photo by gbohne, through Creative Commons.

Figure 140. *Braunia secunda*, food for an unidentified member of the **Lagriidae**. Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Nevertheless, *Adelium alpicola* (see Figure 141) larvae are known from damp forest moss in Australia (Watt 1974). But there is no evidence that they eat the mosses – or that they don't.

Figure 141. *Adelium pustulosum* adult; *Adelium alpicola* larvae occur among damp forest mosses in Australia. Photo by Tamara Leitch, through Creative Commons.

Tetatomidae – Polypore Fungus Beetles

The **Tetatomidae** is a small Palearctic and Nearctic family (~30 species) that is typically associated with fungi, especially wood-decay fungi and those on tree boles (Lawrence 1991; Pollock 2008, 2012). They are poorly known, both taxonomically and biologically.

Tetratoma fungorum (Figure 142) is not generally a moss dweller, as implied by its name. Nevertheless, it finds mosses to be suitable hiding places to survive the winter (Curtis 1823-1840).

Figure 142. *Tetratoma fungorum* adult with mosses, a species that overwinters under mosses. Photo by Tim Faasen, with permission.

Summary

There are probably more families of beetles among bryophytes than the ones represented here. Some of these are full-time bryophyte dwellers, some go to the bryophytes at specific times in the life cycle or for specific purposes, and others may simply traverse them while going from one point to another.

One of the largest families, **Staphylinidae**, has bryophyte dwellers among them. They range in size from tiny to large, even on mosses, and seem to have little specialization among the bryophyte dwellers. These include both casual visitors and those that spend part of their lives among mosses. Their lack of well-developed wings suggests they don't travel far. Some of these are bog dwellers. For many of them, mosses appear to be just more litter on the forest floor. The best and most common adaptations to living among bryophytes seems to be those of being small, roundish, smooth, and perhaps shiny and black, as seen in many of the **Chrysomelidae**.

There is some suggestion that bryophytes as food may provide a means to survive the cold, providing gut contents that have lower nucleation temperatures than the surrounding beetle.

Families like **Latridiidae** find suitable food among mosses, particularly slime molds.

The weevils (**Curculionidae**) are among the most abundant species among bryophytes. Their sizes vary; some seem to have camouflage. A few unique taxa have depressions in the elytra and bryophytes and lichens grow there, anchoring among hairs or spikes and being facilitated by a type of glue secreted by the beetle. A number of weevil species also eat bryophytes, sometimes on a seasonal basis when tracheophyte food becomes unavailable or unpalatable.

For those that eat bryophytes, suitable food includes a wide range of bryophyte species. Nevertheless, some bryophytes seem to be avoided. Liverworts may be eaten because of the rich food source in their oil bodies. Some beetles may take advantage of the fatty acids that remain fluid at low temperatures.

Sphagnum habitats often have rare species. They also provide places to survive forest disturbance or to survive the dry season (for those that can fly). Beetles can change the form of the habitat in ways that affect the mosses. In bogs, they can destroy the cover, causing the mosses to dry and more tolerant species to replace them. Bark beetles damage the spruce forests, but recovery of the forest, mosses, and moss-dwelling beetles is faster than it is from clear cutting.

Some terrestrial beetles in aquatic families use mosses as a limnoterrestrial habitat, maintaining their moisture because the moss remains damp.

Sunita Kapila suggested several internet images and provided examples of moss-carrying weevils. Rob Gradstein and Tamás Pócs provided me with needed images. Google and Wikipedia have been invaluable in helping me fill in information on families. Thank you to Scott Zona for alerting me to the publication of a picture of *Lithinus rufopenicillatus* as a species that carries bryophytes on its body. Paul Berner has provided me with the image of this species. Thank you to Richard Caner for pointing out my labelling error for the previous Figure 83.

CHAPTER 12-10

TERRESTRIAL INSECTS:

HOLOMETABOLA – HYMENOPTERA

Figure 1. Ant hill in Finland with leafy liverworts (*Barbilophozia hatcheri*, *B. floerkei*, *Tritomaria quinquedentata*, *Lophozia ventricosa*) and the moss *Pohlia nutans*. Photo by Des Callaghan, with permission.

HYMENOPTERA – Sawflies, Wasps, Bees, and Ants

Andrew *et al.* (2003) examined the variation in bryophyte fauna in Tasmania and New Zealand using different spatial scales along altitudinal gradients. Among these collections, they found six families of **Hymenoptera**. Although 77% of the faunal families were represented by 44 families, these 44 contributed only 10% of the total abundance.

This order is absent among bryophytes in the aquatic habitat, but in the terrestrial habitat, bees and ants find them useful in a variety of ways. As stated by Gerson (1969), some **Hymenoptera** feed on mosses. But others use them for nest materials, to house eggs, to provide water, and to provide cover. And of course some, including the sawflies, use them for pupation (Nägeli 1936).

Ants

Bryophytes, along with ants and grass, had a unique role for one Marine (Anonymous 1983). Trapped in a ravine in California for weeks, this marine subsisted on ants, moss, and grass! No wonder he lost 75 pounds before he found a way out!

The Phenomenal Ants

Ants are perhaps the most ordered insects on the planet. They work together to hunt and to build their trails and nests. In fact, they have been described as superorganisms because of their ability to work together as a unit (Oster & Wilson 1978). Ants are well endowed with defense, and depending on the species, they can bite, sting, or spray chemicals (Figure 2) such as formic acid (Wikipedia 2016). Their well-developed mandibles (Figure

3) serve for protection and prey capture. When an ant is killed, it emits a chemical that attracts ants from some distance, bringing an army to attack the intruder. Ants can also use chemical senses to identify dead colony members and remove them, and the workers are diligent in keeping the nest clean and free of bacteria. Their chemical signals, along with sounds and contact, permit them to communicate with each other. They also recognize their nest mates through the scent of hydrocarbon-laced secretions from their exoskeletons.

Figure 3. *Myrmica* sp. mandibles, a genus with a number of bryophyte dwellers. Photo from <fir0002/flagstaffotos.com.au>, through Creative Commons.

Ants are common among bryophytes, especially in bogs. Those that frequent the bryophytes don't seem to have any special adaptations, but this has not really been explored systematically. Their body constrictions give them considerable flexibility compared to most other insects, permitting even large species to maneuver among the bryophytes. The bryophytes provide a temperature-buffered environment where many food organisms can be found. They also provide a suitable underground habitat for growing fungi, cultivated by the ants, and kept moist by the bryophytes that reduce moisture loss at the soil surface.

Where Ants Are Absent

Acacia ants, on the other hand, may actually avoid mosses. In Costa Rica, Angela Newton (Bryonet, 20 November 2006) found that ants under ant-acacias left the bryophytes mostly undisturbed, except for some obvious nibbling around the edges. The green patches of moss in the otherwise clear ant-acacia circles were quite healthy and more numerous than in the surrounding forest. The mosses seemed to benefit from the ants' gardening activities, whereby the ants removed the larger plants that could pose a competition threat.

Food Source?

We generally think of the ants with their large jaws and sharp bite as carnivores. But Plitt (1907) found moss capsules that were gnawed and spores removed. A patch of "*Webera sessilis*" (probably *Diphyscium foliosum*, Figure 4) occurred immediately over an ant's nest. Both *Myrmica ruginodis* (Figure 39) and *Formica picea* (Figure 5) fed on the mosses and managed to gnaw a hole in nearly every capsule to obtain the spores. And beware – they were on the mosses in the collector's vasculum.

Figure 4. *Diphyscium foliosum* with capsules. Spores in these capsules serve as food for *Myrmica ruginodis* (Figure 39) and *Formica picea* (Figure 5). Photo by David T. Holyoak, with permission.

Figure 5. *Formica picea* on *Sphagnum*. This ant species feeds on the spores of *Diphyscium foliosum*. Photo by Barbara Thaler-Knoflach, with permission.

Loria and Herrnstadt (1980) found that in the Negev desert the harvester ant (*Messor*, Figure 6) ate capsules of *Aloina aloides* (Figure 7-Figure 8), *Crossidium crassinerve* (Figure 9), and *Bryum bicolor* (Figure 10) in winter when other food was not available. The ants climbed the seta of *C. crassinerve*, chewed off the capsules, and carried them to their nests, forming a parade 15 m long. An average of 30 capsules per minute arrived at the nest! Longton (1984) considered this behavior to be opportunistic because capsules are not available every year in the desert climate. It is possible that this behavior is advantageous for the mosses as well – the ants are likely to place the capsules in places more suitable for spore maturation in this environment where such sites are rare. However, Loria and Herrnstadt (1980) emphasized that mosses do not seem to derive any advantage from this harvesting process.

Bear feces are known to contain mosses, with one study reporting 50-90% mosses, primarily *Pleurozium schreberi* (Figure 30) (Dalen *et al.* 1996). But when the

feces contained 15% *Brachythecium reflexum* (Figure 11), Dalen and coworkers concluded that it was unlikely that the mosses were eaten by choice. Rather, they probably came along with its inhabiting food organisms – the ants.

Figure 11. *Brachythecium reflexum*, a moss where ants can dwell and the moss seems to be eaten by bears along with the ants. Photo by Michael Lüth, with permission.

The Green Salamander, *Aneides aeneus* (Figure 12), is a well-known moss-dwelling insectivore. At Cooper's Rock in West Virginia, USA, the gut consisted of 53% ants, but also included moss fragments (Lee & Norden 1973). It is likely that this is another case of a moss inhabitant getting mosses along with its intended prey. Gunzburger (1999) likewise concluded that mosses in the gut of the Red Hills Salamander *Phaeognathus hubrichti* (Figure 13) got there in the process of eating moss inhabitants, including ants.

Anthills

Anthills range in size from those tiny volcanoes in the cracks in the sidewalk to massive structures that rival termite mounds (Figure 1). And some are simple entrances to a series of underground tunnels. In British chalk grasslands, King (1977) found that anthills have shorter vegetation, more rabbit dung, drier soil, smaller structural aggregates, lower bulk density, and more temperature extremes than the surrounding pasture. Several of these factors also lead to less moisture.

Eiseman and Charney (2010) report mosses on the abandoned anthill mounds of *Formica exsectoides* (Figure 14). Des Callaghan (Bryonet 3 August 2014) recently visited Finland and photographed a giant ant nest. The ants had cleared the nest of its tracheophytes, but, as he put it, they appear to have a fondness of leafy liverworts. Several species of liverworts [*Barbilophozia hatcheri* (Figure 15), *B. floerkei* (Figure 16), *Tritomaria quinquedentata* (Figure 17), *Lophozia ventricosa* (Figure 18)] cover one of the mounds. In addition the mound served as substrate for the ubiquitous *Pohlia nutans* (Figure 19).

Pekka Punttila (pers. comm.) explained the mound nests of the two species that may be inhabiting the mounds photographed by Des Callaghan (Figure 1). *Formica lugubris* (Figure 20) is **monogynous** (has only one queen in a mound). The longevity of this queen and her colony lasts typically only about 20 years. This loss opens the mound to invasion by other species or simply to die off if something happens to the queen. *Formica aquilonia* (Figure 21-Figure 23), on the other hand, is **polygynous**, meaning it has more than one queen in a mound. That strategy permits the species to maintain its nest for a long time. Furthermore, if many mounds are present, it is likely to be that of *F. aquilonia*, a **polydomous** species. These mounds may reach dozens or even hundreds in an area. *Formica lugubris* typically builds single mounds.

Figure 23. *Formica aquilonia*, attacking its prey. Photo by Brian Eversham, with permission.

The monogynous species such as *Formica lugubris* (Figure 20) are able to disperse during their nuptial flight, temporarily parasitize other nests, and establish in young forests or older forest fragments (Punttila 1996). The polygynous species, including *F. aquilonia* (Figure 21-Figure 23), disperse primarily by "nest budding," permitting them to form large colonies of cooperative nests. These are found in older forests and larger old forest fragments.

Anthills create microhabitats of their own. This is evidenced by the moss *Pseudoscleropodium purum* (Figure 24). This species predominates on the north-facing sides of anthills constructed by *Lasius flavus* (Figure 25-Figure 26) (King 2003). King experimented with survivorship of the moss by rotating the anthills either 360° or 180°. Hence, half the anthills were now facing south. For those mosses facing south, over half the shoots turned white at the tips and up to 20 mm from the apex. Those rotated 360°, thus still facing north, remained green and healthy. Nevertheless, most of the mosses on the south side survived. Those on the north side grew faster and King concluded that it may be more difficult for the fragments to establish on the south side due to the longer periods that were dry and unfavorable for growth. Carl

Farmer found anthills of this species in Scotland completely covered by mosses while the ants thrived inside.

In acidic grasslands, bryophytes may be confined to anthills. King (1981) found that the acrocarpous mosses *Dicranum scoparium* (Figure 27), *Polytrichum juniperinum* (Figure 28), and *Polytrichum piliferum* (Figure 29), all colonizers, were almost confined to the anthills in the Gower Peninsula of South Wales. King considered dispersal ability and ability to withstand burial to be primary factors to favor these mosses over surrounding tracheophyte plants, downplaying the importance of soil chemical and physical factors. *Lasius flavus* (Figure 25-Figure 26) builds mounds that are 15-20 cm high and 50-70 cm in diameter. In these acidic habitats, King found that *Pleurozium schreberi* (Figure 30), like *Pseudoscleropodium purum*, is abundant on the north-facing sides of the mounds. On the other hand, *Polytrichum juniperinum* and *Polytrichum piliferum* are more frequent at the summit of the mound than at the periphery, but *P. piliferum* is more frequently on the south side, a location consistent with its habitation of more exposed, xeric habitats. *Polytrichum juniperinum* has its base 15 cm below the soil, suggesting that it grew up through the anthill as the anthill increased in size.

Figure 30. *Pleurozium schreberi*, a moss that grows on north-facing slopes of anthills made by *Lasius flavus*. Photo by Michael Lüth, with permission.

Des Callaghan (Bryonet 10 May 2017) has seen *Buxbaumia viridis* (Figure 31) living on the ant hills of the wood ant, *Formica rufa* (Figure 53-Figure 55). Many Bryonettors have reported what appears to be herbivory on this species of *Buxbaumia*, but thus far there is no direct evidence that these are consumed by ants.

Figure 31. *Buxbaumia viridis* capsules, a species that can inhabit wood ant (*Formica rufa*) nests. Photo by Hermann Schachner, through Creative Commons.

For mosses in deciduous forests, anthills provide a substrate that rises above the forest floor. This permits the leaf litter to fall downward, keeping the anthill exposed and preventing burial of the bryophytes by leaf litter.

Ants as Gardeners

In several tropical areas, ants make ant gardens (Ule 1901; Blüthgen *et al.* 2001). These aerial gardens usually consist of plants, started as seeds by the ants, and used as a matrix in which soil is placed to construct a nest. But Ule reported only flowering plants in these ant gardens. In 1985, Frahm reported risk of life to collect a nest 15 cm in diameter with a yellow-green center surely of moss. The escapade began when he and Rob Gradstein chopped down the tree holding the nest, using machetes. But alas, the tree fell, only to land within the arms of another tree, with the nest still out of reach. Again, the second tree was cut in like manner, but it fell 10 meters deep into the river, thus drowning the ants in their nest! Not to be discouraged from their quest, the two bryologists then had to cross the river, as the tree was accessible only down a steep and rocky slope and to the other side of the valley. Attempts to raise the nest to the bridge with a rope destroyed most of it, but they were able to rescue the moss, determined as *Brachymenium columbicum* (Figure 32), a moss known also from Colombia and Ecuador, and now, for the first time, from Peru.

Figure 32. Ant garden, primarily of *Brachymenium columbicum* (and seedlings), from a tree in Peru. Photo by Jan-Peter Frahm, with permission.

Blüthgen *et al.* (2001) suggested the importance of these aerial ant gardens. Nutrients are scarce in the canopy. Some plants are adapted by producing **adventitious** roots (roots that arise from stems and other non-root axis points) that are able to grow and penetrate animal debris, bromeliad tanks, bryophytes, and plant cavities. But some lack the ability to take advantage of these nutrient sources. Among these some are able to form commensalistic associations. The association between ants and epiphytes is one such association. The ants carry seeds that they imbed in the garden. The ants then care for the garden by protecting it and providing a stable germination and establishment state. As noted by Frahm (1985), some of these gardens, as already noted, have bryophytes that can further help by maintaining moisture and trapping airborne dust and nutrients.

The leafy liverwort *Nardia* sp. (Figure 33) is a pioneer on volcanic ash, forming layered deposits up to 15 cm thick (Jongmans *et al.* 2001). These growths are able to adhere to vertical cliffs and to form bridges between volcanic boulders, facilitating the establishment of vascular plants.

These carpets sometimes are invaded by ants and other insects that help to keep the liverworts clean and bring seeds and spores to continue the garden. In Costa Rica ants took up residence among the fronds of the hanging garden liverwort *Nardia succulenta* on the ash of volcano Arenal (Jongmans *et al.* 2001).

Figure 33. *Nardia scalaris*. *Nardia* is a genus that forms bridges between volcanic boulders and is maintained by ants. Photo by Hermann Schachner, through Creative Commons.

Gibson (1993a, b) found that ants placed seeds of the cow wheat (*Melampyrum lineare*, Figure 34-Figure 36) more frequently under *Polytrichum* (Figure 28-Figure 29) than expected by chance, based on its relative cover (Figure 37). In the oak-pine forest of the New Jersey Pinelands, Gibson and Good (1987) found that the seeds of *Melampyrum lineare* were restricted to mossy patches. Ants gather these seeds and store them, later using the oily and nutrient-rich eliasome (Figure 36) as a food source without damaging the seed to which it is attached (Gibson 1993a, b). Litter and lichens were also used, but *Polytrichum* seemed to be highly selected. *Dicranum* (Figure 27) and *Pleurozium* (Figure 30), although more abundant than the *Polytrichum*, attracted far fewer ants to store seeds. This behavior afforded the seeds a safe place where mice did not eat them and they retained sufficient moisture to survive. These seeds have low survival if they dry out and will die if they fall to the soil and remain exposed. If they remain in the capsules until evening, the mice will eat them.

Forest Ants

I have found little literature on forest floor bryophytes and their ant inhabitants. Ward (2000) reviewed some of these from leaf litter communities. Wilson and Hölldobler (2005) included bryophytes among the sites offering the desirable small spaces to ponerine ants on the forest floor. While these species are relatively abundant in the tropical and warm-temperate forests, they are scarce in the cool-temperate forests, deserts, and arid grasslands.

Myrmica rubra (Figure 38), *M. ruginodis* (Figure 39), and *Formica lemani* (Figure 40-Figure 41) are widespread among forest mosses (Stenhouse 2007). The latter nests in stumps. *Myrmica rubra* is the most moisture-loving of the *Myrmica* species, preferring moist, shady forests (Kupianskaya *et al.* 2000). It builds its nests in decaying stumps and logs, under mosses, and other moist locations. *Myrmica ruginodis* is the most abundant of the red ants in the North Vidzeme Biosphere Reserve, Latvia (Gluhovs 2013). Gluhovs determined that soil pH, bryophyte cover, and coarse woody debris did not have a significant effect on the ant communities in the forest.

Figure 38. *Myrmica rubra* workers drinking from a water droplet on a leaf. Photo by Richard Becker at <www.bwars.com>, through open source permission.

Figure 40. *Formica lemani* queen on moss. Photo by Brian Eversham, with permission.

Figure 41. *Formica lemani* worker carrying pupa across moss. Photo by Brian Eversham, with permission.

In addition to *Myrmica rubra*, it is likely that moisture is important to other species and may account for vertical distribution of species and location of nesting sites. Billings and Drew (1938) demonstrated that bryophytes created a microhabitat that held six times as much water as the bare bark of old-growth tulip trees (*Liriodendron tulipifera*) in Tennessee.

Myrmica lobifrons and *Dolichoderus pustulatus* are the dominant ants in bogs in New England, USA (Gotelli & Ellison 2002). In fact, *M. lobifrons* seems to specialize in bogs and other humid habitats.

In forest sites in the Czech Republic, the **Formicidae** were among the most abundant taxa in the biggest bryophyte samples (400 cm²) (Božanić 2011). *Lasius brunneus* (Figure 42) was abundant among epiphytic mosses on trees with a diameter of 60-110 cm, especially on old oak trees.

Figure 42. *Lasius brunneus* adult, an inhabitant of old oak trees where it lives among epiphytic mosses. Photo by Stanislav Krejčík, through Creative Commons.

Božanić (2008) examined the aspects of forest mosses that made them suitable environments for invertebrates. He suggested that ants may live there or go to mosses to search for food or shelter or to lay eggs. The microclimate, especially in retaining moisture, provides a haven for forest dwellers. On the other hand, the invertebrates help the bryophytes by spreading spores. Using heat extraction with a Tullgren funnel, Božanić extracted invertebrates from 66 moss samples. The richest fauna of invertebrates, including **Formicidae**, occurred with the moss *Brachythecium curtum* (Figure 43). The most important factors for number of taxa were type of substrate, height above ground, and moss sample area. The species were affected by the type of substrate, height above ground, and tree diameter.

Figure 43. *Brachythecium curtum*, a preferred moss for habitation by members of **Formicidae**. Photo by Janice Glime.

Božanić *et al.* (2013) investigated the factors that affected invertebrate communities among bryophytes in forests of the Czech Republic. The dominant bryophyte was *Hypnum cupressiforme* (Figure 44) and Božanić and coworkers reported on 13 invertebrate groups, encompassing 45 species. Of these classes, orders, and families, 4 species of **Formicidae** (ants) were present. Height above ground was an important parameter in describing the **Formicidae** communities. But unlike the epiphyte communities in Costa Rica described by Longino and Nadkarni (1990) discussed below, Božanić *et al.* found that the **Formicidae** preferred habitats on the ground or

close to it. It is likely that the epiphyte cover in the Czech Republic is much less developed and protective compared to that in the cloud forests of Costa Rica.

Figure 44. *Hypnum cupressiforme*, a dominant bryophyte in forests of the Czech Republic and home to ants there. Photo by Michael Lüth, with permission.

Epiphyte Communities

As seen above, Blüthgen *et al.* (2001) have demonstrated one importance of ants as epiphyte gardeners. Yanoviak *et al.* (2007) likewise considered the epiphytic mats as important habitats. In Costa Rica, these mats were thinner and exhibited less structural diversity in secondary forests compared to undisturbed forests. But for ants, the diversity was significantly greater in the secondary forests, especially *Solenopsis* spp. (subterranean fire ants). During the dry season, arthropod diversity declined among the epiphytes.

Nadkarni and Longino (1990) used the Winkler sifting apparatus to extract arthropods from Costa Rican canopy soils. They found that ants were among the dominant invertebrate groups in these habitats. In fact, the ants were the only group that did not have higher densities on the ground than in the canopy.

Longino and Nadkarni (1990) demonstrated a vertical zonation of ants in these Costa Rican cloud forests. The genera were similar in the canopy (litter and humus that include mosses) to those among the ground litter, but represented a subset of those genera. But at the species level, the two habitats were distinct with rare overlap in species between the two. Surprisingly, their new find was on the ground, where *Stenamma* JTL-3 (see Figure 62) was nesting under moss mats.

Ant activity in the tropical forests seems to be greater in the canopy than on the ground. Yanoviak and Kaspari (2000) used bait defense to determine these differences. The bait indicated more defense in the canopy (60%) than in the litter (32%), independent of tree species and bait type. It also indicated higher activity in defending protein baits than carbohydrate baits. Furthermore, the litter and canopy had no species in common.

Epiphylls as Defenders

Not all bryophytes favor the ants. The leafcutter ant *Atta cephalotes* (Figure 45) is repelled by epiphylls,

including bryophytes, on citrus leaves. Mueller and Wolf-Mueller (1991) removed the epiphylls from citrus leaves and found 2-3 times as much herbivore damage from ants compared to leaves with epiphylls intact. These epiphylls consisted of leafy liverworts and crustose lichens. They suggested that the epiphylls increased the cutting effort, or that secondary compounds in the liverworts might have been major contributors to the antiherbivory (see Swain 1977). A further possibility is that the epiphylls inhibited the growth of the fungi that served as food for these ants.

Coley *et al.* (1993) looked at the relationship from a different perspective. They found that long-lived tracheophyte leaves have better defenses against herbivores and pathogens than those with deciduous leaves. They suggested that liverworts may provide protection of the leaves, citing the rich concentration of terpenoids in liverworts. It takes only two years to cover leaves with species that have rapid colonization rates.

Dispersal

The busy ants run all over their habitats and the tiny, widely spaced hairs on their bodies would seem to provide ideal locations for some sizes of dispersal units. Rudolphi (2009) set out to discover if such a hypothesis was indeed viable. He reasoned that both ants (*Lasius platythorax*, Figure 82) and mosses, *Aulacomnium androgynum* (Figure 46) in particular, occurred on the same dead wood in Swedish forests. Therefore, it is reasonable that the gemmae (Figure 47) of this moss might be transported by the ants. First he tested whether the gemmae would adhere to the ants. He put one tuft of moss in each of eight Petri dishes and released eight ants into each dish, repeating the experiment 8 times. Once the ants ran across the moss (at least 30 seconds), they were removed by letting them crawl into a bottle. Ants were frozen and examined for adherence of gemmae. As many as six gemmae did, in fact, adhere, with 1/3 of the ants having gemmae within less than two minutes of exposure. He found that while moisture on the moss did not influence time the ant spent on the moss (42 sec wet vs 48 sec dry), the adherence was five times as great on the dry mosses (mean 0.94) vs wet (mean 0.19).

Figure 46. *Aulacomnium androgynum* showing gemmae that adhere to ants that share the same dead wood. Photo by Michael Lüth, with permission.

Figure 47. *Aulacomnium androgynum* gemmae. Photo by Des Callaghan, with permission.

Rudolphi (2009) followed this with a second experiment to determine residence time of the gemmae on the ants. Using nine ants in each of five time periods (0, 1, 2, 4, 8 hours), he attached two gemmae to the dorsal abdomen and let the ants run around. Ants were then frozen and examined for gemmae. Each time interval experiment was again repeated 8 times. After two hours, ants averaged retention of one gemma. After eight hours, 24% of the ants still had at least one gemma attached, suggesting that ants could be an effective dispersal agent of these gemmae.

But why more dry propagules? Wet gemmae tend to stick together, making the dispersal unit larger and heavier, thus easier to dislodge. This greater success of dry gemmae is actually advantageous because the ants are more active when the weather is dry (Elchuk & Wiebe 2003).

Now we just need to watch the ants to see if they traverse the mosses on the logs and if they drop the propagules in suitable sites for successful establishment. Surely both of these conditions are met at least some of the time.

Ants are able to make trails – trails that we can see and follow. They do this by cutting vegetation that slows them down, and that includes cutting bryophytes. This activity provides an opportunity for dispersal. Korpelainen *et al.* (2011) explored the importance of this role in the leafy liverwort *Barbilophozia attenuata* (Figure 48). Using microsatellite markers, they showed significant kinship relationships up to 8 m. After that the relationship coefficients approached 0, then decreased to negative correlations. At more than 25 m they again approached 0, indicating random distribution. They suggested that the large gemmae permit effective establishment more easily than do spores. Gemmae were favored over spores along the ant trails (and are more likely in other areas of disturbance). Nevertheless, the researchers concluded that ants do not have a large role as dispersal agents, and the physical structure of the ant trails likewise does not lead to greater dispersal. Rather, the trails provide colonization sites available to this liverwort.

Spain (2012a) puzzled over a section of moss lawn where the mosses exhibited a trail (Figure 49). It ended at the base of a tree, ruling out a watering hose as the causal factor. Finally he observed the trail long enough to see carpenter ants (*Camponotus* sp.; Figure 50) following the trail (Figure 49) in both directions, one after the other. The ants had apparently removed thousands of moss plants to make the trail, hence making travelling easier (Figure 52). They no longer needed to climb up and down across the stems (Figure 51). Although the trail was only 10 m long, by ant lengths it was equivalent of the length of more than 7 football fields traversed by a human. This trail had actually been cut to remove the obstructing branches. Spain suggests if you want to get rid of the ants, give the nests frequent disturbance, such as hosing them, or fill the entrance with disturbing powders such as cinnamon, diatomaceous earth, or cloves (Spain 2012b).

Recognizing the importance of bryophyte fragments, Heiken *et al.* (2007) sampled nesting material from 25 *Formica rufa* (Figure 53-Figure 55) group nest mounds in five different forest types in Germany. In these nests they found numerous fragments of 20 bryophyte species occurring on almost all sampled mounds. Although both lichens and bryophytes occurred in the nests, 20 species represented bryophytes, whereas only 10 were lichens. The choices indicated some specificity. Those used were the abundant ones – no surprise there, but life form seemed to matter. Weft bryophytes accumulated on the mounds, but tall turfs seemed to be ignored. *Hypnum cupressiforme* (Figure 44) was the most abundant on the nests, appearing in 16 of the 25 samples and comprising 67.5% of the fragments detected. Other common flora were *Pleurozium schreberi* (Figure 30) and species of *Brachythecium* (Figure 63-Figure 64, Figure 43). Certain life forms (weft bryophytes, reindeer lichens) accumulate on mounds, while others (tall turfs, cup-type *Cladonia* spp.) discriminate, reflecting fragmentation features of the species.

Figure 53. *Formica rufa* nest in which bryophyte fragments are incorporated. Photo through public domain.

Figure 55. *Formica rufa*, ready to bite or fire chemical weapons in its defense. Photo by Brian Eversham, with permission.

Some bryophytic nest contents were restricted by forest type (Heiken *et al.* 2007). *Pohlia nutans* (Figure 19) and *Polytrichum piliferum* (Figure 29) occurred in *Cladonio-Pinetum* nests; *Pleurozium schreberi* (Figure 30) in *Leucobryo-Pinetum*; *Polytrichastrum formosum* (Figure 56) and *Rhytidiadelphus squarrosus* (Figure 57) in spruce forests; *Campylopus pyriformis* (Figure 58) in low-mountain ranges; *Plagiothecium* spp. (Figure 59) in *Calamagrostio-Piceetum*.

Figure 59. *Plagiothecium laetum*. Several species of this genus are ant nest components in the *Calamagrostio-Piceetum*. Photo by Michael Lüth, with permission.

Heiken *et al.* (2007) concluded that the ants were important dispersal agents by dropping fragments during transport and providing a colonization site on the mounds, especially those that were abandoned.

Anthills are not friendly bryophyte sites. The outer part of the nest dries faster than the forest floor (Heiken *et al.* (2007). Nests are frequently disturbed by ants, birds, and wild boar, suppressing the growth of the bryophytes. Heiken and coworkers determined that at least 25,000 fragments of bryophytes and lichens were carried to ant nests in one year. That is no guarantee they will grow.

Nesting

Ants build elaborate nests in trees or underground (Figure 60-Figure 61) (Wikipedia 2016). They typically maintain the nest at a temperature that is ideal for development of the larvae. They do this by choosing the location, materials, ventilation, and solar radiation. The worker and activity and metabolism help to contribute to heat control. In moist nests, microbial activity helps to control the temperature.

Figure 60. Ant nest under *Dicranum scoparium*. Photo courtesy of Serhat Ursavas.

Figure 61. Ant nest under *Dicranum scoparium* showing closer view of the ants. Photo courtesy of Serhat Ursavas.

Longino (2005) examined nesting behavior of two species of the neotropical *Stenamma* (**Formicidae**; Figure 62). By comparing ants on soil banks, he found that they are absent from new (unvegetated) banks. They are very abundant on the banks at the intermediate stage that has only a sparse covering of small bryophytes. But when the mosses become abundant, the abundance of ants decreases greatly.

Ants use bryophytes to varying degrees to construct nests (Figure 63-Figure 65). Some nest under them (Figure 66). Some incorporate small bits of bryophytes in nest construction. And some use bryophytes almost exclusively. General collecting by Longino and Nadkarni (1990) in Monteverde and other highland sites in Costa Rica has revealed that *Stenamma* (Figure 62) makes nests under moss mats in the forest understory.

Abandoned nests can become the site of moss invasions, as seen in Figure 69.

Figure 66. *Polydesmus angustus* nest under moss, Crowle Moors, UK. Photo by Brian Eversham, with permission.

The Neotropical frog *Agalychnis saltator* (Hylidae) makes nests and lays its eggs among mosses on lianas (vines) (Roberts 1994). Among the dangers to these eggs are cohabiting ants. As adults these frogs are able to escape quickly by parachuting.

My own experience is watching ants repair an ant nest mound made of *Sphagnum* during heavy winds (Figure 67- Figure 68). Bits were flying off the mound as fast as the ants could repair it. Ants are fairly common in bogs, and grabbing a handful of *Sphagnum* can result in an arm full of ants.

Figure 69. Ant hill with moss. Photo by Annette Schimming, with permission.

If you have ever trudged through a peatland with hummocks and hollows, you know how difficult walking can be. It is easy to twist your ankle on the uneven substrate. What you may not know is that ants can be

responsible for some of that rough terrain. They are clever engineers and in the peatlands they build elaborate nests, as you have just seen. But in natural hummocks formed by *Sphagnum* growth, ants can play a role in the changes in microtopography (Luken & Billings 1986). Due to their tunneling behavior, it appears that when the mosses die, hummock retrogression is accelerated by the tunnelling of the ants. In fact, some of these collapsed hummocks can eventually form hollows.

Ants, *Sphagnum* Collars, and Aphids

Robin Stevenson (Bryonet 17 June 2015) reported moss collars around the bases of pine (Figure 70-Figure 73) and birch (Figure 74) trees. "The lower part of the 'trunk' was covered in little bits of dried *Sphagnum* (Figure 78), and the whole plant was swarming with lots of ants. We didn't see the ants actually moving any of the *Sphagnum*, but they did look as if they were coming up from underneath it. We got the impression that it was the ants who were responsible."

Figure 70. Ants, aphids, and *Sphagnum* sleeves on sapling in bog. Photo courtesy of Robin Stevenson.

Figure 71. Ants and basal sleeve of *Lasius platythorax* in bog. Photo courtesy of Robin Stevenson.

Figure 72. Ant (*Lasius platythorax*) *Sphagnum* sleeves on pine. Photo courtesy of Robin Stevenson.

Figure 73. Partial sleeve made by *Lasius platythorax* around branching point in Durham Bog. Photo courtesy of Robin Stevenson.

Figure 74. Birch sleeve of *Sphagnum* built by *Lasius platythorax*. Photo courtesy of Robin Stevenson.

I have several hypotheses for the *Sphagnum* ant nests:

1. The ants are just beginning a nest and the pine serves as a central support column.
2. The nest has been mostly destroyed and the ants are repairing it.
3. The *Sphagnum* is tucked into the pine to maintain higher moisture for laying eggs. (I doubt that is the case.).
4. There is some commensal/symbiotic relationship going on, probably aphids, and the ants are improving conditions for aphids or other insects that will serve as food.

Stevenson returned to the site and found three more of these constructions (pers. comm. 22 June 2015). Not all were at the bases, but rather formed collars farther up the sampling trunk (Figure 75). The ants were scurrying about, on, and through, the moss collars (Figure 76). These collars were made of a variety of the materials available (Figure 77), but mostly of *Sphagnum fallax* (Figure 78) and *Aulacomnium palustre* (Figure 79-Figure 80), but also included leaves of *Polytrichum commune* (Figure 81), *Erica tetralix*, and *Calluna vulgaris*. Much of the composition was *A. palustre* tomentum (Figure 80). *Sphagnum* was tucked in among the leaves of the pine, well above the substrate (Figure 75).

Figure 75. Partial sleeve by *Lasius platythorax* at branching point on pine. This nest is at some distance from the tree base. Photo courtesy of Robin Stevenson.

Figure 81. *Polytrichum commune* fragments from nest of *Lasius platythorax*. Photo courtesy of Robin Stevenson.

So let's return to the moss collars to shed more light on these hypotheses. On another return visit, Stevenson had a "good look to see what the ants were up to: lots of scurrying about, and a few interactions with aphids – of which there didn't seem to be too many. However... when I broke a bit of sleeve off, there were a lot of aphids all huddled together underneath. So, it looks as if the ants are herding them under the cover of the sleeve – or might they shelter there of their own volition? Herding sounds more likely – but how does that work? I'd have thought that pine bark was a bit tough, even for an aphid's mouth parts, and they would have been better off up among the leaves?"

The ants were ultimately identified as *Lasius platythorax* (Figure 82-Figure 83) (Wells 2015). The aphids provide **honeydew** (Figure 84-Figure 85) for the ants, and the ants, in turn, police the stems with the nests (Figure 83, Figure 86), warding off a number of kinds of predators. Interestingly, the aphids are species-specific. That is, the birch aphids are *Symydobius oblongus*,

whereas those on the pine are *Cinara pini* (Figure 84-Figure 86).

Figure 85. Ant feeding on aphid honeydew. Photo by Jmalik, through Wikipedia Commons.

Bauer-Dubau (2000) found that *Cinara pini* (Figure 84-Figure 86) produces more offspring when attended by ants. In Germany, the aphids on several pine species are heavily attended by the ant *Lasius fuliginosus* (Figure 87). The density of ants increased from 10-20 to 26-48 ants per colony in one generation. Without the ants, the aphid anus becomes covered with honeydew and the colony disperses.

Beattie (1985) reviewed ant service to aphids. That review demonstrated that the ants provide not only protection, but also sanitation and transportation, decrease their development time, and increase the colony growth rate, survivorship, and fecundity (Kennedy & Stroyan 1959; El-Ziady 1960; Banks 1962; Way 1963; Banks & Macauley 1967; Bristow 1982). Furthermore, the ants reduce parasitism by wasps (27.4-98.4% reduction) by preventing the egg-bearing female parasites from landing

on the aphids and ovipositing there (Bartlett 1961). Disturbance by ants resulted in 27.4% to 98.4% reduction in parasitism, depending on the parasite species. Ants even place aphids in areas that give them better access to the phloem that provides their food source (Banks 1962; Way 1963). The ants build shelters that protect them from rain and enemies, using soil, vegetation, and other materials (Andrews 1929; Levieux 1967; Duviard 1969; Duviard & Segeren 1974).

Ants are known for feats of strength and strong societal behavior. In one recent study in Israel, Gelblum *et al.* (2015) describe their seemingly undirected behavior while carrying a Cheerio. The ants doing the carrying can't see what is ahead and often get off course. But navigator ants (scouts) occasionally enter the scene and direct the Cheerio carriers back on course. The communication between the scout and the carrier ants seems to be through the changed direction felt through the Cheerio. It would be interesting to observe whether similar carriers and scout leaders exist in the movements of mosses to make the mounds observed in bogs and fens or the collars around birch trees.

Bogs and Fens

One must be careful when reaching deep into a moss hummock to collect the moss because a swarm of ants may soon be on its way up one's arm! I have experienced this in several locations in North America. Rosengren (1969) and Collingwood (1979) relate the commonness of ants among *Sphagnum* turfs in Central Europe, where such ants as *Formica uralensis* (Figure 88) likewise carve nests (Figure 89) out of the peat (Stankiewicz *et al.* 2005) and hibernate under mosses in winter (Collingwood 1979). This species is restricted mostly to *Sphagnum* habitats. Matthey (1971) reported that both *Myrmica ruginodis* (Figure 39) and *Formica picea* (Figure 5) make nests in *Sphagnum*. As mentioned above, I have observed nests made of *Sphagnum* (Figure 90), but I was unable to identify the species. Blank Shaw found a similar nest in Maine (Figure 91).

Figure 88. *Formica uralensis*, an ant that nests in *Sphagnum* in Europe. Photo by Ruth Ahlburg, with permission.

Figure 90. These ants are busy repairing their nest in this *Sphagnum* hummock on a windy day in Michigan's Upper Peninsula. Photo by Janice Glime.

Figure 91. Ant nest made of *Sphagnum rubellum* in Maine. Photo by Blanka Shaw, with permission.

Šteffek and Wiezik (2008) reported 11 species of ants in a peat bog at Hrabušice, N Slovakia. *Myrmica scabrinodis* (Figure 92) is dominant there in patches with the highest humidity. They build their colonies among the thick mosses. In Switzerland, the inhabiting *Myrmica ruginodis* (Figure 39) and *Formica picea* (Figure 5) form nests among the *Sphagnum* (Matthey 1971).

Figure 92. *Myrmica scabrinodis*, a dominant ant in peat bogs of northern Slovakia. Photo by Tim Faasen, with permission.

Certainly many insects are housed in mosses, but one of the most distinctive nests is the smooth dome built by ants in a fen. I watched these industrious creatures groom

their mound of *Sphagnum* continuously on a windy day, weaving each loose fragment of moss back into the construction (Glime, personal observation). They could barely move against the wind and often were moved backward by its force.

Lesica and Kannowski (1998) reported that the ants *Formica podzolica* (Figure 93), *Myrmica fracticornis* (Figure 94), and *M. incompleta* (Figure 95) are common in large rich fen complexes of Montana, USA. All three of these species build nests there. *Formica podzolica* nests are much larger than nests of the two species of *Myrmica* and occur in the hummock-hollow complex. The nests are about the size of a hummock, and likewise have elevated levels of K, PO_4^- , Mg, and Na similar to those of hummocks. Lesica and Kannowski (1998) suggested that the hummocks were actually abandoned ant mounds. Even here, the *Formica podzolica* gains most of its nutrition by tending the aphids that feed on the shrubs. And the shrubs are provided a rich habitat for establishment when they germinate in the mounds. Because of this germination relationship, the ants become ecosystem engineers that permanently change the structure and composition of the rich fen vegetation. But there is a feedback mechanism in which the ants benefit from the increase in host plants for the aphids.

Figure 93. *Formica podzolica* adult, a species that nests in large, rich fen complexes in Montana, USA. Photo by Tracy Barbaro, through Creative Commons.

Figure 94. *Myrmica fracticornis* adult, a species that nests in large, rich fen complexes in Montana, USA. Photo by Dan Kjar <www.discoverlife.org>, through Creative Commons.

Figure 95. *Myrmica incompleta* adult, a species that nests in large, rich fen complexes in Montana, USA. Photo by Tom Murray, through Creative Commons.

In a Norway mire, Collingwood (1976) found even greater diversity. Using pit-fall traps, Collingwood recorded 18 species in 13 mires habitats at Eidskog. Among these, *Formica forsslundi* and *F. transcaucasica* are ture mire species. Among the most abundant species were *Myrmica scabrinodis*, *M. ruginodis*, *F. transcaucasica*, and *Leptothorax acervorum*.

Ants can influence the distribution of other invertebrates in peatlands. Antonovic *et al.* (2012) suggested that the higher diversity of terrestrial isopods could in part be the result of predator pressure by *Myrmica* ants (and lycosid spiders).

Bees

Bees are disappearing in alarming numbers, so anything new we can learn about them may be important in saving them. It may surprise you to learn that a number of bees use mosses for various purposes.

Guy Brassard (Bryonet 31 March 2016) reported that bees on Ellesmere Island in the Canadian High Arctic use bryophytes in their nests! He identified more than 50 species of mosses and about 8 species of liverworts among the 47 nests, with an average of 6-7 species per nest. Some of the moss species were present in more than 25 nests and some in very few nests, suggesting that the bees are selective about the bryophytes chosen.

Annie Martin (Bryonet 31 March 2016) reported observations of honey bees, wasps, and butterflies gathering on mosses at her Mossery. They would sit for up to half an hour instead of just a quick stop. A beekeeper explained that worker bees gather water and take it back to the hive or nest. Given the choice between a puddle or larger water body compared to moss colonies, the bees seem to prefer the moss option! There didn't seem to be any species preference.

And if you are a moss gardener, beware. Martin also has found yellow jackets, carpenter bees, wasps, ants, and termites making their homes in giant *Polytrichum commune* (Figure 81) colonies.

Apidae – Honey Bees, Bumblebees, Carder Bees, etc.

Honey Bee

The small red dwarf honey bee, *Apis (Micrapis) florea* (Apidae; Figure 96-Figure 98) has a mysterious habit of collecting "something" from mosses. Sunil Chaturvedi observed this species probing the pots with mosses, whereas they were not doing this in nearby pots of similar moisture but no mosses (Bryonet 26 February 2011). Daniel McConnell, a US Forest Service botanist, reported seeing this behavior for many years (probably with a different honey bee species), and observed that it seemed to be much more common on calcareous mosses (Bryonet 27 February 2011). Wolfgang Hofbauer (Bryonet 28 February 2011) stated that "bees love to take in water at open moist places. For this purpose moss cushions seem to be very suitable. In spring beekeepers even offer them moistened moss cushions near their beehives."

Figure 96. *Apis florea* adult, a species that collects something, probably water, from bryophytes. Photo by John Ascher <www.discoverlife.org>, through Creative Commons.

Figure 97. *Apis (Micrapis) florea* on moss, apparently getting water, but perhaps not. Photo by Sunil Chaturvedi, with permission.

In their blogspot, the Hive Honey Shop recommends providing bees with water in summer (Beekeeping 2013). They warn not to use fresh water because the bees will not touch it. Rather, they prefer mature mineral-rich water.

Provide them with a number of places where they can land to get water without drowning. They suggest putting moss around the edges or in the water dish not only for safe footing, but also to filter the water and prepare it for drinking (Figure 98).

Figure 98. Close-up of *Apis (Micrapis) florea* on *Pohlia*, apparently getting water, or is it simply attracted by UV reflectance by the bulbils of the *Pohlia*? Photo by Sunil Chaturvedi, with permission.

But what draws the bees to the mosses? Sunil Chaturvedi suggested that the mosses may bring more bees to the area because of UV reflectance, hence increasing pollination of crop plants. These observations recalled to my mind the interesting observations of Gisela Nordhorn-Richter that demonstrated UV reflectance of *Pohlia* bulbils (Figure 99). Could it be that the bees are attracted to some bryophytes by UV waves, seen by bees but not by humans? Jon Shaw (pers. comm.) noted that the mosses observed by Sunil Chaturvedi appeared to be *Pohlia* with abundant bulbils (Figure 99). In any case, the mosses seem to be important sources of seasoned water for the bees.

Figure 99. *Pohlia bulbifera* bulbils. These fluoresce under ultraviolet light and could possibly attract bees. Photo by Des Callaghan, with permission.

Annie Martin (2015) reports that honey bees rest on the mosses in her moss garden, simply sitting quietly for a period of time. These bees drink the water on the leaves of the mosses. Beekeepers have suggested that the bees prefer moss water, possibly because of antibiotics in the water (Adventures in Natural Beekeeping 2017). This needs to be verified.

Grdović and Sabovljević (2008) also observed bees visiting bryophytes in beehive yards. They suggested that the bryophytes influence the humidity, maintaining a milder microclimate for the flowering plants and enabling those plants to remain moist longer and grow better. The same moisture provides a water source for the bees.

Figure 100. Honey bee (*Apis* sp.) on *Sphagnum* cf. *palustre*, where it is able to get a drink of water and rehydrate. Photo courtesy of J. Paul Moore.

One could pose several hypotheses for this bee activity on mosses. Tom Thekathyl stated that bees and wasps often "imbibe water" from the surfaces of mosses and suggested that the mosses may have tiny pools of free water that are not available on the bare soil. This is a reasonable hypothesis, given the tiny capillary spaces on mosses that typically hold water longer than the soil surface. The straw-like mouth parts (Figure 101) of the honey bees would permit them to extract water from these tiny droplets.

Figure 101. Honey bee proboscis. Photo from <www.MzePhotos.com>, through Creative Commons.

Another hypothesis is that the water quality might be different on the mosses. On calcareous soil, high concentrations of carbonates might deter the bees, whereas the capillary water of the mosses could be altered by the cation exchange on the moss surface, or by the addition of oxygen from photosynthesis. This suggestion is supported by the observations at the Hive Honey Shop (Beekeeping 2013).

Water certainly seems to be a likely motivator. Bashir Yusuf Abubakar, Bryonet 28 February 2011, pointed out that water is a prime requirement of bees in culture such

that they are always available in moistened areas. One can even find them surrounding a dripping tap. The water retention capacity of mosses varies between mosses and could account for differences in visitation frequencies.

The bee mouthparts facilitate the use of tiny drops of water such as those on bryophytes. The proboscis (Figure 101) uses capillary action and suction to draw a fine stream of liquid to the mouth (Krenn *et al.* 2005).

Bumblebees

Guy Brassard (Bryonet 1 June 2010) identified bryophytes from 47 bumblebee nests, primarily *Bombus polaris* (Figure 102) and *Bombus hyperboreus* (Figure 103) on northern Ellesmere Island, in the Canadian High Arctic (Richards 1973). The use of mosses helps to insulate the nests, permitting these two bees to survive farther north than other bumble bees (Heinrich 2004). But then, *B. hyperboreus* is a parasite on *B. polaris*. Hence, the behavior of *B. polaris* determines the temperature control for both species.

Bombus polaris sometimes takes advantage of the activities of rodents, building their own nests in lemming and other burrows, but these locations are too cold. Instead, most build their nests in meadows and marginal pools on flat areas, in depressions, and beside small hummocks of mosses or other vegetation. Entrances typically faced the sun during the daily temperature peak, and rearranging the mosses to suit their needs (Richards 1973). The female pulls the moss with her mandibles and forelegs, pushing it under her body with her mid- and hind legs to the desired position. The queens and assisting workers continue to rearrange the bryophytes as the colony expands. Guy Brassard (pers comm. 1 April 2016) reported to me that an individual nest typically had 2-14 species of bryophytes and an average of about 6 or 7 species per nest. These comprised at least 56 species of mosses and 6 species of liverworts overall (see Richards 1970). Only one of the nests lacked any bryophytes. Bryophytes were typically intermixed with dried sedge leaves to cover the nest and create a thick, tight surface of insulation. The most frequent bryophyte species were all common in the region. The following were the most often found (with total number of nests out of 47): *Campylium arcticum* (33) (Figure 107); *Orthothecium chryseum* (29) (Figure 109); *Drepanocladus revolvens* (28) (Figure 108); *Distichium capillaceum* (21) (Figure 105); *Ditrichum flexicaule* (19) (Figure 106); also *Bryum* sp. (38 – tiny unidentifiable scraps) (Figure 10). The three pleurocarpous species were usually dominant or abundant; the others were often very minor components.

Bumblebees (*Bombus*; Figure 110) can use abandoned mouse nests in areas with tussock grass or moss (Saunders 2015). Goulson (2010) found that suitable sites for nesting provided insulating materials for the nest. Such materials include mosses, feathers, hair, and grass. Harvey (2015) echoed this advice for rearing bees, including the need for attracting mice and voles to create nesting sites. In fact, Sladen (2014) reported that a carder bee may build its own nest when moss is abundant instead of occupying abandoned nests of small animals.

Figure 110. *Bombus* sp. adult, a genus that uses abandoned mouse nests that often contain mosses. Photo by Yann, through Creative Commons.

Fussell and Corbet (1992) found that nesting sites differed significantly among color groups of British bumblebees. These involved position of the nest relative to ground level, time of day at which direct sunlight reached the nest, and nature of the immediate environment of the nest.

Bumblebee visits to bryophytes may be facultative (Grdović & Sabovljević 2008). These researchers did find that a relationship of the bees with the bryophytes was supported statistically, suggesting that humidity and a milder microclimate supported the relationship.

Even bumblebees that do not build nests of mosses may find them useful for overwintering. *Bombus lucorum* (white-tailed bumblebee; Figure 111), *B. lapidarius* (Figure 112), and *B. hortorum* (garden bumblebee; Figure

113) spend their winter in mosses (Alford 1969). *Bombus pratorum* (early bumblebee; Figure 114) uses mosses facultatively – overwintering sometimes in moss, sometimes underground.

Carder Bees

Carder bees include the moss carder bee, *Bombus muscorum* (Figure 115). These bees are so-named because they cleanse/comb the mosses before inserting them into the nest construction (Smith 1876). They typically build the nest entirely of moss, working it with their feet into a compact mass that resists the weather (Cuthbert 1895). If mosses are abundant, the nest may be made entirely of mosses, but if mosses are scarce, they may build nests with no mosses. The nest is comprised of a series of cells connected by coarse brown wax (Cuthbert 1895).

Figure 115. *Bombus muscorum* adult, a species that uses mosses to build its nest. Photo by J. C. Schou <www.biopix.com>, through Creative Commons.

Rennie (1857) describes the nest-building of *Bombus muscorum* (Figure 115) as a series of backward pushes. The bees establish a line of up to 6 bees to transport the moss from the source to the nest. The last bee in the file grabs some moss with her mandibles, disentangling it and carding it with her forelegs into a small bundle. She pushes this bundle under her body to the next bee, who passes it to the next with the same under body move, and so forth.

The nest has a long, arched passageway that is formed by a variety of mosses, wide enough to permit free passage for the bees (Smith 1876). The final nest has a dome of 10-15 cm above the ground (Rennie 1857). Wax from the bees forms the ceiling, repelling rain and preventing high winds from carrying away the nest. During the day, the top of the dome may be opened more than 2.5 cm, apparently to ventilate the nest. It is not used for entry, and it is closed again at night. Instead, there is an entrance passage at the bottom of the nest that is about 30 cm long and 1.2 cm

wide. The larvae spin cells. When the grubs are ready to emerge, it is the older bees that chew off the cover to free them. One of these spheres may house 3-30 eggs. Rennie found that the adults were of a color similar to the moss they used.

Bombus muscorum (Figure 115) carders collect mosses and dry grass, constructing the nests on or just under the ground (Wikipedia 2015a). The mosses and grass are used to cover the nest. Once the nest is completed, the bee aggressively protects it, attacking intruders by biting and stinging them simultaneously.

The carder bees differ from other members of *Bombus* that nest underground (Carvell 2002). The partially above ground nesting by carder bees seems to necessitate the grass-moss habitat to maintain warmth. Nevertheless, there is a negative relationship between number of carder bees and depth of moss. On the other hand, Jukes (2008) reported that *Bombus muscorum* (Figure 115) in Sussex made its nest in deep moss in exposed places.

Iles (2010) listed the carder bees *Bombus humilis* (Figure 116), *B. sylvarum* (Figure 117), and *B. muscorum* (Figure 115) as species that require tall grassland with "plenty of leaf litter or moss" to use as nesting material. *Bombus pascuorum* (Figure 118) appears to be more flexible, as indicated by its many habitats. Similarly, *Bombus ruderarius* (Figure 119) builds its nest at the surface or just below, using grass and mosses, and likewise often utilizing an abandoned mouse or vole nest (Benton 2008).

Figure 119. *Bombus ruderarius* adult, a species that nests under mosses and grasses. Photo by James K. Lindsey, with permission.

The common carder bee, *Bombus pascuorum* (Figure 118), is widespread in Europe, living in meadows, waste ground, ditches, embankments, roads, gardens, parks, and forests (Wikipedia 2015b). Like the moss carder bee *B. muscorum*, this species also collects mosses and grasses, constructing a small, hollow sphere. Walls of this sphere are bonded with wax and sealed off. Inside they form a large bowl (5 mm diameter) of brown wax filled with pollen. They deposit 5-15 eggs, then close the cell. They fill a second chamber (20 mm high) with nectar to provide a food reserve for days when weather is not suitable for foraging. Larvae hatch in 3-5 days, then spend only a week to mature as they feed on the food reserves.

Braconidae – Parasitic Wasps

In New Zealand, a new genus, *Shireplitis*, was described as mostly in moss, litter, or tussock grasslands (Fernández-Triana *et al.* 2013). *Parolitis wesmaeli*, also **Braconidae**, from Europe, is a parasitic wasp that uses larvae of *Scoparia basistrigalis* (Pyralidae) and *Bryotropha umbrosella* (Gelechiidae) (both **Lepidoptera**) as hosts. Larvae of both of these hosts feed from their silken tube or tent, grazing on mosses and grasses. Four of the *Shireplitis* species (*e.g.* Figure 120) were themselves collected from mosses and may likewise live on moss-eating **Lepidoptera**. Fernández-Triana *et al.* considered the robust body and legs with shortened antennae of these

Braconidae to be adaptive for moving among "litter" while searching for hosts. See Chapter 12-14 for further discussion of the **Lepidoptera** hosts.

Figure 120. *Shireplitis bilboi* adult, an inhabitant of *Sphagnum* and grasses. Photo through Creative Commons.

Cynipidae and Mimicry

Some members of the **Cynipidae** take advantage of mosses in a different way. *Diplolepis rosae* (Figure 121) causes a gall formation that resembles a moss to house its eggs and larvae (Callan 1940).

Figure 121. *Diplolepis rosae* gall, a mimic of real mosses. Photo by Björn Appel, through Creative Commons.

Diprionidae – Conifer Sawflies

Jarmo Holopainen (pers. comm. 16 September 2011) found that in experiments pupae of pine sawflies (*Neodiprion sertifer* – **Diprionidae**; Figure 122-Figure 125) had a higher emergence rate when kept in *Sphagnum* peat. He suggested that the antibiotic properties of peat helped to increase wasp survivorship.

Figure 124. *Neodiprion sertifer* larvae, a species that survives better when cultured in *Sphagnum*. Photo by Jarmo Holopainen, with permission.

Ichneumonidae

Among the **Ichneumonidae**, twelve genera are able to overwinter as adults (Duffield & Nordin 1970). These take advantage of the insulating properties of logs, rocks, and mosses to endure the extreme conditions of winter. Those that overwinter accumulate glycerol and sorbitol when

subjected to cold temperatures of winter. Dana <Abundantnature.com> tells of lifting a clump of moss from a rock and discovering not one, but two, species of *Ichneumon* hibernating there as adults (Figure 126-Figure 128).

Figure 125. *Neodiprion sertifer* pupa, a species that has higher emergence rates when cultured in *Sphagnum*. Photo by Jarmo Holopainen, with permission.

Figure 128. *Ichneumon cf mendax* hibernating adult that has been disturbed. Photo by Dana <Abundantnature.com>, with permission.

Lungu-Constantineanu and Constantineanu (2014) found the importance of mosses as hibernation sites for at least 10 species of **Ichneumonidae** in the Bârnova Forest Massif, Romania. They found six types of hibernation sites, two of which required mosses. Ten of these sites were between the cracks of bark covered by moss. Others were in dense carpets of mosses on stones. They found that pollution reduced the moss cover, resulting in the disappearance of large ichneumonid clumps with dozens of hibernating individuals. Instead, the hibernating ichneumonids were mostly isolated individuals. The mosses that contributed to the large number of habitats for ichneumonid hibernation between cracks of bark of old but living trees were *Anomodon attenuatus* (Figure 130-Figure 131), *A. viticulosus* (Figure 132-Figure 133), *Brachythecium salebrosum* (Figure 134), *Hypnum cupressiforme* (Figure 44), *Platygyrium repens* (Figure 135), and *Porella platyphylla* (Figure 136). These ichneumonids under mosses in the cracks in tree bark were *Apaeleticus mesostictus*, *Deloglyptus pictus*, *Diadromus troglodites* (Figure 137), *Herpestomus brunnicornis* (Figure 138), *Heterischnus truncator*, (Figure 139),

Ichneumon balteatus (Figure 140), *Ichneumon simulans* (Figure 141), *Rhadinodonta flaviger* (Figure 142), and *Tycherus cephalotes* (= *Phaeogenes cephalotes*). Only one species of ichneumonid (*Cinxaelotus erythrogaster*) hibernated on the rocks, where *Mnium stellare* (Figure 143) covered them.

But overwintering is not the only use they make of mosses. Sarah Lloyd caught one in the act of ovipositing among mosses (Figure 144).

Figure 144. Ichneumonid wasp ovipositing on moss. Photo courtesy of Sarah Lloyd.

Pompilidae

Bees and wasps do not seem to be usual active inhabitants of bryophytes, but the rare spider wasp, *Anoplius caviventris* (Pompilidae; Figure 145) in Sweden lives in a *Sphagnum* habitat (Berglind 1993). In Sweden, this species was found in 1991 and 1993 in a reed swamp (*Phragmites communis*) where it was living on mosses, primarily *Sphagnum* in three different mires.

Figure 145. *Anoplius caviventris* adult, a *Sphagnum* dweller in Sweden. Photo from Zoologische Staatssammlung Muenchen, through Creative Commons.

Scelionidae

It appears that among the **Hymenoptera**, the ants are the only ones with well-developed relationships in peatlands. However, Austin (1988) did find a new genus of wasps in the **Scelionidae** to be associated with mosses in New Zealand. Austin (1988) described this new genus, based on *Neobaeus novazealandensis*. Austin found that collection data indicate this species lives on moss-covered ground, with 80% of the specimens collected by putting mosses in Berlese funnels. This species differs from *Baeus* in having a micropterous (short-winged) male. Austin suggested that wings would hinder movement in this mossy habitat.

Sphecidae

O'Brien (1987) observed *Tachysphex aethiops* (Sphecidae; Figure 146) digging at the bases of clumps of moss on sand. They inspected the burrow entrances throughout the day at various times. Females of this species typically nest in mossy sand slopes where they use pre-existing burrows made by other kinds of insects. One female intermittently removed sand from a burrow, raking the sand onto the nest mound after carrying several loads out of the nest.

Figure 146. *Tachysphex aethiops* adult, a species that nests in mossy sand slopes. Photo by BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Vespidae – Wasps

The yellow jackets [*Vespa* (Figure 147) and *Dolichovespa* (Figure 148); **Vespidae**] are best known for their papery aerial nests (Figure 149). But they also can inhabit mosses such as *Polytrichum* (Figure 28-Figure 29) with at least 15-20 cm of soil attached, where they constantly go in and out (Annie Martin, pers. comm. 6 October 2013).

A Calyptra Mimic

This story lacks a critical detail – the name of the wasp. But it is too interesting to omit, and perhaps someone can shed light on the wasp involved.

Györfy (1952) tells of checking out the twin capsules on the seta of *Polytrichum strictum* (Figure 150). Upon

closer examination, he found that these were not Siamese twins, but rather a capsule with its calyptra and a wasp cocoon, both perched on a single seta. In one of his favorite haunts in Austria, Györfy had seen these "twin capsules" among the "billions" of plants of this moss species in the harvested peat bogs. In this exploration, what he found was that the second twin was a lemon yellow cocoon closely adjacent to the calyptra, and from these cocoons deep black larvae hatched. Mimicry of a calyptra by Hymenoptera – or any other invertebrate – seems to be reported only here. Györfy concluded that such mimicry protected the larvae from cocoon-eating birds as they would prefer to do their "gymnastics" on tree branches.

Figure 150. *Polytrichum strictum* capsules with calyptrae – a structure mimicked by the egg cocoon of a wasp. The insect shown here appears to be an orthopteran – also somewhat resembling the covered capsules. Photo by Michael Lüth, with permission.

Summary

Ants have flexible bodies that permit them to maneuver among the bryophytes. The ants are able to chew and move the bryophytes, permitting them to build trails through the bryophytes, making their foraging easier. They defend themselves with strong mandibles, stings, and chemical sprays. They keep their nests clean. Some remove the tracheophytes around their nests, thus creating space where bryophytes can grow.

Bryophytes provide insulation that maintains a buffered temperature and moisture. For some ants such as *Messor*, bryophytes also provide food, especially the capsules, but some are also known to eat the leafy plants. Bryophytes also provide a suitable habitat for some of their predators such as salamanders. Even bears may forage in the bryophytes for ants. As the ants move about, spores, fragments, and gemmae may be trapped between the body hairs and get transported to a new location.

Some bryophytes are prone to growing on ant hills, possibly taking advantage of the higher concentration of nutrients or being raised above the forest floor where

they can avoid burial by leaf litter. They also avoid competition. Some take advantage of the north-facing slope to reduce desiccation.

A number of ant species use bryophytes in building nests. *Sphagnum* in particular is used, in some cases to make a nest for aphids that provide honeydew for the ants. Ants may be responsible for the hummocks in some peatlands. Some ants create arboreal gardens, using mosses and planting seeds among them. Others place seeds under mosses on the ground, providing them with a suitable protected germination site.

Bryophytes in the environment provide sites for finding drops of water and seeking cover. Others use them for finding food or laying eggs. Epiphylls on leaves, especially in tropical forests, may produce compounds that discourage herbivory on the leaves.

Honeybees appear to use bryophytes for obtaining water from that resting on the bryophytes. Beekeepers often place bryophytes near hives to provide watering sites, but species such as *Pohlia* spp. may attract more bees by reflecting UV light.

Bumblebees use bryophytes in their nests. Some species overwinter under the bryophytes. Carder bees build elaborate nests, partly above ground, lined with bryophytes.

Some species of the parasitic wasps in **Braconidae** are consistently associated with mosses because their lepidopteran hosts live there. One member of the **Cynipidae** mimics mosses with the galls it makes. For some **Hymenoptera**, the peat helps survival, possibly through antibiotic properties. A number of **Ichneumonidae** overwinter in and under mosses and some may oviposit there. Some members of **Pompilidae** live in *Sphagnum* habitats. The scelionid *Neobaesus novaezealandensis* lives on moss-covered ground. Even the wasps sometimes nest under mosses such as *Polytrichum*.

Acknowledgments

Christian Berg helped me obtain permission to use the photograph of *Formica uralensis*. Des Callaghan and Pekka Puntilla provided me with the lead image for the chapter and the story of the *Formica* ants that make the mounds. Thank you to Robin Stevenson for sharing his story about ants and *Sphagnum* on pine and birch saplings. Sunil Chaturvedi shared his story about bees visiting mosses and provided me with photographs. I am most grateful to Gerhard Winter for translating the article by van Gyorffy on calyptra mimicking wasp cocoons. Thank you to Annie Martin for helping me get a picture of a honey bee on a moss and to Paul Moore for providing it. Thank you to Jose L. Fernandez-Triana for pointing out an error and checking my presentation of his work on *Shireplitis* and *Paroplitis*.

CHAPTER 12-11

TERRESTRIAL INSECTS:

HOLOMETABOLA – TRICHOPTERA

Figure 1. *Eniocyba pusilla* larva, the most common terrestrial caddisfly and often a moss dweller. Photo by John Bingham, with permission.

The adults of caddisflies are terrestrial, but most caddisflies have aquatic larvae. Nevertheless, a few have adapted to living in wet places on land. And mosses can provide those wet places. For example, Sleight (1913) described one member of **Limnephilidae** in mosses at tree roots, but not in the water.

Some aquatic larvae are able to feed near the surface of water. The aquatic *Pycnopsyche guttifera* (Figure 2) will sometimes eat terrestrial mosses, but this occurs when the mosses are just below the water line (Williams & Williams 1982).

Figure 2. *Pycnopsyche guttifera* larva, a larva that eats terrestrial mosses when they become submersed. Photos by Tom Murray, through Creative Commons.

Larvae

We now know that there are three species of terrestrial *Enoicyla* (**Limnephilidae**; Figure 1) in Europe, and that larvae of these live in the humid and temperate mosses of deciduous forests and rock crevices (Crampton 1920; Meidl & Molenda 2000), often far from water (Crampton 1920). Perhaps the best known of these terrestrial larvae are those of *Enoicyla pusilla* (Figure 3-Figure 5). These larvae build cases from fine grains of sand and vegetable matter among mosses (Butler 1886). In Britain, *Enoicyla pusilla* is restricted to woodlands, and Harding (1998) suggested that it may have been accidentally introduced from the European continent. This species has five larval instars, becoming more scarce by late summer. Eggs hatch in October and November, and larval success may depend on rainfall during those months. The larvae of this species typically occur among mosses and leaf litter.

Figure 3. *Enoicyla pusilla* larvae, a species that inhabits mosses and leaf litter. Photo by Ernest van Asseldonk, through Creative Commons.

Figure 4. *Enoicyla pusilla* larva feeding on a slime mold. Photo by John Bingham, with permission.

Figure 5. *Enoicyla pusilla* adult, a species whose larvae live among terrestrial mosses. Photo by James K. Lindsey, with permission.

Green (1997) reported that in the UK the larvae of *Enoicyla pusilla* (Figure 3) feed on the soft tissues of dead leaves, mosses, and algae. In one observation, 50 or more individuals were actively climbing up logs and apparently browsing on black slime molds (Green 2012). Their requirement for nearly 100% humidity limits their terrestrial habitats. They have no gills and must rely on cutaneous respiration. If they get too wet, they climb upward and "hang themselves out to dry." When the humidity decreases to 70%, they drop again to the ground. Sometimes many larvae occur together on the surfaces of mosses and liverworts on stream banks after a rain (Green & Westwood 2005; Green 2012).

Flint (1958) considered that *Ironoquia pusilla* in northeastern United States closely resembled *Enoicyla pusilla* in its pupal stage. He reported that the larvae of *I. parvula* left the water and climbed to land where they spent their pupal stage among the leaf litter.

Another genus of caddisfly that lives on land as larvae is *Manophylax* (**Apataniidae**) (Chuluunbat *et al.* 2010). *Manophylax futabae* larvae can be found on the vertical sides of large rocks 10-30 m from mountain streams, as well as on vertical rocky outcrops. Chuluunbat and coworkers found that these larvae were often covered with mosses and lichens, but assumed that their only water usually came from precipitation. *Manophylax alascensis* and *M. annulatus* both construct their cases (4.0-9.8 mm) from fine rock fragments with attached moss and algal fragments dorso-laterally.

It may be that the movement of Trichoptera to land began with species that moved there to feed. *Desmona bethula* (**Limnephilidae**) is one such species (Erman 1981). When it reaches its fifth instar, it adventures from the water to feed on semiaquatic plants. But for this species, inclusion of bryophytes is not known.

Oviposition

If there are larvae on land, then there must be oviposition on land, at least for species that are not adjacent to water. It is interesting that the information I have found on the terrestrial caddisflies is not well linked. We know about the larvae of *Enoicyla* (Figure 3-Figure 5) feeding on bryophytes, but I have found no discussion of their oviposition. On the other hand, I have found information on egg-laying in the **Leptoceridae**.

Leptorussa darlingtoni (**Leptoceridae**) females become active in late afternoon in oviposition (Towns 1983). In Australia, most had congregated in damp mosses near the water surface, with 30 adults along an 80-cm line at 10-20 cm above the water. *Leptorussa darlingtoni* deposits its egg masses in communities above the water, whereas *Lectrides varians* (Figure 6), also in the **Leptoceridae**, deposits a single egg mass at 65-95 cm above the water. For *Leptorussa darlingtoni*, the egg masses are placed in small crevices, but they are always near extensive moss cover. Nevertheless, the moss moisture does not seem to be important as the eggs survive in these same locations when the mosses are dry in years with little rainfall. Towns suggested that the terrestrial deposition may be an avoidance of the fluctuating oxygen levels in the water. In fact, when Towns attempted to rear the eggs on damp mosses in the laboratory, fungal infections caused death of the eggs. Towns asserted that *Leptorussa darlingtoni* is the only species of caddisfly that has communal oviposition and hatching without water.

Figure 6. *Lectrides varians* larva, a species that deposits its eggs where there are lots of mosses. Photo by BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Pupation

Most of the aquatic larvae of **Trichoptera** remain in the water to pupate, emerging onto vegetation or rocks to climb out of the water as adults. But if larvae can live on land, we can assume that their pupae, and perhaps pupae of others, may survive terrestrial life. Erman (1984) suggested that terrestrial pupation in this group evolved as an adaptation to living in intermittent streams. Some larval members of **Limnephilidae** leave the water in the final instar to pupate on land. *Limnephilus peltus* (see Figure 7) leaves spring streams shortly after the snow melts in the Sagehen Creek basin, California, USA, to burrow into the mosses at the edges of fen streams. If the spring flow ends too early and the mosses dry, some pupae may die without any adult emergence.

Another caddisfly, in the **Goeridae**, *Archithremma ulachensis*, spends its larval days in a layer of *Sphagnum* (Figure 8) on a springbank (Levanidova & Vshivkova 1984). Its pupa seems to be adapted to this dense terrain. It lacks long setae and projections used by other pupae in

the family to clean the silk disks that close the case. The first abdominal segment lacks posterior rugosity, and there are no swimming legs. The larvae, however, live in water courses that have cold summer temperatures (3-5°C). The authors consider these cold brooks to have less food competition, thus favoring the larvae of this species.

Figure 7. *Limnephilus* sp. larva; *L. peltus* burrows into mosses to pupate. Photo by Jason Neuswanger, with permission.

Figure 8. *Sphagnum capillifolium*; *Sphagnum* is home for the larvae of *Archithremma ulachensis*. Photo by Bernd Haynold, through Creative Commons.

Hayashi *et al.* (2008) cite the terrestrial habits of the limnephilid *Nothopsyche*. This genus has species in which both pre-pupae and pupae are entirely terrestrial. Their mitochondrial data indicate that this genus was originally aquatic and that just one lineage became terrestrial in the pre-pupal and pupal stages. In this terrestrial lineage, *Nothopsyche montivaga* became completely terrestrial. The terrestrial line also exhibit a switch in case materials from plant matter to sand.

Bogs

For an order of insects evolving from water to land, bogs would seem to be the ideal place to begin. The mosses wick water upward, remaining moist most of the year. Furthermore, water can often be reached by moving downward.

Buczyńska *et al.* (2012) searched for the rare *Hagenella clathrata* (Phryganeidae; Figure 9-Figure 10) in Poland. This species is associated with bogs, making it even more threatened due to habitat destruction. This research team was able to collect larvae in the mountain area using Barber pitfall traps, indicating their mobility in terrestrial habitats.

Summary

Few of the caddisfly larvae have adapted to terrestrial living, and even fewer use bryophytes for their terrestrial adventures. Several of the bryophyte associates are in the **Limnephilidae**. *Pycnopsyche guttifera* sometimes eats terrestrial mosses that extend below water. *Limnephilus peltus* burrows into mosses to pupate. But the best known example is that of *Enoicyla pusilla*, larvae that live terrestrially and include mosses in their varied diet.

Larvae of *Manophylax* (Apataniidae) may include mosses in their cases. *Leptorussa darlingtoni* (Leptoceridae) lays eggs near water in damp mosses, but the eggs can dry safely and thus may not require mosses. Larvae and pupae of *Archithremma ulachensis* (Goeridae) live among *Sphagnum*. *Hagenella clathrata* (Phryganeidae) likewise live in bogs.

CHAPTER 12-12

TERRESTRIAL INSECTS:

HOLOMETABOLA – LEPIDOPTERA

BIOLOGY AND ECOLOGY

Figure 1. These **Lepidoptera** seem to be on these epiphytic bryophytes for a reason, but often we don't know why. Photo by Janice Glime.

Lepidoptera

I was surprised to find that in one study in Romania Dincă (2005) found that 1.8% of the approximately 1000 Macrolepidoptera taxa were "moss" consumers. Pierce (1995) stated that larvae that live in mosses have an environment that is close to aquatic. But few **Lepidoptera** live in the water, so we can expect that these terrestrial insects may have other reasons for visiting or living in bryophytes. On the other hand, the **Trichoptera** and **Lepidoptera** are closely related (Crampton 1920; Shields 1988; Britannica 2008), and most **Trichoptera** larvae are aquatic. Shields contends that the **Lepidoptera** evolved from aquatic **Trichoptera**, so it is therefore predictable that some have strong needs for moisture. This divergence

most likely occurred in the late Triassic at a time when many streams were dry and water was scarce, eliminating many insects that were dependent on water.

Klok and Chown (1997) report that water balance is important for the sub-Antarctic caterpillar, *Pringleophaga marioni* (**Tineidae**; Figure 2). But these moths seem to have no mechanisms for preserving or regulating their water, hence requiring moist habitats. One of these habitats for the larvae is in the mire moss *Sanionia uncinata* (Figure 3) (Burger 1978). These moths are wingless as adults and thus have a limited distribution on Marion Island.

Figure 2. *Pringleophaga marioni* adult, a sub-Antarctic moth with no known mechanism to regulate water. Photo by S. L. Chown, B. J. Sinclair, H. P. Leinaas, and K. J. Gaston, with permission.

Figure 3. *Sanionia uncinata* with capsules. This species is home for *Pringleophaga marioni* on Marion Island in the sub-Antarctic. Photo by Andrew Hodgson, with permission.

Like all creatures, adult **Lepidoptera** need water. Bryophytes collect water and it often stays at leaf bases and other capillary spaces where cohesion keeps it from rolling away. These water droplets are suitable for the tube-feeding adult **Lepidoptera** to get a drink of water (Figure 4). Martin (2015) has observed butterflies and moths pausing for a drink of water from the moss leaves in her moss garden.

Figure 4. Butterfly on *Palustriella commutata*, a place where one can often find water droplets. Photo by Serhat Ursavas, with permission.

Life Cycle

All stages of **Lepidoptera** (egg-larva-pupa-adult) are known from bryophytes. The adult females of bryophyte-feeding larvae often lay eggs there. Several families include members whose larvae live in and feed on bryophytes, a number of which specialize on liverworts. These bryophyte-feeding larvae are often in primitive families that originated before flowering plants.

Eggs

For those **Lepidoptera** that use the bryophytes for egg-laying, the bryophytes provide a safe haven for emerging larvae. This is the case for the hemlock looper (*Lambdina fiscellaria*; Figure 5) (an inchworm; **Geometridae** – see Chapter 12-13), which is a serious conifer pest (Shepherd & Gray 1972).

Figure 5. The hemlock looper (*Lambdina fiscellaria*) larva hiding in moss in autumn. Photo from USFS, through public domain.

Some females create cocoons in which they lay eggs (Figure 6-Figure 7). Timea Deakova sent me images of a cocoon of eggs from the moss *Climacium dendroides* in Oregon, USA. The larvae eat moss and grass.

Larvae

Larvae of **Lepidoptera** can be recognized by the presence of **crochets** (hooks; Figure 11) on their **prolegs** (fleshy short legs on the abdomen). Some **Lepidoptera** spin their cocoons in mosses or use bits of mosses or liverworts as part of the cocoon (Figure 12-Figure 13). Buchanan (1971) reported this behavior for *Pyrusta cingulata* (Crambidae; Figure 13-Figure 14), *Phycis subornatella* (Pyralidae), and *Eana penziana* (Tortricidae; Figure 15) near Perth, Australia. Buckler (1871) reported silken cocoons of larvae of *Acronicta myrica* (Noctuidae; see Figure 16-Figure 17) covered with moss.

Pupation

Bryophytes offer a safe site for pupation of **Lepidoptera** (Figure 18-Figure 20). It is likely that a number of **Lepidoptera** pupate among the bryophytes, but this stage is difficult to identify and is easily overlooked. Hence the records of this stage may not be truly representative of the usage of mosses for overwintering and escape from desiccation. Nevertheless, I have been pleasantly surprised not only by the number of records, but by the identification of the bryophytes involved for both larvae and pupae.

Some **Lepidoptera** pupae, for example the privet hawk moth *Sphinx ligustri* (**Sphingidae**; Figure 21-Figure 24), survive winter in rotting logs covered with mosses, but the necessity for the moss has not been assessed (Brackenbury 1994).

Food Sources

Gerson (1982) reviewed what could be found regarding bryophytes as food sources for **Lepidoptera**. He reported that the larvae of **Meessiinae** feed on both lichens and mosses, but they also incorporate the fragments of these two groups of organisms in their cases. *Nudaria mundana* eats both saxicolous lichens and liverworts (Forster & Wohlfahrt 1960). Some larvae have a safe haven while they feed on the bryophytes. The *Sabatinca* larva is a liverwort mimic with its greenish color and large setae (Tillyard 1922; Yasuda 1962; Gerson 1982; Holloway 1993).

Feeding on Leafy Gametophytes

As I worked on this chapter, I became amazed at the number of **Lepidoptera** that feed on bryophytes. Most feed on the leafy plants (Figure 25). Some of them feed on mosses and others feed exclusively on liverworts.

Figure 25. Caterpillar feeding on the moss *Fabronia leikipiae*. The caterpillar has an ideal color and pattern to blend in with the bryophyte branches. Photo by Min Petiot.

As early as 1894, Chapman noted that some **Lepidoptera** larvae feed on mosses, especially in the primitive families. We now know that some are bryophyte

specialists. Robin Stevenson shared his image with me to demonstrate feeding on mosses (*Tortula truncata*) by **Lepidoptera** larvae (Figure 26).

Figure 26. *Tortula truncata* showing feeding damage by larval **Lepidoptera**. Photo courtesy of C. Robin Stevenson.

A number of **Lepidoptera** larvae feed on the leafy gametophytes of bryophytes. Members of the primitive lepidopteran suborder **Zeugloptera** are moss feeders (Chapman 1894; Tillyard 1926), suggesting that the advent of flowering plants opened new food sources for them. Among these bryophyte feeders is *Micropterix calthella* (**Micropterigidae**; Figure 27-Figure 28) (Chapman 1894).

Figure 27. *Micropterix calthella* adult, a bryophyte feeder in its larval stage. Photo by Wouter Bosgra, through Creative Commons.

Figure 28. *Micropterix calthella* adult of a larval bryophyte feeder. Photo by Tom Deroover, through Creative Commons.

Feeding on Capsules

Fang and Zhu (2012) reviewed accounts of **Lepidoptera** feeding on bryophyte capsules. They found that the known feeding habits of lepidopteran larvae included capsules in only four families: **Micropterygidae** (Gerson 1969), **Mnesarchaeidae** (Grehn 1984), **Arctiidae** (as **Lithosiidae**) (Liu 1989), and **Geometridae** (Maciel-Silva & dos Santos 2011). Thus, theirs is the first record of **Noctuidae** larvae that feed on mosses. *Agrotis* sp. (**Noctuidae**; Figure 29) larvae commonly feed on capsules of *Haplocladium microphyllum* (Figure 30) in Shanghai in the spring (Fang & Zhu 2012).

Butterflies

"Among those groups of butterflies that feed on plants, none is known to feed on bryophytes or on Psilopsida, Lycopsida, or Sphenopsida, nor is any known from ferns" (Ehrlich & Raven 1964). This statement surprised me because I had already found a number of **Lepidoptera** that feed on bryophytes. But I soon realized these are almost entirely moths. However, there are exceptions (see **PAPILIONOIDEA** in Chapter 12-14) in the **Lycaenidae** (Callaghan 1992), **Nymphalidae** (Singer & Mallet 1986; Hamm 2015), and **Rionidae** (DeVries 1988). It is interesting that two of these exceptions are butterfly larvae that feed on the epiphylls that live on tracheophyte leaves.

It is not unusual for **Lepidoptera** to eat plants, but it is unusual among the butterflies. While bryophytes are not a main fare, some satyrid butterflies do consume bryophytes (Singer & Mallet 1986). In Japan, the primitive *Sabatinca* (Figure 31) and *Neomicropteryx nipponensis* (both in **Micropterygidae**; Figure 32) feed on liverworts (Figure 33) (Yasuda 1962).

Epiphylls as Food

Bodner *et al.* (2015) found that in southern Ecuador the caterpillar assemblages often did not feed on their expected hosts. Rather, they chose foliose lichens, dead leaves, and the epiphylls, including bryophytes.

Invertebrates on the Menu

One normally thinks of caterpillars, the larvae of the **Lepidoptera**, as plant eaters. But Murawski (2003) describes "killer" moths that are carnivores, usually on soft-bodied insects and spiders. They use camouflage, seductive odors, and armor shields to enable them to sneak up on their prey. Some (*Maculineaalcon* – **Lycaenidae**; Figure 34) visit flowers to obtain a waxy cover of hydrocarbons that smell like *Myrmica* (Figure 35-Figure 36) ant larvae, enabling them to enter the ant nest. They then trick the ants into accepting them and feeding them while they attack the ant larvae! The ants whose nests are invaded include *Myrmica scabrinodis* (Figure 35), *Myrmica ruginodis* (Figure 36), and *Myrmica rubra* (Figure 37). All three of these ant species are associated with mosses, often nesting under them, hence the **Lepidoptera** live under mosses as well.

Figure 34. *Maculineaalcon* adult; larvae of this species trick ants into accepting them and feeding them. These ants typically associate with mosses, hence, so does the *Maculineaalcon*. Photo by Joris Egger, through Creative Commons.

Figure 37. *Myrmica rubra* workers, a species whose nests are invaded by *Maculineaalcon*. Photo by Gary Alpert, through Creative Commons.

Some **Lepidoptera** that are indeed carnivorous caterpillars take advantage of the mosses to gain their food in a quite different way. In Hawaii, these carnivores are camouflaged as leaf litter, lichens, twigs, or mosses (Figure 38), permitting them to stalk their invertebrate prey (Murawski 2003).

Figure 38. *Adelpha serpa celerio*, a moss-mimicking caterpillar from Panama, but in this case, not a carnivore. Photo by Arthur Anker, with permission.

Antiherbivory

The limitation of **Lepidoptera** larvae primarily to leaves of seed plants may be due to antiherbivore compounds. Wada and Manakata (1971) demonstrated that some liverwort terpenoids inhibit feeding by **Lepidoptera** larvae. Ottosson and Anderson (1983) showed that fewer species were associated with ferns than with other tracheophytes and provided evidence that the wide range of chemical defenses in the ferns discouraged many insects from eating them. Nevertheless, the **Lepidoptera** seemed able to exhibit spatiotemporal adaptations that permitted them to avoid the unfavorable biochemistry of the ferns.

Krishnan and Murugan (2013) investigated feeding by **Lepidoptera** on bryophytes, using 20 species. They chose two species [corn earworm, *Helicoverpa zea* (Figure 39) – Noctuidae, and armyworm, *Spodoptera litura* (Figure 40) – Noctuidae]] that do not eat bryophytes. They compared the effects of protein extracts from bryophyte species with those from the normal food plant *Glycine max* (Figure 41) cultivar using bioassays. In these experiments, protein extracts from four species [*Octoblepharum albidum* (Figure 42), *Fissidens virens* (see Figure 43), *Bryum argenteum* (Figure 44), and *Marchantia linearis* (Figure 45)] caused the greatest decrease in damage in leaf-disk assays and in insect larval growth. They also caused a reduction in efficiency of digestion and food conversion. Further discussion of antiherbivory in **Lepidoptera** is in the following subchapters.

Adaptations

Bryophytes can provide a number of characteristics that are favorable for small invertebrates. They absorb water rapidly, reduce evaporation, and provide insulation against extremes of temperature and wind (Gerson 1982).

Most adult **Lepidoptera** associated with bryophytes do not have morphological adaptations for the bryophytic habitat, but rather blend with the flowers they visit. Others, however, are dull grays and browns that permit them to blend with the bark where they rest.

Larvae, on the other hand, are usually colored with browns, grays, and greens, and have tubercles or spines. Some have behaviors that cause them to include bryophytes in the construction of cocoons or cases. Their biggest adaptation, however, seems to be the ability to eat and digest the bryophytes. On the other hand, for at least some families, this is a primitive trait (Powell *et al.* 1999; Hashimoto 2006).

Some of the larvae, but few of the adults, have color patterns that would camouflage them among the bryophytes (Figure 46-Figure 47). Intermixed greens, browns, and black would make it easy for the larvae to hide among bryophytes, but these colors do not always coincide with known uses. Is this just our lack of sufficient observations, or are they adapted to walking among the mosses on their way from one location to another?

Figure 46. Caterpillar on moss, showing greens, black, and a brown head capsule. But does it live there? Photo by Carrie Andrew, with permission.

Figure 47. Moth adult on bryophytes, showing cryptic coloration. Photo courtesy of Sarah Lloyd.

One type of mimicry that seems not to be reported elsewhere is that reported by Györfy (1952). He relays his adventures in checking out twin capsules, only to discover that one was not a capsule at all. On the setae of *Atrichum undulatum* (Figure 48) he found not only a capsule, but also a cocoon. He reared the cocoon successfully to its maturity, from which emerged a moth. He did not describe it in this case, so it is not clear if it truly resembled a capsule of the moss, but especially noticeable as the animal it was.

Figure 48. *Atrichum undulatum* with capsules, home for some **Lepidoptera** pupae on the setae. It is easy to see how a pupa might be inconspicuous among these capsules. Photo by Michael Lüth, with permission.

Habitats

In their altitudinal study in Australia and New Zealand, Andrew *et al.* (2003) collected bryophytes and extracted invertebrates using the kerosene phase separation method. They identified these to family and found only one family of **Lepidoptera**. Nevertheless, bryophyte-dwelling **Lepidoptera** are more common than most of us might suspect in the forests and peatlands.

Forests

Diversity of **Lepidoptera** in forests is related to, but not limited to, the layers of the forest, disturbance, and management (Thorn *et al.* 2015). These researchers found that abundance of moth larvae of the **saproxylic** (pertaining to decaying wood) and detritus-feeding guilds was higher under a regime of natural disturbance and in multi-layered

stands. Larvae of moss-feeding moths, on the other hand, was lower in multi-layered stands.

Some of the relationships may be indirect, but nevertheless, important. *Liphyra brassolis* (**Lycaenidae**; Figure 49-Figure 51) is a rarely found species, protected as larvae from ant bites by a leathery "hide." Larvae of this species enter green tree ant (*Oecophylla smaragdina* – **Formicidae**; Figure 52) nests (Figure 53) to feast on larvae. These don't involve bryophytes, but similar behavior in aerial moss nests of ants is possible (See Chapter 12-10). It is certainly worth looking for them.

Epiphytes

In the tropical tree canopy, bryophyte and other epiphyte assemblages can be important food sources. Yanoviak *et al.* (2004). observed that larvae of the **Lepidoptera** on bryophytes occurred exclusively in the green fraction. The distribution of small epiphytes is influenced by the gross epiphyte morphology and location (Martin 1938; Gerson 1982).

Events such as hurricanes can have a severe impact on the epiphytic flora, including bryophytes, and the fauna living among them (Loope *et al.* 1994). Loss of bryophytes may not only be a loss of food and cover, but the **Lepidoptera** that live among them may be dispersed during the hurricane, but not necessarily to a suitable habitat.

But not all leaf dwellers feed on the leaves they inhabit. Some species of **Lepidoptera** occur regularly in the canopy leaf habitat and feed on the epiphylls, including bryophytes, algae, lichens, and fungi (Lucking 2000). Some are broad spectrum feeders, but the larvae of **Lepidoptera** seem to specialize on either the lichens or bryophytes.

Pettersson *et al.* (1995) found that larger invertebrates (>2.5 mm) served as food for foraging perching birds. These food invertebrates are higher in number in natural

forests and include **Lepidoptera** among the dominant species. Their number and biomass relate to the abundance of lichens. This suggests that it would be worthwhile to look for similar relationships with bryophytes.

Bogs and Wetlands

Peatlands can be ideal habitats for many butterflies and moths. Spitzer and Jaroš (1993) found 569 **Lepidoptera** species in a single peat bog in Central Europe! Jaroš *et al.* (2014) found 1040 species of moths and butterflies in just five peat bogs in the Třeboň Basin up to the montane/subalpine zone of the Bohemian Forest. These included 33 relict species of cold-adapted **tyrphobionts** [species living only in peat bogs and mires (Peus 1928)] and 74 **tyrphophilous** species that prefer peatlands. Spitzer and Jaroš (2014) contend that the bogs are refugia for northern **Lepidoptera** species by creating a climate that is suitable. The *Sphagnum* (Figure 54) is responsible for temperature-buffered microclimates that are suitable for these northern relict species of **Lepidoptera**.

Väisänen (1992) used a belt transect to sample butterflies and day-active moths in a raised bog in southeastern Finland. The species richness was higher in the adjacent mineral land, with the highest number of both species and individuals on the **lagg** [nutrient-enriched zone that grades to land (Paradis *et al.* 2015)] and marginal slope. The **Lepidoptera** communities were related primarily to the structural characteristics of the bog, including tree height and undergrowth floristic characteristics (Väisänen 1992).

Figure 54. *Sphagnum magellanicum*, dominant *Sphagnum* in a raised bog that has 11 tyrphobiontic and 14 tyrphophilous **Lepidoptera**. Photo by James K. Lindsey, with permission.

A number of butterflies (**Lepidoptera**: especially **Lycaenidae**, **Nymphalidae**, and **Satyridae**) complete their entire life cycle within peatland habitats of the Lake Superior drainage basin in northwestern Wisconsin (Nekola 1998). Nekola surveyed 70 peatlands in the drainage basin. The highest number of taxa occur in the muskeg sites, including five species that do not occur in other peatlands. In both the muskegs and kettlehole peatlands, butterfly species richness correlates highly with habitat size. These sites provide the southernmost locations for these northern species.

Chapman (1894) noted that some moth caterpillars in bogs use *Sphagnum* (Figure 54) for nests. And some eat the *Sphagnum*. But more commonly, the *Sphagnum*

provides a suitable habitat for the host plant. For example, one species, *Nola aerugula* (Nolidae; Figure 55), seems to be present as a dominant in a number of bogs, at least in Lithuania (Dapkus 2004a, b). It occurs throughout most of Europe, east to Japan. The larvae feed on *Trifolium* (Figure 56) and *Lotus corniculatus* (Figure 57), but also on *Betula* (Figure 58), *Salix* (Figure 59), and *Populus* (Figure 60) species, indicating its wide habitat distribution, but not indicating any direct use of the bryophytes.

Dapkus (2000) compared **Lepidoptera** in two peatlands and a raised bog in Lithuania. The raised bog was dominated by *Sphagnum magellanicum* (Figure 54) and exhibited true tyrphophilic and tyrphobiontic species, but none was present in the two peatlands that had been affected by disturbance due to peat extraction. In all, the raised bog had 11 tyrphobiontic and 14 tyrrophilous **Lepidoptera**, whereas the Baloža peatland had 4 tyrphobiontic and 9 tyrrophilous **Lepidoptera** species. The Palios peatland fared even worse with only 3 tyrrophilous and no tyrphobiontic **Lepidoptera** species.

Spitzer and Jaroš (1993) conducted an extensive survey of the **Lepidoptera** of a bog in southern Bohemia. They noted that all the tyrphobionts feed on peat bog plants. But for some of the tyrrophilous species, mosses are on the dinner table. These include *Bryotropha boreella* (Gelechiidae; Figure 61-Figure 63), *Phiaris micana* (Tortricidae; Figure 64-Figure 65), and *Phiaris palustrana* (Tortricidae; Figure 66-Figure 67). In addition, *Thumatha senex* (Erebidae; Figure 68) feeds on both mosses and lichens.

The question remains, why are bogs important to these tyrphobiotic and tyrphophilous species? What is the role of the bryophytes? Do they simply provide the habitat needed by tracheophyte food plants, or are they necessary to survive in some stage of the life cycle?

So far, it appears that few studies indicate that any bog species feed on the bryophytes. In New Zealand Grehan and Patrick (1984) found that the larvae of *Cladoxycanus minos* (Hepialidae; Figure 69) build feeding tunnels in the moss, extending to 300 mm deep and under the water. This species eats *Sphagnum cristatum* (Figure 70). Two other unidentified species of Hepialidae likewise make tunnels into the moss mat. In the same bog *Wiseana umbraculata* (Hepialidae; Figure 71) occurs on saturated mosses that are in close contact with the soil surface.

Figure 69. *Cladoxycanus minos* male adult; this species builds larval feeding tunnels in mosses. Photo from Landcare Research, Manaaki Whenua, with online permission.

Figure 71. *Wiseana umbraculata* male adult, a species that occurs on saturated mosses. Photo from Landcare Research, Manaaki Whenua, with permission.

Sunny peatlands seem to be suitable for the mustard white butterfly, *Pieris oleracea* (Pieridae; Figure 72). But where *Sphagnum* (Figure 54) grows, danger often lurks. Chew (1978) observed one of these butterflies stuck to the sticky hairs of sundew leaves (Figure 73) in Vermont, USA, quite dead. And this species is not alone in being snared by bog-dwelling sundews (Figure 73). As these butterflies and moths struggle to get free, they only get further entangled in the sticky hairs.

Disappearing Species

Local species extinctions have been occurring at a high rate, and members of **Lepidoptera** are no exception (Franco *et al.* 2006). Both climate change and habitat loss account for these losses. Typically, the species retract northward. Franco and coworkers concluded that mountain and northern species may be in jeopardy due to climate warming.

By contrast, Nöske *et al.* (2008) compared moths in **Geometridae** and **Arctiidae** (**Erebidae**?) in mature and recovering forest and in open vegetation of the montane belt in Andes of Ecuador. There was no uniform pattern of change in species richness with increasing disturbance. Rather, species richness of geometrid moths was significantly higher in the recovering forest than in the mature forest or the open habitats. The **Arctiidae** were also most species-rich in the recovering forest, but also in the open vegetation compared to the mature forest.

Any recovery of species following logging depends on the availability of colonists (Niemelä 1997). Butterflies, in particular, suffer from logging of old-growth forests, as do bryophytes (Hydén & Sjökvist 1993), and sometimes the **Lepidoptera** may suffer because of loss of bryophytes.

Maelfait *et al.* (2007) reported the loss of the butterflies *Aricia agestis* (**Lycaenidae**; Figure 74-Figure 77) and *Issoria lathonia* (**Nymphalidae**; Figure 78-Figure 79) from Dutch coastal dunes. This loss was attributed to loss of the varied vegetation structure that included patches of mosses and bare sand, both of which disappear when tall grasses expand coverage (Brouwer *et al.* 2005).

Figure 79. *Issoria lathonia* adult, a species that disappears when dune mosses are replaced by grasses. Photo by Korall, through Creative Commons.

Schtickzelle and Baguette (2004) expressed the importance of demographic parameters in fragmented landscapes. For the bog fritillary butterfly (*Proclossiana eunomia* – Nymphalidae; Figure 80), a specialist glacial relict, density dependence seemed to be related to parasitism of the larvae. Dispersal was dependent on the ability to move between patches of suitable bog habitat.

Hence, destruction of bogs can easily lead to the demise of this species, in part due to crowding and increased parasitism.

Figure 80. *Proclossiana eunomia*, a bog dweller. Photo by Gilles San Martin, through Creative Commons.

Because of their vulnerability due to changes in drainage, bogs are disappearing habitats. Murdock (1994) claims that one-third of the threatened and endangered species in the USA live in wetlands. In the Southern Appalachian Mountains, USA, bogs and fens house many rare and unique species that occur in no other habitats. Among these is the rare Baltimore butterfly, *Euphydryas phaeton* (Nymphalidae; Figure 81-Figure 83).

Many examples, such as those reported by Pescott *et al.* (2015), attest to the effect of changing air quality in causing the disappearance of bryophytes. They provided the first evidence for the indirect association between returning air quality and the increase of lichenivorous moths.

Changing climate can put life cycle stages out of sync. Food plants may mature at the wrong time for developing larvae. Males and females may respond to different stimuli, causing them to be ready for mating at different times. The Earth's mean global temperature has increased by about 0.6°C in the past century (Walther *et al.* 2002). Migrant butterflies are arriving at their spring destinations earlier and breeding earlier than times recorded before the 20th century. Bryophytes may play a role in retaining moisture as the climate dries.

Summary

The **Lepidoptera** are primarily plant eaters as larvae, and for some this includes bryophytes. This appears to be a relict trait from the early **Lepidoptera** that appeared at about the same time as bryophytes became abundant. Many of these bryophyte dwellers have similarities to their sister group, the **Trichoptera**, including case making, wings that rest like a pup tent, and hairs on the wings. Larvae often have appendages and coloration that help them to blend with the bryophytes. They are holometabolous, having eggs, larvae, pupae, and adults in their life cycle.

Pupae develop in bryophytes in some taxa. Adults use the bryophytes for resting sites, in some cases having coloration that camouflages them. Some lay their eggs among bryophytes. Butterflies are less represented than moths and few feed on them.

Although most of the lepidopteran bryophages eat the leaves, some are specialists on capsules. And some eat only liverworts, especially the thallose liverwort *Conocephalum conicum*. Others specialize on epiphyllous bryophytes and some eat the periphyton on the bryophytes. But some bryophytes seem to be inedible, presenting terpenoids and other compounds that serve as chemical defense. A few larvae are carnivorous and ambush prey by resembling bryophytes and hiding there to attack.

Many of the bryophyte dwellers have poor or no flying ability and therefore have limited dispersal ability and distribution. This makes them susceptible to extinction as forests and bogs are destroyed. While peatlands can have a huge number of species, some of these are very rare and easily extirpated as these relict habitats disappear. Bog drainage, climate change, peat harvesting, pollution, and logging all contribute to the losses of these rare species.

Acknowledgments

Thank you to John Steel for his continued support and for sending me articles from the Otago Daily Times about Lepidoptera associated with mosses. David Glenny and Javier Martínez-Abaigar provided me with the paper on Micropterigidae that feed on *Conocephalum conicum*. David Glenny provided me with the *Riccardia* cocoon image. Yume Imada provided me with additional information on Japanese Micropterigidae and their diet. I appreciate help from Steve Palmer and John Grehan in getting permission for some of the images. Bob Heckford sent me many images of larvae and George Gibbs provided many images and several references. Hamish Patrick was helpful in providing additional information and images.

CHAPTER 12-13

TERRESTRIAL INSECTS:

HOLOMETABOLA – LEPIDOPTERA:

MICROPTERIGOIDEA – GELECHIOIDEA

Figure 1. Upper altitude limit of *Sabatinca chrysargyra* (Micropterigidae). Photo by George Gibbs, with permission.

MICROPTERIGOIDEA

Micropterigidae – Mandibulate Archaic Moths

As flowers rapidly expanded into numerous colors, sizes, and shapes, so did the **Lepidoptera** (see Powell *et al.* 1999). But these new flowers fed the adults, not the larvae.

This family is an ancient group, so it is not surprising that there are bryophyte specialists among them. Among these is the rarely collected *Epimartyria* sp. in the moth family **Micropterigidae** (Loren Russell pers. comm. Jan. 2008). The *Epimartyria* (Figure 11-Figure 16) larvae feed on *Conocephalum conicum* (Figure 2) and other liverworts in mountain springs, as well as on *Pellia neesiana* (Figure 3-Figure 4), the leafy liverworts *Scapania bolanderi* (Figure 5), and the *Calypogeia-Riccardia* association on logs, and once on *Porella navicularis* (Figure 6), an epiphyte.

Figure 2. *Conocephalum conicum*, home and food source for members of *Epimartyria*. Photo by Janice Glime.

Figure 6. *Porella navicularis*, home and food for species of *Epimartyria*. Photo by Tonya Yoder, through Creative Commons.

In the lab, *Epimartyria* sp. survived feeding on *Riccardia latifrons* (Figure 7) and the leafy liverworts *Calypogeia fissa* (Figure 8), *Jungermannia obovata* (Figure 9), and *J. rubra* (Figure 10) (Loren Russell pers. comm. Jan. 2008). Russell found them to be most abundant in wet seepage zones with abundant *Pellia neesiana* and *Conocephalum conicum*.

In northeastern USA and Canada, *Epimartyria auricrinella* (Figure 11) lives in shaded locations of wet, swampy woods, boggy ditches, and streamsides where leafy liverworts are abundant (Gibbs 2010). One of its food plants is the leafy liverwort *Bazzania trilobata* (Figure 12-Figure 13) (Davis & Landry 2012). *Epimartyria bimaculella* (Figure 14), in the northwestern USA and Canada (Gibbs 2010), likewise feeds on leafy liverworts, including *Lepidozia* (Figure 15) (Davis & Landry 2012). Davis and Landry (2012) successfully reared them in the lab from larvae that were provided with only the leafy liverwort *Jungermannia obovata* (Figure 9). The larvae have a plastron mechanism (see Chapter 11-10) that permits them to survive short periods of flooding.

In 1989, Gibbs considered the **Micropterigidae** and **Mnesarchaeidae** to be similar in their habitats and seasonal requirements, often occurring together in New Zealand. But the **Micropterigidae** have a distribution around the Pacific rim, whereas the **Mnesarchaeidae** are endemic to New Zealand. Gibbs also considered the larvae of both families to live in the "periphyton layer" of their bryophytic habitat. In this often moist layer the larvae can find algae, bacteria, and fungi that provide suitable food.

The basal lineage of **Lepidoptera** – many as members of the **Micropterigidae** – continued their habit of feeding on cryptogams as larvae (Powell *et al.* 1999; Hashimoto 2006). Powell and coworkers pointed out that in East Asia there are about 25 endemic species that exclusively eat the thallose liverwort *Conocephalum conicum* (Figure 2). Nevertheless, the worldwide distribution of this family is patchy (Imada *et al.* 2011a). Its greatest species diversity is in Japan and Taiwan (greater than 25 spp.), New Caledonia (greater than 20 spp.), New Zealand (20 spp.), and Madagascar (ca 15 spp.) (Gibbs 2010). The **Micropterigidae** of Japan represent the largest radiation of

herbivorous insects known from a single host taxon (Imada *et al.* 2011a).

Epimartyria pardella (Figure 16) is one such example of the dispersal limitations. This species lives in northern California to northern Oregon, USA (Tuskes & Smith 1984). Its flight is very sporadic, and on those occasions when it does fly, it fails to go more than 21 cm! These moths are day-active as adults and associate closely with liverworts [*Conocephalum* (Figure 2) and *Pellia* (Figure 3-Figure 4)]. They frequent canyon walls and streamsides. When they are protected from the wind, they often perch on the upper surfaces of fern fronds, but always near liverworts. When it is windy or dry, they remain among the moist bryophytes such as *Hookeria lucens* (Figure 17), *Atrichum undulatum* (Figure 18), and *Conocephalum conicum* (Figure 2). But unlike the Japanese members of this family, larvae of this species prefer the thallose *Pellia* for food. Young larvae are active both day and night, but older larvae become night active. They typically do not damage the margin of the thallus. Instead, they feed on the underside of the thallus, removing it but not chewing through the upper surface.

The poor dispersal ability of this group with its limited flying ability has created localized populations where the liverwort is available, creating geographic isolation that has resulted in this high diversity of endemic *Conocephalum* (Figure 2, Figure 19) specialists. In fact, larvae of the modern species in this family feed on either detritus or bryophytes (Kristensen 1999; Powell & Opler 2009).

The **Micropterigidae** in Japan illustrate the species radiation of this family, and it goes beyond *Epimartyria*. In the Japanese archipelago, 17 species of **Micropterigidae** are present (Hashimoto 2006). These species are typical of moist riverine environments, a habitat suitable for lush growths of bryophytes and ferns. Kobayashi and Ando (1981) demonstrated that both larvae and eggs of *Neomicropteryx nipponensis* (Figure 19-Figure 21) are easily harmed by drought stress. Four [*Palaeomicroides* (Figure 21), *Neomicropteryx*, *Kurokopteryx* (Figure 22), *Issikiomartyria* (Figure 23)] of these five genera feed exclusively on *Conocephalum conicum* (Figure 2) (Yasuda 1962; Imada *et al.* 2011a). This is in habitats where as many as 14 other bryophyte species commonly co-occur. It is interesting that despite their specificity on this species, these larvae do not discriminate (Imada *et al.* 2011b) among the three cryptospecies (Akiyama & Hiraoka 1994; Miwa *et al.* 2009) of *C. conicum*. Only *Paramartyria* (Figure 24) uses several liverworts as food: *Makinoa crispata* (Figure 25), *Heteroscyphus coalitus* (Figure 26), and *Conocephalum conicum*.

Figure 25. *Makinoa crispata*, food for larvae of *Paramartyria*. Photo through Creative Commons.

These genera are spatially separated (**allopatric**) (Imada *et al.* 2011a; Imada & Kato 2018). Among these, *Issikiomartyria* (Figure 23) occurs only in the snow-rich

area facing the Sea of Japan. *Kurokopteryx* (Figure 22) occurs only in south central Japan, facing the northwest Pacific Ocean. Yet their diets are the same, representing the "largest radiation of herbivorous insects that does not accompany any apparent niche differentiation" (Powell *et al.* 1999). These five genera [*Palaeomicroides* (Figure 21), *Neomicropteryx* (Figure 19-Figure 20), *Kurokopteryx* (Figure 22), *Issikiomartyria* (Figure 23), *Paramartyria* (Figure 24)] of larvae feed on the thalli of *Conocephalum conicum* (Figure 2) by grazing the surface, with no apparent differences in feeding mode among these micropterigid species (Imada *et al.* 2011a).

In Japan and New Caledonia, the larvae of the endemic *Sabatinca* live (Harris 2012) and feed on bryophytes (Figure 1) (Yasuda 1962; Holloway 1993). *Sabatinca* larvae have cryptic coloration that is greenish with large setae that help to camouflage them among the liverworts (Tillyard 1922). On Mt. Cargill, N. Z., *Sabatinca quadrijuga* (Figure 27-Figure 28) lives on leafy liverworts as larvae (Harris 2015). Most of the adults of *Sabatinca* are day-active and feed mostly on fern spores, but they also eat club moss (Lycopodiaceae) spores or pollen from sedges and other flowers (Gibbs & Lees 2014). The adult still has an affinity for bryophytes, however. It "hops" around on the mosses on rocks (flying close to the ground), but only when the sun is shining (Harris 2015).

Figure 28. *Sabatinca quadrijuga* adult, a species that lives among and eats liverworts as larvae and hops around on mosses as an adult. Photo by George Gibbs, with permission.

Sabatinca caustica (Figure 29-Figure 31) illustrates the bryophytic adaptations of this genus. The hunch-backed caterpillars (Figure 29) are camouflaged by their pigments (Gibbs & Lees 2014). Like all members of *Sabatinca*, they feed on leafy liverworts and are known as **exposed feeders** because they feed on the surface.

Figure 29. *Sabatinca caustica* larva, illustrating bryophytic adaptations. Note the hunched back, bryophytic coloring, and projections that resemble bryophyte leaves. Photo by George Gibbs, with permission.

Gibbs (2014) described four new species of *Sabatinca* in New Zealand. All 19 of the New Zealand species are confirmed liverwort feeders. The life cycle of this genus is typically annual. Larvae grow throughout the winter and the pupal stage is short. The larvae exhibit cryptic coloration (Figure 32), but the adults instead often have brilliant iridescent colors (Figure 33, Figure 36, Figure 38). Nevertheless, the adult coloration helps to conceal these small moths in the spotty light of their wooded and streamside habitats. *Sabatinca calliarcha* (Figure 32-Figure 33) and *S. doroxena* (Figure 35-Figure 36), and a number of other *Sabatinca* species, exhibit on the upper forewing (at rest) a black patch with several brilliant white spots in it (Figure 33, Figure 36). Gibbs speculated that these might serve as mimics of one of their main predators, a jumping spider in the *Salticidae* (Figure 34).

Gibbs (2014) was able to name specific larval hosts, mostly leafy liverworts, for a number of the New Zealand *Sabatinca* (Table 1). Larvae of *Sabatinca* on *Plagiochila* not only feed there, but they roll the leaves or otherwise use them to form a cocoon (David Glenney, pers. comm.; Figure 45).

But not all members of the **Micropterigidae** are bryophyte feeders. Some are not able to eat bryophytes and choose other food sources (Lorenz 1961; Luff 1964). Instead, these larvae eat fungi, detritus, and flowering plant green leaves (Kristensen 1998). For example, *Micropterix calthella* (Figure 55) and *M. aruncella* (Figure 56-Figure 57) ate the flowering plant *Stellaria* spp. in the lab and refused both mosses and liverworts (Carter & Dugdale 1982). But Shield (1856) recorded them from mosses and Meyrick (1895) found that both live on wet mosses in the British Isles, claiming that the genus feeds on mosses. Likewise, Chapman (1894) found that they eat mosses. Later, Coutin (2004b) stated that the larvae of *M. calthella* feed on mosses and liverworts. Perhaps they are choosy about the mosses they eat.

Figure 55. *Micropterix calthella* adult, a member of **Micropterigidae** whose larvae bryophytes sometimes, but refuse them at other times. Photo by Tom Deroover, through Creative Commons.

Figure 56. *Micropterix aruncella* adult, a species of **Micropterix** that sometimes refuses to feed on bryophytes. Photo by Marko Mutanen, no rights reserved.

Figure 57. *Micropterix aruncella* adult, a species of **Micropterix** may eat bryophytes but at other times refuses to feed on them. Photo by Marko Mutanen, no rights reserved.

Gibbs (1983) noted that in Australia the evolution of the **Micropterigidae** is paralleled by the evolution of the eastern Australian rainforests. In other locations, particularly in New Caledonia, the developing lineages seem to mirror the development or disappearance of different land masses.

Recently, Imada and Kato (2018) discovered four new species of *Issikiomartyria* [*I. catapasta* (Figure 58), *I. hyperborea*, *I. leptobelos*, *I. trochos* (Figure 59-Figure 60)], and a new genus (*Melinopteryx*) in the subalpine zone in Japan. These species of *Issikiomartyria* and the new *Melinopteryx bilobata* (Figure 61) are all associated with *Conocephalum conicum*, which serves as the food source for larvae. How many more undescribed species and genera are hiding inside liverwort thalli?

MNESARCHAEOIDEA

Mnesarchaeidae – New Zealand Primitive Moths

When the **Micropterigidae** emerged, the New Zealand endemic **Mnesarchaeidae** likewise was becoming established. *Mnesarchaea acuta* (Figure 62) can occur in large numbers on the damp moss-covered banks of streams in a variety of New Zealand forests and at a wide range of altitudes (Gibbs 1979). But it is the **periphyton** (algae and **Cyanobacteria** – Figure 63) layer on the mosses and liverworts that serves as their food. Their fecal matter indicates that they ingest pieces of both live and dead moss leaves, liverwort leaves and rhizoids, fern sporangia, fungal spores and hyphae, and filamentous algae. This is an unusually diverse diet for any lepidopteran. When the females are placed in vials with sufficient periphyton on mosses and liverworts, *M. loxoscia* (Figure 64) and *M. acuta* lay their eggs on the bryophytes. The suitable bryophytes live on rotting logs, tree trunks, and soil in the damp portions of the forests.

HEPIALOIDEA

Hepialidae – Ghost Moths

The **Hepialidae** can be considered indicators of the ancient fauna of New Zealand (Patrick 1988). Their larvae are common in bogs among the mosses. They have poor

dispersal ability because the females generally either have short wings or are reluctant to fly. Even with mobile males, reproduction in a distant location is not possible.

Grehan (1989) considered the mosses to be among the food sources for the **Hepialidae** larvae. Grehan suggested that this family was originally fungivorous (feeding on fungi) and that its change to primarily tracheophytes resulted from suppression of mycophagy. But in pastures and grassland species mosses may be important food sources, whereas liverworts seem to be ignored. Among these moss feeders is *Korscheltellus gracilis* (Figure 65- Figure 67) (Brower 1984). Larvae of this species feed above ground in thick mosses.

Figure 65. *Korscheltellus gracilis* larva, a species where larvae feed above ground under mosses. Photo by Johnathan Leonard, with permission.

Figure 66. *Korscheltellus gracilis* host tree where larvae live under mosses. Photo by John Grehan, with permission.

Larvae of *Korscheltellus gracilis* (Figure 65) typically take two years to mature, following an egg development of 16-19 days at 22°C. Pupation occurs on the forest floor in the second year. These require another month to develop before the adult (Figure 67) emerges. It is the larval stage that is of interest to us. These larvae are **polyphagous** – that is, they eat a variety of foods, including leaf litter, fungi, mosses, and below ground tissues of ferns and seed plants.

Figure 67. *Korscheltellus gracilis* adult, a species that emerges from pupae on the forest floor. Photo by Matthew Priebe, with permission for educational purposes.

Korscheltellus gracilis (Figure 65-Figure 67) has an interesting mating behavior that may give insight into other members of the family. Using wind tunnel experiments, Kuenen *et al.* (1994) found that when light intensity was reduced to 11-25 lux after a 16-hour photophase of 450 lux, females initiated wing fanning. Males downwind of them began wing fanning, rapid walking, or both, and flew upwind toward the female soon afterwards. If the hind wings of the females were removed, the fanning activity of the females failed to evoke a male response. Hence, Kuenen and coworkers concluded that the hind wings emit a pheromone that elicits the male's mating behavior.

Bogs seem to be the best site for bryophyte-feeding members of this family. *Cladoxycanus* (Figure 68) and *Heloxycanus* (Figure 78-Figure 79) both feed on cushion plants in bogs, including both mosses and tracheophytes (Dugdale 1994). *Heloxycanus* larvae eat other mosses as well as *Sphagnum* (Figure 69) by cutting the stems to create fragments. It would be interesting to see if this results in dispersal and establishment. *Cladoxycanus* larvae live at the margins of moss-covered bogs and seepages and feed by cropping the mosses. *Cladoxycanus minos* (Figure 68) larvae live in the bogs but also probably occupy mosses in adjoining forests. These two *Hepialidae* genera are restricted to bogs where they live deep in the *Sphagnum* and keep warm because the *Sphagnum* absorbs heat.

Figure 68. *Cladoxycanus minos* male adult, a bog inhabitant that lives in and feeds on cushion plants, including mosses. Photo by Landcare Research, Manaaki Whenua, with online permission.

For *Cladoxycanus* (Figure 68) and *Heloxycanus* (Figure 78-Figure 79) in New Zealand, growth form seems to be important in food choice. These two genera browse on both mosses and higher plants that have a cushion growth form in moss-bog communities (Dugdale 1994).

Figure 69. *Sphagnum* habitat of *Heloxycanus patricki*. Photo by Hamish Patrick, with permission.

Larvae and pupae of *Cladoxycanus* (Figure 68) live in areas where the *Sphagnum* (Figure 69) is harvested and the larvae contribute to cropping the moss, as do *Heloxycanus* (Figure 78-Figure 79) species (Patrick *et al.* 1987; Barratt *et al.* 1990). Both cut the stems and fragment the *Sphagnum* in a way that could reduce its commercial value.

Larvae of soil and moss-inhabiting larvae in bogs in this family excavate a silk-lined shaft (Figure 71). Typically this shaft has side chambers where fecal pellets are stored, but in *Wiseana* (Figure 73-Figure 75) (Barratt *et al.* 1990), *Aoraia* (Figure 70-Figure 71) (Grehan 1989), *Oncopera brachyphylla* (Figure 72) (in Australia; Elder 1970), and *Eudalaca rufescens* (in South Africa; Joubert 1975), another chamber may be used as a storage room for cut plant material. For those living in bogs [*Cladoxycanus* (Figure 68) and *Heloxycanus* (Figure 78-Figure 79)] the *Sphagnum* (Figure 69) surface absorbs radiant heat and larvae spend the daytime up in that warm chamber. These bog dwellers have larval shafts that reach or even penetrate the water surface (Grehan & Patrick 1984). *Cladoxycanus minos* (Figure 68) occurs in water as deep as 300 mm and eats *Sphagnum cristatum* (Figure 76) (Grehan & Patrick 1984). A similar construction is present for *Wiseana umbraculata* (Figure 74-Figure 75) (Dugdale 1994). This permits it to avoid submersion during high water levels; this species is only known from saturated mosses where it is in relatively close contact with the soil surface (Grehan & Patrick 1984).

Figure 76. *Sphagnum cristatum*, a species consumed by *Cladoxycanus minos* in New Zealand. Photo by Jan-Peter Frahm, with permission.

Wiseana (Figure 73-Figure 75) lives among litter and mosses and has a predator in the beetle family Staphylinidae (Eyles 1966). This beetle, *Thyreocephalus chloropterus* (Figure 77), attacks the *Wiseana* and sucks out its fluids. Some of the *Wiseana* larvae may be killed to protect the beetle eggs. Both live in a habitat with plant litter and mosses and are often associated with ants.

Figure 77. *Thyrecephalus chloropterus*, a beetle that attacks *Wiseana* larvae to suck out its fluids. Photo by Ken Walker, Living Atlas of Australia, through Creative Commons.

Heloxycanus patricki (Figure 78-Figure 79) is a New Zealand ghost moth that feeds on *Sphagnum* (Figure 78-Figure 79) (Hamish 2011). It is an endemic and is in danger of extinction as its habitat has become severely fragmented and further suffers from collection for horticulture. Its adults disappear in even-numbered years, presumably indicating that the larvae require two years to develop.

Figure 79. *Heloxycanus patricki* adult on *Sphagnum*. Photo by Hamish Patrick, with permission.

Many of the bryophyte-dwelling larvae in **Hepialidae** spin a web in which they feed or pupate, or both (Figure 80). The larvae of the borer *Aenetus virescens* (Figure 81-Figure 85) live on trees (Grehan 1983). The larva enters its host by positioning itself axially with its head uppermost. It then places silk threads over itself, fastening them to the bark to form a roughly oval web that covers the larva. The larva is still visible through the cover at this stage. Sometimes the larva does this from within a depression so that the cover is nearly flat with the substrate surface. Once this cover is completed, the larva removes the mosses and lichens growing on the surface and places these particles inside the web. This task completed, the larva begins construction of the feeding tunnel by excavating the bark and wood tissue under the top part of the web. These fragments likewise are placed within the net cover, creating a cover that completely hides the larva inside. This chamber becomes filled with wood chips, causing the larva to make an inner silk lining to form a bag-like cavity extending from the entrance to the tunnel. Fecal pellets are placed in the lower third of the cover. *Aenetus virescens* larvae (Figure 81, Figure 83) feed primarily on the fruiting bodies of eight species of wood-inhabiting fungi (Grehan 1984).

Phymatopus hecta (Figure 87) was originally reported as a feeder on dandelion (*Taraxacum*) (Stainton 1857). But Sterling and Heckford (2005) found the final three larval instars feed on the moss *Mnium hornum* (Figure 89-Figure 90) at the bases of oak trees. Later, Heckford and Stella Beavan found a larva that had spun its silken web over *Mnium hornum* in an open woodland (Grehan 2016). The larva lived in a tunnel in the soil, but it fed on the moss. They also succeeded in rearing the third instar larvae to adulthood with only *Mnium hornum* as a food source. Nevertheless, multiple records indicate that it is also a root feeder.

Palaeosetidae – Miniature Ghost Moths

Although their small size would suggest that bryophytes could make a suitable home for these ghost moths, few actually are known to live there. Heppner *et al.* (1995) has collected both males and females of *Ogygioses caliginosa* (Figure 91) that were congregating on mossy banks of streams where the mosses were kept wet. The larvae in the lab were provided a variety of food plants, but only the mosses appeared to be eaten. Surely there are other bryophyte associates in this family awaiting our discovery.

Figure 91. *Ogygioses caliginosa* adult, a species in which adults congregate on mosses and the larvae eat them. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

TINEOIDEA

Psychidae – Bagworm Moths, Case Moths

These moths construct cases or bags as larvae (Figure 92-Figure 93). These larvae are mobile, although they may attach when at rest. The bag is later used for pupation and at that time is attached to its substrate.

Figure 92. **Psychidae** case moth on moss. Photo courtesy of Sarah Lloyd.

Figure 93. **Psychidae** case moth on bryophytes, with lichen decorations on case. Photo courtesy of Sarah Lloyd.

Although the case moths usually occur with lichens and algal films, some feed on grass and a few feed on mosses. For example, Dugdale (1987) recommends beating low shrubs and branches covered by bryophytes in order to collect more larvae of *Grypthea* (Figure 94). Sapphire McFish (Bryonet 31 March 2016) reports accidentally collecting some of the case moth larvae in Tasmania. These were on mossy buttresses and logs in a

wet forest gully. The larvae stuck 2-3 mosses in their cases in about the same proportions as the mosses appeared in the area. Among these was *Thuidiopsis sparsa*.

Figure 94. *Grypthea triangularis*, a genus whose larvae live among bryophytes on low shrubs and branches. Picture from America Pink, with online permission for educational use.

Dincă (2005) surveyed the **Macrolepidoptera** at Istrița Hill in Romania and found that *Canephora hirsuta* (Figure 95-Figure 97, a bryophyte feeder, occurs there.

Figure 95. *Canephora hirsuta* larva in case. This species eats bryophytes. Photo through Creative Commons.

Dr. Peter B. McQuillan of the University of Tasmania described a larva that may be a species of *Narycia* (Figure 98-Figure 99). This larva makes an "untidy case" near the ground. This seems to be an advantage in providing camouflage. The larvae include grasses and mosses and other small plants in their diet.

Tineidae – Fungus Moths

Tinea (Figure 100-Figure 101) is a stone mason caterpillar. The larvae cement together grains of stone, including small fragments of mosses and lichens (Rennie 1857; Zagulyayev 1970). This encasement is carried around much like the cases of the caddisflies.

Figure 100. *Tinea pellionella* larva in case that earned it the name of stone mason. Photo from ©entomart, through Creative Commons.

Figure 101. *Tinea pellionella* adult; larvae sometimes incorporate bryophytes in their cases. Photo from ©entomart, through Creative Commons.

Klok and Chown (1997) looked at temperature tolerance in a member of this family. Using *Pringleophaga marioni* (Figure 102), they found that this moth had a tolerance range from -0.6°C to 38.7°C , a range it might encounter on any day in its larval life in the sub-Antarctic Marion Island. These larvae are able to supercool to -5.0°C , with 100% of the caterpillars surviving freezing to -6.5°C . Their high temperature survival, however, was poor at 35°C and above. Larvae of this species have no osmoregulatory ability. Klok and Chown suggest that they are able to survive by living in damp situations.

Figure 102. *Pringleophaga marioni* adult, a sub-Antarctic species that tolerates temperatures to -6.5°C as larvae. Note reduced wings that seem to characterize many moss dwellers. Photo by Steven L. Chown, through Creative Commons.

Pringleophaga marioni (Figure 102) is a decomposer (Sinclair *et al.* 2004). It often nests in old albatross nests (Haupt *et al.* 2014). Haupt *et al.* suggested that the moths might select habitats that meet their thermal requirements. They choose newly abandoned nests of the Wandering Albatross (*Diomedea exulans*) more frequently than other habitats. But nests are short-lived, so other resources seem to be important. The researchers looked for possible chemosensory and thermal cues among choices in the laboratory, but they found no significant difference in larval preferences for newly abandoned nest material over old nests, the common mire moss *Sanionia uncinata* (Figure 104-Figure 103), or no choice. Larvae commonly occur in this mire moss species (Burger 1978). Although the larvae preferred lower temperatures (5°C) over higher ones (15°C), the researchers concluded that temperature and chemical cues were not the basis for the choice of substrate materials. Furthermore, the caterpillars apparently do not seek the materials that compose the nests, but rather avoid high temperatures.

Figure 104. *Pringleophaga marioni* (Figure 102) choice of bird nest material vs the moss *Sanionia uncinata* (Figure 103) for their nests. Adapted from Haupt *et al.* 2014.

GELECHIOIDEA

Gelechiidae – Twirler Moths

This is one of the largest families of **Microlepidoptera** (Powell 1980). They are common in north temperate zones and use mosses and liverworts as their larval food. However, the family includes leaf and needle miners, gall makers, and scavengers. Of these 2% of the records of food are from mosses (18 records). Fewer than 2% of the larvae have multiple host plant species.

The **Gelechiidae** are characterized by being concealed while feeding. Some accomplish this by feeding within tracheophyte leaf tissue. The bryophyte feeders seem to accomplish this by hiding under bark or bryophytes, or by creating their own cover (e.g. *Bryotropha umbrosella* – Figure 105) by making silken tubes or tents (Fernández-Triana *et al.* 2013). Unfortunately, these do not protect them from the parasite *Shireplitis* spp. (**Hymenoptera: Braconidae**; Figure 106) that uses this caterpillar as a host (Fernández-Triana *et al.* 2013).

Kullberg *et al.* (2013) lamented that we know little about the role of mosses for the many **Lepidoptera** species living in the Arctic tundra of European Russia. Yet *Bryotropha* (e.g. Figure 105-Figure 107; originally considered part of *Gelechia*) is one of the most common **Gelechiidae** in the Holarctic (Rutten & Karsholt 2004). The genus *Bryotropha* is among the relatively few **Lepidoptera** known to feed on bryophytes, especially mosses (Heckford & Sterling 2002, 2003; Rutten & Karsholt 2004).

Figure 105. *Bryotropha umbrosella* adult, a larval moss dweller that is subject to parasitism by **Braconidae**. Photo by Janet Graham, through Creative Commons.

Figure 106. *Shireplitis bilboi* adult, member of a genus that is parasitic on *Bryotropha umbrosella*. Photo through Creative Commons.

Kullberg and coworkers (2013) were able to report that *Bryotropha galbanella* (Figure 107) lives on mosses. In Europe, this species lives on the mosses *Dicranum scoparium* (Figure 108) and *Homalothecium lutescens* (Figure 109) as its food source (Rutten & Karsholt 2004). In 1856, Shield reported *Bryotropha desertella* (Figure 110-Figure 111) and *B. umbrosella* (= *B. mundella*; Figure 105) from among bryophytes on sandhills in Europe.

Figure 107. *Bryotropha galbanella* adult, a species whose larvae live among mosses and eat them. Photo by Roy Leverton, with permission.

Figure 110. *Bryotropha desertella* larva on moss, a common substrate for it. Photo by R. J. Heckford, with permission.

In the Netherlands, one can often collect large numbers of adults of these drab *Bryotropha* moths (e.g. Figure 112, Figure 115-Figure 117, Figure 119-Figure 120) (Rutten 1999). Most of them occur in open heaths and dunes, some in forests or urban areas. But all are thought to feed on mosses as larvae. *Bryotropha basaltinella* (Figure 112)

feeds on mosses, especially *Syntrichia ruralis* (Figure 113), on walls and thatched roofs (Britain – Meyrick 1895; Netherlands – Rutten 1999).

Figure 111. *Bryotropa desertella* adult on moss. Photo by Phil Boggis, with permission.

Figure 113. *Syntrichia ruralis*, home and food for *Bryotropa basaltinella*. Photo by Hermann Schachner, through Creative Commons.

Bryotropa affinis (Figure 114-Figure 115), *B. senectella* (Figure 116-Figure 117), and *B. domestica* (Figure 118-Figure 119) larvae feed on mosses on walls, but they make a silken gallery in which to live and move about, affording them cover and camouflage (Meyrick 1928; Rutten 1999). But for the Netherlands, Rutten was only able to list "possible" food plants for *B. similis* (Figure 120): *Hypnum cupressiforme* (Figure 121), *Brachythecium rutabulum* (Figure 122), *Syntrichia ruralis* (Figure 113), *S. montana* (Figure 123), *Grimmia pulvinata* (Figure 124), *Rosulabryum capillare* (Figure 125), and *Bryum caespitium* (Figure 126) (see also Stainton 1871). Only *Bryotropa basaltinella* has a preference for urban areas, the location of most of the walls covered with mosses. Rutten reminds us that it is easier to locate the larvae on wall mosses and that in non-urban areas the adults are abundant in dry areas with no mosses.

Figure 130. *Hypnum jutlandicum* with capsules, a moss where *Bryotropha boreella* builds silken feeding tubes. Photo by J. C. Schou, with permission.

Bryotropha terrella (Figure 133-Figure 134) in the British Isles feeds on the moss *Rhytidiadelphus squarrosus* (Figure 131) and the grass *Agrostis capillaris* (Palmer & Palmer 2016b). But elsewhere in Europe it is also known from the mosses *Syntrichia ruralis* (= *S. ruraliformis*; Figure 113), *Hypnum jutlandicum* (Figure 130), and *Calliergonella cuspidata* (Figure 135). Early instars construct a tough, opaque silken tube low among moss or grass, the upper end reaching near the moss surface. The tube is covered with chewed moss fragments and bits of grass. But in the final instar, the larva makes a flimsy, transparent gallery with no attached plant material.

Figure 131. *Rhytidiadelphus squarrosus*, a moss where *Bryotropha boreella* builds silken feeding tubes. Photo by Michael Lüth, with permission.

Figure 135. *Calliergonella cuspidata*, larval home of *Bryotropa terrella*. Photo by Michael Becker, through Creative Commons.

Larvae of *Bryotropa politella* (Figure 136), also from the British Isles, feeds on *Rhytidiadelphus squarrosus* (Figure 131) (Palmer & Palmer 2016a). But these larvae also can occur under the moss *Schistidium* (Figure 137), although its food relationship to that species is not known (Heckford & Sterling 2003).

Figure 136. *Bryotropa politella* larva on moss. Photo © Bob Heckford, with permission.

Figure 137. *Schistidium apocarpum* with capsules, a moss genus that sometimes provides cover for *Bryotropa politella* larvae. Photo by Hermann Schachner, through Creative Commons.

In the USA and Canada, the genus *Bryotropa* is less common. *Bryotropa gemella* (Figure 138) sometimes occurs on mosses (Rutten & Karsholt 2004). The bryophage *Bryotropa galbanella* is also known from Alaska.

Figure 138. *Bryotropa gemella* adult, a North American species that sometimes lives among mosses as larvae. Photo by Jeremy deWaard, through Creative Commons.

In Russia, Bidzilya and Li (2010) reported that *Agnippe echinuloides* (Figure 139) lives in moss bogs.

Figure 139. *Agnippe echinuloides* adult, a bog species in Russia. Photo by Marko Mutanen, through Creative Commons.

Monochroa tenebrella (Figure 140) lives among mosses in Europe (Shield 1856). *Pseudotelphusa scalella* (Figure 141) larvae feed on mosses, lichens, and *Quercus robur* in Europe (Wikipedia 2015b).

Hoare (2011) found a new species of *Kiwaia* in northern New Zealand. Two specimens were found on the dominant moss *Campylopus introflexus* (Figure 142). Laboratory experiments verified that these larvae could grow to adulthood when only this moss was available as food. On the other hand, *K. jeanae* live on *Raoulia* (Asteraceae; Figure 143-Figure 144) mats, cushions that somewhat resembles a cushion of *Campylopus introflexus*, suggesting that the growth form may be important for moisture conservation.

Figure 140. *Monochroa tenebrella* adult, a species whose larvae live among mosses. Photo by Patrick Clement, Gelechiid Recording Scheme, with permission.

Figure 144. *Raoulia* sp. cushion with a few flowers, home for *Kiwaia jeanae*. The cushion suggests a similarity to a moss cushion. Photo from the University of Basel, through Creative Commons.

But food is not the only use this family makes of mosses. The pupal stage of *Teleiodes luculella* (Figure 145-Figure 147) in the Maltese Islands overwinters (Patocka 1987). Sorhagen (1996) found that this stage can occur under mosses or bark (Zerafa 2009).

Oecophoridae – Concealer Moths

At least some of the **Oecophoridae** (concealer moths) prefer mossy habitats (Coutin 2004a). The larva of the rare *Aplota palpella* (Figure 148-Figure 149) lives among mosses on tree trunks; this species was recorded in England by Phil Sterling and Derek Hallett in Dorset County for the first time since the 19th century! (Butterfly Conservation 2001). *Crassa tinctella* (Figure 150) develops from September to May among the arboreal plant bodies of mosses and lichens, which also serve as its food (Coutin 2004b).

Figure 148. *Aplota palpella* adult, a species whose larvae live among mosses on tree trunks. Photo by Peter Huemer, through Creative Commons.

Summary

The Microlepidoptera include the **Micropterigidae** and the **Mnesarchaeidae**, but it is really a group of small Lepidoptera without close phylogenetic ties. The **Micropterigidae** is a primitive family that specializes on liverworts, although some (e.g. *Epimartyria pardella*) eat mosses. The **Mnesarchaeidae** seem to prefer the periphyton living on the moss leaves and stems. The **Hepialidae** seem to ignore liverworts and feed mostly on mosses, but they are less likely to be specialists. Some include both bryophytes and tracheophytes or fungi in their diets. Bryophyte feeders seem to prefer bogs. *Heloxycanus* prefers cushion plants – mosses or otherwise. Many of the bryophyte dwellers spin a web on the bryophytes for feeding or pupation.

In the **Palaeosetidae**, only one species is known as a moss dweller and moss feeder. The **Psychidae** construct "bags" and cases that sometimes include bryophytes. The **Tineidae** make stone cases and these may include small moss fragments. The **Gelechiidae** hide, while feeding in such places as interiors of tracheophyte leaves, under bark or bryophytes, or in silken tubes of their own making, and some eat mosses. In the **Oecophoridae**, mosses are eaten by at least a few members, typically epiphytes on trees.

Acknowledgments

Sarah Lloyd has been very helpful in this project and introduced me to the moss-dwelling bagworms by sending me some of their pictures. Thank you to John Steel for his continued support and for sending me articles from the Otago Daily Times about Lepidoptera associated with mosses. David Glenny and Javier Martínez-Abaigar provided me with the paper on Micropterigidae that feed on *Conocephalum conicum*. David Glenny also helped me in identification of the liverwort used for the *Sabatinka heighwayi* cocoon and provided me with the *Riccardia* cocoon image. Yume Imada provided me with additional information on Japanese Micropterigidae and their diet. I

appreciate help from Steve Palmer and John Grehan in getting me permission for some of the images. Bob Heckford sent me many images of larvae and George Gibbs provided many images and several references.

CHAPTER 12-14

TERRESTRIAL INSECTS:

HOLOMETABOLA – LEPIDOPTERA:

TORTRICOIDEA – PAPILIONOIDEA

Figure 1. Larva of *Lepidoptera* (Crambidae?) on the moss *Syntrichia*. Photo courtesy of Wynne Miles.

TORTRICOIDEA

Tortricidae – Tortrix Moths, Leaf-roller Moths

This family has larvae that live among bryophytes on tree trunks. A male *Pammene albuginana* (Figure 2) was reared from mosses collected from decaying beechwood in Ireland (Bond & O'Connor 2012). Buchanan White (1971) reported *Eana penziana* (Figure 3) from among mosses near Perth, Australia, where it spins its feeding web (Buchanan White 1971). It is also known from Europe and the Near East where it apparently feeds on tracheophyte roots (Wall 2016).

Figure 2. *Pammene albuginana* adult, a species that can survive on mosses in its larval stage. Photo by Patrick Clement, with permission.

Figure 3. *Eana penziana* adult. Larvae of this species spin feeding webs on mosses in Australia. Photo by Kurt Kulac, through Creative Commons.

Another sometimes bryophyte user is *Cnephasia pasiuana* (Figure 4) – a cereal leafroller in Europe. The young, 1 mm long larvae of this species crawl about on the bark for about 2 days, then hide in bark crevices or among mosses (Ulenberg 2015). They then weave a small white cocoon (**hibernaculum**). They spend the summer there and continue there into a winter dormancy.

Figure 4. *Cnephasia pasiuana* adult, a species whose larvae hide in bark crevices and among mosses. Photo by James K. Lindsey, with permission.

Celypha aurofasciana (Figure 5) lives in galleries on trunk-dwelling mosses and liverworts, but is also suspected of eating rotting wood in the UK (Meyrick 1895; Cryer 2016).

Figure 5. *Celypha aurofasciana* adult; larvae make galleries on mosses and liverworts on tree trunks. Photo by Phil Boggis, with permission.

Mosses may contribute to providing suitable breeding grounds for *Merophyas* sp., in Danseys Pass, New Zealand (Patrick 1982). These moths fly from March to May, but the females have short wings. Two females were found on mosses in wet locations, suggesting that the mosses may be suitable egg-laying sites, or that both the moths and bryophytes like the same habitats.

PYRALOIDEA

Crambidae – Grass Moth; Sod Worms

Members of this family are often included in the **Pyralidae**. I have separated them here because the crambids seem to have a relationship with bryophytes that is seldom seen in the remaining **Pyralidae**.

Members of this family construct silken tunnels on their food plants (grasses and mosses) and reside there in relative safety as they feed (Shield 1856). The subfamily **Scopariinae** is listed in The Peterson Field Guide to Moths of Northeastern North America (Beadle & Leckie 2012) as the moss-eating Crambidae. These include *Scoparia* and *Eudonia*. Munroe (1972) has found species of *Eudonia* (e.g. Figure 8-Figure 12), *Scoparia* (e.g. Figure 25-Figure 28), and *Cosipara* (Figure 6) adults among the mosses in forests of Vancouver, Canada.

Figure 6. *Cosipara* adult, a genus whose adults frequent forest mosses in Vancouver, Canada. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

I was introduced to this family when Will Haines (pers. comm. 17 February 2012) sent me a picture of *Eudonia* (Figure 7) from Hawaii. Over 60 species of this genus occur in Hawaii, many of which feed on mosses. This one came along with some mossy rocks that Haines collected for his terrarium. Loren Russell (pers. comm.) likewise suggested that this genus feeds on mosses in the forests of Vancouver. This suggestions is based on reports of the genus in the area (Munroe 1972) and Russell's own observations of adults in the genus in mossy habitats there.

Figure 7. *Eudonia* sp. caterpillar eating moss in Hawaii. Photo courtesy of Will Haines, with permission.

Eudonia meristis (Figure 8), an endemic in Hawaii, feeds on mosses (Wikipedia 2015a). In Europe, northwest Africa, and Asia, larvae such as *Eudonia lacustrata* (Figure 9-Figure 10) feed on mosses, usually on walls or tree trunks (Doremi 2016b). In eastern North America, *Eudonia strigalis* (Figure 11) larvae are moss eaters (Beadle & Leckie 2012).

Figure 11. *Eudonia strigalis* adult, a moth species whose larvae feed on mosses in eastern North America. Photo by Elizabeth, through Creative Commons.

Hoare (2011) suggested that *Eudonia steropaea* (Figure 12) feeds on the moss *Campylopus* (Figure 13) in New Zealand. To these *Eudonia* species, Patrick *et al.* (2011) added larvae of *Eudonia aspidota* (Figure 14), *E. dinodes* (Figure 15), and *E. minualis* (Figure 16) as having moss hosts in New Zealand; *Eudonia philerga* (Figure 17) lives in and presumably eats moss on wood. These researchers even added a new species of *Eudonia* feeding on mosses on coastal rocks.

Figure 17. *Eudonia philerga* adult, a species whose larvae eat mosses on logs in New Zealand. Photo by Donald Hobern, through Creative Commons.

Shield (1856) described *Eudonia murana* (Figure 18-Figure 19) as a species that occupies mosses on walls in the British Isles, spinning their webs among these plants.

Figure 18. *Eudonia murana* larva on moss. Photo © Bob Heckford, with permission.

Figure 19. *Eudonia murana* adult, a species whose larvae live among mosses on walls in the British Isles. Photo by Chris Johnson, with permission.

Heckford (2009) found one larva of *Eudonia pallida* (Figure 20-Figure 22) on the moss *Calliergonella cuspidata* (Figure 23) in Cornwall, England. It had spun a small silken ball covered in frass (insect feces). In captivity, the larva constructed a silken gallery along the moss stems and was reluctant to leave it. Wegner and Kayser (2006) reported four larvae of the species with similar silken tunnels on the moss *Pleurozium schreberi* (Figure 24). These were enclosed in a strong cocoon made of moss fragments; their frass was usually attached. These larvae laid eggs on the mosses in the lab.

Included among the moss eaters in eastern North America are larvae of *Scoparia biplagiata* (Figure 25) and *S. basalis* (Figure 26) (Beadle & Leckie 2012).

Figure 25. *Scoparia biplagiata* adult, a species of larval moss eaters in eastern North America. Photo by Andy Reago and Chrissy McClarren, through Creative Commons.

Figure 26. *Scoparia basalis* adult, a species whose larvae eat mosses in eastern North America. Photo by Andy Reago and Chrissy McClarren, through Creative Commons.

Stainton (1871) likewise considered *Scoparia* larvae to be moss eaters, citing a number of species that live among mosses in Europe. Larvae of *Scoparia basistrigalis* (Figure 27) feed on moss (Heckford & Sterling 2005). Heckford (2011) made it clear that not all members of *Scoparia* are moss eaters. Rather, based on experiments by Thurnall (1907, 1908) we know that at least *S. pyralella* (= *S. dubitalis*; Figure 28) feeds on roots of *Rumex acetosella* (Figure 29), and possibly other roots.

Figure 27. *Scoparia basistrigalis* adult, a moth whose larvae are parasitized by *Braconidae* and that feeds on mosses. Photo by J. C. Schou through Biopix.com, with permission.

Figure 29. *Rumex acetosella*, host for *Scoparia pyralella* larvae in Europe. Photo by Forest and Kim Starr, through Creative Commons.

Paroplitis wesmaeli is a European species of **Braconidae**, a parasitic wasp that has larval **Lepidoptera** as hosts (Yu *et al.* 2012). Two of the **Lepidoptera** host larvae, *Scoparia basistrigalis* (**Crambidae**; Figure 27) and *Bryotropha umbrosella* (**Gelechiidae**; see Figure 30), feed on mosses (Heckford & Sterling 2005; Hantmoth 2012), the latter while living in a silken tube.

Figure 30. *Bryotropha boreella* larva on moss *Rhytidiadelphus squarrosus*. Photo © Bob Heckford, with permission.

In New Zealand, *Scoparia minusculalis* (Figure 31) uses mosses as host plants (Patrick *et al.* 2011). But mosses are not the only food for the Crambidae. Cowley (1988) found that in Waikato hill country (New Zealand) the **Scopariinae** larvae were abundant in mossy regions but consumed most of the pasture grasses. When they laid their eggs, they chose both grasses and moss stems, laying to depths of 10 mm just below the ground level. The larvae that hatched constructed silk **hibernacula** (cocoons). To these they attached fine soil particles and mosses. If mosses were prolific, the larvae constructed their retreats at the bases of moss plants. The large larvae cut whole blades of grass or stems of mosses and dragged them into their burrows for food. These mosses and grasses were clipped near the burrow so that eventually the burrows were surrounded by an area that was entirely clipped. This clearing resulted in weed invasion, hence affecting the vegetation. Cowley found that all the Waikato hill country species of the **Scopariinae** were able to survive on mosses alone in the lab.

Figure 31. *Scoparia minusculalis* adult with epiphylls on a leaf. Photo by Maurice, through Creative Commons.

Heckford (2009) provides us with a rare view of the details of moss use by the **Lepidoptera**. When *Scoparia ambigualis* (Figure 32-Figure 33) larvae were reared in the lab with only the moss *Polytrichum commune* (Figure 34) for food and home, these first instar larvae spun fine silken strands in the leaf axils. Heckford interpreted these silken nets as cushions because the larvae curled up on them when they were not feeding. These are not very hairy larvae, but nevertheless, Heckford suggested that this net cushion may permit the larvae to get support for their bodies without crushing their hairs.

Figure 32. *Scoparia ambigualis* larva on moss. Note the spun cushion under it and the frass around it. Photo © Bob Heckford, with permission.

Figure 33. *Scoparia ambigualis* adult, a species whose larvae spin "cushions" in the leaf axils of *Polytrichum commune*. Photo by James K. Lindsey, with permission.

Figure 34. *Polytrichum commune*, home and food for *Scoparia ambigualis* larvae. Photo by Michael Lüth, with permission.

These *Scoparia ambigualis* (Figure 32-Figure 33) larvae ate only moss leaves in this lab observation (Heckford 2009). Their feces (**frass**) were pale greenish or yellowish for young larvae. In later instars these became reddish brown. Then Heckford added the mosses *Rhytidiadelphus loreus* (Figure 35) and *Dicranum scoparium* (Figure 36), as well as fragments of fern fronds of *Pteridium aquilinum* (Figure 37), to the choices for the larvae. Larvae occur on all three of these species in Devon, England. The larvae fed on all the mosses, but none ate the fern fragments.

Patrick *et al.* (2011) reports *Gadira acerella* (Figure 38) and *Glaucoccharis elaina* (Figure 39) in moss on rocks in New Zealand, whereas *Helastia corcularia* (Geometridae; Figure 40-Figure 41) lives on moss and herbs there – an unusual non-specialist strategy. Gaskin (1971) also reported *Glaucoccharis elaina* on mosses, including *Funaria* (Figure 42). Hudson (1928) reared *G. microdora* (Figure 43) and *G. metallifera* (Figure 44-Figure 45) on bryophytes.

Beever and Dugdale (1994) observed severe damage to a colony of the moss *Dawsonia superba* (Figure 46) on a stream bank on the southern slopes of Mt Ruapehu, North Island, NZ. This damage was later determined to be the work of the moth larva *Glaucoccharis epiphaea* (Figure 47). Its feeding resulted in chewing off terminal portions of many leaves. They left the shoots with heavy encrustations of refuge tunnels made with silk, leaf fragments, and frass from the larvae. Leaves were severely chewed, with only 1-5 mm of green lamina remaining and the shoot apex completely destroyed. Beever (Beever & Dugdale 1994) also reared *G. bipunctella* (Figure 48) on liverwort cushions from a forest remnant.

Figure 48. *Glucocharis bipunctella* adult male. Larvae of this species develop successfully on liverworts. Photo from Landcare Research, NZ, with online permission for non-commercial educational use.

Beever and Dugdale (1994) followed these observations by collecting larvae of *Glucocharis epiphaea* (Figure 47) in September and rearing them to adults on shoots of *Polytrichadelphus magellanicus* (Figure 49). *Glucocharis epiphaea* is an endemic that lives in the montane rainforests and alpine seepage areas in New Zealand.

Members of the **Acentropinae** make cases or tunnels (Yen 2016). Many are aquatic and feed on aquatic plants, including mosses. However terrestrial larvae live in portable cases or make tunnels under mosses or lichens. The pupa of the *Paracymoriza nigra* (Figure 50) group rests in a chamber-like cocoon under mosses. Larvae of *Nymphicula morimotoi* (Figure 51) in the Philippines occur along streams on stones and rocks with rich growths of liverworts in the **Jungermanniaceae** (Yoshiyasu 1997). Females of *Nymphicula morimotoi* in the laboratory laid eggs one by one between the leaves of the liverwort. The hatchlings spin fine soil particles around themselves to construct small cases.

In Australia, *Pyrausta cingulata* (syn=*Ennychia cingulalis*; Figure 52-Figure 53) lives among mosses and spins its web in them (Buchanan White 1971). This behavior was known more than a century ago in Europe, where its retreat is among mosses and dead leaves (Heyden 1861). It can be located by the large heaps of frass nearby.

Figure 52. *Pyrausta cingulata* larva, a species that lives among mosses and spins its web there. Photo by Bob Heckford, with permission.

Crambus tristellus (see Figure 54) occurs in damp locations along ditches where it makes silken galleries on mosses (Shield 1856). Other former members of *Crambus* (Figure 54) that dwell among mosses have been reclassified into a variety of genera. Buckler (1901) reported that members of *Crambus* feed among stems and roots of grasses or on moss (Stainton 1852), but these bryophages may now belong to other genera.

Figure 54. *Crambus pascuella* male adult. *Crambus tristellus* makes silken galleries on mosses in damp locations. Photo by Jérôme Albre, with permission.

Catoptria falsella (syn=*Crambus falsellus*; Figure 55) is a wall dweller (Doremi 2016a). The larva builds a silk tube that helps to hide it while it is feeding, typically on mosses, and especially on the moss *Tortula muralis* (Figure 56). This is the ultimate site for its pupation. Shield (1856) found larvae of *Catoptria falsella* in the unique habitat of mosses on thatch of a barn. This species primarily hides among mosses on walls, stones, and rocks in the daytime, feeding at night on mosses, including *Tortula muralis*, *Syntrichia ruralis* (Figure 57), *Barbula* (Figure 58), and *Brachythecium rutabulum* (Figure 59) (Wikipedia 2014). South (1890) reported *Catoptria verellus* (syn=*Crambus verellus*; Figure 60) among mosses on tree trunks, particularly older plum, apple, and poplar trees. The species also occurs in fir woods with moss-covered ground.

Chrysoteuchia culmella (= *Crambus hortuellus*; Figure 61) larvae build silken galleries on the ground under mosses (Shield 1856). Where it is damp along ditches, one can also find larvae of *Agriphila straminella* (syn=*Crambus culmellus*; Figure 62) with their silken galleries. The larvae mature there and spend their pupation there.

Figure 61. *Chrysoteuchia culmella* adult. Their larvae build their silken galleries under ground mosses. Photo through Wikimedia Commons.

Figure 62. *Agriphila straminella* adult; the larvae occur along damp ditches, including among mosses. Photo by André Karwath, through Creative Commons.

Huggins (2011) listed *Oxyelophila callista* (Figure 63) as a species of moss shredders, but these are aquatic mosses.

Figure 63. *Oxyelophila callista* adult; larvae are shredders of aquatic mosses. Photo by BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Some evidence that **Crambidae** live among mosses is indirect (Russell 1979). Their head capsules have been found numerous times in mosses on logs and deciduous tree trunks. Webbing and fecal pellets occur among damaged mosses. Based on this evidence, it appears that *Hypnum circinale* (Figure 64) and *Tetraphis pellucida* (Figure 65) are most likely eaten by larvae of **Crambidae** (formerly placed in **Pyralidae**).

Pyralidae – Snout Moths

There are few known bryophages remaining in this family in its more restricted definition. Fraenkel and Blewett (1947) suggested that some of this snubbery of the bryophytes may be due to the chemical composition. However, they failed to show that bryophytic linoleic acid was detrimental, and bryophyte arachidonic acid actually promotes growth of the larvae of *Ephestia kuehniella* (Figure 66-Figure 67).

Figure 66. *Ephestia kuehniella* larva, a species whose growth is promoted by arachidonic acid from bryophytes. Photo by Simon Hinkley and Ken Walker, Museum Victoria, through Creative Commons.

Synaphe punctalis (Figure 68) and *S. angustalis* (Figure 69) builds its scant webs among damp mosses on the ground (Meyrick 1895). In addition to these, in

Australia, *Phycis subornatella* lives among mosses and spins its web in it (Buchanan White 1971).

HESPERIOIDEA

Hesperiidae – Skippers

These lepidopteran differ from both moths and butterflies. They have short, fat bodies like moths, hooked antennae unlike the club antennae of butterflies or the feathery antennae of moths, and a unique rapid, skipping flight (Bartlett 2004; Wikipedia 2015c).

The skippers are generally not associated with mosses. However, *Polites mardon* (Figure 70-Figure 73) builds a larval shelter of silk with mosses, dry grass blades, litter, and dry frass serving to camouflage it (Henry & Beyer 2013). These are located at the bases of grasses near the soil surface.

PAPILIONOIDEA

Lycaenidae – Blues, Coppers, Hairstreaks, Harvesters (Butterflies)

Some Lepidoptera seem to have switched from feeding on leaves to feeding on the **epiphylls** (Figure 74) on the leaves (Callaghan 1992). It appears that in this case, the bryophytes, mostly the leafy liverworts in **Lejeuneaceae**, were an important food source. In a Nigerian cola forest, *Pentila picena cydaria* (Figure 75) lays its eggs singly on live trees. Its substrate includes not only the woody stems, but also green lichens and mosses. These eggs are initially white, but within a day they become dark brown, making them less conspicuous.

Figure 75. *Pentila picena* adult, a species whose larvae feed on epiphylls, including bryophytes. Adults include mosses among their oviposition sites. Photo by Sáfíán Szabolcs, with permission.

Nymphalidae – Brush-footed Butterflies

Singer and Mallet (1986) expressed excitement at finding *Euptychia insolata* (Figure 76) alighting on "green" tree trunks in Costa Rica. As they continued observations, they found six green spherical eggs, then observed the female ovipositing on the epiphytic moss *Neckeropsis undulata* (Figure 77). This species landed on tree trunks with green bryophytes, searching for oviposition sites. The larvae of this butterfly are well camouflaged on the moss. They are "moss-shaped" and moss-colored. This appears to be the first record for butterfly larvae that feed on a moss (Singer *et al.* 1983; Singer & Mallet 1986), but they were unable to determine if they were restricted to this moss species. Singer and Mallet (1986) were able to raise 5 adults from 6 eggs by using *Neckeropsis undulata* as the only food source. The larvae of this species are "moss-shaped" and have cryptic coloration, rendering them safe on this moss.

Figure 76. *Euptychia insolata* adult, a butterfly that oviposits on epiphytic mosses on tree trunks and its larvae eat there. Photo by Will & Gill Carter, with permission.

Figure 77. *Neckeropsis undulata*, oviposition site for *Euptychia insolata*. Photo by Bobby Hattaway, from <www.discoverlife.org>, through Creative Commons.

Hamm (2015) expressed surprise that members of *Euptychia* have switched from feeding on grasses to feeding on low-nutrient plants like *Selaginella* (a fern ally; Figure 78) and mosses (Scriber & Slansky 1981). On the other hand, Egorov (2007) concluded that the epiphytic mosses had sufficient nitrogen due to contributions from epiphytic *Cyanobacteria* (Figure 79) and the slow growth of the mosses. Furthermore, in experiments with *E. westwoodi* (Figure 80), Hamm (2015) found that the larvae would not eat grasses (*Lasiacis ruscifolia*, a preferred food of close relatives) when those were the only choice, losing weight and ultimately dying. Those fed with *Selaginella* ate and developed normally.

Figure 78. *Selaginella*, a fern ally that resembles a moss, has low nutrients, and serves as food for some species of *Euptychia*. Photo by Tim Waters, through Creative Commons.

Figure 80. *Euptychia westwoodi* adult, a species that will not eat grasses as larvae. Photo by Daniel H. Janzen, through Creative Commons.

The genus *Euptychia* occurs elsewhere in South America. Pulido *et al.* (2011) describe it as living in the mountain foothills and montane forests of the Andes in Colombia and Peru. Neild *et al.* (2014) described a new species from the Amazon Basin and the Guianas, describing the genus as occurring throughout the Neotropical region. This is a small butterfly and seems to generally have singular hosts among fern allies and mosses. Singer and Mallet (1986) predicted that we will eventually find that many South American *Euptychiines* feed on "lower" plants.

But not all members of *Euptychia* are bryophages. Beccaloni *et al.* (2008) reported that *Euptychia hilara* feeds on a member of *Poaceae* (grasses).

Bryophytes are often among a group of convenient locations for pupation. This is the case for the White Mountain Arctic butterfly (*Oeneis melissa semideia*; Figure 81) (Lucking 2000). Its larvae are night-active feeders, spending their day between or under rocks (Scudder 1874, 1889; Gradish & Otis 2015). Pupation, however, uses safe sites under rocks, moss, or soil. Male adults perch in areas with considerable Bigelow's sedge, the probable substrate for oviposition and food plant for the larvae (Scudder 1891, 1901).

Figure 81. *Oeneis melissa semidea* (White Mountain Arctic) adult, a species whose pupae often occur under mosses. Photo by Kent McFarland, through Creative Commons.

Some adult **Lepidoptera** provide very interesting mimics. The moth in Figure 82 resembles a leaf with epiphyllous liverworts (Figure 74). Is there some advantage to adding the liverworts? The leaf itself is brown, suggesting it may be high in tannins and not very palatable. Do the liverworts further discourage carnivory? Might the Lejeuneaceae they seem to mimic have secondary compounds that discourage "herbivory" (in this case on a fake)? Or do they just blend with leaves, hence avoiding larger carnivores such as birds?

Figure 82. Moth mimicking a leaf with epiphyllous bryophytes, especially liverworts, in Malaysia. Photo courtesy of Tamás Pócs.

The bog fritillary, *Boloria eunomia* (Figure 83-Figure 87), is of special concern in Wisconsin, USA (WDNR 2009). Its habitat is in classical acid bogs (Wikipedia 2011), a habitat that is diminishing. Schtickzelle and Baguette (2004) warn that glacial relict species such as this one are increasingly more vulnerable as their fragmented habitat becomes more and more rare. Typically, the *Sphagnum* (Figure 88) mosses provide the right conditions for the host plants. Natives of Scotland have been concerned about the conversion of the classic bog at Aucheninnes Moss to a landfill (Buglife 2011). This is the

location of the small pearl-bordered fritillary *Boloria selene* (Figure 89-Figure 92), a species of conservation concern, and the only site in Scotland for the sorrel pigmy moth *Enteucha acetosae* (Figure 93). A third species there, *Coenonympha tullia* (Figure 94-Figure 97), is listed as vulnerable in Europe. These moss-dominated bog habitats house many insects that are in danger of disappearing as these bogs disappear.

Some members of this family are so well adapted to living among mosses that their cryptic form and coloration has earned them the name of moss caterpillars. At least some of these unusual caterpillars are in the Western Hemisphere genus *Adelpha* (Figure 98-Figure 103). The earliest record of these seems to be that of Moss (1933) for *Adelpha melona leucocoma* larvae that resemble a moss. In Costa Rica, *Adelpha serpa celerio* resembles mosses on a twig (DeVries 1987). Wilmott (2003) cited several species in *Adelpha* that mimicked mosses, including *Adelpha leucophthalma leucophthalma* larvae that resemble moss-covered twigs. There seem to be multiple forms of these mimics, and those forms may contribute to their occurrences in different habitats, potentially leading to separation as species.

Rionidae – Tropical Butterflies

This small family of butterflies does not seem to have a common name.

The species *Sarota gyas* (Figure 104) in the tropics can be found on leaves of tracheophytes, but Mota *et al.* (2014) pointed out that these are not the real hosts. Instead, the larvae are there to feed on the **epiphylls** (Figure 74) – the non-nitrogen-fixing epiphylls (DeVries 1988). In one case, larvae on a member of the Urticaceae fed on leafy liverwort epiphylls in the **Lejeuneaceae** (Figure 74). Apparently the host tree is unimportant for either oviposition or larval feeding. These larvae have long setae that provide defense and they are camouflaged among the epiphylls.

Figure 104. *Sarota gyas* adult, a species whose larvae live on leaves of tracheophytes where they feed on epiphylls (Figure 74). Photo by Harold Greeney, through Creative Commons.

Summary

The **Tortricidae** include a few bryophyte associates, particularly those on tree trunks. The **Crambidae**, on the other hand, construct silken tunnels on mosses and grasses where they feed in safety. The subfamily **Scopariinae** is known as the moss-eating **Crambidae**. This family has been separated from the **Pyralidae** and few bryophyte associates remain in the **Pyralidae**. The **Hesperiidae** are skippers and seem to have only one member (*Polites mardon*) that associates with mosses. The **Lycaenidae** feed on the **epiphylls** on leaves, particularly the leafy liverworts in the **Lejeuneaceae**. In the **Nymphalidae**, *Euptychia insolata* adults are cryptically colored to be able to alight on moss-covered tree trunks without being obvious. These are butterflies and among the ones that feed on mosses. They may use the mosses as a source of nitrogen derived from their epiphytic **Cyanobacteria**. *Adelpha*, in the **Nymphalidae** also exhibits moss mimicry. Members of this family are common bog dwellers. The **Rionidae** has one member, *Sarota gyas*, that feeds on epiphylls such as members of the **Lejeuneaceae**, in particular to obtain nitrogen from the associated nitrogen fixers.

CHAPTER 12-15

TERRESTRIAL INSECTS:

HOLOMETABOLA – LEPIDOPTERA:

GEOMETROIDEA – NOCTUOIDEA

Figure 1. *Geometridae* larva eating *Hypopterygium tamarisci*. Photo by Adaises Maciel da Silva, with permission.

GEOMETROIDEA

Geometridae – Geometrid Moths (Inch Worms)

The **Geometridae** get their name from their larvae, popularly known as inch worms (Figure 2). The method of movement has suggested that the larvae are measuring the earth. This family has cryptic coloration as larvae (Figure 2) (Bodner *et al.* 2010). In the montane rainforest of southern Ecuador, the brown, green, and gray tones help them to blend with the montane rainforest. For example, *Phyllodonta semicava* (see Figure 3) and *Cargolia arana* (Figure 4-Figure 5) resemble the mossy bark where they live.

Figure 2. *Geometridae* larva "inching" along the stem. Photo by Jérôme Albre, with permission.

Figure 5. *Cargolia arana* adult with cryptic coloration. Photo by James Sullivan, with online permission.

In tropical montane rainforests of Brazil, larvae in the **Geometridae** are the culprits that feed on the mosses *Hypopterygium tamarisci* (Figure 7-Figure 14) and *Lopidium concinnum* (Figure 15), especially at the beginning of the rainy season (September to December)

(Maciel-Silva & dos Santos 2011). Using an index of damage (ID) in 2007 and 2008, Maciel-Silva and dos Santos found that *H. tamarisci* had higher damage (68%, 35%) than *L. concinnum* (38%, 23%) in these two years (Figure 6), but they were unable to separate that of the geometrid from that of a cohabiting snail. Furthermore, these rates were lower than those for tracheophytes. They found no correlation of herbivory with phenols, proteins, or the ratio between these (Figure 6).

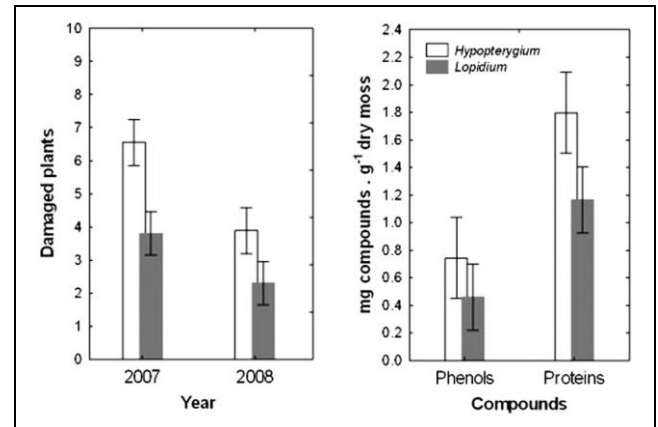

Figure 6. **Charopidae** (snail) and **Geometridae** damage to mosses in 10 colonies of plants. Modified from Adaises Maciel-Silva and Nivea Dias dos Santos.

Orthonama obstipata (= *Camptogramma fluviata*; Figure 16) is not a moss feeder as far as I can tell, but it does "retire" among mosses or just below the soil surface (Hellins 1871). One must wonder if the mosses are an important component of its niche. It constructs a cocoon that is weak, thin, and made of silk. Mosses may help to buffer the temperature and maintain moisture.

Figure 16. *Orthonama obstipata* adult, a species that "retires" among mosses, or in the soil just below them. Photo by Ben Sale, through Creative Commons.

Helastia mutabilis (Figure 17) larvae feed on mosses in eastern Otago, New Zealand (Patrick 2016). The larva of *Helastia mutabilis* feeds on the moss *Racomitrium* (Figure 18) in the local area of Otago, thus far the only known host plant for it.

Figure 18. *Racomitrium lanuginosum*. *Helastia mutabilis* larvae feed on members of this genus. Photo by Juan Larrain, through Creative Commons.

Perizoma taeniatum (= *Martania taeniata*; Figure 19) is one of the macro-moths that most likely feeds on mosses as larvae (Pescott *et al.* 2015). Pescott and coworkers expressed concern that air pollution is harming the lichens and bryophytes and may lead to the demise of those that feed on them.

Figure 19. *Perizoma taeniatum* adult, a species whose larvae apparently feed on mosses and may be harmed by loss of mosses and lichens due to air pollution. Photo by M. Virtala, through Creative Commons.

Eupithecia austeraria (Figure 20) pupae occur among mosses on stumps, close to the moisture of the rotting wood (Shield 1856). *Eupithecia irriguata* (Figure 21) spends its pupal winters under bark and mosses (Dietz 1871). Krampl (1994) reported *Eupithecia thalictрата* (Figure 22) pupation in cocoons, usually in dry mosses near the base of its host plants. The pupae overwinter and adults emerge that spring.

Figure 22. *Eupithecia thalictрата* adult, a species that pupates in dry mosses. Photo by Püngeler, through Public Domain.

Scotorythra paludicola (Figure 23) larvae don't eat mosses – they eat leaves and phyllodes of *Acacia koa* (Haines *et al.* 2013) and other members of the Fabaceae (Barton & Haines 2013). But the adults do use the mosses. The females lay their eggs in bark crevices and in mosses on the trunks of host trees, providing them with cover during development while keeping them close to their host leaves.

Figure 23. *Scotorythra paludicola* larva, a species that begins its life among mosses on *Acacia koa* where females lay eggs on tree trunks. The larvae then move to the leaves and phyllodes to feed. Photo by Forest Starr and Kim Starr, through Creative Commons.

Hyposidra talaca (Figure 24-Figure 25) lives in the tea plantations of northeastern India (Sinu *et al.* 2013). The species is a pest there, and the tree bark and its moss cover offer protection for the eggs of this species. This is one of the moths that oviposits in different places from the ones where it feeds (Wiklund 1977; Tammaru *et al.* 1995). Similarly, the Bruce spanworm (*Operophtera bruceata*; Figure 26-Figure 27) infests tree leaves, but the eggs are often laid among mosses growing at the bases of these trees (Ives 1984).

Figure 24. *Hyposidra talaca* larva, a pest in tea plantations. The female deposits eggs where they are hidden by mosses. Photo by Vaikoover, through Creative Commons.

Figure 27. *Operophtera bruceata* adult. Females lay their eggs among mosses at the base of trees. Photo by Cody Hough, through Creative Commons.

Not all bryophyte associates are drab browns and grays. *Milionia isodoxa*, although not a bryophyte dweller, does make use of them and is quite colorful. The adults of *Milionia isodoxa* (Figure 28) in Papua New Guinea illustrate the method that seems typical for obtaining water among many **Lepidoptera** (Wylie 1982). These moths probe and feed at moist sand and mud and in soil of puddle margins. Occasionally they obtain their water from mosses on rocks or on stream debris, but they do not drink from the free water itself.

Figure 28. *Milionia isodoxa* adult, a species that drinks from the moist mosses on rocks or along streams. Photo by David Polluck, through Creative Commons.

Camouflage is important, and even adults may rest where they are not easily seen. In New Zealand, *Declana griseata* (Figure 29) larvae feed on mistletoe that grows as a parasite in the trees, but as adults these moths rest on the mossy trunks of trees in the vicinity, blending with the color patterns there (Patrick & Dugdale 1997).

Figure 29. *Declana griseata* male adult, a species that rests on mossy tree trunks. Photo by Landcare Research, Manaaki Whenua, with permission.

Shaking a carefully removed clump of epiphytic moss may reveal the cocoon of *Odontopera bidentata* (Figure 30) attached to the tree trunk and looking like "dark whitey-brown paper with a few pieces of moss attached to it" (Shield 1856). The larvae are good mimics of lichens on a twig (Figure 31).

Figure 30. *Odontopera bidentata* adult showing its cryptic coloration for resting on bark. Photo by Donald Hobern, through Creative Commons.

Figure 31. *Odontopera bidentata* larva, a species that builds a cocoon on tree trunks, attaching mosses to it. This one is a lichen mimic. Photo by Kimmo Silvonen, with permission.

Hydriomena impluviata (syn=*Ypsipetes impluviaria*; Figure 32) pupates in mosses and Shield (1856) describes the method to look for them. He warns that one must remove the moss carefully from its bark substrate, starting at the moss tips and holding it on both sides. A sample the size of one's hand should be removed, then shaken to dislodge the black pupae. The moss should be kept intact as a sheet. Unfortunately, this method is quite destructive of the mosses.

Figure 32. *Hydriomena impluviata* adult, a species that pupates among mosses. Photo by Fvlamoen, through Creative Commons.

Erannis jacobsoni (Figure 33) larvae defoliate the trees in the spruce-fir forests of Russia (Тырова & Юрченко 1996). Outbreaks of this species are primarily in the "green-moss" types of these forests, suggesting that the mosses may be important in their life cycle, perhaps as a place for laying eggs. For example, Kinghorn (1952) found that the western hemlock looper lays eggs among mosses and that oviposition increases when the density of the mosses is greater. On the trees, having mosses grow to higher positions increases the correlation between egg density and height on tree. Kinghorn suggested that moss density might be the strongest single factor influencing the place where eggs were deposited.

Figure 33. *Erannis jacobsoni* larva, a species that defoliates trees in spruce-fir forests with abundant moss ground cover. Photo by Vladimir Petko, through Creative Commons.

The western hemlock looper, *Lambdina fiscellaria lugubrosa* (Figure 34), along the western coast of North America lays most of its eggs in mosses on tree trunks, branches, and logs (Hopping 1934; Carolin *et al.* 1864; Shore 1990). But in the forests of the interior, their preferred oviposition sites are on the pendant lichen *Alectoria* spp. (Figure 35) (Thomson 1958). *Lambdina fiscellaria fiscellaria* (Figure 36) usually lays its eggs singly, but sometimes these are in groups of 2 or 3 (Carroll 1956). These are typically placed on mosses and lichens on the tree trunk or under old bark scales, but also on mosses covering stumps and logs.

Figure 36. *Lambdina fiscellaria fiscellaria* larva. Photo from Pennsylvania Department of Conservation and Natural Resources, through Creative Commons.

Shepherd and Gray (1972) bemoaned the difficulty of counting the eggs (Figure 37) of the hemlock looper (*Lambdina fiscellaria lugubrosa*; Figure 34) that were attached to mosses. Finding it both tedious and inaccurate, they devised a more consistent method for this process. They treated moss samples with 0.5% NaOH for 1 minute to release the eggs. These were then washed and filtered out of the moss sample. A solution of 15% NaCl helps to separate other debris from the sample by flotation. Using this method, they were able to obtain density estimates with two standard errors.

Figure 37. *Lambdina fiscellaria* eggs on fir. Photo from Natural Resources Canada, Canadian Forest Service, with online permission.

Otvos and Bryant (1972) likewise tested methods for assessing the eggs present on mosses and bark. They tried a range of bleach solutions and found that a 2% bleach solution bath for 45 minutes would release eggs of *Lambdina fiscellaria* (Figure 38) eggs without deleterious effects.

Figure 38. *Lambdina fiscellaria* adult, the hemlock looper. Photo by D. Gordon E. Robertson, through Creative Commons.

Dobesberger (1989) developed a management plan for *Lambdina fiscellaria fiscellaria* (Figure 36). Dobesberger determined that only six midcrown branches were adequate to obtain an average sample number. More eggs were present on the midcrown area of the balsam fir, *Abies balsamea* (Figure 39), than on other substrates including ground mosses – mostly *Hylocomium splendens* (Figure 40), *Pleurozium schreberi* (Figure 41), and *Ptilium crista-castrensis* (Figure 42), as well as loose bark of paper birch and lichens in the crown (mostly *Usnea longissima*; Figure 43).

Figure 43. *Usnea* sp., one of the substrates for egg laying of *Lambdina fiscellaria fiscellaria*. Photo by T.cegy, through Creative Commons.

Eggs of *Lambdina fiscellaria lugubrosa* (Figure 34) in coastal forests of British Columbia, Canada, could be sampled at 6-7 m intervals from the ground level to the top of tree trunks by sampling the mosses (Richmond 1947). When defoliation averaged 82%, the egg count was 226 healthy eggs per 30 cm square of moss from ground level

to the top of the tree at 27 m elevation. But at 427 m, the mean defoliation dropped to 10% and the egg count to 0.3 eggs per 30 cm square of moss.

But why are the entomologists so interested in counting eggs of this species on mosses? Feeding on the leaves by the hemlock looper can devastate a hemlock forest in only one year, fir trees in 2-3 (USDA 2016). Hébert *et al.* (2003) found that the outbreaks of *Lambdina fiscellaria* (Figure 38) have a sudden rapid increase and patchy distribution across wide areas. This means that predicting where control is needed can be difficult. To be prepared, it is necessary to conduct egg surveys, a tedious and expensive process. But Hébert and coworkers found a simpler means. They used white polyurethane foam substrates with the Luminoc insect trap and a portable light trap. These oviposition traps were highly efficient for sampling eggs and the results were highly correlated with those of extracting eggs from mosses on 1-m branches.

Otvos and Bryant (1972) pointed out the importance of assessing *Lambdina fiscellaria* eggs (Figure 37), present September to June, as a means to help them prepare for potentially devastating years. The larvae that cause the damage are present for only two weeks before the damage becomes serious. By counting eggs, managers can assess and prepare for the upcoming year. These larvae are able to cause great damage not by fully consuming leaves, but by nibbling the ends of leaves, causing rapid and permanent desiccation (USDA 2016).

But all is not well for the eggs of the eastern hemlock looper (*Lambdina fiscellaria fiscellaria*; Figure 36). A pest on the balsam fir, *Abies balsamea* (Figure 39), the eggs (Figure 37) of this species are subject to parasitism (Otvos 1977). Otvos experimented with these in the lab using eggs collected on the peat moss *Sphagnum* spp. (Figure 44), the lichen (*Usnea* sp.; Figure 43) and on birch bark (*Betula* spp.; Figure 45). Otvos found that the percentage of mortality for overwintering eggs is inversely related to the difference between the mean winter temperature and normal winter temperature. Mortality from parasites was about the same for eggs collected in autumn and spring.

Figure 45. Birch (*Betula*) bark where *Lambdina fiscellaria fiscellaria* deposits eggs. Photo by Sue Sweeney, through Creative Commons.

The hemlock looper also uses mosses for pupation. *Lambdina fiscellaria somniaria* (Figure 46-Figure 48) uses both mosses and bark crevices on the lower branches and tree trunks as well as debris on the ground near the host trees, providing them with protection during this stage (Willhite 2013). In Alaska, when it is time for pupation, the full-fed larvae of *Lambdina fiscellaria* extend a silken thread and descend from the conifer needles to the ground where they pupate under mosses or bark scales or in crevices of rotting tree stumps (Torgersen & Baker). In 14-20 days the adult emerges.

LASIOCAMPOIDEA

Lasiocampidae – Snout Moths

Norman (1871) noted that *Macrothylacia rubi* (as *Lasiocampa rubi*; Figure 49-Figure 50) larvae swarm on mosses in autumn in Morayshire, Scotland. These larvae are known to the ophthalmologists because their hairs cause conjunctivitis of the eye.

Figure 49. *Macrothylacia rubi* female adult. In Scotland, larvae of this species swarm on mosses in autumn. Photo by Jérôme Albre, with permission.

Figure 50. *Macrothylacia rubi* female adult. Larvae of this species swarm on mosses in autumn in Scotland. Photo by Jérôme Albre, with permission.

Some of the interactions get complicated. *Bracca* sp. occurs on the ground where moss and leaf litter are common in their habitat between tree buttresses (Brown 2006). What makes this interesting is that the *Bracca* sp. mimics the coral snake (*Hemibungarus calligaster*) in the Philippines. These two species share this habitat.

NOCTUOIDEA

Arctiidae – Tiger Moths etc.

You may be familiar with this family through the woolly bear caterpillar. Few members of the family seem to be bryophyte dwellers. Nevertheless, I have already noted that the subfamily **Lithosiinae** eat bryophyte capsules (Liu 1989 in Fang & Zhu 2012). Yuanfu (1989) concluded that the large number of species and individuals in this family that occur in the tropical mountain rainforest of Hainan Island can "be explained" by the large number of mosses and lichens here.

The larvae of *Cybosia mesomella* (Figure 51-Figure 52) (sometimes placed in **Erebidae**) consume liverwort leaves, particularly the genus *Jungermannia* (Figure 53), as well as lichens (Coutin 2004). Some of the larvae of the lichen moths (**Lithosiinae**) (e.g. *Hypoprepia miniata*; Figure 54-Figure 55) feed on mosses as well as algae and lichens (Rawlins 1984; Anonymous 2011). Members of this subfamily normally feed on cryptogams such as algae, lichens, and bryophytes, eating only the photosynthetic partner in the lichens (Simonson 2016).

Figure 55. *Hypoprepia miniata* adult. Photo by Tom Peterson, Fermilab, through Public Domain.

In northern Europe *Nudaria mundana* (Figure 56) larvae feed on both lichens and liverworts growing on rocks (Forster & Wohlfahrt 1960).

Figure 56. *Nudaria mundana* adult; larvae feed on lichens and liverworts on rocks. Photo by James K. Lindsey, with permission.

Erebidae

Many of the bryophyte-feeding species have been removed from **Arctiidae** and placed in **Erebidae**, whereas other systematists keep them in **Arctiidae**. I have chosen to list them under **Erebidae** because the majority of bryophyte feeders are grouped here. My usual source for nomenclature, Encyclopedia Online, is inconsistent in its placement of them.

Atolmis rubricollis (Figure 57-Figure 59) is one of these species. Its larvae feed on mosses and lichens growing on the trunks of trees (epiphytes) (Shield 1856; Dincă 2005). Hence, it is not surprising that the pupae occur under moss, but on decaying trees. *Atolmis rubricollis* is a tiny, inconspicuous moth that makes its winter cocoon in mosses and litter (Coutin 2004).

Figure 59. *Atolmis rubricollis* adult, emergent from a pupa that overwinters in mosses and litter. Photo by Sanja565658, through Creative Commons.

Larvae of both *Miltochrista miniata* (Figure 60-Figure 62) and *Lithosia quadra* (Figure 63-Figure 64) are bryophyte and lichen feeders in Romania (Dincă 2005). Likewise, *Dysauxes ancilla* (Figure 65-Figure 67) and the genus *Eilema* include bryophytes in their larval diet there, including *E. lurideola* (Figure 68-Figure 70), *E. complana* (Figure 71-Figure 72), *E. pseudocomplana* (Figure 73), and *Eilema sororcula* (Figure 74-Figure 76). In addition to these, Wagner (2016b) adds *E. morosina* (Figure 77-Figure 80) as a species that includes mosses in its diet in Europe.

Hypercompe scribonia (syn. = *Ecpantheria deflorata*; Figure 81-Figure 82) actually eats the thallose liverwort, *Conocephalum conicum* in western Indiana, USA (Figure 83) (Spencer *et al.* 1984). It normally feeds on two species of *Plantago* (Figure 84), a seed plant, and Spencer and coworkers suggest that the surface is similar to that of the liverwort and the two plants grow intermixed, possibly causing the shift despite major differences in chemistry. They noted this liverwort feeding behavior in the autumn, which suggests the possibility that the chemical shift may be a means of preparing for winter. Nevertheless, they raised several larvae to adults in the lab, using *C. conicum* as the only food source.

Figure 81. *Hypercompe scribonia* larva, a herbivore on *Conocephalum conicum*. Photo by Micha L. Rieser, through Creative Commons.

Figure 84. *Plantago major*, a genus that is normal food for *Hypercompe scribonia*. Photo by Olivier Pichard, through Creative Commons.

The secondary compounds of *Conocephalum conicum* (Figure 83) are well known. This liverwort is rich in mono- and sesquiterpenoids (Asakawa *et al.* 1976; Markham & Porter 1978; Spencer 1979). We also know that some terpenoids from liverworts inhibit Lepidoptera feeding (Wada & Munakata 1971). *Plantago* (Figure 84), on the other hand, is rich in iridoid glycosides (Jensen *et al.* 1975). It is possible that whatever permits the larvae to feed on the toxic glycosides also permits them to feed on the terpenoids in liverworts.

The **Lithosiini** have been known from several studies as bryophyte feeders (Forbes 1960; Holloway 1988; Aba 2013). Moreno *et al.* (2014) summarized feeding in the family by stating that the members of the tribe **Arctiini** feed on a wide range of plant species whereas the **Lithosiini** specialize on lichens, algae, and bryophytes (Wagner 2009).

Several species of Tribe **Lithosiini** resemble **Microlepidoptera** as adults (Coutin 2004). Furthermore, the larvae consume liverworts. Larvae of *Thumatha senex* (Figure 85) likewise consume liverwort leaves, particularly the genus *Jungermannia* (Figure 53), as well as lichens. Manley (2009) treated *Thumatha senex* as a nighttime cryptogam feeder that includes mosses in its diet (Macek *et al.* 2007; Manley 2009).

Lymantriidae – Tussock Moths

Lymantria dispar (Figure 86-Figure 87), the gypsy moth, spins threads over its retreat in a crack in the bark (Rennie 1857). Occasionally they may use a curtain of moss such as *Hypnum* (Figure 88) growing there instead of spinning these threads.

Noctuidae – Owlet Moths

Haines and Renwick (2009) summed up the paucity of bryophagous insects. They considered that three deterrents were responsible for their limited consumption: chemical defenses, low digestibility, and low nutrient content. They examined this phenomenon by testing pre and post-ingestive defenses of four species of mosses [*Bryum argenteum* (Figure 89), *Climacium americanum* (Figure 90), *Leucobryum glaucum* (Figure 91), *Sphagnum warnstorffii* (Figure 92)]. Even when they had no other choice, larvae of *Trichoplusia ni* (cabbage looper; Figure 93-Figure 94) ate considerably more lettuce or wheat germ than they did any of the moss species. Post ingestive responses could only be evaluated in *C. americanum* because the larvae ate too little of the other species for evaluation. Digestibility, assimilation, and overall utilization efficiency did not differ between lettuce and *C. americanum*. In disk choice experiments, ethanol extracts of *Leucobryum glaucum* were deterrent, explaining why this was the least consumed moss in the experiment and providing evidence of pre-ingestive mechanisms. The hypotheses of poor nutrient content and low digestibility were not supported in these experiments.

Several species in Romania feed on mosses (Dincă 2005). These include *Parascotia fuliginaria* (Figure 95), *Calymma communimacula* (Figure 96), *Cryphia receptricula* (Figure 97), and *Cryphia raptricula* (Figure 98). Wagner (2016a) also includes *Cryphia muralis* (Figure 99) and *C. algae* (Figure 100-Figure 102) among the moss feeders in Europe.

Kimmo Silvonen (pers. comm. 1 March 2016) told me about *Caradrina montana* (Figure 103) in Europe. He found this larva on a rocky hill on a moss. It accepted the moss as food during rearing, but it may be a polyphagous species that eats a variety of plants. Among these, it feeds on alfalfa leaves in northwestern North America (McLeod 2005).

The feeding of *Agrotis* sp. (Figure 104) on moss capsules (Figure 105-Figure 106) of *Haplocladium microphyllum* (Figure 107) is well documented. Fang and Zhu (2012) experimented to see what else they would eat and found they would feed to various degrees on capsules of *Ditrichum pallidum* (Figure 108), *Funaria hygrometrica* (Figure 109), *Physcomitrium sphaericum* (Figure 110), *Pogonatum inflexum* (Figure 111), and *Trematodon longicollis* (Figure 112). The latter two species were only sparsely grazed and caused a high mortality rate. Fang and Zhu suggested that the lipid content may be important in their selection.

Figure 112. *Trematodon longicollis* capsules that serve as food for *Agrotis*. Photo by Bobby Hattaway, through Creative Commons.

Agrotis sp. avoids the capsules of *Pogonatum inflexum* (Table 1; Fang & Zhu 2012). On the other hand, when only *Haplocladium microphyllum* was available as food, a late-instar larva consumed 190 capsules (Figure 113). Similar herbivory occurred on *Physcomitrium sphaericum* and *Funaria hygrometrica* (Figure 113) Fang and Zhu compared the phenolic content (Figure 114) and nutrient content (Figure 115) among several mosses. They found that These capsules contained significantly more lipids than the tracheophyte leaves from the same environment (Figure 115).

Table 1. 24-hour consumption of moss capsules in three samples of 30 capsules each by an individual *Agrotis* sp. in early, mid, and late instar stages. Based on Fang & Zhu 2012.

	instars		
	early	mid	late
<i>Haplocladium microphyllum</i>	30	– 30	– 30
<i>Funaria hygrometrica</i>	30	– 30	– 30
<i>Physcomitrium sphaericum</i>	30	– 30	– 30
<i>Trematodon longicollis</i>	30	– 30	– 28
<i>Ditrichum pallidum</i>	30	– 2	– 3
<i>Pogonatum inflexum</i>	5	– 4	– 7

Larvae of the green mahoe moth (*Feredayia graminosa*; Figure 120-Figure 123) in New Zealand feeds on mahoe (*Melicytus ramiflorus*; Figure 124), a woody member of the violet family (Harris 2015). But when it becomes an adult, it rests on tree trunks, where its 18 mm length makes it very obvious on white bark. Fortunately for these moths, they are able to seek out epiphytic mosses on these trees, resting on them during the day undetected because their cryptic coloration hides them from the casual view of avian predators. They feed at night when their predators are sleeping. The males smell like vanilla and use their enlarged hind wings to fan this odor over females during mating.

Rennie (1857) discovered interesting behavior of a species of the moth in the genus *Bryophila* (Figure 125-Figure 126). This caterpillar is small and feeds on minute mosses and lichens on old walls. It builds its cocoons from moss branchlets cut into suitable lengths, including a portion of earth with these detached pieces (Figure 126). In making its cocoon, it arranges the earth on the inside and moss on the outside to make a vault. If this species is

deprived of soil in the lab, but provided with moss, it will build a hollow ball by interweaving the moss.

Shield (1856) reported that larvae of *Bryophila domestica* (= *Cryphia domestica*; Figure 125) include bits of mosses in their webbing (Figure 126). They bite their way out of these cocoons when the weather is warm, returning to them and resealing them when it is again too cold. The included mosses and other bits help to conceal them while they are in hiding. Shield observed them biting off bits of moss and weaving them between the threads of silk, completely hiding the larva inside.

Figure 125. *Bryophila domestica* adult, a species whose larvae include mosses in their webbing. Photo by Ian Kimber, with permission.

Figure 126. *Bryophila domestica* (maybe) nest with mosses and caterpillar. Image by James Rennie (book from 1800's), through public domain.

Acronicta myricae (see Figure 127) is also among the moths that spin silken cocoons, in this case covered with mosses (Buckler 1871).

Figure 127. *Acronicta euphorbiae* larva; *Acronicta myricae* builds its cocoons on mosses. Photo by Harald Süpfle, through Creative Commons.

We don't always know the role of the mosses, and they may only be indicators of a suitable environment. For example, in areas with boreal forest, *Xestia rhaetica* (Figure 128) is distributed in the old, moist spruce forests where mosses form a thick layer (Mönkkönen & Mutanen 2003). But what is the role of these mosses, if any?

Figure 128. *Xestia rhaetica* adult, an occupant of old, moist spruce forests with a thick layer of mosses. Photo by Dumi, through Creative Commons.

Now there appears to be a new noctuid added to the bryophages. Timea Deakova has sent me images that appear to be those of *Noctua pronuba* (Figure 129-Figure 130). A hoard of these hungry larvae devoured a large portion of her experiments on nitrogen. Could it be the nitrogen in the experiment or do these larvae just like mosses?

Figure 129. *Noctua pronuba* larva eating *Bryum capillare* and surrounded by frass. Photo courtesy of Timea Deakova.

Figure 130. *Noctua pronuba* larva on *Polytrichum juniperinum*. Photo courtesy of Timea Deakova.

Summary

In the **Geometridae**, larvae are often colored to blend with their surroundings (including bryophytes), having patterns of brown, green, and gray. Some of these larvae can do considerable damage to the bryophytes, particularly mosses, through herbivory. Some overwinter among mosses as pupae. Others lay eggs on mosses, close to the tree leaves that are eaten by the larvae. And some use the water associated with the bryophytes. The hemlock looper often lays eggs among mosses, then becomes a nuisance when its larvae migrate to conifer leaves and consume the leaf tips, killing the leaves.

One member of the **Lasiocampidae** swarm on mosses in autumn – for whatever reason. Few of the **Arctiidae** are bryophyte associates, but some members of the subfamily **Lithosiinae** eat bryophyte capsules. Other members feed on liverwort leaves or moss leaves. The **Erebidae**, sometimes included in the **Arctiidae**, includes most of the bryophyte dwellers that were once **Arctiidae**. **Lymantridae** sometimes use mosses in place of making a web to hide themselves.

Some **Noctuidae** find bryophytes distasteful; in *Climacium americanum*, digestibility, assimilation, and overall use efficiency did not differ from that of lettuce, but there was far more consumption of lettuce. However, some species do feed on mosses. And a species of *Agrotis* feeds on moss capsules, but avoids those of *Pogonatum inflexum*. In fact, the other moss capsules contained more lipids than the local tracheophytes. Some species also use mosses for pupation sites. And some adults have coloration that permits them to rest on tree-trunk bryophytes without being seen easily. Some species incorporate bryophytes in their cocoons.

Acknowledgments

Thank you to John Steel for his continued support and for sending me articles from the Otago Daily Times about

Lepidoptera associated with mosses. Timea Deakova has generously shared ongoing research and images with me. Thank you to Rui-Liang Zhu for sharing research and images from his lab with me. Adaisies Maciel-Silva provided me with images from research in his lab. Once again, I appreciate all the photographers who have placed their images in Creative Commons or given me permission for use. Scott Zona alerted me to the wonderful image of the lampet moth caterpillar.

CHAPTER 12-16

TERRESTRIAL INSECTS:

HOLOMETABOLA – MECOPTERA

Figure 1. *Boreus hyemalis*, female, among *Polytrichum piliferum*, Thetford Warren Lodge, Norfolk, UK. Photo by Brian Eversham, with permission.

MECOPTERA – SCORPIONFLIES

The **Mecoptera** comprise a small order of about 550 known species (Wikipedia 2016), 9 families, and 32 genera (Byers & Thornhill 1983). They were more abundant in the Permian, Mesozoic, and Tertiary periods, with 348 species in 87 genera and 34 families known. They are known as scorpionflies because of the position of the

Scorpionfly larvae (Figure 2) are among those that live in mosses (as well as damp soil) (Miall 1902). It is interesting that many of the relatively few **bryophagous** animals (including arthropods) often show unusually high levels of winter activity. Larvae of snow scorpionflies (**Mecoptera: Boreidae**) are active **ONLY** in the winter in temperate regions, hopping about and even mating on the snow (Figure 3). Some insects, including gall aphids, move from a summer angiosperm host to a winter moss host. Could these snow scorpionflies and gall aphids, and probably other insects, be sequestering compounds from mosses that allow them to remain active at sub-freezing temperatures? Aside from chemistry, the correlation

between bryophagy and cold weather could be explained by the simple fact that mosses remain green throughout the winter, and therefore might become a more attractive host plant during this period. Or do the winter-active fauna simply have the right enzymes or gut pH to permit them to gain nutrients from mosses and survive by being active at a time of year when predators are limited in their activity?

Choristidae

Tillyard (1926) was among the early reporters on the relationship of the **Mecoptera** with bryophytes. He considered the Australian *Choristes* to be both a bryophyte resident and a **bryophage** (eats bryophytes). However, this genus name has been pre-empted by other phyla (the genus *Choristes* is a sea snail in the Gastropoda) and was changed to *Chorista* (Figure 4) in the **Mecoptera** (see <<http://direct.biostor.org/reference/80557.text>>).

Figure 4. *Chorista australis* adult, a bryophyte dweller and bryophage. Photo by John Tann, through Creative Commons.

Chorista is a small genus of only two apparent species. Its family, the **Choristidae**, lives among mosses as larvae (Wikipedia 2015). The larvae are unusual among holometabolous insects in having **compound eyes** with ommatidia, a trait shared by the scorpionflies *Neopanorpa* (Figure 93) and *Panorpa* (Figure 94), both in the **Panorpidae** and also bryophyte dwellers (Ramel 2016). Compound eyes are best at detecting motion. Could it be that living among bryophytes selects for these compound eyes in an environment where there is limited light and many of the inhabitants tend to blend in until they move?

The food of *Chorista* (Figure 4) seems to be contested, or perhaps just wide ranging. Tillyard (1926) considered them to eat mosses. On the other hand, in the lab both larvae and adults fed on dead insects, fresh fruit, strained carrots, and beef (Bush 1967; Byers & Thornhill 1983).

Members of *Chorista* (Figure 4) oviposit loose clusters of eggs, using pre-existing cavities in moist soil (Miyake 1912; Tillyard 1926; Byers 1963; Riek 1970). We need to look for the eggs among or under the bryophytes as well. If the larvae feed on bryophytes, surely the eggs must be near the host plants.

Boreidae

The family **Boreidae** has only three genera (Cannings & Scudder 2005). *Boreus* (Figure 1, Figure 3, Figure 5-Figure 14, Figure 18-Figure 20, Figure 24, Figure 27) has 14 known species in Eurasia and 12 in North America; only two of these are in the eastern USA. *Hesperoboreus* (Figure 89) has only two species, confined to western North America from Washington to California. *Caurinus* (Figure 28-Figure 30, Figure 38-Figure 39) has two species, one occurring only in Oregon and Washington, USA, and another in Alaska. Both larvae and adults of the **Boreidae** feed exclusively on bryophytes (Russell 1979a, b). Because of their small size and clandestine habitat, it is likely that more species await our discovery.

The **Boreidae** are small (2-5 mm), dark-colored mecopterans and are most easily seen when they are on the snow (Figure 5) (Byers 2002). They resemble fleas, but use their legs to propel them. When they land, they tuck their legs against their bodies (Figure 6) and resemble a bit of dirt on the surface of the snow. The dark body color (Figure 5-Figure 13) may help them to maintain sufficient temperature when they are bouncing around on snow (Cannings & Scudder 2005).

Figure 5. *Boreus brumalis* on snow. Photo by J. Mihuc, through Creative Commons.

Figure 6. *Boreus brumalis* adult, showing the legs tucked against the body as they are when the adults land after a hop. Photo by Tom Murray, through Creative Commons.

The **Boreidae** are boreal, with the adults appearing in winter or at high elevations. They are sufficiently different from other **Mecoptera** that some systematists consider them to be a separate order, the **Neomecoptera** (Cannings & Scudder 2005). The larvae lack both abdominal prolegs and conspicuous dorsal setae. They have lateral eyes and usually have three **ommatidia** (units of the compound eye) per eye.

Several researchers have provided lists of moss species from which boreids have been collected or on which they have been reared (e.g. Svensson 1972; Cooper 1974; Penny 1977). Both larvae and adults in the **Boreidae** feed on mosses (Svensson 1972; Cooper 1974; Penny 1977; Byers & Thornhill 1983). But Brauer (1863 in Carpenter 1931) found that they also feed on other small animals that live among the moss rhizoids. And Penny (2006) stated that they feed on leaves of mosses, club mosses (*Selaginella*?), and liverworts as adults, but feed on the rhizoids of these same plants as larvae. They seem to require little food (Withycombe 1926), but need "a great deal of moisture" (Penny 2006). Penny (1977) concluded that **Boreidae** prefer mosses that form low, compact cushions with their rhizoids tightly matted. The loose mats, which had fewer **Boreidae**, may have more predator **Carabidae** beetles. Or they may lose moisture too quickly.

In contrast to *Chorista* (Figure 4), the **Boreidae** oviposit single eggs or small clusters in the soil surrounding moss rhizoids (Cooper 1974; Penny 1977; Byers & Thornhill 1983). Some deposit eggs among epiphytic bryophytes (Russell 1979a; Byers & Thornhill 1983).

As one might guess for a boreal species that hops about on the snow, temperature is an important parameter in the niche of **Boreidae** (Byers & Thornhill 1983), even more important than light (Cooper 1974). Nevertheless, the minimum temperature for adult activity is close to 0°C (Sauer 1966; Svensson 1966; Penny 1977; Byers & Thornhill 1983). When their mossy habitat becomes dry,

the boreid larvae may go as much as 20 cm down into the soil below the mosses to attain suitable humidity (Strübing 1950).

Scorpionfly larvae [*Boreus* (Figure 1, Figure 3, Figure 5-Figure 14, Figure 18-Figure 20, Figure 24, Figure 27), *Caurinus* (Figure 28-Figure 30, Figure 38-Figure 39)] feed on moss cushions on trees in damp woodlands (Penny 1977; Russell 1979a, b; Shorthouse 1979), making mosses their principal food. Adults of the family **Boreidae** are well known for their moss diet (Cooper 1974; Penny 1977).

Boreus

Although *Boreus* (Figure 1, Figure 3, Figure 5-Figure 14, Figure 18-Figure 20, Figure 24, Figure 27) seems always to be associated with mosses, its distribution is clearly not limited by its host mosses, but rather by some other parameter of its environment that is more restrictive (Cooper 1974). I suggest that limitation is moisture, combined with bryophytes that are suitable food. Both larvae and adults of *Boreus* eat mosses (Withycombe 1922; Fraser 1943; Strübing 1950; Svensson, 1966; Hågvar 2010).

Boreus brumalis (Figure 7, Figure 13) includes the mosses *Dicranella heteromalla* (Figure 8-Figure 9) and *Atrichum angustatum* (Figure 10-Figure 11) in its diet in Illinois, USA (Webb et al. 1975) and New England, USA (Maier 1984).

Figure 7. *Boreus brumalis* male showing modified wings that are used to clasp the female. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Figure 10. *Atrichum angustatum*, home and food for *Boreus brumalis*. Photo by Michael Lüth, with permission.

Figure 11. *Atrichum angustatum*, home and food for *Boreus brumalis*. Photo by Michael Lüth, with permission.

Desiccation can be a problem, and the moss habitat would seem to be ideal for these organisms. It typically stays moist longer than other kinds of plants, it provides cover against not only desiccation but also many kinds of predators, and it is a food source. Furthermore, being flightless, it is an advantage to have your food and cover in the same place.

This genus has a somewhat different mating behavior from that of other **Mecoptera** (Byers 2002). The male has slender, hardened wings that he uses to grasp the female (Figure 7). He manipulates her to a position above his back (Figure 12) with the lower part of her ovipositor inserted into his ninth (genital) segment (Figure 12) (Cockle 1908).

Figure 12. Mating pair of the snow scorpionfly, *Boreus westwoodi*. Note the female is on top of the male, held by two wings of male. Photo by Barbara Thaler-Knoflach, with permission.

Boreus brumalis (Figure 7, Figure 13) feeds primarily on bryophytes (Gerson 1982). Shorthouse (1979) determined that both larvae and adults of *Boreus brumalis* (Figure 13) in Ontario, Canada, eat the bryophytes in the winter under the snow.

Figure 13. *Boreus brumalis* female adult on snow. Photo by Tom Murray, through Creative Commons.

Boreus hyemalis (Figure 1, Figure 14), an inhabitant of heaths and moors, is well known for its habitation of mosses (Plant 1994; Winnall 2009). Nevertheless, because of this seclusion, it is often overlooked (Whitehead 2010). This insect is flightless (Hågvar 2010) and can be seen moving about on the snow in exposed locations. Carpenter

(1931) reported that adults could be seen in spring and early summer among moss rhizoids and under stones, but that their activity is confined to winter. On sunny winter days they hop on the snow, as far as 15 cm in a single leap.

Figure 14. *Boreus hyemalis* in moss at Ellerburn Beck, UK. Photo by Roger S. Key, with permission.

Bingham (2012) found that the typical habitat for *Boreus hyemalis* (Figure 1, Figure 14) in Wyre Forest (UK) seemed to be oak woodlands or other open woodlands with sparse ground flora to compete with the mosses, mostly *Polytrichastrum formosum* (Figure 15) and *Dicranum scoparium* (Figure 16). He also perceived a possible connection between acid woodland and the presence of *B. hyemalis*.

Figure 15. *Polytrichastrum formosum*, home of *Boreus hyemalis*. Photo by David T. Holyoak, with permission.

Figure 16. *Dicranum scoparium*, home for *Boreus hyemalis*. Photos from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Boreus hyemalis (Figure 1, Figure 14) lays its eggs among mosses and the larvae make tunnels between the moss and the substrate – soil, logs, walls (Russell 1979a). Although many entomologists have reported this species from the mosses, only Fraser (1959) has identified the moss used for oviposition as *Polytrichum commune* (Figure 17). Most likely other species of bryophytes are also used. Carpenter (1931) observed that the larvae eat both moss "roots" and liverworts.

Figure 17. *Polytrichum commune*, home and oviposition site for *Boreus hyemalis*. Photo by Michael Lüth, with permission.

Boreus in Norway takes advantage of mosses to provide protective space. This is a safe space in which they lay their eggs (Hågvar 2001). And it appears that mosses might be a site of copulation (Figure 12), an event rarely observed on the snow (Figure 3). The chambered air spaces most likely also provide space for this winter-active scorpionfly to move about in safety. Adults of *B. elegans* (Figure 18) and *B. californicus* (Figure 19-Figure 20) feed on *Racomitrium heterostichum* (Figure 21); larvae and pupae of *B. elegans* can be found under *Brachythecium* (Figure 22) and other mosses (Russell 1979a). Russell (1979a) has found *B. elegans* on mosses on a north-facing roadcut, in mosses near a hillside spring, and among mosses on logs in a coastal forest in the Pacific coastal states, USA. Both larvae and pupae were present under a mat of *Brachythecium* sp. and other mosses.

Figure 22. *Brachythecium rutabulum*, home for *Boreus elegans*. Photo by Michael Lüth, with permission.

Boreus californicus (Figure 19-Figure 20) occurs primarily east of Cascade Mountain (Russell 1979a). In western Oregon, it seems to occur in more open, rocky sites than *B. elegans* (Figure 18), but in some sites both species occur. Larvae of *B. californicus* also occur in soil under mosses in crevices of jointed basalt and under moss among grasses in deep sandy loam on a stream bank. In California, Penny (2006) found *B. californicus* on the tightly compacted *Grimmia* (Figure 23).

Figure 23. *Grimmia longirostris*, exhibiting the compact cushion character of many **Grimmiales**. Photo by Hermann Schachner, through Creative Commons.

Boreus reductus (Figure 24) is likewise east of the Cascades, but in semi-arid regions of the Northwest (Russell 1979a, b). Although the larvae usually inhabit mosses (Russell 1979a, b), they can also occur in mats of *Selaginella* (Figure 25-Figure 26), a moss look-alike that is related to club mosses (tracheophytes) (Penny 1977).

Figure 24. *Boreus reductus* female, a species east of the Cascades that eats mosses and *Selaginella*. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Figure 26. *Selaginella wallacei*, home for *Caurinus dectes*. Photo by Paul Slichter, with permission.

In Fennoscandia, *Boreus westwoodi* (Figure 3, Figure 12, Figure 27) and *B. hyemalis* (Figure 14) larvae develop in the soil that occurs among the mosses (Hågvar 2010). The adults hatch in autumn before the new snow becomes established. Each adult migrates in its own separate and fixed direction by continuous jumping, achieving 1.2 m per minute (Hågvar 2001). The adults spend most of winter below the snow, among the mosses. On warmer days when the temperature is just above freezing, they climb tree trunks to reach the snow surface where they hop about. Jumping about on sunny, cloudless days may be risky because the temperature is likely to drop rapidly as the sun sets.

Figure 27. *Boreus westwoodi* adult female on one of the mosses where it lives. Photo by Petr Kočárek, with permission.

These adults lay eggs throughout the winter (Hågvar 2001) and *Boreus hyemalis* (Figure 14) is able to produce a maximum of 320 eggs per female (Steiner 1937). They oviposit in mosses in the **subnivean** (beneath snow) air spaces (Hågvar 2001), laying 1-2 eggs at a time (Withycombe 1922; Strübing 1950; Svensson 1966; Cooper 1974). Larvae develop there, feeding on the mosses, and continue to feed on them as adults.

Caurinus

I was delighted when, in January of 2008, David Wagner sent me a note about his former student who had studied a small boreid, *Caurinus dectes* (Figure 28-Figure 30) (Russell 1979a, b, 1982). Unlike *Boreus* (Figure 1, Figure 3, Figure 5-Figure 14, Figure 18-Figure 20, Figure 24, Figure 27), this insect feeds primarily on liverworts! Wagner helped me contact his former student, Loren Russell, who has been very helpful in providing me with further information. Russell learned how to find his study insect by a change in the branching pattern of the leafy liverwort, *Scapania bolanderi* (Figure 31), the preferred food of the boreid (David Wagner, pers. comm. January 2008). It chewed the tender tips, which caused the liverwort to branch, causing a fluffy appearance that is in evidence even from a distance! The larvae feed on the liverwort in mines or galleries constructed there (Penny 2012).

Fabian *et al.* (2015) took advantage of this knowledge of food choice to locate larvae of *Caurinus dectes* (Figure 28-Figure 30) for their study on larval morphology. Penny (2012) used heat to cause adults of this species to drop from the epiphytic liverworts (*Porella navicularis*; Figure 32) on vine maple (*Acer circinatum*). Penny noted that the most common mosses associated with these vine maple stems are *Rhytidiadelphus loreus* (Figure 33), *Metaneckera menziesii* (Figure 34-Figure 35), and *Neckera douglasii* (Figure 36-Figure 37). Nevertheless, its favorite food is *Porella navicularis*. Penny contends that *C. dectes* breeds in these epiphytes.

Caurinus dectes (Figure 28-Figure 30) survives in a warmer climate than other members of the **Boreidae**. Its distribution is in Washington and Oregon, USA (Russell 1979a, b; Rood *et al.* 2015). It occurs in moist forests where mosses are abundant both on trees and on the ground. Knowing where to look often adds new species. In 2013, Sikes and Stockbridge described a new species, *Caurinus tlagu* (Figure 38) from Prince of Wales Island, Alaska, USA. Its habitat is different from the primary forested habitat of *C. dectes* (Figure 28-Figure 30), but *C. dectes*, like *C. tlagu*, also occurs in open rocky sites with the moss *Rhytidiadelphus loreus* (Figure 33). This moss species provides 20% of the cover at the Alaskan alpine tundra site where *C. tlagu* occurs.

Figure 38. *Caurinus tlagu*, a moss dweller in Alaska, USA. Photo by Derek Sikes, through Creative Commons.

Byers and Thornhill (1983) conjectured that *Caurinus* (Figure 28-Figure 30) probably pupates in damp mosses without making a cell (Russell 1979a). Russell (1982) pointed out that its larvae, unlike other **Mecoptera**, make a silk-lined cell or cocoon where pupation occurs. Pupation occurs in July to August in northwestern USA. The life cycle is **univoltine** (one generation per year), but two generations may overlap for a period.

Penny (2006) pointed out that in *Caurinus dectes* (Figure 28-Figure 30), the larvae (Figure 30) are almost legless. Furthermore, the adults lack hind wings (Figure 28-Figure 29). Hence, this small (1.4-1.9 mm) insect is not going to travel very far to escape unfavorable conditions of weather or other environmental change. It lives in moist forests where both epiphytic and terrestrial bryophytes are abundant. The adults feed on the epiphytic leafy liverwort *Porella navicularis* (Figure 32), but also occur on mosses (Russell 1979a). When females lay their eggs, the eggs are coated with black cement and they are attached to the bryophytes (Figure 39) (Russell 1982).

Figure 39. *Caurinus dectes* eggs on a leafy liverwort. Photo courtesy of Loren Russell.

Because other boreids are known to feed on mosses, Russell (1979a, b) provided his *Caurinus* (Figure 28-Figure 30) with several epiphytic moss choices: *Antitrichia curtispindula* (Figure 40-Figure 41), *Isoetecium spiculiferum* (Figure 43), *Metaneckera menziesii* (Figure 34-Figure 35), and *Rhytidadelphus loreus* (Figure 33), all common on the trees in forests where *C. dectes* occurs. Although most of the larvae survived for three weeks, there was no evidence of feeding. He broadened their choices, providing *Rhizomnium glabrescens* (Figure 44), the foliose lichen *Peltigera canina*, the common mushroom *Agaricus campestris*, apple slices, and springtails. Again, nothing was eaten. Finally, when the leafy liverwort *Porella navicularis* (Figure 32) was presented, the boreids had dinner.

The boreid *Caurinus dectes* (Figure 28-Figure 30) apparently feeds only on leafy liverworts and completes its life cycle on *Scapania* (Figure 45), and several other liverwort epiphytes (Loren Russell, pers. comm. Jan. 2008). Among 11 liverwort taxa tested, the adults accepted about two-thirds of the species. *Scapania* serves as both

food and home for depositing eggs. Russell studied three other local species of boreids, but these three are all moss specialists, never feeding on liverworts.

Russell (1979a) learned that *Caurinus dectes* (Figure 28-Figure 30) is an excellent liverwort taxonomist. In its various habitats, it recognized certain species to eat or to avoid, both as larvae and adults. On deciduous trees and shrubs, it readily accepted (as host and food) *Porella navicularis* (Figure 32) and *Frullania tamarsci* (Figure 46) (less so, and only if primary hosts were not available), but would not accept *Radula bolanderi* (Figure 47) or *Metzgeria conjugata* (Figure 48). On decaying logs and stumps with bark, it recognized a new array of species, accepting *Scapania bolanderi* (Figure 31) and *Bazzania tricenata* (Figure 49) and less preferentially (when given no choice) *Ptilidium californicum* (Figure 50), *Bazzania ambigua*, and *Lophocolea cuspidata*. Here *Lepidozia*

reptans (Figure 51) was not accepted, even under starvation conditions. On older logs and stumps that had lost their bark, it found *Calypogeia fissa* (Figure 52), *C. muelleriana* (Figure 53), *Kantius trichomanis*, *Scapania bolanderi*, *S. umbrosa* (Figure 54-Figure 55), and *Lophocolea heterophylla* (Figure 56) to be highly acceptable, whereas *Geocalyx graveolens* (Figure 57), *Lophozia incisa* (Figure 58), *Cephalozia bicuspidata* (Figure 59) (larvae only), *C. lunulifolia* (Figure 60) (adults only), *Calypogeia fissa*, *Jamesoniella autumnalis* (Figure 61), *Jungermannia atrovirens* (Figure 62), and *Riccardia latifrons* (Figure 63) were only secondary hosts, used when preferred choices were unavailable. *Cephalozia bicuspidata* (adults only), *C. lunulifolia* (larvae only), *Blepharostoma trichophyllum* (Figure 64), *Chiloscyphus pallescens* (Figure 65), and *Lepidozia reptans* were not accepted. Although refusing some members, *Caurinus decetes* is apparently mostly a *Jungermanniales* specialist.

On compacted soil, highly accepted food species for *Caurinus decetes* (Figure 28-Figure 30) included *Gyrothya underwoodiana* (Figure 66), *Nardia scalaris* (Figure 67),

Diplophyllum albicans (Figure 68), and *D. obtusifolium* (Figure 69), with secondary hosts of *Gyrothya underwoodiana* (adults only), *Jungermannia rubra* (Figure 70), and *Blasia pusilla* (Figure 71) (Russell 1979a). They did not accept *Pellia neesiana* (Figure 72), *Athalamia hyalina* (Figure 73), *Conocephalum conicum* (Figure 74), or *Anthoceros punctatus* (Figure 75), all thallose species. On boulders and outcrops they preferred *Plagiochila porelloides* (Figure 76), with *Porella cordaeana* (Figure 77) and *Scapania americana* (Figure 78) serving as alternatives when their preferred foods were unavailable. Even forest litter provided a suitable host in the form of *Plagiochila porelloides*.

Russell (1979a, b) was not able to locate any highly acceptable hosts for *Caurinus dectes* among liverworts from streams and seepages, but *Chiloscyphus polyanthos* (Figure 79), *Riccardia multifida* (Figure 80), and *Blasia pusilla* (Figure 71) served as "emergency" foods when others were not available. *Scapania undulata* (Figure 81) and *Anthoceros punctatus* (Figure 75) were rejected.

Figure 81. *Scapania undulata*, a rejected food for *Caurinus polyanthos* from streams and seepages. Note that some species of *Scapania* are eaten. Photo by Hermann Schachner, through Creative Commons.

One of the most interesting observations by Russell (1979a, b) was that although these boreids had accepted

Porella navicularis (Figure 32) as food, and readily tasted *Porella roellii* (Figure 82), they soon showed a distinct distaste for *P. roellii*. Evidence included regurgitation, signs of distress, and repeated grooming of their mouthparts. This behavior commenced within 30 seconds of tasting the *P. roellii*. Once eating this species, they subsequently would no longer eat *P. navicularis*, a previously staple food source for them in the lab. *Porella roellii* is known for its "violent, burning taste" which is evidenced after a few seconds of delay.

Figure 82. *Porella roellii*, a leafy liverwort that appears to be repugnant to *Caurinus dectes*. Photo by Paul Wilson, with permission.

Russell (1979a, b) rejected the hypothesis that liverworts provided better nutrient quality than the less preferred mosses. In fact, the liverworts seemed to have less nitrogen, an essential component of protein, and rarely exceeded the content of mosses for any of the nutrients tested (Table 1). The switch in some cases from larval to adult preferences is interesting. Also of interest is that this insect specializes on Jungermanniales, with 18 species accepted in laboratory tests.

Hesperoboreus

In Oregon, USA, *Hesperoboreus brevicaudus* (see Figure 89) larvae are inhabitants of epiphytic mosses, whereas adults may also occur among thick, matted mosses on rocks (Russell 1979a, b). Penny (2006) reported them from vertical moss banks and epiphytic mosses in

California, USA. In the lab, adults feed on *Polytrichum* (Figure 1, Figure 17) leaf lamellae (Figure 86), *Rhizomnium glabrescens* (Figure 44), and *Dicranum fuscescens* (Figure 83) (Russell 1979a). Larvae feed extensively on *Funaria hygrometrica* (Figure 87), *Rhytidiadelphus loreus* (Figure 33), *Antitrichia curtipendula* (Figure 40-Figure 41), and *Plagiothecium undulatum* (Figure 88) in the lab.

These mossy habitats, especially among epiphytic mosses, dry out in seasons with little rainfall (Gerson 1982). To accommodate for this unwelcome dryness, the larvae of *Hesperoboreus notoperates* (Figure 89) make hardened cells, using salivary secretions, among the moss rhizoids (Cooper 1974). These cells apparently conserve water until moisture returns. After sufficient rainfall, the larvae break out of the cells and begin feeding again.

Figure 89. *Hesperoboreus notoperates*, a species that prefers compact cushion mosses. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Cooper (1974) noted parasites, especially on *Hesperoboreus notoperates* (Figure 89) in Southern California. Living in such confined quarters may be dangerous for the young boreids because it most likely makes transfer of the parasites from one to another easy. Nevertheless, tight cushions of *Grimmiales* (Figure 23) and *Isobryales* (Figure 90) (Cooper 1974) seem preferable to open mats (Penny 1977), perhaps for greater conservation of moisture.

Figure 90. *Fontinalis antipyretica*, a member of *Isobryales*. Photo by Tab Tannery, through Creative Commons.

Nannochoristidae

Nannochorista (Figure 91) has carnivorous aquatic larvae that feed on larvae of *Chironomidae* (midges) (Tillyard 1917; Byers & Thornhill 1983; Byers 1989; Palmer 2009). The adult diet is unknown. But during

pupation, *Nannochorista* sometimes uses damp mosses as a substrate, avoiding the need to make a special cell for that purpose (Pilgrim 1972; Byers & Thornhill 1983). Those larvae that migrate to soil or bark for pupation create a cell by excavating the soil or wet wood. They pupate above the water, but within 10-20 cm of it (Pilgrim 1972). *Nannochorista philpotti* (Figure 91) is a predatory species that sometimes spends part of its life among bryophytes.

Figure 91. *Nannochorista philpotti* adult, a predatory species that sometimes spends part of its life among bryophytes. Photo by Steve Kerr, with permission.

Panorpidae

It is the **Panorpidae** that have earned the name of scorpionflies for the order **Mecoptera** (Wikipedia 2016). The genitalia of the males are enlarged and curved upward, arching over the back, much like the stinger of a scorpion (Figure 92).

Figure 92. *Panorpa nuptialis* male adult. Note the resemblance to a scorpion. Photo by Karen Perez, through Creative Commons.

The larvae of **Panorpidae** are unusual among holometabolous insects in having compound eyes with ommatidia, a trait shown by *Neopanorpa* (Figure 93) and *Panorpa* (Figure 94) (Ramel 2016). As Farkač *et al.* (2005) have reminded us, *Panorpa hybrida* (Figure 94) is an endangered species in the Czech Republic. And this species lives mostly among mosses.

Figure 93. *Neopanorpa* sp. adult, a species whose larval eyes are compound. Photo by E. S. Ross <www.discoverlife.com>, with online permission.

Figure 94. *Panorpa hybrida* adult, a moss dwelling species in Europe. Photo by Ivelina Assyova, with permission.

But the members of the genus *Panorpa* (Figure 94) are not all associated with bryophytes. Some are carnivores, eating freshly killed katydids, grasshoppers, and caterpillars in the lab (Cai & Hua 2009).

Panorpa (Figure 94) has three types of mating (Ramel 2016). In all cases, the male emits a **pheromone** that attracts females, and unfortunately, also other males. In one strategy, the male offers the female a gift, food of course (Figure 95), that she devours during copulation (perhaps helping to prevent her from eating her mate as is known in other carnivores such as the preying mantis). In fact, Cockle (1908) observed the female of *Boreus californicus* (Figure 19-Figure 20) drag the male around on his back until he died. The second strategy is similar – the male finds a dead arthropod, which he partially consumes (Ramel 2016). Then the male stands beside it and emits the pheromone attractant or secretes a salivary mass on a nearby leaf or other substrate, again resting beside it and secreting a pheromone. Copulation occurs while the female feeds, either on the arthropod or the salivary mass. In the third strategy, the male offers nothing – no food and no pheromones. Rather, he rushes at the female and attempts to mate with her, a strategy known as **forced copulation**, and often he succeeds. This latter strategy is most used by those males who lose to other males in their

attempt to gain food for a gift. Not surprisingly, females prefer the males with gifts, and those that do receive gifts lay more eggs than females that have had forced copulation.

Figure 95. Male *Panorpa communis* with prey item (*Diogma glabrata glabrata*) such as that offered to females before mating. Photo by Richard Bartz, through Creative Commons.

Kullmann and Sauer (2005) investigated other species of *Panorpa* and learned that other strategies are present as well. They found that the males of both *Panorpa similis* and *Panorpa connexa* carry out their copulations with one salivary mass as a nuptial gift or have copulations without any nuptial gift, but always without the use of force.

Earlier researchers reported that *Panorpa* oviposits loose clusters of eggs, using pre-existing cavities in moist soil (Miyake 1912; Tillyard 1926; Byers 1963; Riek 1970; Byers & Thornhill 1983). But *Panorpa communis* (Figure 95-Figure 96), the common scorpionfly that was named by Linnaeus, oviposits beneath mosses (Malyshev 1968). Byers (1963) found that in *P. nuptialis* (Figure 92, Figure 97) size increase is rapid in the young larvae, but the prepupal stage is prolonged. Adults emerge from pupae in about 20 days.

Figure 96. *Panorpa communis* male adult, a species that oviposits under mosses. Photo by Gail Hampshire, through Creative Commons.

Figure 97. *Panorpa nuptialis* adult. Photo by Robby Deans, through Creative Commons.

Apteropanorpidae

This tiny family has only one genus (*Apteropanorpa*; Figure 99) with four species known as Tasmanian snow scorpionflies (Palmer *et al.* 2007; Wikipedia 2011). The larvae live among mosses in Tasmania and southern Australia (Byers & Yeates 1999; Wikipedia 2011). Adults are wingless predators, but likewise live among mosses (Kaltenbach 1978; Byers & Yeates 1999).

Like the **Boreidae**, the **Apteropanorpidae** are active in the cold of winter (Byers & Thornhill 1983). Both larvae and adults live among mosses (Kaltenbach 1978; Ferrington 2008) where conditions remain moist most of the time (Russell 1979a). Although Ferrington (2008) considered this family to be aquatic, Palmer (2009) argues that they are not, stating "There is no evidence suggesting that adults of any species of *Apteropanorpa* predictably occupy riparian or aquatic vegetation." Further, Evans (1942) collected two **Mecoptera** larvae from mosses at 600-900 m on Mt. Wellington and these have now been determined to be *Apteropanorpa* (Palmer 2009). Balian *et al.* (2008) noted the ability of mosses to retain a film of water that permits limnoterrestrial invertebrates to live there. But Palmer cautions that larval stages of this genus are poorly known and mosses may not be their only habitat.

But danger lurks among the bryophytes. Like several other mecopteran families, this one is plagued by parasitism. Adults of *Apteropanorpa tasmanica* (Figure 99-Figure 99) are parasitized by larvae of the mites *Leptus agrotis* and *Willungella rufusanus* (Seeman & Palmer 2011).

Figure 99. *Apteropanorpa tasmanica*, a species whose larvae live among mosses. Photo © Simon Grove, Tasmanian Museum and Art Gallery, with permission.

Meropeidae

This tiny family has only two members, one in eastern USA – *Merope tuber* (Figure 100-Figure 101) and one in Australia – *Austromerope poultoni* (Byers 1973, 1988; Kaltenbach 1978). It appears to be an ancient family that was once more widespread.

Merope tuber (Figure 100-Figure 101) adults live among aquatic or riparian vegetation or bryophytes (Ferrington 2008). Presumably the bryophytes provide sufficient moisture for these terrestrial living sites.

Figure 100. *Merope tuber* adult, a species that includes bryophytes among its substrates. Photo by Tom Murray, through Creative Commons.

Figure 101. *Merope tuber* adult male showing claspers. Photo by R. Machado, R. Kawada, and J. Rafael, through Creative Commons.

Merope tuber is a poorly known species (Dunford *et al.* 2007). Its larvae have never been described and its habits are largely unknown. We do know that the adults are nocturnal, and flight traps have revealed that the species is more common than we had imagined (Byers 2005). Its range is from southeastern Canada to Florida and west to Kansas, Minnesota, and eastern Iowa Byers (1973, 1993; Dunford *et al.* 2007). The Appalachian Mountain range and eastern mesic forests provide it with suitable habitat (Dunford *et al.* 2007). Its presence in the more western and southern parts of its range suggest that these disjunct locations may be relict habitats where it found refuge during glacial advances (Byers 1969, 1993; Schiefer & Dunford 2005). The two species are able to survive in these two distant geographic locations on opposite sides of the Earth along streams in ravines (Killington 1933; Byers 1988) that provide temperatures that vary little from 20°C (Means 1985).

Bittacidae

The **Bittacidae** are not true bryophyte associates, but they do occasionally feed on mosses (Setty 1931). More commonly they are **saprophagous** and feed on things like dead earthworms or dead insects (Setty 1931, 1940; Byers & Thornhill 1983). Like the **Nannochoristidae**, *Harpobittacus australis* (Figure 102) uses pheromones for mating attraction (Crossley & Waterhouse 1969). Most of the bittacids hang on vegetation by their legs to drop their eggs to the ground (Ramel 2016). Hence, any association of eggs with bryophytes is probably coincidental.

Figure 102. *Harpobittacus australis* adult, a species that uses pheromones to attract his mate. Photo by John Tann, through Creative Commons.

Currie (1932) relates fascinating observations of the larval behavior of *Harpobittacus tillyardi* in the lab. In preparation for molting, the larvae move to a higher location on a soil mound or on a liverwort leaf. When the larvae molt, they move their body fluids forward, causing the anterior to swell. Eventually the head capsule splits and the larva crawls out, then eats its former skin. After a 10-minute rest, the larvae moved the posterior end up above the head capsule. They then proceeded to expell sand and soil from the anus and to cover the larval skin with it as they moved the anus backward. After about 20 minutes, this process was repeated. This covering rendered the larvae nearly invisible on its substrate. During feeding, which was almost entirely on dead matter, the larva occasionally took a bit of liverwort in the lab. Maintenance of moisture was important, and larvae would expel fluids from the mouth to spread over the body to keep it moist. If it ran out of this fluid, it would die in the dryness.

Summary

The **Mecoptera** include the snow scorpionflies, and these typically feed on mosses or algae associated with them. **Chorista** (**Choristidae**) is among the bryophages. The **Boreidae** has three genera, all of which feed almost exclusively on bryophytes as both larvae and adults. In addition to food, the mosses may be important as a moist refuge. Many lay their eggs on mosses under the snow. For *Boreus*, mosses seem to be important, whereas for *Caurinus*, liverworts are important. *Hesperoboreus brevicaudus* species occur among epiphytic mosses as larvae but migrate to mosses on rocks as adults.

In the **Nannochoristidae**, has aquatic larvae that are carnivorous, but the larvae may move to damp mosses for pupation. The **Panorpidae** have compound eyes, unusual in this order, that may help them to detect motion in their dark bryophyte habitat. However, not all **Panorpidae** are bryophyte associates. Both larvae and adults of **Apteropanorpidae** live among mosses and are winter-active. *Merope* (**Meropeidae**) adults can live among aquatic vegetation or among bryophytes. The **Bittacidae** only occasionally associate with bryophytes and feed on them.

Acknowledgments

Thank you to David Wagner and Loren Russell for sharing their information and images, and for their encouragement. As always, I appreciate all the photographers who either made their images available through Creative Commons or gave me permission to use them.

CHAPTER 12-17

TERRESTRIAL INSECTS:

HOLOMETABOLA – DIPTERA OVERVIEW

Figure 1. Adult **Diptera** resting on mosses in a canyon in Ohio, USA. Insects this large are unlikely to move within the moss mat, but the mat can still be important in keeping them alive. Such rest stops may be for getting from one place to another, rehydrating the body, drinking, or ovipositing. Photo by Janice Glime.

Diptera Overview

Diptera derive their name from having only two wings (Figure 1). In place of the second pair of wings, they have a pair of **halteres** (Figure 2), structures that resemble a knob on a stalk, like the dumbbells of the same name. The halteres instead serve as a guidance system (Wikipedia 2016). They record both vertical and horizontal changes in direction, permitting the flies to maintain balance and stabilize the head and to perform their acrobatic maneuvers quickly.

Wagner (1980) concluded that in the Breitenbach of Germany, changes in fly populations are linked with changes in the bryophyte cover. When Andrew and Rodgerson (1999) developed a kerosene extraction technique for removing invertebrates from bryophytes, they found that **Acari**, **Collembola**, and **Diptera** were the most

abundant arthropods. This chapter will explore the many ways in which the **Diptera** are associated with bryophytes and often depend on them. Bryophytes play an important role in the life cycles of a number of dipteran taxonomic groups (Kinchin 1992).

The **Diptera** are part of the panorpidae complex (Britannica 2008). This group includes the **Mecoptera**, **Trichoptera**, **Lepidoptera**, **Siphonaptera**, and **Diptera**. It is a current belief that all these orders evolved from a moss-dwelling ancestor. They are all 4-winged insects (except the halteres of **Diptera**) that resemble crane flies, some making cases as larvae.

Most bryologists are probably unaware that some **Diptera** larvae behave as parasites in the thalli of liverworts. Pettet (1967) reported such an interaction in

thalli of *Riccia frostii*. The rosettes of thalli each had 5-25 small, yellow-orange larvae. The thallus loses its turgidity and becomes flabby. In the last larval stage, the upper surface of the thallus disintegrates. Pupation follows inside the thallus.

Figure 2. Cranefly (*Tipula* cf. *scripta*) halteres. Photo from BugBlog, through Creative Commons.

Role of Bryophytes

As with other insects, bryophytes provide a safe haven for small dipterans to hide from predators. They likewise provide a moist haven from the sun and drying winds. And they are a source for food. For some dipterans, the bryophytes themselves are eaten. For others, microorganisms, fungi, and other arthropods that live among the bryophytes provide food sources. Galas *et al* (1996) reported that in the cave water they tested the amount of energy released by the bryophyte microorganisms was greater than that for the litter species they tested.

Andrew *et al.* (2003) summed up the advantage of bryophytes – they are able to absorb water rapidly, reduce evaporation, and provide insulation against extreme environmental conditions of cold and wind (see also Gerson 1982; Smrz 1992). Several researchers suggest that by modifying the environment, bryophytes permit aggregations of **Diptera** to live where they would not otherwise be able to tolerate the dry conditions (Joosse & Verhoef 1974; Leinaas & Somme 1984; Usher & Booth 1984).

Clément and Touffet (1981) examined the role of bryophytes in the big picture of heathlands in Brittany. The larvae of *Tipula* (**Diptera**; Figure 3) were responsible for the death of many bryophytes following fire. Bryophytes were destroyed by the scraping of rabbits and roe-deer. Once bryophytes returned, led by *Funaria hygrometrica* (Figure 4) and *Ceratodon purpureus* (Figure 5) following fire, organic matter built up quickly, permitting the invertebrate fauna to flourish.

Figure 5. *Ceratodon purpureus*, bryophytes that colonize after a fire, permitting invertebrates such as **Diptera** to begin colonization. Photo by Janice Glime.

Substrate type is important in the establishment and emergence of **Diptera** from lakes (Čmrlec *et al.* 2013). In lake outlets in Poland, mosses were the most preferred substrate for emergence, especially on tufa and pebbles. Mosses provide a place to climb to the surface without being carried away by the current, then extending above ground to give a solid surface from which to escape the aquatic realm. In particular, the **Athericidae** (Figure 6) select mosses for emergence, but then, they also select mosses for their pupation, making this a readily available emergence site (Thomas 1997). The **Chironomidae** (Figure 7-Figure 10) and **Dixidae** (Figure 11-Figure 12)

(Poepperl 1999) have no substrate preference, but **Empididae** (Figure 13-Figure 15) not only use the mosses for emergence, but also use them for food and shelter (Watson & Rose 1985; Nolte 1991; Ivković *et al.* 2007).

Figure 13. **Empididae** larva, a moss inhabitant and feeder. Photo through Manaaka Whenua, NZ, with online permission.

Like many other orders discussed earlier, the **Diptera** have their parasites. The crane fly **Limonia** (**Limoniidae**; Figure 16) is one of these (Wohltmann *et al.* 1994), as is **Paradixa** (**Dixidae**; Figure 17). Larvae of **Limonia** are subject to the parasitic mite, **Johnstoniana tuberculata** (Figure 18) (Wohltmann *et al.* 1994). It appears that the moss provides suitable conditions for both the crane fly and the parasite. This mite overwinters in its egg stage and the

larvae emerge in May-June – the same time their hosts become available.

Collection and Extraction Methods

Several methods of collection are usually necessary to assess the **Diptera** fauna. Most larvae are difficult to identify and often must be reared to adults for certain identification. This need can sometimes be eliminated by a thorough sampling of the adult fauna during their active seasons. The most common method I encountered for adult surveys was the use of the **Malaise traps** (e.g. Salmela 2001; Salmela & Ilmonen 2005; Figure 19). These are large, tent-like structures used for trapping flying insects, especially **Hymenoptera** and **Diptera**. Insects are directed to the top of a slanted pyramid where they encounter a vial of preservative. Other methods for flying insects include **window traps** (Figure 20) and **sweep netting** (Figure 21) (Salmela 2001).

Figure 19. Malaise trap for emergent and flying insects. Photo by Ceuthophilus, through Creative Commons.

Figure 20. Window-pane trap used to capture adult insects including **Diptera**. Photo from North Dakota State University, with online permission.

Figure 21. Sweep net used to catch adult insects, including **Diptera**. Picture from Peter Oboyski, with permission.

Window-pane traps (Figure 20) are made with clear plexiglass to serve as a barrier over a container of ethylene glycol (anti-freeze). The window is mounted on a wooden frame that is suspended between two pipes anchored in the ground. The frame height should be at the top of the

growing vegetation, or at least above the peak of the bryophyte clumps.

Ground dwelling **Diptera**, including larvae and pupae, are often sampled by **pan traps** (Figure 22) (Taillefer & Wheeler 2010) or **pitfall traps** (Figure 23-Figure 24) (Galbraith *et al.* 1993; Horsfield & MacGowan 1997; Miller *et al.* 2008). These are placed among the vegetation, and for our purposes this would be among mosses. The rim should be below the moss surface so that insects don't have to climb up to enter the trap. **Pan traps** (Figure 22) are simple small pans with soapy water in them (MacGowan 2015). One drop of detergent in the pan or bowl is sufficient to break the surface tension and cause the insects to drown. The pans can be in colors chosen to suit the insect group you are interested in, with meat red being a suitable color for catching **Diptera**. On the other hand, a neutral color may give a more representative sample, avoiding the bias of attracting a particular group. The traps should be checked at least once a day to prevent mold. When removing the insects, pour the soap-water solution through a fine aquarium mesh net. Then rinse the net with water into a jar of 95% ethanol. The water will dilute the solution to the approximately 70% ethanol needed for preservation.

Figure 22. Pan trap used for ground insects. These are usually positioned so the rim is at the same height as the tops of the ground vegetation such as mosses. Photo by Peter Oboyski, with permission.

Figure 23. Pitfall trap to capture ground-dwelling insects. Photo from Stephen F. Austin State University, through Creative Commons.

Figure 24. Barber pitfall trap. The cover helps keep out rain and debris. Photo by Mnolf, through Creative Commons.

A **pitfall trap** (Figure 23) is similar to a pan trap. It is used for small animals, including insects, especially for ecological studies. Two types of traps can be used: dry and wet. The **dry pitfall trap** is simply a container buried in the ground with its rim at the soil surface. The **wet pitfall trap** differs only in containing a preserving liquid such as 10% formaldehyde, methyl alcohol, ethanol, ethylene glycol (anti-freeze), trisodium phosphate, or picric acid. A drop of detergent will remove the surface tension, making it easier for insects to fall to the bottom and be preserved. Water (plus soap) can be used if traps are checked within a day. Both wet and dry traps usually have a raised cover to reduce entry of rainfall and debris. If the insect is one that can climb or fly out, then the wet trap is preferable.

Extracting invertebrates from bryophytes is always challenging, and sorting the **Diptera** from the bryophytes is no exception. This separation is further complicated by the small size of some of the members. Andrew and Rodgerson (1999) tested several methods for extracting the invertebrates. They used **Tullgren funnels** with sugar flotation and a new technique using **kerosene phase separation**. Bryophyte samples were placed in 95% ethanol when they were collected to preserve the insects, some of which would die in the changed conditions of their habitat and others would be eaten if their predators were not immobilized. In the kerosene method, the bryophyte samples are placed in two large test tubes and 95% ethanol added to make the tube ~3/4 full. Kerosene is added to within 1 cm of the top. The tubes are shaken vigorously to ensure thorough mixing of the kerosene and ethanol. After

10-15 minutes the tubes should be rolled to eliminate any trapped bubbles of kerosene, causing them to rise from the bottom and sides. Once the ethanol and kerosene separate (kerosene on top), the invertebrates settle onto the interface layer. When this separation is complete, the kerosene should be pipetted off to within 5 mm of the interface and discarded. Then the remaining interface plus kerosene is collected. A second ethanol wash should be used to dislodge kerosene from the sides of the tube and the new interface pipetted and collected. This whole procedure should then be repeated, a part of the technique that Andrew and Rodgers found increased the number of invertebrates collected by 16%. The collected interface material should then be examined in a Petri dish under the binocular microscope in a fume hood. Any invertebrates trapped in the kerosene should be pushed into the alcohol with a fine brush to remove the kerosene. This method retrieved significantly more invertebrates than the sugar extraction.

Identification of larvae often requires rearing to adulthood. Ferreira and Rafael (2006) developed a method for rearing immature horseflies by using bryophytes and sand. They considered this method advantageous for rearing species with long development periods.

Fly Dispersal of Spores

Revill *et al.* (1967) experimented with ability of **Diptera** to carry viable propagules, including moss spores. Using *Tipula triplex* (Tipulidae; Figure 25), *Chaoborus punctipennis* (Chaoboridae; Figure 26-Figure 27), *Chironomus* sp. (Chironomidae; Figure 10), and *Bittacomorpha clavipes* (Ptychopteridae; Figure 28), these researchers demonstrated that moss protonemata could be transported and subsequently germinate. Moss protonemata were among the least frequent, but at least five of them germinated in 51 cultured washings, demonstrating that diptera adults are possible dispersal vectors.

Perhaps the best-known of the dipteran associations with bryophytes is that of flies that help in the dispersal of spores of the bryophyte family **Splachnaceae** (Bequaert 1921; Erlanson 1930; Walsh 1951; von der Dunk 1971; Koponen & Koponen 1978; Troilo & Cameron 1981; Marino 1988, 1991a, b; Koponen 1990; Eriksson 1992; Marino *et al.* 2009). This family of mosses lives exclusively on organic matter, including dung, bone, owl pellets, corpses, and enriched gravel (Koponen 1990). Among the frequent visitors to *Splachnum ampullaceum* (Figure 29) in the Great Lakes area is the muscid dipteran *Eudasyphora cyanicolor* (Figure 30) (Troilo & Cameron 1981).

Figure 29. *Splachnum ampullaceum* capsules showing expanded hypophysis that produces chemicals and a reddish color that attract flies. Photo by Michael Lüth, with permission.

Figure 30. *Eudasyphora cyanicolor*, one of the visitors to capsules of *Splachnum ampullaceum*. Photo by Tristram Brelstaff, through Creative Commons.

The **Splachnaceae** that attract flies are adapted for that attraction by their substrate, capsule shape, and chemical attractants that typically mimic the odor of dung (Koponen 1990; Koponen *et al.* 1990). These odors are produced only in the capsule and its **hypophysis** (enlarged portion at base of spore-bearing part of capsule). The odors are created by volatile compounds – octane derivatives and organic acids including acetic, propionic, and butyric acids.

It is of evolutionary significance that four families of flies are known to visit the aromatic **Splachnaceae** (Cameron & Wyatt 1986). About half the members of the **Splachnaceae** use wind dispersal, and insect dispersal arose more than once in the family, with dispersal mechanisms going back and forth between wind and insects (Goffinet *et al.* 2004; Marino *et al.* 2009). Evidence suggests that the moss capsule diversification may have followed the transition to **coprophily** (loving dung and dead animal matter) and **entomochory** (insect dispersal) (Marino *et al.* 2009).

There also appear to be differences in attraction ability. There are a number of cases in which the sporophyte colors and odors differ and the fly visitors differ accordingly (Marino *et al.* 2009). For example, *Splachnum ampullaceum* (Figure 30) associated with dung had more spores carried by the flies than did *S. luteum* (Figure 31-Figure 32) (Marino 1991b). There was also a greater proportion of flies associated with *S. ampullaceum* than with *S. luteum*.

Figure 31. *Splachnum luteum* capsules among peat mosses. Note the broad umbrella-like hypophysis. Photo by Dick Haaksma, with permission.

Figure 32. *Splachnum luteum* capsules. Photo courtesy of Bernard Goffinet.

Members of **Scatophagidae** – *Scatophaga furcata* (Figure 33), **Anthomyiidae** – *Delia platura* (Figure 34), **Phorida** (Figure 35), and **Muscidae** – *Myospila metidabunda* (Figure 36), *Eudasyphora cyanicolor* (Figure

30) are all known as North American and European visitors to the **Splachnaceae** that effect spore dispersal (Bequaert 1921; Cameron & Wyatt 1986; Koponen 1990). Cameron and Wyatt found the **Scatophagidae** to be both the most frequent and the most effective visitors to the capsules in Isle Royale National Park, Michigan, and Alaska, USA. They were able to demonstrate that wind is not an effective mechanism of dispersal for *Splachnum rubrum* (Figure 37-Figure 38) and that the visitation to dung by the **Scatophagidae** was an important component of the restriction of this moss species to dung.

Figure 37. *Splachnum rubrum* capsules showing the umbrella-shaped hypothesis that is the color of red meat and slightly iridescent. Photo by Janice Glime.

Figure 38. *Splachnum rubrum* with fly. Photo courtesy of Bernard Goffinet.

The common **Splachnaceae** visitor *Eudasyphora cyanicolor* (Muscidae; Figure 30) prefers carrion, but

when it is not available, the adults choose dung and thus are able to interact with *Splachnum ampullaceum* (Figure 29) capsules (Troilo & Cameron 1981). Nevertheless, they leave the capsules when they discover no food is present. Troilo and Cameron found that the capsules of *S. ampullaceum* were more attractive to these flies than either carbohydrates or fly medium.

Tayloria dubyi (Splachnaceae; Figure 39) is unusual in that it lives exclusively on bird dung (Figure 40) in the sub-Antarctic Magallanes (Jofre *et al.* 2011). Furthermore, this dung is predominately, and perhaps only, that of the Upland Goose *Chloephaga picta* (Figure 41-Figure 42). Jofre and coworkers set up traps (Figure 43) above the capsules of the moss and above the adjacent *Sphagnum* (Figure 39) to see if this species also attracted flies. In traps above the *T. dubyi* capsules they captured 64 flies comprised of Muscidae – *Palpibracus chilensis*, Tachinidae – *Dasyuromyia* sp., and Sarcophagidae (Figure 44). No flies were captured above the adjoining *Sphagnum*.

Marino (1988) found that few **Splachnaceae** species ever co-existed on the same set of dung droppings. There seemed to be few mechanisms that would promote the co-existence of the mosses. Differences in timing of capsule maturation kept *Tetraplodon angustatus* (Figure 45) and *Tetraplodon mnioides* (Figure 46) from being on the same dung at the same time. Surprisingly, each species of **Splachnaceae** attracted 10-17 spore vector flies (Marino 1991b). The fly species attracted to each moss species had 77-99% different species composition from each other. Furthermore, the competition between species of **Splachnaceae** is strong. When grown together from spores there were fewer individuals of each species than when the species were grown separately (Marino 1991a). The competitive abilities between species grown in the lab related to differences in growth rates. Differences between lab and field growth suggest that habitat differences may keep species separate. Marino (1991b) demonstrated that in wet habitats *Splachnum* (Figure 29, Figure 31, Figure 37) is the primary **Splachnaceae** genus, whereas in dry habitats the dung mosses are primarily *Tetraplodon* (Figure 45-Figure 46).

Figure 45. *Tetraplodon angustatus* with capsules that attract flies. Photo by Des Callaghan, with permission.

Figure 46. *Tetraplodon mnioides* with mosquito on capsules. Photo courtesy of Lynden B. Gerdes.

Bequaert (1921) described details of the behavior of *Phorbia* (**Anthomyiidae**; Figure 35) flies visiting *Tetraplodon mnioides* (Figure 46). They landed on the upper end of the capsules and moved downward to reach the hypophysis, travelling from one capsule to another. They would pass the soft part of the proboscis over the upper part of the hypophysis, licking up its secretions. If they were disturbed, they flew away but returned quickly, apparently unwilling to pass up the treat. As these flies leave the capsules where they alight, they inevitably carry away some of the sticky spores on their hairs, legs, and other parts. The upper half of the hypophysis has exceptionally large, crowded stomata. Bequaert suggested that these stomata may exude the substance that seems so important to the visiting *Phorbia*.

In Chile, *Taylora mirabilis* (Figure 47-Figure 48) is endemic to temperate rainforests. Mighell (2011) used pitfall traps to trap flies over this species, then germinated the spores collected from these flies. Of the 218 flies collected (Figure 48), 63 were carrying spores of *T. mirabilis*. These included seven species from **Muscidae** (4 species of *Palpibracus*) and **Calliphoridae**. The dung represented multiple types, indicating that the mosses, and perhaps the flies were not specific in their dung substrate. Furthermore, the forest mammals providing the dung are introduced species, but the moss is endemic to Chile.

The fascinating dispersal relationships are described in detail in Volume 1 in the chapter on Adaptive Strategies: Spore Dispersal.

Habitats

Wetlands

Peat mosses, as might be expected, have a significant fauna of flies, particularly larvae and pupae. Warner and Asada (2006) concluded that bryophytes contribute the most to species richness in bogs. This richness includes the animals that inhabit them. Holarctic peatlands typically have both diverse and abundant dipteran fauna (Roháček 1982; Blades & Marshall 1994; Taillefer & Wheeler 2010).

In reference to Canadian peatlands, Warner and Asada (2006) reported for mosquitoes (**Culicidae**; Figure 49-Figure 51) 10 species in bogs and 11 species in fens, for horse flies and deer flies (**Tabanidae**; Figure 52-Figure 56) 32 in bogs and 11 in fens, and for the no-see-ums (**Ceratopogonidae**; Figure 57-Figure 59) 3 in bogs. But none of these species seems to be restricted to bogs – *i.e.*, there are no true **bryobionts** among these **Diptera**.

But these numbers seem modest compared to other studies. Salmela *et al.* (2007) reported 156 species of nematoceran **Diptera** in southern Finnish wetlands. Among their 8,606 specimens, they identified **Limoniidae** (80 species; Figure 16), **Psychodidae** (26; Figure 60-Figure 62), **Tipulidae** (20; Figure 3, Figure 25; Figure 80-Figure

82), **Pediciidae** (10; Figure 63-Figure 64), **Dixidae** (9; Figure 11-Figure 12; Figure 17), **Cylindrotomidae** (4; Figure 65-Figure 67), **Ptychopteridae** (4; Figure 68), **Thaumaleidae** (1; Figure 69-Figure 70), **Pleciidae** (1; Figure 71), and **Pachyneuridae** (1; Figure 72). One reason for the high diversity of **Diptera** is the high diversity of microhabitats in bogs and fens. But this also makes it difficult to assess the number of terrestrial species in these sites that live among mosses. In these studies, the microhabitat is often not described. Furthermore, the habitat changes with seasons (Blackstock *et al.* 1993). During the summer, the wetlands, both bogs and fens, become dry. Hence the life cycles of the invertebrates must be synchronized between their moisture needs and availability. And it means that the organisms moving about in the wet season are likely to be different from those that are active when it is dry.

In the examination of the effects of drainage ditches on peatlands, Taillefer and Wheeler (2010) likewise found much greater numbers in southern Quebec, Canada, peatlands. Their study focused on the predominately terrestrial peat remaining near drainage ditches. They examined the **Brachycera** at the Johnville Bog and Forest Park in Quebec. They found 1453 individuals of **Brachycera**, comprising 24 families and 166 species. Simpson's species diversity index indicated a higher diversity at 6 and 11 m than at 1 m from the ditch. Taillefer and Wheeler suggested that this difference may be due to the homogeneous moss cover and moister conditions at greater distance from the ditch. On the other hand, raw species richness was greater at 1 m and the numbers of specimens per sample were 177.5 at 1 m, decreasing to 92 at 11 m, based on pan trap sampling.

Blades and Marshall (1994) identified a range of 62-106 species of acalyptrate **Diptera** in four peatlands in southern Ontario, Canada. Diversity in individual localities ranged from 12 in an **oligotrophic** (low nutrient) fen to 69 in a rich fen. One reason for this high diversity is the wide range of habitats, including both aquatic and terrestrial.

Other select taxa groups studied in peatlands include **Chironomidae** (Figure 7-Figure 10) (Wrubleski 1987), biting flies (Lewis 1987), **Empididae** (Figure 13-Figure 15; Figure 73) (Barták & Roháček 1999), **Dolichopodidae** (Figure 74-Figure 75) (Rampazzi 2002), **Sphaeroceridae** (Figure 76-Figure 77) (Marshall 1994), and multiple other acalyptrate families (Roháček & Máca 1982; Roháček *et al.* 1998).

Autio and Salmela (2010) found 104 species of **Diptera** [**Limoniidae** (Figure 16), **Tipulidae** (Figure 3, Figure 25; Figure 80-Figure 82), **Pediciidae** (Figure 63-Figure 64), **Cylindrotomidae** (Figure 65-Figure 67), **Ptychopteridae** (4; Figure 68-Error! Reference source not found.), **Psychodidae** (Figure 60-Figure 62), and **Dixidae** (9; Figure 11-Figure 12; Figure 17)] in the open mires, wooded mires, rich fens, Baltic shore meadows, ditches, and groves of Åland Islands in Finland. The Baltic shore meadows had the greatest richness, with 44 species. The **Nematocera** of the islands comprised fewer species than did mainland regions of southern Finland, and Autio and Salmela suggested that the theory of island biogeography might explain this lower species number. The island is ~40 km from the nearest continental sites. But they countered this with the fact that some of the most species-rich habitats (e.g. brooks and springs) are lacking on the islands.

Savage *et al.* (2011) found 381 species of **Schizophora** (section of true flies containing 78 families) in temperate Nearctic bogs. Species richness ranged 96-192 per site. The dominant species were usually not peatland specialists. Bog size had no effect on species richness, but vegetation cover at the sampling sites was important. In summary, perhaps referring to the **Diptera** of wetlands is best described as semi-aquatic (Autio & Salmela 2010).

One reason for these seeming contradictions regarding diversity is the paucity of faunal studies in these bog, fen, and mire habitats (Rosenberg & Danks 1987). Salmela and Ilmonen (2005) reiterated this lack of knowledge, specifically for the **Tipuloidea** – the crane flies. They bemoaned the disappearance of many natural mires in Finland. They recorded 29 crane fly species in the Kauhaneva mire system, including some that were regionally threatened. Mesotrophic sites had the highest species richness; **oligotrophic** (having low nutrients) and **ombrotrophic** (dependent on atmosphere for its nutrients) sites had equally low richness.

Loss of peatlands bodes poorly for the invertebrate inhabitants. But this loss is not the only human problem faced by these invertebrates. Peatland crops such as cranberries and other fruits can put them in danger as well. Bayfield (1979) showed that the crane fly *Molophilus ater* (**Limoniidae**) suffers from the compaction of the peat,

especially where trails are developed. Physical crushing in experiments killed large numbers of larvae. It is also possible that eggs were damaged on the foot paths.

Forests

Forest floor bryophytes often harbor **Diptera**. Logs covered with bryophytes are among the important sites. Mosses help to keep them moist and provide safe sites for the **Diptera** (Schuck *et al.* 2005). Others **Diptera** live on roots covered with drier mosses such as *Brachythecium velutinum* (Figure 78) and feed there on the moss (Sevchenko 1966). But these damp logs may have their dangers lurking. It is the site where the parasitic mite *Johnstoniana errans* (Figure 79) larvae and adults actively hunt for **Diptera** larvae and pupae among the damp mosses (Wohltmann 1996). These larvae exclusively parasitize species of *Tipula* (**Tipulidae**) during the pupa (Figure 80-Figure 81) and adult (Figure 82) stages.

Recently, researchers have attempted to find **surrogates** – species or groups that can serve as predictors for the presence or status of other groups. Smith *et al.*

(2008) found that no one of the species groups in their forest survey could serve as a surrogate for the other species groups. However, they did find that forest bryophytes and saproxylic hoverflies (**Syrphidae**; Figure 83) could possibly serve as surrogates for each other. That is, these groups can indicate the biodiversity of each other.

Figure 83. **Syrphidae** adult, a family one can find among the epiphytes. These flies are bee mimics, but they don't sting. Photo by VladimirZh, through Creative Commons.

Epiphytes

Bar-Ness *et al.* (2006) surmised that *Eucalyptus obliqua* forests have strong age effects in the range of 0-80 years on species composition of bryophytes and tracheophytes. Thus they concluded that the same may be true for canopy invertebrates. The **Diptera** fauna on epiphytes is poorly known. In the Northwest, USA, Nelson and Hauser (1021) used Berlese funnels to extract arthropods. They compared the fauna of mosses and liverworts as pairs from the same tree. **Diptera** were only minor contributors to these communities.

Miller and coworkers (Miller 2006; Wagner *et al.* 2007; Miller *et al.* 2008) found a different picture in the Acadian forest of central Maine, USA. Whereas the **Collembola** and spiders were most abundant at the base of red maple (*Acer rubrum*) of the Acadian forest, correlating with the abundance of bryophytes there, the **Diptera** reached their highest abundance above 2 m on the tree. Miller (2006) found fifteen **Diptera** families, but only eight of these were common. These eight common families used the tree habitats differently, depending on the height above ground. For the **Diptera**, lichens were important. Furthermore, they responded differently to forest gaps. When gaps were created, the bryophytes became less abundant, but the other guilds did not seem to be affected by the loss of canopy. At higher positions on the trees, small foliose lichens were more abundant, whereas in the lower positions the bryophytes and cyanolichens were more abundant. In the first 6 m on the bole of *Acer rubrum* on the south-facing side, they found percent frequencies of

Ceratopogonidae (18; Figure 57-Figure 59), **Chironomidae** (22.5; Figure 7-Figure 10), **Dolichopodidae** (8; Figure 74-Figure 75), **Empididae** (4; Figure 13-Figure 15), **Psychodidae** (9; Figure 60-Figure 62), **Sciaridae** (12; Figure 84), **Phoridae** (35; Figure 85), **Cecidomyiidae** (80; Figure 86), **Chaoboridae** (2; Figure 27), **Culicidae** (7.5; Figure 49-Figure 51), **Drosophilidae** (0.8; Figure 87), **Simuliidae** (7; Figure 88), **Syrphidae** (0.8; Figure 83), and **Tabanidae** (0.8; Figure 52-Figure 54). Only the **Chironomidae** occurred in pitfall traps, suggesting that these taxa were true arboreal dwellers. The suborder **Nematocera** was the most abundant of the **Diptera** in the arboreal habitat above 2 m (Miller *et al.* 2007). These flies may use bryophytes for a drink of water, egg laying, pupation, cover, or escape from wind. And some most likely find food there among the smaller invertebrates. These relationships remain to be elucidated.

Forest gaps make the terrestrial environment even less inviting for the moisture lovers. Using the red maple tree

(*Acer rubrum*) in the Acadian forest of central Maine, USA, Wagner *et al.* (2007) compared undisturbed red maple forest and forest areas with gaps. Gap harvesting reduced the major groups of arthropods on the trees.

The tree bark habitat with bryophyte mats can provide an ideal habitat for moisture-requiring larvae. Old-growth *Liriodendron tulipifera* in Tennessee exhibited nearly six times as much water in bark under bryophyte mats at the tree base as that in bare bark at about 2 m (Billings & Drew 1938; Ulyshen 2011). We should expect to find **Diptera** taking advantage of these moisture sources.

Harvesting Stowaways

Epiphytes, and especially bryophytes on logs in old-growth forests, are often harvested for use in floral arrangements and other uses. JeriLynn Peck became concerned at the massive amounts of bryophytes being removed, and was furthermore concerned about the invertebrates that were being shipped with the bryophytes to their place of sale. Peck and Moldenke (2011) reported that more than 3.7 million kg yr⁻¹ of fresh epiphytic bryophytes are harvested from the Coast and Cascade Mountain ranges in the Pacific Northwest of North America.

Peck and Moldenke (2010) researched the processing methods used in the moss trade. Most of the material from the Pacific Northwest is shipped dry, but that is little comfort because many of the invertebrates have means to survive this dry state. One processor tumbles the moss in large cylindrical tumblers with a sieve to remove needles, twigs, and other debris from the mosses. This method seems to have a high degree of success in removing the invertebrates as well. Only a few adult **Sciaridae** (dark-winged fungus gnats; Figure 89-Figure 90), an isopod, and a few oribatid mites were present in the tumbled mosses, whereas the non-tumbled fresh mosses had both high diversity and high abundance.

Figure 89. Fungus gnat (**Sciaridae**) herbivory on *Buxbaumia aphylla* capsules. Photo by Jörg Müller, through Creative Commons.

Altitude

Andrew *et al.* (2003) assessed the invertebrate-bryophyte community on four Australasian mountain ranges. The invertebrates were identified only to family, but the bryophytes were identified to species. In total, they

collected six families of **Diptera** [**Ceratopogonidae** (Figure 57-Figure 59), **Chironomidae** (Figure 7-Figure 10), **Cecidomyiidae** (Figure 86), **Tipulidae** (Figure 3, Figure 25; Figure 80-Figure 82), **Psychodidae** (Figure 60-Figure 62), **Phoridae** (Figure 85)], and these were usually among the top five in number of families among the represented groups. **Diptera** comprised 9% of the fauna in both Tasmania and New Zealand.

Figure 90. Fungus gnat (**Sciaridae**) herbivory on *Buxbaumia aphylla*. Photo by Jörg Müller, with permission.

Summary

Diptera differ from other insect orders in having only one pair of wings and a pair of **halteres**. Larvae of various families (especially **Chironomidae** and **Tipulidae**) often develop among bryophytes, and the same is typically true of the pupae. Some larvae even live in the thalli of liverworts.

The bryophytes provide a safe haven from predators and dry air. They serve as an insulating layer against cold. And in some cases they serve as food.

Collecting bryophyte-dwelling **Diptera** in the larval stage can be done with pan traps and pitfall traps, whereas in the adult stage sweep nets, Malaise traps, and windowpane traps are useful. They can be separated from the mosses with Tullgren funnels with sugar flotation, kerosene phase separation, or hand picking. The bryophytes with their inhabitants can be preserved in 95% ethanol, but rearing is often needed to identify the larvae.

The moss family **Splachnaceae** is adapted for spore dispersal by several families of flies, attracting them with odors in the capsules, colors, and having sticky spores. The mosses themselves grow on dung and other organic substrates, hence reaching there via the flies.

Peatlands and other wetlands typically have high diversity of **Diptera**, with many benefitting from the high moisture content. Forests also harbor a number of species among the bryophytes, especially in the larval and pupal stages, but adults may use the bryophytes for regaining moisture, avoiding predators, and oviposition. Even epiphytic bryophytes often house **Diptera**, and harvesting these epiphytes and other forest bryophytes for commercial purposes is a means of introducing invasive species where they are sold. Food may be available among the bacteria, fungi, protozoa, algae, and small invertebrates. Altitudinal differences of bryophyte dwellers seem to be poorly known in most of the world.

Acknowledgments

Thank you to Sara Altenfelder for alerting me to the mine flies that live on mosses and liverworts and supplying me with copies of old papers. Sarah Lloyd sent me images as she progressed with her research on moss inhabitants. Thank you to Sarah Lloyd who has shared her stories and images. I appreciate the many photographers who gave me permission or made their photographs available through Creative Commons license.

CHAPTER 12-18

TERRESTRIAL INSECTS:

HOLOMETABOLA – DIPTERA

NEMATOCERA: TIPULOIDEA

Figure 1. *Triogma trisulcata* larva among mosses, demonstrating mimicry of mosses with its many leaflike appendages protruding. The moss is probably *Calliergonella cuspidata*. Photo by J. C. Schou <www.biopix.com>, with permission.

NEMATOCERA

The **Nematocera** are elongated flies that have thin, segmented antennae. Their larvae are mostly aquatic, but some are able to live on land, often using the limnoterrestrial habitat of mosses to maintain their hydration.

Using transplant experiments at the Moor House National Nature Reserve, UK, Briones *et al.* (1997) noted that **Diptera** larvae responded to changes in climate. The larvae depended on the moisture in the upper soil layers and populations diminished at higher temperatures and lower moisture levels.

Using Malaise and window traps as well as sweep netting, Salmela (2001) surveyed the **Nematocera** associated with 27 springs and springbrooks in Southern

Finland. Among the 2714 individuals collected, Salmela found 95 species, comprised of 24 **Tipulidae**, 2 **Cylindrotomidae**, 54 **Limoniidae**, 12 **Pediciidae**, and 3 **Ptychopteridae**. This is a habitat that typically has extensive bryophyte cover.

Cylindrotomidae

The **Cylindrotomidae** is one of the families of the **Tipulomorpha**, an infraorder whose families were once included in the family **Tipulidae**; then the family **Cylindrotomidae** and others were separated. But the trend today is that most researchers include these 115 species in the **Cylindrotominae**, back in the family **Tipulidae**. I have maintained the separation here for ease of discussion.

The flies are yellowish to pale brown, 11-16 mm long. Most of the larvae are herbivores, and some are adapted for living among and eating bryophytes (Figure 2-Figure 3).

Figure 2. *Cylandrotomidae* eating *Cratoneuron filicinum*. Photo courtesy of Misha Ignatov.

Figure 3. *Cratoneuron filicinum* eaten by Tipulidae. Photo courtesy of Misha Ignatov.

Adaptations

The *Cylandrotomidae* larvae often occur among bryophytes and appear to exhibit camouflage to that habitat by their coloration and numerous horizontal, elongated, cuticular lobes on the integument. Imada (2021) explored the selective pressures and functions that might be responsible for the retention of these characters. He challenged the notion that this apparent camouflage protected the larvae from predators because of the apparent absence of visual predators such as birds. Could it be that the camouflage is so good that the birds never find these larvae?

So of what importance, if any, are the lobes? Imada (2021) noted that these moss dwellers tended to crawl among the mosses, with movement starting at the posterior end and shifting to the anterior end. Imada then considered that these lobes might contribute to that movement on the soft moss beds. He found that the musculature of the larvae seems to support this movement, but he has not yet been able to demonstrate whether or not this is the case. The coloration of greens and browns, while adaptive as camouflage among the mosses, is common among plant-eating larvae in general and therefore may represent an evolutionary leftover from related families of Diptera.

Triogma

Triogma trisulcata (Figure 1, Figure 5-Figure 4) is one such mimic from upland seepage bogs and streams (Falk 1991), mosses of springs (Hemmingsen 1968), and eutrophic fens (Mannheims 1965; Salmela 2002). In streams the larvae hook themselves onto mosses such as *Fontinalis antipyretica* (Figure 6) or *Calliergonella cuspidata* (Figure 7). This species lives among the mosses and feeds on them, resembling the mosses where they live (Alexander 1920).

Figure 7. *Calliergonella cuspidata*, home for *Triogma trisulcata*. Photo by Michael Becker, through Creative Commons.

Diogma

The genus *Diogma* (Cylindrotomidae) is a terrestrial version resembling the more aquatic *Triogma trisulcata* (Figure 5-Figure 4) (Brinkmann 1997). It often lives near the water in humid terrestrial mosses and like *T. trisulcata* has dorsal processes that help to camouflage it, along with its green color (Müggenburg 1902). The larvae remain small throughout winter, reaching 2 cm at maturity. The pupae likewise live among the mosses. Müggenburg reported that *Diogma glabrata* (Figure 8) not only lived among leaves of the moss *Rhytidiadelphus squarrosus* (Figure 9) as larvae and pupae, but also that it ate them and laid its eggs there in the leaf axils. Adults emerge from the pupae in only a few days.

Cylindrotoma

The terrestrial members of this genus (Figure 10) likewise spend their larval stage among terrestrial mosses or on marsh plants (Brinkmann 1997).

Phalacrocer

This genus is fairly restricted in its range with the exception of *Phalacrocer replicata* (Figure 11). This moss dweller is a cosmopolitan species, occurring in North America, northern Europe, and northern Asia (Wikipedia 2014). *Phalacrocer replicata* larvae (Figure 15) feed on *Sphagnum* (Figure 12) (Clymo & Hayward 1982) and also live on *Warnstorfia exannulata* (Figure 13-Figure 14).

Figure 13. *Warnstorfia exannulata* habitat and home for *Phalacrocer replicata*. Photo by J. C. Schou, with permission.

Figure 14. *Warnstorfia exannulata*, home for *Phalacrocer replicata*. Photo by J. C. Schou, with permission.

The young larvae of the genus *Phalacrocer* (Figure 15) are transparent, permitting the green coloration of the moss to show through (Alexander 1920). Older larvae are

a brownish green with a striping that somewhat resembles the light and dark shades of moss branches. Long filamentous processes on the larvae help provide disruptive coloration that makes them more difficult to see. The larvae can survive for a long time under water, but also can survive a long time out of water. They can even survive frozen in ice for the duration of winter. They are sluggish and hang onto the mosses with their anal hooks, swaying back and forth. When they do move through the mosses, they alternately grab the moss with their mandibles and anal hooks. When they are disturbed, they roll into a ball like roly-polies. The female deposits her eggs in the leaf axils of the mosses.

Figure 15. *Phalacrocer replicata* larva, a moss dweller and moss consumer. Note the green color of the digestive tract and the transparency of the larva. Photo by Paul T, through Creative Commons.

Not surprisingly, these larvae remain in the mosses to pupate (Figure 16). When they emerge, they climb out the pupal encasement in its upright position (Figure 17), emerging from the top.

Figure 17. *Phalacrocer replicata* adult emerging from its pupa on moss in Michigan, USA. Photo by Janice Glime.

Phalacrocer tipulina (Figure 18) is another bog dweller in this family. It lives in or near the mountain peat bogs and as a larva eats mosses and other plants (Alexander 1942; Fetzner 2007).

Figure 18. *Phalacrocer tipulina* adult, a bog dweller. Photo by Chen Young, through Creative Commons.

Liogma

Liogma is one of the genera that exhibits cryptic coloration. The larvae live among mosses and feed on them (Alexander 1920; Byers 1961; Fetzner 2007). And they look like mosses in coloration and markings (Alexander 1920). One of these is *Liogma nodicornis* (Figure 19-Figure 21), a species that lives in *Hypnum cupressiforme* (Figure 22-Figure 23) as larvae and pupae.

Limoniidae

This family is often included as a subfamily in the **Tipulidae**. The species *Limnophila alleni* (Figure 24- Figure 25) was among early reports of members of this family that made use of mosses. Alexander (1919) reported that the females laid their eggs in mosses, flying low over the substrate until they find a suitable place.

Figure 21. *Liogma nodicornis* mating, a species that spends its larval and pupal life in mosses such as *Drepanocladus*. Photo by Stephen Cresswell, with permission.

Figure 24. *Limnophila* larva; some species hatch among mosses. Photo by Tom Murray, through Creative Commons.

Figure 25. *Limnophila alleni* adult, a species that oviposits among mosses. Photo by Chen Young, through Creative Commons.

The **Limoniidae** species tend to be in moist habitats. *Paradelphomyia fuscata* (Figure 26) was among the four most common species along springs in southern Finland (Salmela 2001).

Figure 26. *Paradelphomyia fuscata* adult, a common species along springs in Finland. Photo by Marko Mutanen, through Creative Commons.

Geranomyia vitiella has an unusual habit worth noting. Its larvae live on leaves of *Pandanus* in moist habitats of Fijian rainforest (Beaver & Ryan 1988). The larva makes a tube of jelly on the upper surface of the leaf, living and moving in it and emerging to feed on dead **epiphylls** (mosses, liverworts, fungi, algae, and lichens that live on the leaves) and the associated decaying matter and microbes (Beaver & Ryan 1988). When it is mature, it changes its position to the lower surface, producing an even

larger mass of jelly. It pupates in the jelly. These jelly masses protect both larvae and pupae against both desiccation and natural enemies. Beaver and Ryan assumed that the eggs are laid among the epiphylls.

Hancock (2008) reports that Falk (1991) reared *Gnophomyia viridipennis* from moss collected from a fallen tree trunk of beech in Great Britain. Previous records indicate the species may prefer *Populus* species.

Arroyo-Rodríguez *et al.* (2007) experimented with *Geranomyia recondita* feeding in the lab. They offered three species of **Lejeuneaceae** – small leafy liverworts that are common among epiphylls. Only 30% of the larvae consumed the offered liverworts, but this demonstrates that they can eat live liverworts. They fed mostly on *Lejeunea* (Figure 27) and never ate *Leptolejeunea* (Figure 28). Arroyo-Rodríguez and coworkers suggested that this avoidance indicates they avoid liverworts with aromatic compounds. The larvae also consumed other epiphylls on the leaves. The jelly mass area had a negative correlation with the temperature, a relationship the authors interpreted as an indication the larvae are more active at night since the masses were larger at that time. The larger jelly mass would give them a larger foraging area.

Figure 28. *Leptolejeunea elliptica*, member of a genus rejected as food by *Geranomyia recondita*. Photo by Yan Jia-dang, through Creative Commons.

Geranomyia sexocellata near Cape Town, South Africa, uses a similar gelatinous tube, but it adds minute sand grains and attaches the tube to mosses in small trickles of water (Harrison & Barnard 1972). *Limonia capicola* larvae live among mosses at the edge of rapidly flowing small streams. Similarly, larvae of *L. rostrata* (= *Geranomyia rostrata*; Figure 29) live among mosses, liverworts, and filamentous algae on wet rocks (Rogers 1927). The larvae occur between the layers of liverwort thalli or in contact with stems of the mosses where they feed on the leaves. They seem to prefer the terminal leaves on the smaller stems in the lab, but in the field they are mostly found deep within the mat. Their translucent greenish color and slow movement make them hard to see. The larvae construct a tube and feed from its safety. Pupation occurs at the distal ends of the larval tubes. *Limonia annulata* (Figure 30-Figure 31) adults tend to occur on the moss-covered tree bases in forests (Fetzner 2008).

The genus "*Gonomyia*" has been split into a number of genera, several of which include bryophyte dwellers. Byers (1961) reported use of bryophytes as habitat by at least some *Erioptera* larvae. Salmela (2001) found *Erioptera pederi* (Figure 32) among the *Nematocera* along springs and springbrooks in southern Finland.

Figure 32. *Erioptera pederi* adult, a species that lives along springs and springbrooks and larvae can occur among the bryophytes. Photo by Marko Mutanen, through Creative Commons.

Falk (1991) found that *Ellipteroides alboscuteallatus* (previously in *Gonomyia*; Figure 33) seemed to be associated with wooded mossy calcareous seepages. Several of the *Limoniidae* were published just as *Gonomyia*, so other bryophyte dwellers may be lurking in

that former genus. In their search for indicator species, Salmela and Ilmonen (2005) recorded 29 species of craneflies (**Tipuloidea**) from Malaise traps in the Kauhaneva mire system in Finland. They found the highest diversity in mesotrophic sites, with the oligotrophic and ombrotrophic sites having equally low diversity. *Erioptera flavata* (Figure 34) and *Phylidorea squalens* (Figure 35) were indicators of mesotrophic sites (Figure 36), but they found no indicators for the low-nutrient sites.

Pediciidae

The **Pediciidae** (Figure 38) is another family that is often included as a subfamily in the **Tipulidae**. In addition to the two members of **Limoniidae**, Salmela and Ilmonen (2005) found that *Pedicia rivosa* (Figure 39-Figure 40) and *Tricyphona immaculata* (Figure 41) indicated mesotrophic sites in the Kauhaneva mire system, but there were no indicators for the low-nutrient sites. These two species and *Pedicia straminea* (Figure 42) were among the four most common species and often the most abundant species of the **Diptera** collected around southern Finnish springs (Salmela 2001).

Tipulidae – Craneflies

Most of the craneflies associated with bryophytes are aquatic, but a few terrestrial taxa give the bryophytes special importance. Alexander (1919) considered the **Tipulidae** family to serve as a major food group for the vertebrates. *Tipula* species on the Pribilof group in the Bering Sea are abundant in the summer. Larvae are especially common under mosses where they feed on the rhizoids. As many as 20 larvae can occur in a 30-cm square; considerable areas of mosses are killed by their activity (Figure 3). To add to destruction by the larvae, foxes dig up large areas of mosses to find the juicy larvae for food. Hofsvang (1997) noted the wide range of larval habitats, from water to mosses to dry logs. As adults, the **Tipulidae** typically live only a few days and some don't eat as adults.

In West Germany, changes in some of the fly populations are directly linked to changes in bryophyte cover (Wagner 1980). Morris (1986) reports on "an unusual habitat" for the overwintering of European cranefly larvae, but it appears that craneflies are the most important group utilizing the terrestrial bryological habitat. Craneflies are those insects that tend to cling around the ceiling and look like giant mosquitoes.

Adaptations

Some craneflies (**Tipulidae**) are highly adapted to their mossy habitat, with some taxa colored in such a way as to resemble a moss branch, as discussed under the various genera. Brindle (1957) observed that the **Tipulidae** that live among bryophytes have special anal papillae (Figure 44-Figure 45) to help them gain oxygen. I have been unable to verify that with the more recent data available.

Figure 45. *Tipula abdominalis* larval respiratory disk with large grey papillae. This species likewise is not a moss dweller. Photo by Thomas Palmer (Ophis), with permission.

Among the bryophytes they select, growth form is important (Gerson 1982). The compact species like *Bryum argenteum* (Figure 46) and *Ceratodon purpureus* (Figure 47-Figure 48) hinder tunnelling by the larvae, whereas loose growth forms like those of *Climacium* (Figure 49), *Polytrichum* (Figure 50), and *Plagiomnium cuspidatum* (Figure 51) are too diffuse for making tunnels (Byers 1961). Byers also concluded that *Polytrichum* and thallose liverworts were not soft enough. I have to wonder if secondary (antiherbivory) compounds might be important for protecting the thallose liverworts.

Figure 51. *Plagiomnium cuspidatum* showing the openness of the branches, unsuitable for tunnelling by *Tipulidae*. Photo by Michael Lüth, with permission.

Mosses can be a major portion of the diet of *Tipulidae* larvae (Richardson 1981; Pritchard 1983). However, the feces of some species have undigested vegetable particles in the feces, including mosses, suggesting that the food value may be from periphyton on the mosses and that the

mosses are not digested (Pritchard 1983). At least *Tipula abdominalis* (Figure 52-Figure 53) larvae have a high pH in the gut that permits them to digest leaf litter (Martin *et al.* 1980; Sharma *et al.* 1984). But leaf litter typically has fungi that begin the process to prepare them for digestion (Barlocher 1985). The mosses are living cells and thus gaining access to the contents inside the cell walls is more difficult.

Tipula

Tipula (Figure 55-Figure 60) is a worldwide genus with 59 species in Britain alone (Freeman 1967). It is a typical wet habitat fly, especially in its larval stage. Using sweep nets (catching adults), Freeman (1968) found more species in wet or woodland habitats than in dry or non-woodland habitats. Not surprisingly, it feeds on the mosses in these habitats. And it is also not surprising that in the open and drier habitats the peak in number of species present occurs in spring and late summer, whereas in the more moist and shaded habitats the diversity remains relatively constant during the entire period of spring to late summer. And of course Freeman found more species in the more shaded or moist habitats.

Sevchenko (1966) found that larvae of *Tipula stigmatella* (Figure 55) / *T. submaculata* (Figure 56) live among dry mosses, especially *Brachythecium velutinum* (Figure 54) on tree roots, and feed on the moss. Savchenko

(1964) likewise found that *Tipula benesignata* (Figure 57) feeds on mosses living under the forest cover. In fact, the association of fly larvae, and especially the crane flies (*Tipulidae*), is so strong that Oldroyd (1964) suggested that flies arose from ancestors that had larvae that lived in wet moss.

Figure 57. *Tipula benesignata*, a species that feeds as larvae on mosses under forest cover. Photo by Marko Mutanen, through Creative Commons.

Brindle (1960) found a correlation that may be a moss adaptation for moss-dwelling *Tipula* (Figure 58-Figure 59). The moss feeders always have four pairs of short anal papillae at the posterior end. They never have long papillae like the ones on larvae from wetter environments. On the other hand, this may simply be an evolutionary correlation of two divergent groups. But spiracular disk size also differs (Todd 1993) and it would be interesting to compare the size of this respiratory organ with available airspace within the bryophyte mat inhabited.

Figure 58. *Tipulidae* – herbivore on the moss *Cratoneuron filicinum*. Photo courtesy of Misha Ignatov.

Figure 59. *Cratoneuron filicinum* – food for a *Tipulidae* larva. Photo courtesy of Misha Ignatov.

Zasypkina and Ryabukhin (2001) described the insects that lived in intermediate habitats in northeast Asia. They reported that the larvae of *Tipula glaucocinerea* live in wet depressions with no open water, living in moss litter under snowfields as well as those on the banks of bog pools and small lakes. Larvae of *T. melanoceros* live in boggy forest clearings, in peat mosses, or in decaying *Sphagnum* where they occur in groups.

Tipula confusa (Figure 61-Figure 60) not only chose to live in clumps of *Brachythecium rutabulum* (Figure 62) on walls and buildings, but it also consumed its mossy housing (Todd 1993). *Tipula confusa* had a significant preference for *Dicranella heteromalla* (Figure 63-Figure 64) ($70.0 \pm 1.4\%$ S.E. of observations), with *Brachythecium rutabulum*, a woodland species, preferred second ($47.3 \pm 1.3\%$ S.E.); both a woodland species, *Mnium hornum* (Figure 65) ($41.7 \pm 1.5\%$ S.E.), and a moorland species, *Sphagnum recurvum* (Figure 66) ($40.0 \pm 1.4\%$ S.E.) were third in preference. *Tipula subnodicornis* (Figure 67) spent significantly more time on *Eurhynchium praelongum* (Figure 68) than on *Sphagnum recurvum*, and exhibited the greatest preference for *Eurhynchium praelongum* ($42.8 \pm 1.7\%$ S.E. of obs), but not significantly higher than for *Dicranum scoparium* (Figure 69-Figure 70) ($40.6 \pm 1.5\%$ S.E.), for which preference was not significantly higher than that for *Sphagnum recurvum* ($38.0 \pm 1.4\%$ S.E.). Both *Tipula confusa* and *T. subnodicornis* preferred *Polytrichum commune* (Figure 71) significantly less than any other moss studied. Brindle (1960) found that on moorlands *T. subnodicornis* is typically associated with semi-aquatic mosses such as *Sphagnum* and "*Hypnum*" (presumably *Drepanocladus* s.l.; Figure 72).

Figure 72. *Drepanocladus exnnulatus*, a typical emergent moss home for *Tipula subnodicornis*. Photo by Michael Lüth, with permission.

In lab choice experiments, Todd (1993) showed that *Tipula confusa* (Figure 61-Figure 60) preferred mosses from woodland habitats, whereas *Tipula subnodicornis* (Figure 67) did not show any overall preference for either woodland or moorland mosses. Todd found that eight (of 11 studied) species of *Tipula* were moss feeders, seven of which were in the subgenus *Savtshenkia* [*Tipula rufina* (Figure 73), *T. confusa*, *T. pagana* (Figure 74), *T. staegeri*, *T. limbata* (Figure 75), *T. alpium* (Figure 76), *T. subnodicornis*]. Only *Tipula montana* (Figure 90) was in the separate subgenus *Vestiplex*. On recently burned *Calluna* heath larvae live among and feed on dead introduced mosses, *Campylopus introflexus* (Figure 77). Falk (1991) reported that *Tipula limbata* also occurs in boggy forests in Scotland.

Figure 77. *Campylopus introflexus*, an introduced moss in Europe that serves as home and food for some *Tipula* species. Photo by Michael Becker, through Creative Commons.

Approximately one fourth of the British species of *Tipula* feed on mosses, but in some species the ingested mosses depart in the feces with no evidence of breakdown (Todd 1993). That does not appear to be the case for *Tipula montana* (Figure 90) – it feeds exclusively on mosses. This species does not grow at temperatures below 7°C (Todd 1996). Perhaps the moss maintains a higher temperature where it can successfully complete its life cycle in a timely manner.

Mandible size seems to be an important character in bite size. **Grass feeders** typically have longer mandibles than moss feeders. *Tipula paludosa* (Figure 78-Figure 82) has significantly larger mandibles and ingests larger particles than the smallest mandibles of this group, exhibited by *T. rufina* (Figure 73), a species that ingests smaller particles. There was no evidence that the cell walls had been broken down, indicating that crushing of cells by the mandibles was the only means by which larvae could obtain the nutrients within the cells. Furthermore, biflavonoids in the cell walls of mosses apparently resist fungal invasion, thus making it difficult or impossible for the larvae to digest the cell walls. This explains the reason for the approach of taking the same size of particles throughout their growth because larger particles would not offer much more digestible food. Other kinds of insect larvae are known to increase particle size as they grow. The larvae apparently, as one might expect, eat from edge inward on the leaf, leaving less damage in the mid-cell region. Some *Tipula* species do switch moss species as they grow. Heavy metals accumulated by the bryophytes from pollution can also deter feeding.

Figure 78. *Tipula paludosa* larva, a species with large mandibles that feeds on mosses. Photo by Roger S. Key, with permission.

To these members of the subgenus *Savtshenkia*, Savchenko (1964) adds *Tipula benesignata* (Figure 83). This species likewise feeds on mosses under forest cover.

Figure 83. *Tipula benesignata*, a moss feeder under forest cover. Photo by Marko Mutanen, through Creative Commons.

It is of interest that the tipulid populations do not appear to support **Gause's law**. That is, in this group, closely related species tend to occur together. However, several factors may actually separate their niches. The adults in the same subgenus may be separated in time. Other factors such as mating behavior also help to keep the species from interbreeding.

Freeman (1967) explored **Gause's law** in the **Tipulinae**. Using a 350 x 350 m area, Freeman was able to demonstrate that each of the 23 species of *Tipula* was restricted to one or occasionally two of the five plant communities represented. Within each of those plant communities there was no evidence of competition for food in the soil-dwelling *Tipula* species, but some species, especially *T. paludosa* (Figure 78-Figure 81), became aggressive, directly attacking competitors. Ten species of *Tipula* were able to co-exist for nine years in one plant community, the **carr** (waterlogged wooded terrain). They seemed to accomplish this co-existence through use of microhabitats.

Coulson (1962) found that *Tipula paludosa* (Figure 78-Figure 81) was restricted to mineral soils in the Pennine, UK, moorland. Morris (1986) found a more unusual habitat for *Tipula paludosa*. These crane fly larvae, known as leatherjackets in their larval stages and numbering in the hundreds, were living among mosses on the roof of a covered picnic table in Newfoundland, Canada. The roof shingles had accumulated sand and organic matter that sustained the mosses.

Tipula subnodicornis (Figure 67) has wide occurrence in the Pennine moorland of the UK, but it occurs only in areas with peat (Coulson 1962). It demonstrates niche separation from *T. paludosa* (Figure 78-Figure 81) in the moorland by emerging mostly within an 11-day period, whereas for *T. paludosa* emergence is spread mostly over 23 days in late July and early August. The time of day for emergence differed, with *T. subnodicornis* emerging around mid-day and *T. paludosa* emerging at 21:00 h, shortly after sunset. Mating of both species occurred shortly after emergence, thus separating the two species in time. Both species began laying eggs immediately after mating, with *T. subnodicornis* occurring deeper than those of *T. paludosa*. Densities of final instar larvae of *T. subnodicornis* reached more than 100 per m² on *Juncus squarrosus* moorland (Figure 84) but was much lower on the *Sphagnum* (Figure 12; Figure 84) bog areas. In dry

spells such as that of 1955, there was high mortality among eggs and first instars in *T. subnodicornis*. Density similar to previous years was maintained only in areas such as *Sphagnum* flushes (Figure 84) where water was retained.

Figure 84. *Sphagnum* in flush with *Juncus* on Mt. Snowdon, Wales. Photo by Janice Glimme.

With so many *Tipula* species occurring among mosses as larvae, we must assume that the mosses are suitable, perhaps preferred or exclusive egg-laying sites for many species (Figure 85). One such species that was identified early was *Tipula nobilis* (Figure 86) that laid eggs in mosses (Alexander 1919).

Figure 85. *Tipula williamsiana* female laying eggs on mosses. Photo by Chen Young, through Creative Commons.

Figure 86. *Tipula nobilis* adult, a species that uses mosses for oviposition. Photo by Chen Young, through Creative Commons.

Among this group are crane flies that eat mosses. Sevchenko (1966) found that crane flies live among and feed on dry *Brachythecium velutinum* (Figure 54) on tree roots. The larvae of *Tipula oropezoides* (Figure 87) are regular feeders on *Rhizomnium punctatum* subsp. *chlorosum* (see Figure 88) along streams in eastern deciduous forests of the United States (Wyatt & Stoneburner 1989). The larvae typically strip the leaves of their lamina, leaving the costa and border. Could it be that borders discourage feeding by some invertebrate herbivores?

Some of the crane flies require 4 years to complete larval development, especially in Arctic ecosystems (MacLean 1980). The soil organisms there, and especially the **Diptera**, support the breeding populations of many breeding bird species, with crane flies being the most important prey. Hence, timing is important and the bird breeding is timed so that the young birds can feed on the emerging adult **Diptera** in early to mid July. In June and again in August, the **Diptera** larvae, especially crane flies, become the most important prey items. An overproduction of crane flies is necessary to compensate for the predation. These birds consume 35-70% of the annual production of *Tipula carinifrons* (Figure 89) and 50% of the peak emergence of all adult crane flies.

Figure 89. *Tipula carinifrons* male adult, a moss dweller in dry *Sphagnum* hummocks. Photo by Ashley Bradford, through Creative Commons.

In the blanket bogs of British moorland, larvae of *Tipula subnodicornis* (Figure 67) feed on liverworts (Coulson & Whittaker 1978; MacLean 1980). In a *Sphagnum* (Figure 12) bog, Smirnov (1958, 1961) found large quantities of *Sphagnum* leaves in gut analyses only in

Tipula larvae. In the coastal tundra of Barrow, Alaska, USA, *Tipula carinifrons* (Figure 89) is common in dry moss hummocks. Smirnov estimated that more than 25% of the energy consumed by crane fly larvae came from living plants.

Smith and coworkers (Smith 1997; Smith *et al.* 2001) examined the balance between the need for food and the need for shelter in the crane fly *Tipula montana* (Figure 90). Larvae were reared on single genera of mosses and the resulting growth in weight differed by a factor of two. When the larvae were given a choice between two genera, they chose the moss that had the most beneficial food quality. However, their response to *Pleurozium schreberi* (Figure 91-Figure 92) was a surprise. Although this food had the best food quality and resulted in the best growth, it was among the least eaten by the larvae. Fecal pellet analysis gave different results from those of observations, perhaps due to differences in digestibility. The sedge *Carex bigelowii* was eaten in preference to any of the mosses during the experiments, suggesting that the crane flies benefitted from using the bryophytes as a refuge, overriding the importance of dietary quality and making the trek to sedges less advantageous.

Tipulids are important contributors to the food web, and *Tipula montana* (Figure 90) is no exception. In Scotland the Dotterel (*Charadrius morinellus*; Figure 93) adults and chicks feed selectively, with adults eating mostly beetles, sawflies, and both adults and larvae of *T. montana* (Galbraith *et al.* 1993). The adult Dotterels contained a high proportion of beetles. The chicks, on the other hand, took more soft-bodied food. Every two years the adults of *T. montana* emerge *en masse*. At that time, both chicks and adults feast on tipulids. In one case, the larvae of *T. montana* formed much of the diet soon after the birds arrived at their breeding grounds and again just before they left in the autumn. The preferred feeding habitats were the moss *Racomitrium lanuginosum* (Figure 94) or the rush *Juncus trifidus* (Figure 95) heaths or the transition zone between the moss heath and montane bog. When the montane bogs were close to the *R. lanuginosum* heaths, they met the feeding needs of both the chicks and adults, respectively.

Figure 95. *Juncus trifidus*, one of the preferred feeding habitats for *Tipula montana*. Photo by Opiola Jerzy, through Creative Commons.

Tipula borealis (Figure 96) is a species of wet woodlands. The larvae occur in well-rotted logs, often occupying the interface space under the surface mosses (Gelhaus 1986).

Figure 96. *Tipula borealis* adult, a species whose larvae often live under mosses on rotten logs. Photo by Chen Young, through Creative Commons.

One of the more unusual relationships is the use of the hornworts *Anthoceros agrestis* (Figure 97) and *Phaeoceros carolinianus* (Figure 98) (Bisang 1996). *Tipula* sp. larvae consumed both the gametophytes and sporophytes of these hornwort species. *Bryum* sp. (see Figure 99) and several seedlings in the same pots were not eaten.

Figure 99. *Bryum capillare*, a food source refused by hornwort-dwelling *Tipula*. Photo by Michael Lüth, with permission.

Prionocera

In the coastal tundra at Barrow, Alaska, USA, *Prionocera recta* (Figure 100) is restricted to mossy depressions (MacLean 1980).

Figure 100. *Prionocera recta* adult, a species that in Alaska is restricted to mossy depressions. Photo by Jukka Salmela, with permission.

Dolichopeza

Alexander (1920 in Gerson 1982) and Byers (1961) reported that *Dolichopeza* lives in and eats the mosses. Like several other *Tipulidae* (*s.l.*), larvae of *Dolichopeza americana* (Figure 101) has cryptic coloration of green with irregular markings and dark lines, permitting it to blend with its mossy environment (Byers 1961).

Figure 101. *Dolichopeza americana* adult, a species whose larvae have cryptic coloration among bryophytes. Photo by Tony Gallucci, through Creative Commons.

Dolichopeza americana (Figure 101) and *Oropeza* larvae, also craneflies, have color patterns that make them inconspicuous among the mosses and permit them to browse without being easily detected by predators (Byers 1961). *Dolichopeza barnardi*, *D. hirtipennis*, and *D. peringueyi* live in wet moss and liverwort cushions on the sides of waterfalls on Table Mountain, South Africa (Harrison & Barnard 1972). *Dolichopeza* females lay eggs in mosses (Gerson 1982). *Dolichopeza* larvae are bryophagous (Byers 1961).

Figure 102. This cranefly adult is emerging from its pupal case where it has spent the last few months in the moss mat. Photo by Janice Glime.

Lauren Russell (pers. comm.) found species of *Dolichopeza* in the Pacific Northwest, USA, to feed on living tissues of mosses and occasionally on liverworts. Roper (2001) reported *Dolichopeza albipes* (Figure 103) as a bryophage on mosses and liverworts in ghyll woodlands in Sussex, UK.

Figure 104. This pupa of a cranefly (**Tipulidae**) can be found among mosses. Photo by Janice Glime.

Dicranomyia

It is not unusual for bryophytes to house rare species. This habitat is time-consuming to sample, and sampling is destructive of the habitat, so the inhabitants are often overlooked. Most members of *Dicranomyia* (Figure 105) are aquatic, but *D. lackschewitzi* lives in seepages where there are sparse mosses in slumping coastal cliffs (Falk 1991). The species is considered extremely rare in Europe (Stubbs 1998).

Figure 105. *Dicranomyia chorea* adult; *D. lackschewitzi* lives in mosses in seepages on coastal cliffs. Photo by James K. Lindsey, with permission.

Dicranomyia goritiensis has a sporadic distribution (Kolcsár *et al.* 2015). It is associated with mosses and algae on rocks around waterfalls and rocky coastlines of Croatia and Greece.

***Nephrotoma* – Tiger Craneflies**

Immature stages of *Nephrotoma* typically occur among mosses, in soil, and in decaying wood (Alexander & McAtee 1921). *Nephrotoma virescens* (Figure 106) larvae live among wet mosses (Johannsen 1969).

Figure 106. *Nephrotoma virescens* adult, a species whose larvae live among wet mosses. Photo by Odin Toness, through Creative Commons.

Summary

Many species of **Diptera** lay their eggs among bryophytes, develop as larvae there, and pupate there. Some eat the mosses. And some eat the associated algae, bacteria, fungi, and microorganisms. And they are often selective in their food choices. Others have looser associations, landing there for moisture regulation or hiding there to avoid predation or escape wind and cold. Bryophyte structure affects colonization, with very compact mosses making tunneling difficult, and very loose structure providing too little protection for some.

The several families that were once **Tipulidae** have numerous species that live among bryophytes both in the water and on land. Some of these (especially *Triogma trisulcata*) are adapted to bryophyte living by being bryophyte mimics. Often members of *Tipula* seem to defy Gause's law, but on closer inspection we find they mate at different times of the day or in different time periods, live in different parts of the moss, or have other needs that separate their niches.

CHAPTER 12-19

TERRESTRIAL INSECTS:

HOLOMETABOLA – DIPTERA

NEMATOCERA 2

Figure 1. Fungus gnat herbivory on *Buxbaumia aphylla* capsules. Note the topless setae. Photo by Jörg Müller, with permission.

Cecidomyiidae – Gall Midges

Some members of this family that are typical of trees can be found in moss tussocks or among the mosses on tree trunks. These include members of the genus *Peromyia* (Figure 2) (Perkovsky & Fedotova 2004). Mosses are so important to some species as to be the source of the name – including *Bryocrypta dubia*, *Cryptoneurus muscicola*, *Bryomyia bergrothi*, and *Peromyia muscorum*, as well as *Peromyia palustris* (Mamaev & Krivosheina 1993).

Stabaev (in Mamaev & Krivosheina 1993) found that larvae of gall midges comprised an important part of the fauna in primary soils under mosses. But Mamaev and Krivosheina comment that there has been little study of the moss-inhabiting gall midges, promising surprises for those who explore them.

Figure 2. *Peromyia* adult, a genus that sometimes lives among bryophytes on the ground and on tree trunks. Photo by Charley Eiseman, through Creative Commons.

Mycetophilidae – Fungus Gnats

This family primarily feeds on fungi, but a few species eat algae, mosses, and liverworts, while others are **saprophagous** (feeding on or obtaining nourishment from dead or decaying animal matter) in bird nests (Hackman *et al.* 1988; Økland 1994). *Cordyla fusca* (see Figure 3) is significantly correlated with mosses (Økland 1994). On the other hand, *Boletina gripha* (Figure 4) and *Acnemia nitidicollis* have high negative correlations with mosses. The correlation of some members of this family with mosses may relate to a concentration of host fungi in the soil that likewise correlates with the mosses or their habitat.

Figure 3. *Cordyla fissa* adult; the presence of *C. fusca* correlates with mosses in European forests. Photo by Hanna Koivula, through Creative Commons.

Pettet (1967) reported that larvae in the **Mycetophilidae** parasitize the thallose liverwort *Riccia frostii* (Figure 5). The infestation occurred when the Nile floodwaters receded in Sudan. The infestation spread and increased until virtually all thalli were infected and remained so until flooding returned. The infestation then completely disappeared and although Pettet watched for it closely for the next five years, it never returned. The larvae eat the internal tissues of the thalli, causing the thallus to become non-turgid and flabby. In the last stages of the infestation, the liverwort surface disintegrates. Each rosette revealed 5-25 small, yellow-orange larvae. Pupation likewise occurred inside the thallus. Such interactions can easily go unnoticed and close observation may reveal other interesting bryological habitats for insects.

Figure 4. *Boletina gripha* adult, a species that is negatively correlated with mosses. Photo by Hanna Koivula, through Creative Commons.

Figure 5. *Riccia frostii*, a species that is parasitized by **Mycetophilidae**. Photo by Rosemary Taylor, with permission.

Müller (2012) found several adult fungus gnats (Figure 1, Figure 6) feeding on spores in capsules of *Buxbaumia aphylla* (Figure 7) in Germany. It is likely that at least some of the spores escape being eaten and are transported by the fungus gnats, later being deposited elsewhere.

Figure 6. Fungus gnat herbivory on capsules of *Buxbaumia aphylla*. Photo courtesy of Jörg Müller.

Figure 7. *Buxbaumia aphylla* with fly. Photo courtesy of Sabovljevic.

Sciaridae – Dark-winged Fungus Gnats

Fungus gnats (Sciaridae) deposit eggs in organic matter, including mosses (Hurley 2006). When such habitats are present in greenhouses, the fungus gnats become pests. Shin *et al.* (2012) reported that these gnats inhabit peat bogs, thus making this a source of the gnats in nurseries and greenhouses. Peck and Moldenke (2010) are concerned with invertebrate invasions through commercial uses of mosses. Among those invertebrates, they found a few adult sciarid flies.

Ponge (1991) found that some of the **Sciaridae** larvae on the Scots pine (*Pinus sylvestris*) forest floor consumed mosses, but they also consumed fungi. But not all interactions of this family with bryophytes are so casual. Sawangproh (2014) notified me of finding the larvae of a black-winged fungus gnat, *Scatopsciara cunicularius* (Figure 8-Figure 14), feeding and tunnelling on a liverwort thallus, *Marchantia polymorpha* (Figure 8-Figure 10), in the greenhouse. The feeding causes serious damage to both growth and survival of the liverwort. The gnat population expands when the ambient temperature increases in early spring. When it is cool (12°C), the larvae take longer to develop and consequently do more damage to the thalli than when reared at 22°C (Sawangproh & Cronberg 2016; Sawangproh *et al.* 2016). Following the larval damage, the thalli are more susceptible to secondary attacks by other pests and fungal infections.

It does not appear that these bryophagous fungus gnats need fungi. *Scatopsciara cunicularius* (Figure 8-Figure 14) can complete its entire life cycle with only liverworts as food (Sawangproh & Cronberg 2016; Sawangproh *et al.* 2016). This is an unusual relationship because few insects are known to eat liverworts. Sawangproh and coworkers (2016) suggested that the liverwort oil bodies with their essential oils may serve as a deterrent to herbivory. We still have little understanding of the mechanisms that permit some insects to eat the bryophytes, especially those with antiherbivore compounds, whereas most insects seem unable to. Just imagine what the world might be like with no insects. Bryophytes would most likely be far more speciose, whereas the insects may have eliminated those that did not develop antiherbivore compounds early in their evolution.

Bradysia sp. (Figure 15-Figure 16) larvae (Figure 15) can be found under several species of *Bryum* [*B. argenteum* (Figure 17), *B. dichotomum* (Figure 18), and *B. pachythea* (Figure 19)], at least in flower pots (Downing & Selkirk 1996). Downing and Selkirk observed that the mosses had a rough, patchy appearance, "like they had been ploughed." These larvae eat the moss rhizoids. My surprise was that after drenching the pots with a solution of 2 g Alsystarin in 10 L water the bryophytes grew back in two weeks!

Ceratopogonidae – Biting Midges

One might not expect chocolate to be involved in this chapter, but certain members of the **Ceratopogonidae** (Figure 20) are associated with cacao (chocolate) flowers as important pollinators (Winder 1977). On the same trees, among the epiphytic mosses, one can find *Atrichopogon* (Figure 21-Figure 22), *Stilobezzia* (Figure 23), and *Dasyhelea* (Figure 24-Figure 26), all members of **Ceratopogonidae**.

Many of the **Ceratopogonidae** have aquatic larvae, so it is natural that the adults hang out in moist conditions, near the water sources where they can lay eggs. Hence, some will naturally land on mosses to rest or obtain moisture (Figure 27).

Figure 27. **Ceratopogonidae** male on moss. Photo by Christophe Quintin, through Creative Commons.

Kolenohoelea calcarata occurs among mosses in springs, and *Serromyia femorata* (Figure 28) occurs among damp mosses (Strenzke 1950). But *Culicoides impunctatus* (Figure 29) (biting midge) larvae at one site in western Scotland actually avoided most mosses (Blackwell *et al.* 1999). Their distribution and larval counts had a significantly negative correlation with all mosses other than species of *Sphagnum*. This species increases its number of eggs when provided with *Sphagnum* egg-laying sites (Carpenter *et al.* 2001). Members of the genus *Forcipomyia* (Figure 30), another biting midge, also builds nests in *Sphagnum* (Oldroyd 1964).

Chironomidae – Midges

Bettis (2008) compared the abundance of invertebrate fauna in two different *Grimmia* (Figure 31) morphotypes, one on exposed granitic outcropping and one at a protected seasonal riparian habitat. In both cases, **Chironomidae** larvae were among the major invertebrates present. Some of the **Chironomidae** can emerge from mosses in large numbers (Figure 32), especially in polar regions, and adults cover mosses as they emerge (Figure 33) (pers. obs.).

Figure 31. *Grimmia laevigata* on boulder, potential home for **Chironomidae**. Photo by Alan Cressler, with permission.

Figure 33. **Chironomidae** adults on moss at Helfdi, Myvatn, Iceland. Photo by Janice Glime.

Although **Chironomidae** are abundant aquatic larvae, they also occur on land. The *Cricotopus* (Figure 34-Figure 35) larva occurs with **epilithic** (growing on rocks) and **epiphytic** (growing on plants, usually trees) liverworts in western Oregon and Washington, USA, and feeds on the leafy liverworts *Calypogeia* (Figure 36), *Gyrothyra underwoodiana* (Figure 37), *Jungermannia rubra* (Figure 38), *Porella navicularis* (Figure 39), and *Scapania bolanderi* (Figure 40) in the lab (Russell 1979). In the field they do considerable feeding damage to *Calypogeia fissa* (Figure 36) and *Jungermannia rubra*.

The **Chironomidae** may do an important service to some mosses. Harvey-Gibson and Miller-Brown (1927) reported that these midges, as adults, seem to be agents of fertilization for *Polytrichum commune* (Figure 41-Figure 42). In this species, the **paraphyses** (Figure 43) associated with both antheridia and archegonia exude mucilage (but no sugar). Small midges were among the continuous visitors to these gametangial areas. The insects lap the mucilage and get it on their body parts. If they visit at the right time, sperm may become attached as well and the midges that subsequently visit females may transfer live sperm to the appropriate location.

Moss-dwelling **Chironomidae** are abundant in and around springs. Lencioni *et al.* (2011) studied **Chironomidae** distribution in 81 springs in the Italian PreAlps and Alps. In 173 samples they found 26,871 **Chironomidae** representing all life stages except eggs. To illustrate the abundance of moss-dwelling **Chironomidae**, Nolte (1991) sampled and compared mosses that were intermittently out of the water on semi-submersed mosses near a spring with those in permanently submersed locations 700 m downstream. All of these larvae were small, and 98% were less than 5 mm in length. The total sampling revealed 65 species of chironomids in 26 genera, with greater species richness near the source in the semi-submersed mosses. But the mean abundance was 5X higher in the permanently submersed mosses compared to those that were semi-submersed at the spring. On the other hand, the maximum abundance anywhere was 830 larvae per 10 cm² in one semi-submersed sample. The dominance of the various chironomid taxa was dependent primarily on the location of the moss along the stream.

Ponge (1991) examined gut contents of forest floor animals in a 5x5 cm Scots pine litter. The subsequent feces were followed to determine the ultimate fate of the ingested material. Some of the fecal material included bryophytes and was the primary material in feces of both enchytraeid and lumbricid worms. In turn, the chironomid larvae consumed and digested the fecal material.

Chironomidae may play an important role in initial stages of both primary and secondary succession. These species specialize on open patches created by these

successional conditions and live in the early stage that is fallow, having mosses and lichens as pioneers (Frouz & Kindlmann 2001). The habitat generally has good quality food, but it is prone to severe desiccation in the summer that can decimate the larval population. In the Czech Republic and elsewhere, winter conditions permit the populations to replenish. The larvae are poor dispersers, but winged adults have the opportunity to move about. To explore the ability of these species to survive in this hostile environment, Frouz and Kindlmann studied *Smittia aterrima* (Figure 44), an abundant species in old fields. They found that eggs laid by the females from adjoining more developed vegetation were sufficient to replenish the lost populations.

Figure 44. *Smittia aterrima* adult, a species that includes mosses in its diet. Photo by James K. Lindsey, with permission.

Smittia aterrima (Figure 44) is common in disturbed areas, with up to 12,000 individuals per m² (Delettre & Lagerlöf 1992). These larvae live in the surface soil horizon and feed on plant litter, fungi, soil algae, and mosses (Frouz & Lukešová 1995). In České Budějovice, Frouz and Kindlmann (2001) tested the **source-sink hypothesis** [idea that organisms move from a favorable habitat (source), often as a result of overcrowding, to a sink that is less favorable, where they remain and accumulate] with this species and demonstrated that as their preferred open habitat became unsuitable, the larval population disappeared there. Ducrotoy (1980) and Delettre (1986) had observed the same phenomenon for terrestrial chironomids living among mosses on rocks, again as a result of drought. The larvae continue to exist in sub-optimal habitats during the drought and re-colonize the preferred habitats (including mosses) when favorable conditions return (Frouz & Kindlmann 2001). This migration maintains the source-sink survival strategy.

Other **Chironomidae** species have similar abundance patterns in these pioneer habitats. *Bryophaenocladus* cf. *illimbatus* (Figure 45) is a **parthenogenic** (having unfertilized eggs that develop into new individuals) moss dweller that lives in habitats with open and low vegetation (Frouz 1997). Both *Bryophaenocladus* cf. *illimbatus* and *Smittia aterrima* (Figure 44) decreased from the first to third year of the study as the field became less open and forbs taller than 20 cm became more prominent. Soil algae and mosses form an important component of food for both species (Frouz & Lukešová 1995).

Figure 45. *Bryophaenocladus illimbatus* adult, a species of mosses in sites with low, open vegetation. Photo by Marko Mutanen, through Creative Commons.

Sometimes one can find exciting new species by knowing the general habits of the genus. The snow-dwelling adults of *Bryophaenocladus thaleri* were discovered in barren areas of Dolomite Alps in Italy above 3100 m altitude. This species probably mates in **leks** (assembly areas where males gather during mating season to exhibit competing mating displays and attract females) on the ground because their males cannot fly (Willassen 1996). But the immature (larval) stages are so far unknown. Willassen suggests that we look for them among terrestrial mosses because that is a preferred habitat of other members of the genus. *Bryophaenocladus virgo* lives among mosses as larvae and adults and solves the flight problem by being **parthenogenetic** (giving birth without fertilization) (Cranston 1987). *Bryophaenocladus vernalis* (Figure 46) has been caught in the act of damaging rare mosses growing in chalk quarries in southern England.

Figure 46. *Bryophaenocladus* cf. *vernalis* adult male, a species that damages rare mosses in chalk quarries in England. Photo from NTNU Museum of Natural History and Archaeology, through Creative Commons.

Limnophyes minimus (Figure 47-Figure 49) is likewise a pioneer that lives in the shallow soil that is formed by the mosses, lichens, and raw humus (Delettre 1986). On rocks, mosses trap dust and soon accumulate a thin soil on rock surfaces. This provides suitable habitat for *Limnophyes minimus* in Brittany, France. This species also occurs in the sub-Antarctic where the adult females are parthenogenic (Hänel & Chown 1998). And these females do not feed. As larvae, this species joins *Pringleophaga marioni* (Lepidoptera, Tineidae; Figure 50) in their contribution to nutrient recycling on sub-Antarctic Marion Island.

Figure 50. *Pringleophaga marioni* adult, a lepidopteran moss-dwelling contributor to nutrient cycling on Marion Island in the sub-Antarctic. Photo by Steven L. Chown, with permission.

The females of *Eretmoptera murphyi* (Figure 51) from the Antarctic and sub-Antarctic are **brachypterous** (short-winged), making dispersal difficult. Not only is the female apparently parthenogenic, but males are unknown (Cranston 1985). This species has terrestrial larvae that live among damp mosses and peat.

Figure 51. *Eretmoptera murphyi* on a leafy liverwort, Prince Olav Harbour, South Georgia. Photo courtesy of Roger S. Key.

As already seen in the aquatic midges, living among mosses could present a danger from parasitic mites (Stur *et al.* 2005). But when those mosses are semi-terrestrial, the **Chironomidae** become unavailable to those aquatic parasitic mites.

Belgica

One of the best known of the moss-dwelling **Chironomidae** is *Belgica antarctica* (Figure 52-Figure 54). These larvae are abundant in damp mosses, grass roots, detritus, and around penguin rookeries and seabird nests in the Antarctic (Wirth & Gressitt 1967; Cranston 1985). The species overwinters as larvae (Strong 1967); all four larval instars overwinter (Benoit *et al.* 2007). Some also occur in meltwater pools and small ponds with algae.

Belgica antarctica (Figure 52-Figure 54) is the largest arthropod in Antarctica and is wingless (Gressitt 1967). The females lay their eggs in a gelatinous mass in damp mosses and the larvae disperse among the mosses about 10 days later. The mosses most likely make survival of this larger animal possible by providing a warmer refuge than the ambient temperature. Gressitt showed that temperatures in *Polytrichum* (Figure 41-Figure 42) there exceed that of the air by as much as 13°C. The temperatures in *Drepanocladus* (probably *Sanionia uncinata* – Figure 55) were closer to those of the air.

Figure 55. *Sanionia uncinata*, potential home for *Belgica antarctica*, but temperatures in this moss differ little from that of the air. Photo by Franz Xaver, through Creative Commons.

Temperature is not the only factor limiting the distribution of *Belgica antarctica* (Figure 52-Figure 54). Hayward *et al.* (2007) considered moisture to be as important as cold resistance in these polar invertebrates. With temperatures most of the year below 0°C, water is hence inaccessible for a long period of time. Hayward and coworkers found that when the larvae were desiccated at a high relative humidity (98.2%) they were more tolerant of desiccation and also exhibited increased freezing tolerance to -10 and -15°C. Nevertheless, all larvae were frozen at -10°C. Slow drying was important for this acclimation. The researchers found that osmolality increased, reaching its highest levels after five days at 98.2% RH, but that these values returned to predesiccation values with just one hour of rehydration, well before water content returned to predesiccation levels. They found no evidence of heat-shock proteins contributing to desiccation tolerance. Membrane phospholipid adaptation and metabolite synthesis appeared to be the important physiological mechanisms that enhanced both cold tolerance and desiccation tolerance, a conclusion also supported by Lee *et al.* (2006). I would consider it likely that the mosses are important in ensuring a high initial humidity and a slow rate of desiccation, permitting the larvae to acclimate.

Teets *et al.* (2011) examined the effects of repeated cold exposure on survival, energy content, and stress protein expression of the larvae of *Belgica antarctica* (Figure 53). Most of the larvae (>95%) survived a single 12-hour stint of -5°C when frozen in both the presence of

water and in a dry environment. However, after five cycles of repeated cold exposure to -5°C , survival of frozen larvae dropped to below 70%. On the other hand, survival of controls and supercooled (dry) larvae remained unchanged. Freezing during these repeated cold exposures resulted in a drastic reduction in energy reserves. After five of these cold exposures, the larvae had 25% less lipid, 30% less glycogen, and nearly 40% less trehalose than supercooled larvae. There were further indications of protein damage in this frozen group. There seemed to be no difference in larvae frozen for 60 continuous hours and those that had a total of 60 hours accumulated from repeated cold exposure. Teets and coworkers concluded that both survival and energy conservation benefitted from a dry microhabitat that remained unfrozen during repeated cold exposures. Do bryophytes provide such an environment, or must the larvae migrate into the soil to survive?

The larvae of *Belgica antarctica* (Figure 53) spend most of the year (7-8 months) encased in ice with soil (Elnitsky *et al.* 2008; Lopez *et al.* 2009), creating desiccating conditions. Elnitsky *et al.* (2008) explored the possibility that they use cryoprotection to survive. They found that after 14 days of subzero exposure in the lab the larval survival remained above 95%. They interpreted this as an indication that the larvae underwent cryoprotective dehydration. But they also considered that in their natural environment **cryoprotection** (low-temperature protection) may be constrained by **inoculative freezing** (process in which organisms actually freeze) because of the close contact of the larvae with environmental ice. Their ability to undergo cryoprotective dehydration during slow cooling within frozen soil is dependent on the soil moisture. The percentage of larvae that were able to resist inoculative freezing increased as the soil moisture decreased. The researchers suggest that the larvae are likely to undergo cryoprotection under the right conditions.

Lee and coworkers (2006) demonstrated that rapid **cold-hardening** (physiological or anatomical preparation for cold) increases freezing tolerance in *Belgica antarctica* (Figure 53). Larvae that were summer acclimated had less cold tolerance at -10°C for 24 hours than those that were cold-acclimated. Cold-acclimated larvae had higher supercooling points than summer larvae. But when summer-acclimated larvae were maintained at 4°C , then transferred to -5°C for 1 hour prior to exposures to -10 , -15 or -20°C , rapid cold hardening occurred; rapid cold hardening significantly increased larval freeze tolerance to both -15 and -20°C . Adults, which typically live for only a week, did not respond to rapid cold hardening. Living among mosses can protect the larvae from sudden changes in temperature, permitting them to acclimate.

But even during the summer the larvae are subject to summer storms, osmotic stress from salt spray, and desiccation due to wind and sunlight (Lopez-Martinez *et al.* 2009). In contrast to Hayward *et al.* (2007), Lopez-Martinez and coworkers found that the genes that were the most responsive to hydration changes were the ones encoding heat-shock proteins, as well as those for antioxidants, detoxifications, and those involved in altering cell membranes. Fast dehydration elicited both the

highest expression and the greater number of genes expressed. As the larvae were rehydrated, most of the same genes were once again expressed. Fatty acid desaturase was the only gene upregulated during rehydration.

Strong (1967) considers the living mosses to serve only as shelter for *Belgica antarctica* (Figure 52-Figure 54), providing little nourishment. Instead, detritus, algae, lichens, and fungal hyphae are the primary food sources. Other researchers include mosses as part of the diet during the two-year life cycle (Sugg *et al.* 1983; Convey & Block 1996). But there is no comprehensive food study to indicate the diet throughout the life cycle and seasonal changes. The larvae demonstrate cryoprotectants, including erythritol, glucose, sucrose, and trehalose, but adults are freezing-susceptible and lack adequate quantities of these cryoprotectants (Baust & Edwards 1979). Maintenance on artificial diets indicate that cryoprotectant complexes are dependent on food source and temperature. We have seen how gene expression changes as freezing occurs. Could it be that these new compounds are supported by a change in diet to one that includes more bryophytes?

Leaf Miners

Most of us have seen the evidence of leafmining activity on deciduous leaves or herbaceous plants. But have you ever seen it on liverwort thalli? It is a world needing exploration.

Eisman *et al.* (2023) have just described the behavior of *Paraphaenocladus exagitans* in the thalli of *Marchantia polymorpha* (Figure 56). They discovered that unlike the miner *Metriocnemus*, which scatters its frass throughout its mines, the mines of *P. exagitans* are clean; the frass instead accumulates around the rim of the entry hole. These larvae were first noticed in Iowa in mid-October. On 23 November, the first adult emerged from an oblong, dark brown cocoon made of frass and located on the thallus of the liverwort. The larva had apparently fed on the surface of the thallus. However, two larvae were seen mining the fresh thallus in late December.

Figure 56. *Paraphaenocladus exagitans* pupa on a *Marchantia polymorpha* thallus. Photo courtesy of John van der Linden.

In a different collection, Eisman *et al.* (2023) found larvae of *Paraphaenocladus exagitans exagitans* and adults of *Boreochlus persimilis* in association with *Marchantia polymorpha* in Oregon, this time in late April. However, the authors were unable to determine what the midges were feeding on.

Culicidae – Mosquitoes

Gert Mogensen told an interesting mosquito story on Bryonet (13 March 2011). Arctic mosquitoes (Figure 57) struggle with low moisture on sunny days. They compensate for this dry atmosphere by spending much time on mosses, keeping in the shadows when possible. They are able to shelter on the undersides of leaves of shrubs (Figure 57), but there they are subject to spider predation. These spiders, in turn, are food for the group of birds called waders (Figure 58). The chicks of these waders benefit from the dwarfed nature of the shrubs. The females migrate south again once the eggs are laid and the males remain behind to care for the young!

Figure 58. The Common Gallinule (*Gallinula galeata*), a wading bird that is part of the food chain of moss inhabitants (Culicidae→spiders→wading birds). Photo by Jim Rathert, USFWS, through public domain.

Simuliidae – Blackflies

I have discussed this family in the chapter on aquatic insects. But when I began researching the terrestrial Diptera, I was quite surprised to find that not all Simuliidae begin life in the water. *Prosimulium hirtipes* (see Figure 59-Figure 61), *P. tomosvaryi*, and *P. subrufipes* all oviposit on moist terrestrial mosses, usually about 20 cm above streams (Zwick & Zwick 1990). This is no small contribution as they lay up to 20,000 eggs per cm². The eggs form a dense crust on mosses with small leaves, especially *Brachythecium rivulare* (Figure 62). These eggs are dependent on moisture and cannot survive complete desiccation.

Figure 59. *Prosimulium hirtipes* larva, a species that begins life on land among mosses at streamside. Photo by Janice Glime.

Figure 62. *Brachythecium rivulare*, a site for egg-laying by *Prosimulium hirtipes*, *P. tomosvaryi*, and *P. subrufipes*. Photo by Norbert Stapper, with permission.

Two Japanese blackfly species, *Simulium japonicum* and *S. rufibasis* (see Figure 63-Figure 66), lay their eggs in bryophytes (Baba & Takaoka 1989). These do not make large masses and lay their eggs singly on bryophytes on water-splashed rocks. Later, Baba and Takaoka (1991) discovered that *Prosimulium kiotoense* likewise oviposited on land, using mosses on riverbank rocks as their oviposition sites. They likewise laid eggs singly, but the females deposited many eggs in small areas, often forming large, irregular egg masses. These wet oviposition sites had dense bryophyte cover and were 0-15 cm above water level. If you want to watch, the event occurs mostly between 12:00 and 14:00 hours in the latter part of April on Kyushu Island, Japan.

Psychodidae – Drain Flies, Sink Flies, Moth Flies, or Sewer Gnats

This family includes species with aquatic larvae, so it is not surprising that terrestrial species are often associated with bryophytes in locations where they can maintain high moisture. Roper (2001) reports several of these species in the ghyll woodlands (linear valley features cut into the sandy beds of the Weald of south-eastern England where temperatures are buffered and moisture levels are high; they have a rich flora of bryophytes). In Sussex, England, the very ornate *Sycorax* species occur among mosses near springs and "trickles" (Roper 2001).

Sycorax silacea larvae are wormlike and live on wet stones or mosses near cascades, springs, trickles (Andersen 1992), on mosses in the neighborhood of streams (Omolkova & Ježek 2012), and on mosses on half-submerged tree branches (Kroča & Ježek 2015), making them semiaquatic. Their decorations are quite ornate, permitting them to blend well among the mosses (Roper 2001).

Like *Sycorax silacea*, many of the **Psychodidae** are semi-aquatic. *Peripsychoda fusca* lives in wet mosses and leaf litter piles in Europe (Kroča & Ježek 2015). Another European psychodid, *Feuerborniella obscura*, lives among wet moss cushions, springs, and small streams. *Parabazarella subneglecta* (Figure 67) similarly prefers wet moss cushions, springs, and streams. *Pneumia stammeri* (Figure 68) lives among mosses in wetlands. Larvae of *Bazarella neglecta* occur among mosses around mill races and waterfalls (Roper 2001). This species has been reared successfully on the moss *Platyhypnidium riparioides* (Figure 69-Figure 70), a moss that typically occurs around the water-air interface where it is almost constantly wet or submerged. *Parajungiella longicornis* is a widespread and common species in Europe and western Siberia (Omolkova & Ježek 2012; Kroča & Ježek 2015). This species lives in both shaded and unshaded habitats in moss cushions on banks of streams, as well as ponds and forest seepages.

Pericoma larvae (Figure 71-Figure 72) and pupae both live in damp locations along streams in the UK, frequently

among mosses (Satchell 1949). Suitable habitats can often support several species within a few meters. *Pericoma* species, including *P. nubila* (Figure 73-Figure 74), *P. fuliginosa* (Figure 75), and *Tonnoiriella pulchra* (syn.=*P. pulchra*) emerge in ghyll woodlands from rotting vegetation and mosses along streambanks (Roper 2001). *Pericoma blandula* (Figure 76) and *P. fallax* are both widespread species in Europe and parts of Asia, living among mosses in both shaded and unshaded locations (Omelkova & Jezek 2012; Kroča & Ježek 2015). The latter species is mostly aquatic, but also occurs in swampy meadows and bottomlands. *Pericoma blandula* is more common among mosses on riverbanks and the banks of springs (Duckhouse 1962).

For *Psychoda cinerea* (Figure 77) larvae, moisture is important, accounting for their habitat in mud and among mosses (Ježek 1990). *Paramormia ustulata* is more ubiquitous, living in a variety of habitats in both fresh and salt water, but it also includes mosses and moist soil (Vaillant 1971).

Figure 77. *Psychoda cinerea* adult. Larvae of this species live in mud and among mosses. Photo by Luis Miguel Bugallo Sanchez, through Creative Commons.

In some cases we don't know why the flies visit the mosses. Martin Cooper found a species of *Philosepedon* (Figure 78) resting on the capsules of a moss, but perhaps it was just a convenient resting place, serving no other purpose. Its larvae are known from dead snails (Corbet 2006)! It is clear that we need more behavioral studies on these flies and their interactions with bryophytes.

Figure 78. *Philosepedon*, probably *P. humeralis* adult, on moss capsule. Photo by Martin Cooper, through Creative Commons.

Anisopodidae (=Rhyphidae) – Wood Gnats

I was introduced to the larvae (Figure 79) of this family when I found a larva feeding on mosses on a wet ledge. The larva was green and blended well with the bright green mosses. I watched for a time and found that mosses went in the mouth covered with detritus and came out the other end clean. It appeared the the larva was unable to digest the moss leaves it consumed.

Figure 79. *Anisopodidae* larva; some larvae in this family eat wet mosses, apparently to obtain the detritus and associated organisms on the moss surface. Photo by Walter Pfliegler, with permission.

Summary

Some adult members of fungus gnats (*Mycetophilidae*) feed on spores in the capsules of *Buxbaumia aphylla*. Others, as larvae, develop within the thalli of liverworts, also completing pupation there. The dark-winged fungus gnats (*Sciaridae*) tunnel in liverwort thalli.

The midge (*Chironomidae*) adults include some members that are attracted to exudates from antheridia and archegonia of mosses, accomplishing the transfer of sperm to the eggs. And even the blackflies (*Simuliidae*) have some members that begin their lives among mosses on land. The moth flies (*Psychodidae*) live among bryophytes as larvae in both aquatic and terrestrial habitats. The biting midges (*Ceratopogonidae*) live in moist places and are common on mosses. Few mosquitoes (*Culicidae*) or gall midges (*Cecidomyiidae*) are known to use mosses.

Acknowledgments

Thank you to Sara Altenfelder for alerting me to the mine flies that live on mosses and liverworts and supplying me with copies of old papers. My appreciation to Weerachon Sawangproh for providing me with images and information of the herbivory on liverworts by *Scatopsiara*

cunicularius. Irene Bisang answered my questions about the liverwort thallus parasite. As usual, many photographers provided kind permission for use of their images.

CHAPTER 12-20

TERRESTRIAL INSECTS:

HOLOMETABOLA – DIPTERA

BRACHYCERA

Figure 1. Bee fly (**Syrphidae**) on *Cratoneuron filicinum*. Many flies use bryophytes for resting sites where the bryophytes reduce the danger of dehydration or the flies take a drink of water. Photo by Serhat Ursavas, with permission.

BRACHYCERA

Rhagionidae sensu stricto – Snipe Flies

The **Rhagionidae** is a worldwide family that has some members among the most primitive of the **Brachycera**. One of its diagnostic characters is that its head points downward when at rest (Figure 2), earning it the name of "downlooker flies."

In the Czech Republic, *Rhagio latipennis* (Figure 2) is a predaceous fly that prefers moist soil rich in organic matter (Farkač *et al.* 2005). Some prefer decaying wood, mosses, or liverworts along the sides of water courses.

Figure 2. *Rhagio latipennis* adult, a species that sometimes is associated with streamside mosses or liverworts. Note the downward-pointing head. Photo by João Coelho, through Creative Commons.

Spaniidae

Members of the **Spaniidae** family are often included in the **Rhagionidae**. The **Spaniidae** feeding habits may be assumed to be similar, in most cases, to those of the **Rhagionidae**.

Both adults and larvae typically eat small insects. The adults live in forests, especially near moist places. Larvae occur in moist meadow soil, among mosses, in decaying wood, under bark, and a few in water.

Imada and Kato (2016a) investigated **Diptera** in the **Rhagionidae/Spaniidae** to determine apparent adaptations to bryophyte consumption. The **Spaniidae** has larval members with multiple bryophyte-feeding habits. *Spania* (Figure 30-Figure 34) and *Litoleptis* (thallus-miners of thallose liverworts; Figure 3, Figure 17) both have a toothed form of apical mandibular sclerite with an orifice on its dorsal surface, contrasting with those of the members of **Rhagionidae** that possess a blade-like mandibular hook with an adoral groove. On the other hand, the moss stem borer *Ptiolina* (Figure 25) has a weak groove on the adoral surface of the mandible and has a highly sclerotized maxilla with toothed projections. Imada and Kato hypothesized that the toothed mandibles with the dorsal orifice would facilitate the leaf miners in scraping plant tissue and imbibing it along with a large quantity of cell sap. Their phylogenetic analysis indicated that the loss or reduction of the adoral mandibular groove and mandibular brush coincides with the evolution of bryophyte feeding.

Litoleptis (Figure 3)

Imada and Kato (2016b) reported the feeding strategy for *Litoleptis* (Figure 3, Figure 17) in Japan. The larvae of this genus mine the thalli of thallose liverworts in the families **Aytoniaceae** and **Conocephalaceae**. These include species of *Conocephalum* (Figure 4), *Reboulia* (Figure 5), and *Asterella* (Figure 6). It is clear that bryophyte miners are an overlooked group of species. While I was working on the original preparation of this chapter, Imada and Kato (2016b) provided me with six new species they described in the genus *Litoleptis*, all from thallose liverworts, in Japan.

Figure 3. *Litoleptis japonica* adult on *Conocephalum* sp. Photo courtesy of Yume Imada.

Figure 4. *Conocephalum conicum* on wet rock; the dipteran *Litoleptis japonica* deposits eggs on its thallus and the larvae mine the interior. Photo by Fotis Samaritakis, through Creative Commons.

Figure 6. *Asterella cruciata*, an endangered species in Japan and home of *Litoleptis asterellaphile*. Photo by Misao Ito, with permission from Digital Museum of Hiroshima.

Litoleptis japonica (Figure 3) larvae occur in thalli of *Conocephalum conicum* (Figure 4) in shaded habitats in Japan (Figure 7-Figure 8). The adult female deposits eggs on the thallus of *Conocephalum conicum* (Figure 9-Figure 11), and its larvae (Figure 12-Figure 14) subsequently mine the thallus of this liverwort.

Figure 11. *Litoleptis japonica* eggs (arrows), deposited on liverwort thallus. Photo by Yume Imada, with permission.

Figure 12. *Litoleptis japonica* first instar larva (arrow) mining in a thallus of *Conocephalum conicum*. Photo by Yume Imada, with permission.

Figure 13. *Litoleptis japonica* larva. Photo by Yume Imada, with permission.

Figure 14. *Litoleptis japonica* larva mining *Conocephalum conicum*. Photo by Yume Imada, with permission.

Figure 15. *Litoleptis japonica* pupa (arrow) on *Conocephalum conicum*. Photo by Yume Imada, with permission.

Litoleptis küiensis (Figure 16-Figure 17) occurs in *Reboulia hemisphaerica* (Figure 5) on rocky or clayey slopes in both evergreen and deciduous forests (Imada & Kato 2016b). *Litoleptis küiensis* is a thallus miner on *Reboulia hemisphaerica* (Figure 5). The larvae mine the middle layer of the thalli, making mines nearly invisible from outside the thallus. The final instar of the larvae individually mine along the mid-vein and pupate near the adaxial layer of thalli in that mine in early spring. In their observations, this pupa was visible from the outside of the thallus. Adults emerge from the thallus later in the spring.

Figure 16. *Litoleptis küiensis* larva (arrow) on thallose liverwort. Photo by Yume Imada, with permission.

Figure 17. *Litoleptis küiensis* larva, a bryophyte inhabitant. Photo courtesy of Yume Imada.

Litoleptis niyodoensis occurs in *Reboulia hemisphaerica* (Figure 5) (Imada & Kato 2016b). *Litoleptis himukaensis* occurs along streams in *Reboulia hemisphaerica*. *Litoleptis izuensis* occurs in *Reboulia hemisphaerica* on shaded clayey slopes along streams and roads in evergreen *Castanopsis* forests. *Litoleptis asterellaphile* (Figure 18) occurs in *Asterella cruciata* (an endangered species in Japan; Figure 6) on rocky cliffs along streams and roads in deciduous forests.

Figure 18. *Litoleptis asterellaphile* pupa (arrow) among liverworts. Photo by Yume Imada, with permission.

***Ptiolina* (Figure 19)**

Lane and Anderson (1982) found immature adults of *Ptiolina* cf. *zonata* (Figure 19) by hand sorting moss-covered soil samples (Figure 20). Apparently mosses also provide oviposition sites for the genus (Figure 21-Figure 23), hence also providing homes for the larvae (Figure 24-Figure 26).

Since that publication, we have learned that a number of species in this family are adapted to mining bryophytes, and they seem to be very specific about their choice of bryophyte. Furthermore, they deposit their eggs on the same bryophyte that the larvae will later eat. *Ptiolina* sp. (Figure 19-Figure 22) deposits eggs (Figure 21, Figure 23) on the moss *Brachythecium buchananii* (Figure 27), and the larvae (Figure 25) are stem borers on this same species (Imada & Kato 2016a).

Figure 27. *Brachythecium buchananii*; *Ptiolina* deposits eggs on this species and larvae are stem borers in it. Photo by Michael Lüth, with permission.

Spania

The original record I found of a member of **Spaniidae** among bryophytes is that of *Spania nigra* (Figure 29-Figure 34). Larvae of this species live on mosses and liverworts in damp shade such as the ghyll woodlands of Sussex (Roper 2001). Boyce (2002) reported it from the

thallose liverwort *Pellia* (Figure 35) in England. Yume Imada (pers. comm.) has also found *Spania* sp. tunnelling in *Conocephalum* (Figure 34).

Figure 28. *Spania* sp. habitat. Photo by Yume Imada, with permission.

Figure 29. *Spania nigra* adult, a species whose larvae live among forest mosses and liverworts in the UK. Photo by Marko Mutanen, through Creative Commons.

Imada and Kato (2016a) observed that *Spania* sp. (Figure 29) deposited eggs exclusively on the thallus of the liverwort *Pellia endiviifolia* (Figure 35), a species it also mines.

Dolichopodidae – Long-legged Flies

The **Dolichopodidae** is likewise a family of water-loving species. I mention here a few that are somewhat amphibious. *Dolichopus maculipennis* (Figure 36) lives in calcareous wet habitats near small permanent pools, in bryophyte flushes (Figure 37), flushed grasslands, and wet mires (Horsfield & MacGowan 1997), but it also occurs in bogs (Ringdahl 1928). *Hydrophorus rufibarbis* (see Figure 39-Figure 38) seems to prefer small, peaty pools, but it also lives in grassy flushes and bryophyte springs (Horsfield & MacGowan 1997).

Figure 36. *Dolichopus maculipennis* adult, a species whose larvae live in bryophyte flushes. Photo by I. Grichanov, with online permission.

Figure 37. Bryophyte flush in Wales, potential home for some **Dolichopodidae**. Photo by Janice Glime.

Empididae – Dance Flies

The **Empididae** are somewhat common on aquatic bryophytes (Gootaert 2004), so it is no surprise that some terrestrial species likewise find bryophytes to be suitable homes. Plant (1993) found adult females of *Monodromia fragilis* (Figure 40) by sweeping the damp mosses on a cloud forest floor at 550 m asl in New Zealand. In Malaysia the adults are only 3-5 mm long and are mostly yellow or black (Gootaert 2004). These seem to prefer boulders covered with mosses or a splash zone where there is constant high humidity.

Figure 38. *Hydrophorus litoreus* adult; *H. rufibarbis* lives in bryophyte springs and peaty pools. Photo by James K. Lindsey, with permission.

Figure 39. *Hydrophorus oceanus* larvae; *H. rufibarbis* lives in bryophyte springs and peaty pools. Photo by Hans Hillewaert, through Creative Commons.

The larvae of *Hemerodromia* (Figure 41) occur in fast-flowing streams and are predaceous. The adults are yellow or black and occur on moss-covered boulders or in the splash zone, both habitats that ensure moisture.

Figure 40. *Monodromia fragilis* adult, a species whose adults are associated with damp mosses on the floor of a New Zealand cloud forest. Photo modified from one by Stephen Thorpe, through Creative Commons.

Figure 41. *Hemerodromia* adult, a genus whose adults are associated with moss-covered boulders or in the splash zone. Photo from BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Some insects only use bryophytes as landing and resting places. That appears to be the case with the empidid fly in Sarah Lloyd's pictures below (Figure 42- Figure 44). This family is mostly predaceous on other small invertebrates (Tony Daley, pers. comm. 19 November 2011).

Figure 42. Empidoid fly, possibly *Hybotidae*, on a leafy liverwort. Note the greatly arched thorax and long legs. Photo courtesy of Sarah Lloyd.

Clinocera nivalis (*nivalis* refers to snow; Figure 44) in Scotland is primarily on wet stony and mossy slopes, especially below melting snow, and always above 850 m asl (Edwards 1933a, b; Horsfield & MacGowan 1997). It also is abundant on bryophyte springs and occurs in *Racomitrium* moss heaths (Figure 45) and moss-dominated snowbed communities. Horsfield and MacGowan consider that it might be restricted to areas with bryophyte springs and flushes, common in the highlands. J. M. Nelson found it in an *Anthelia julacea* (leafy liverwort; Figure 46-Figure 47) spring in Coire Raibert at around 1000 m.

Figure 43. Adult member of **Empididae** resting on a moss capsule. Photo courtesy of Sarah Lloyd.

Larvae of *Wiedemannia impudica* (see Figure 48) probably live in mosses on emergent boulders (Horsfield & MacGowan 1997), again where they will be constantly moist.

Figure 48. *Wiedemannia bistigma* adult; *W. impudica* is a likely moss inhabitant on emergent boulders. Photo by Marko Mutanen, through Creative Commons.

Hybotidae – Hybotid Dance Flies

Smith (1965) described a new species of *Stilpon* (Figure 49-Figure 50) from Portugal. The immature stages of this genus were still unknown, but the adults occur in grass tufts, heaps of cut sedge, and *Sphagnum* (Figure 51). The new species was similar to *Stilpon nubilus*.

Figure 49. *Stilpon* sp. adult, a genus in which some adults occur in *Sphagnum*. Photo by Tom Murray, through Creative Commons.

Syrphidae – Syrphid Flies

This is a family of flies that often resemble bees. If you find a "bee" with only two wings and a pair of halteres, you have found a bee fly. *Platycheirus melanopsis* (Figure 52) is known from moss-dominated summit heaths (Figure 45) and grasslands in Scotland (Horsfield & MacGowan 1997). *Cheilosia sahlbergi* (Figure 53) occurs in habitats where bryophytes are abundant, including ericaceous dwarf shrub heaths, flushes, and bryophyte springs.

Figure 52. *Platycheirus melanopsis* adult, a species from moss-dominated summit heaths. Photo from America Pink, with online permission.

Figure 53. *Cheilosia sahlbergi* adult, a species that occurs in habitats with abundant bryophytes. Photo by Ladislav Táb, with permission.

Phoridae – Scuttle Flies

Mosses often provide a safe overwintering shelter. Herbert and Braun (1958) reported moss polsters as the overwintering quarters for adult dipterans in the family **Phoridae** (Figure 54).

Figure 54. **Phoridae** mating in Rock Creek Park, MD. Photo by Katja Schulz, through Creative Commons.

Agromyzidae – Mine Flies

This family has bryophyte specialists, but not on mosses. Rather, these bryobionts are known only from hornworts and liverworts (Spencer 1990). D'Aguilar (1945) described a new species of *Liriomyza* (Figure 55) from the thallose liverwort *Ricciocarpus natans* (Figure 56). *Phytoliriomyza mesnili* (formerly *Liriomyza*; see Figure 57-Figure 58) is known from *Ricciocarpus natans* in France as well as being present on the thallose liverwort *Riccia beyrichiana* (Figure 59). It feeds in the thallus and pupates there and also pupates in the thallus of *Nothoceros vincentianus* (Figure 60-Figure 62) in Peru. In Mexico, it is known on *Dumortiera* (Figure 63) and *Monoclea* (Figure 64).

Reporting from Spain, Marta Infante and Patxi Heras (Bryonet 2 May 2019) described a larva living in *Riccia cavernosa* (Figure 65). They noted that it tried to defend itself from the dissecting needle. Later, they observed many pupae and larvae inside the thallus. The species proved to be *Phytoliriomyza mesnili* (Figure 66).

Ron Porley (Bryonet 3 May 2019) relayed a similar experience with *Riccia cavernosa* (Figure 65). Although he did not identify the insect, it was present as black pupae in the thalli of this species on the muddy margin of a reservoir in Algarve, Portugal, in November. Pettet (1967) reported a similar parasitism on *Riccia frostii* (Figure 67) by flies. Porley suggested that such habitation may only occur in section *Ricciella* because of its spongy thalli with large air chambers.

Some relationships of flies with their bryophyte hosts are obligatory. In Mexico, Juan Carlos Villarreal (pers. comm. 9 September 2014) found the larvae (Figure 71) of leaf-mining flies crawling within the hornwort *Nothoceros aenigmaticus*, making traces. While in his custody, it became a pupa (Figure 72). Then one day a hatchling appeared. But it was not a young leaf miner. It was a parasitoid wasp that lived on the pupa! So far, no one has successfully reared the larvae or pupae of the agromyzid to adults, but using genetic bar-coding he determined it to be close to *Phytomyza* (Figure 73-Figure 78). He found similar *Diptera* from Panamanian *Nothoceros vincentianus* (Figure 75) and sequenced them. They most closely matched *Phytomyza*. But with only an 87% match, perhaps this is a new species or even a new genus.

Figure 78. *Phytomyza ranunculi* adult, member of a genus in which some species live in liverwort thalli. Photo by James K. Lindsey, with permission.

Villarreal was able to determine (via a letter belonging to John Engel) that Proskauer had seen leaf miners in *Megaceros* (Figure 79) and *Nothoceros* (Figure 75). Hering (1957) described *Phytoliriomyza* sp. (see Figure 57-Figure 58) larvae and pupae from *Megaceros*.

Figure 76. *Phytomyza vitalbae* pupa, member of a genus with some members that live in liverwort thalli. Photo by Malcolm Storey <www.discoverlife.org>, through Creative Commons.

Figure 79. *Megaceros* sp. with capsules, home for some of the leaf-mining flies. Photo by David Tng <www.davidtng.com>, with permission.

In the larvae of *Phytoliriomyza mesnili* (see Figure 57-Figure 58), living in the hornwort *Nothoceros vincentianus* (Figure 75), the anterior spiracles of the larva penetrate the epidermis of the thallus to permit breathing (Herring 1966; Spencer 1990). Members of this family also mine *Dumortiera hirsuta* (Figure 63) and *Monoclea* (Figure 64) in Mexico (Spencer 1990). Although their substrate is generally thallose liverworts and hornworts (never mosses), some feed on ferns, but none is known to feed on flowering plants.

Mining flies seem to have a widespread distribution, albeit scattered. Herring (1957) found leaf-mining flies in *Megaceros* spp. (Figure 79) in the West Indies, Juan Fernandez Islands, and New Zealand. Several reports have revealed them in Europe. And Villarreal has found them in Mexico and Panama.

The combination of thallose liverworts or hornworts, mining fly, and parasitic wasp apparently also has far-reaching geographic presence, although the species involved may differ. Sara Altenfelder (pers. comm.) found *Riccia glauca* (Figure 80) and *R. warnstorffii* (Figure 81) with leaf-mining flies in arable fields in Germany, and these, like the ones found by Villarreal, were parasitized by wasps. She determined that the fly is *Phytoliriomyza mesnili* (see Figure 57-Figure 58), first described by Aguilar (1945) feeding on *Ricciocarpos natans* (Figure 56) and later reported by Sellier (1947) from *Riccia beyrichiana* (Figure 59). The larva eats the thallus, then pupates there (Spencer 1990). Fulnek (1962) mentioned a parasitic wasp – *Dacnusa taras* – that lives on some members of *Phytoliriomyza*.

Figure 80. *Riccia glauca*, home for *Phytoliriomyza mesnili*. Photo by Bernd Haynold, through Creative Commons.

Figure 81. *Riccia warnstorffii*, a species that is home to larvae of *Phytoliriomyza mesnili*. Photo by Bernd Haynold, through Creative Commons.

In 2018, Ohgue *et al.* reported the first bryophyte galls (Figure 82) induced by insects. These were created by a species of *Agromyzidae*, probably related to *Phytoliriomyza* (Figure 57-Figure 58, Figure 66, Figure 68). These occur on the thallose liverwort *Monoclea gottschei* subsp. *elongata* (Figure 82) in a tropical mountain forest. The galls form swellings on the thallus surface, but they resemble the thallus, having no ornamentation or sclerotization. The larvae become pupae (Figure 83) within the gall and adult flies (Figure 84) emerge from the gall by making an exit hole in the upper epidermis of the galled thallus. The galls appear in the apical part of the thallus where archegonia or antheridia would normally occur. Although archegonia and antheridia were plentiful in the population, thalli with galls produced no sporophytes. The need to raise larvae to adults for identification has caused many of these thallus-inhabiting larvae to remain unnamed.

Figure 86. *Plagiochasma* sp., home for species of *Phytoliriomyza*. Photo by Zhang Li, with permission.

Kato *et al.* (2022) found that liverwort-mining *Agromyzidae* were "overwhelmingly widespread and diverse" in the Japanese Archipelago. They found 39 species, 37 of which were new species! All of these were placed in *Phytoliriomyza* (e.g. Figure 57-Figure 58, Figure 66, Figure 68). Five of these were associated with *Marchantia* (Figure 85), two on *Dumortiera* (*Dumortieraceae*; Figure 63), three on *Plagiochasma* (Figure 86), one on *Asterella* (Figure 6), six on *Reboulia* (*Aytoniaceae*; Figure 5), one on *Wiesnerella* (*Wiesnerellaceae*; Figure 87), fifteen on *Conocephalum* (*Conocephalaceae*; Figure 4), and three on *Riccia* (*Ricciaceae*; Figure 59, Figure 65, Figure 67, Figure 70, Figure 80, Figure 81). Another 3 species were associated with hornworts: 1 on *Folioceros* (*Anthocerotaceae*; Figure 88), 1 on *Megaceros* (*Dendrocerotaceae*; Figure 79), and 1 on *Notothylas* (Figure 89), *Phaeoceros* (*Notothyladaceae*; Figure 90), and *Anthoceros* (*Anthocerotaceae*; Figure 91).

Lauxaniidae

Sarah Lloyd described her experiences with some of the mine flies – *Ceratolauxania atrimana* (Figure 92- Figure 94). They like wet places (she never saw them in open, drier areas) and they tend to land on high points, but they sometimes also land on the mosses. That might be a location to rehydrate. They also oviposit on bryophytes, as shown on the *Bazzania adnexa* below (Figure 93).

Figure 92. *Ceratolauxania atrimana* laying eggs on *Bazzania adnexa* in Eucalypt forest in Tasmania. Photo courtesy of Sarah Lloyd.

Anthomyiidae – Root-maggot Flies

Thus far I can find only one paper that discusses the **Anthomyiidae** from bryophytes (Horsfield & MacGowan 1997). From very high altitudes in Britain, *Alliopsis albipennis* (see Figure 95) includes moss-dominated late snow-bed vegetation among its habitats, as well as flushes which are likely to be moss-dominated, but it is not restricted to these mossy habitats. *Alliopsis atronitens* (see Figure 95) exhibits one of its most frequent occurrences in *Racomitrium lanuginosum* moss heaths (Figure 45) on summit plateaus in Scotland.

Figure 95. *Alliopsis billbergi* adult; *Alliopsis albipennis* lives in moss-dominated late snowbeds. Photo by James K. Lindsey, with permission.

Delia caledonica (see Figure 96) occurs in blanket bogs and *Racomitrium lanuginosum* heath (Figure 45), among other montane habitats (Horsfield & MacGowan 1997). *Delia piliventris* (see Figure 96) occurs mostly in the *Racomitrium lanuginosum*, grasslands, and tall herb communities in the montane area of Scotland.

Figure 96. *Delia radicum* adult. *Delia caledonica* is a species living in blanket bogs and *Racomitrium lanuginosum* heaths; *D. piliventris* lives mostly in *Racomitrium lanuginosum* heaths. Photo by Ladislav Tábi, with permission.

Botanophila moriens (see Figure 97-Figure 98) occurs in bryophyte springs and in *Racomitrium lanuginosum* (Figure 45) heaths at high elevations (760-1310 m alt) (Horsfield & MacGowan 1997). *Zaphne spiniclunis* (Figure 99) includes moss heaths (Figure 45) and bryophyte springs among its many habitats, mostly above 800 m near melting snow.

Figure 97. *Botanophila* larva, a species of bryophyte springs and *Racomitrium lanuginosum* heaths. Photo by Malcolm Storey, through Creative Commons.

Figure 98. *Botanophila* cf. *fugax* adult, a species of bryophyte springs and *Racomitrium lanuginosum* heaths. Photo by Martin Cooper, through Creative Commons.

Heleomyzidae

Only *Scoliocentra scutellaris* (Figure 100) seems to utilize mosses for its habitat. This species in Scotland lives in moss heaths (Figure 45), as well as other montane habitats.

Figure 100. *Scoliocentra scutellaris* adult, a species of moss heaths. Photo by Gunnar M. Kvifte, through Creative Commons.

Muscidae – House Flies

This is one of the families you are undoubtedly familiar with because it includes the common housefly. The **Muscidae** have been discussed in part in the first of the **Diptera** subchapters because of their role in dispersing spores of the **Splachnaceae**. Hence we have already seen a relationship with *Myospila meditabunda* (Figure 101), *Eudasyphora cyanicolor* (Figure 102), *Palpibracus chilensis*, and *Palpibracus* spp.

Figure 101. *Myospila meditabunda* female, one of the flies that facilitates transfer of spores in the **Splachnaceae**. Photo by James K. Lindsey, with permission.

Figure 104. *Spilogona falleni* adult; *Spilogona triangulifera* lives in *Racomitrium lanuginosum* heaths. Photo by James K. Lindsey, through Creative Commons.

In montane areas of Scotland, Horsfield and MacGowan (1997) both *Phaonia subfuscineris* (Figure 103) and *Spilogona triangulifera* (see Figure 104) from *Racomitrium lanuginosum* heath (Figure 45), as well as other non-mossy habitats. These two flies have a habit of sunning themselves on rocks and typically associate with snowbeds. In Lithuania, the predaceous larvae of *Phaonia fuscata* (Figure 105-Figure 107) live in soil and mosses of broad-leaved forests (Gregor *et al.* 2002; Lutovinovas & Rozkošný 2009).

Limnophora is mostly aquatic in the larval stage (Roper 2001), but some are more limnoterrestrial. The carnivorous *Limnophora exurda* (current name not found) larvae and pupae live in tufts of wet mosses and liverworts that receive direct water or spray from waterfalls (Tate 1939). *Limnophora riparia* (Figure 108-Figure 109) adults occur singly on stones or mosses or algae in Armenia, but occasionally they may occur as small groups (Pont *et al.* 2011). Roberts (1971) suggested that the mouth parts and musculature of the carnivorous *Limnophora riparia* larvae (Figure 108) were adapted to the type of food they consumed. Larvae of this species are aquatic and prefer mosses as a substrate. They attach to their substrate to anchor themselves as they attack their prey, which includes other invertebrates, especially **Chironomidae** and **Simuliidae** larvae. *Limnophora petallifera* (Figure 110) females and others in the genus use mosses for oviposition, as well as algae (Werner & Pont 2006; Pont *et al.* 2011). They arrived for this purpose at about midday when the rock substrate was in direct sunlight with a temperature of 42°C (Werner & Pont 2006). The female was "running around the rock close to the water and stopped when she found a small indentation, then injected her eggs many times in the mosses and algae. Her forelegs were pointed upward and her abdomen pushed into the wet mosses. She laid the eggs singly, but each egg was placed next to the first one so that ultimately the eggs were in clusters.

Scathophagidae – Dung Flies

This is another poorly represented family in bryophytic habitats. *Gonatherus planiceps* (Figure 111) is a montane species in Scotland, and like many others there, one of its habitats is in *Racomitrium lanuginosum* heaths (Figure 45) (Horsfield & MacGowan 1997).

Figure 111. *Gonatherus planiceps* adult, a species of *Racomitrium* heaths. Photo by Marko Mutanen, through Creative Commons.

Bratton (2012) swept two females of *Gimnomera tarsea* (Figure 112) from mosses beside Loch a' Roe in the Outer Hebrides.

Figure 112. *Gimnomera tarsea* adult, a species whose adults hang out near mosses beside lakes. Photo by Marko Mutanen, through Creative Commons.

Calliphoridae – Blow Flies

And another! For the **Calliphoridae** I found only *Calliphora stelviana* (Figure 113) (Horsfield & MacGowan 1997). Like many other flies in the montane Scotland, these included *Racomitrium lanuginosum* among their habitats.

Figure 113. *Calliphora stelviana* adult, a species that lives in *Racomitrium lanuginosum* heaths. Photo by Marko Mutanen, through Creative Commons.

Summary

The **Rhagionidae** may live among bryophytes and lay their eggs there. The **Spaniidae** are leaf miners and *Litoleptis* species and some *Spania* species mine the thalli of thick thallose liverworts. The **Dolichopodidae** tend to be amphibious, living in wet bryophytes. The **Empididae** may be found on damp mosses as well as aquatic ones. Some **Hybotidae** live among *Sphagnum* as adults. The **Syrphidae** are likewise often aquatic, but some live among terrestrial mosses as larvae. The **Phoridae** are not normal bryophyte inhabitants, but they do overwinter in moss polsters. Several members of **Agromyzidae** are leaf miners in large thallose liverworts and hornworts. The **Lauxaniidae** like wet places and often land on protruding mosses; others oviposit on species of the leafy liverwort *Bazzania*. **Anthomyiidae** live among mosses in late snow-bed vegetation; others live in *Racomitrium* heaths. One **Heleomyzidae** lives in moss heaths. The **Muscidae** are among the important spore dispersers for the moss family **Splachnaceae**. Others occur in *Racomitrium* heaths. The **Scathophagidae** and **Calliphoridae** also sometimes live in *Racomitrium* heaths.

Hence, *Racomitrium*, with its often large hummocks, serves as a home for some members in many of the **Nematocera** families. This habitat is well insulated and capable of maintaining moisture for a longer time than most other terrestrial habitats.

Acknowledgments

Thank you to Yume Imada for sharing his research and images of the **Spaniidae**. Thank you to for alerting me to the mine flies (*Ceratolauxania atrimana*) that live on liverworts and sharing her research and images with me. Likewise, I appreciate Juan Carlos Villarreal for sharing his research on **Anthocerotophyta** and the flies that live in them, providing me with images for this chapter.

CHAPTER 13

FISH

Figure 1. Rainbow trout (*Oncorhynchus mykiss*), a fish that spits out mosses. Photo by Eric Engbretson, through Creative Commons.

Fish Uses of Bryophytes

At the onset, I wasn't sure I could make a chapter on the relationship between bryophytes and fish. I was sure I had read a long time ago that the aquatic moss *Fontinalis* (Figure 3) was found in the gut of a fish, but I couldn't locate the information again. So we tried our own experiments. We placed *Fontinalis* in a tank with rainbow trout (*Oncorhynchus mykiss*; Figure 1, Figure 2). The moss was colonized by aquatic insects, so we considered it a suitable source of food. But these starved rainbow trout ignored it. Finally, in desperation, the grad student doing this experiment tried to force feed the fish. Most of the time, even these "strike-at-anything" fish spit the moss back out. Finally the student managed to get the moss into the mouth and swallowed by force feeding. But the moss passed through the digestive tract undigested (Figure 47). It didn't look good for my hypothesis that fish might serve as upstream dispersal agents for stream bryophytes.

The rainbow trout is native to tributaries of the Pacific Ocean in North America and Asia. The juveniles hang out near the bottom whereas the adults occur more in open water. Although the fish may behave as an **anadromous**

fish (living in the ocean and migrating up freshwater streams to spawn), this seems to be mostly an opportunistic behavior, with many populations never venturing to the ocean. They are known to seek areas of streams that have overhanging vegetation and to subsist on a diverse diet that includes aquatic insects (NRCS 2000). Given these criteria, it would seem that they could take advantage of the bryophytes, especially dangling ones such as *Fontinalis* species, for cover, especially for young fish. And aquatic mosses provide a rich habitat of aquatic insects and other invertebrates that could serve as food. So we must ask ourselves if there really is little connection between fish and bryophytes, or is it simply a neglected area of study. In this chapter we will examine the relationships that have been reported in the hope that they will stimulate further research into natural habitats and the role of the bryophytes in the lives of fish.

As you will soon read, my original contention that at least some fish, in some circumstances, eat bryophytes, is true. But bryophytes provide other roles, probably more important to the fish than their role as a food source. Based

on the meager evidence I could locate, some fish use bryophytes for cover (especially small fish), spawning, and sources of invertebrates. Some even eat bryophytes.

Habitat

One might expect that small fish like **minnows** would seek refuge or cover among large mosses like *Fontinalis* spp. But finding documentation about it is a challenge. Jones (1951) listed three small fish that used *Fontinalis antipyretica* (Figure 3) on bedrock as their habitat in a Welsh river: *Phoxinus phoxinus* (minnow; Figure 4), *Gasterosteus aculeatus* (three-spined stickleback, Figure 5), *Barbatula barbatula* (= *Nemacheilus barbatula*) (loach; Figure 6). He determined that fish mostly under 20 mm length preferred beds of moss and waterweed. Nevertheless, there was no evidence they ever ate the moss. Since fish like *Phoxinus phoxinus* may grow to 8-10 cm (Wikipedia 2012), it means that the mosses serve as a nursery – a place for the young fingerlings to hide from hungry predators.

Figure 5. *Gasterosteus aculeatus* (three-spined stickleback). Photo by D. Ross Robinson, through EOL.com.

Figure 6. *Barbatula barbatula*. Photo by Michal Mañas, through Wikimedia Commons.

In his study of mayfly life histories, Macan (1978) noted that *Cottus gobio* (bullhead) and *Barbatula barbatula* (stone loach) were taken in the moss samples. These mosses were colonies of *Cinclidotus fontinaloides* on permanently submerged rocks.

Spawning

Mills (1981) found that the roach (*Rutilus rutilus*; Figure 7) spawned in thick beds of *Fontinalis antipyretica* (Figure 3), placing their eggs throughout the fronds, but concentrating them away from the base of the moss and near the water surface, especially on those parts of the site that had relatively fast currents adjacent to the moss. This positioning afforded the eggs greater security against desiccation because the ends of the moss fronds could move up and down as the water level rose and fell.

Figure 7. **Roach** (*Rutilus rutilus*), a fish that is known to use the brook moss (*Fontinalis*) for spawning. Photo by T. Voekler, through Wikimedia Commons.

The roach spends larval steps 3-5 in water with macrophytes or woody debris, then moves out of the plant areas when it becomes older and larger (Copp 1990). Copp suggested that the young fish could perceive environmental change, as evidenced by their shift in habitat.

The pike-perch, *Sander lucioperca* (= *Stizostedion lucioperca*; Figure 8), so-named for its pointed nose, also will select mosses for nesting and spawning, in one case selecting the green parts of moss overgrown by bilberry, or moss and roots (Bastl 1969). Bastl recommended that such substrata can be used to improve spawning possibilities for this fish. These fish did not use the plastic strips provided as a substitute, so the moss must embody some beneficial property.

Figure 8. Pike-perch (*Sander lucioperca*). Photo by Piet Spaans, through Wikimedia Commons.

The spawning behavior of the pike-perch in natural habitats is poorly known (Lappalainen *et al.* 2003). One reason for this is the selection by the fish of murky habitats with 1-3 m depth, making them difficult to observe (Lappalainen *et al.* 2003; Zander 2010). Pike-perch typically inhabit deep, calm water of canals, lakes, reservoirs, and rivers (Luna & Bailly 2010). Their habit of feeding on other fish makes them a predator to hide from. The temperature of their habitat changes seasonally,

forcing them to move to a different habitat. In autumn they prefer large pebbles in 1.2-1.8 m water, but as the temperature drops to 5°C, they move to pits and trenches to spend the winter. In spring, a temperature of 2.8°C signals the time to move upstream, where they spawn over large pebbles at 11°C. Their pale yellow eggs attach to emergent vegetation or stones or gravel. The parents then drift downstream to pools, with many of the females dying after spawning.

The pike-perch can be a competitor of the roach, at least in lake habitats (Brabrand & Gaafeng 1993). Its presence can cause the roach to move from the open water to the littoral zone where vegetation is present. In this case, mosses such as *Fontinalis* could provide cover to protect the juveniles from predation by larger fish. But the littoral zone is not without its dangers. Perch (*Perca fluviatilis*; Figure 9) can eat the young fish and compete with them. However, in some situations there are sufficient Chironomidae (midge; Figure 10) larvae to feed the perch, and the perch don't bother the roaches (Persson 1987). One could suppose that if mosses are present, then Chironomidae are present (Glime 1994), and the mosses would provide a food source as well as protection. In this case, providing food for the predator of the roach is a bonus.

Figure 9. *Perca fluviatilis*, a predator that drives fish to hide among dangling vegetation. Photo from Wikimedia Commons.

Figure 10. **Chironomidae**, illustrating their potential abundance. Photo by Simon Carmichael, through Creative Commons.

The things that show up when one does a Google search can be rather amusing, but sometimes one gets some real gems. More often, one must make some educated guesses and dig deeper. Such was the case in trying to find fish that use bryophytes for spawning. It seems logical that fish that use "vegetation" for spawning in mountain or rapid streams are likely to use mosses like *Fontinalis* species as an egg repository. But rarely is the "vegetation" identified further.

Wright, as early as 1901, recognized at least minimal vegetation differences when describing the spawning behavior of the "stickleback" (*Gasterosteidae*) in some detail. He noted that not all sticklebacks were the same and that their nest construction behavior differed. One variety (species?) makes a nest "like a muff among waterweeds." Another little fish collects straw, bits of grass, and moss with his mouth. He tucks these into the gravel and sand and presses them into place with his body. He then glues these with glue exuded from his own skin. This forms a floor, and he builds a small hut of woven fibers and moss. There is a small door at the top of the hut. The fish ultimately tests the strength of this hut by stirring up the nearby water with its tail.

The only other information I have found on nests of sticklebacks is 110 years later on a website (Coarse Fish 2011). In this case, the **nine-spined stickleback** (*Pungitius pungitius*; Figure 11), a circum-Arctic and widespread northern hemisphere fish of quiet water in streams, ponds, and lakes, uses "willow moss," a common name sometimes used for *Fontinalis antipyretica*. The male *P. pungitius* builds the nest and cares for the young. The nest is near the bottom, typically built into the "vegetation." This is a tubular nest about 4 cm long and is made from threadlike algae and **willow moss**.

Figure 11. **Nine-spined stickleback** (*Pungitius pungitius*), a fish that occasionally builds its nest among *Fontinalis antipyretica*. Photo through Creative Commons.

Nancy Auer (pers. comm. 20 Nov 2011), a larval fish expert, explains the scarcity of fish eggs among mosses. "Most moss is not that 'open' so adult fish may not use it and even larvae since most are in the water column."

Aquarium Fish

Aquarium fish keepers have discovered the advantages of adding aquatic mosses such as Java moss (which includes a variety of species, but is mostly *Taxiphyllum barbieri*; Figure 12) for both decoration and spawning

media (Benl 1958; Takaki *et al.* 1982). Axelrod and Vorderwinkler (1983) found that *Fontinalis antipyretica* var. *gracilis* (Figure 13) provided the best spawning grounds for certain tropical fish. The mosses also serve to provide hiding places for smaller fish being chased by larger ones or those fish that just prefer to hide during daylight hours.

Figure 12. Java moss (*Taxiphyllum barbieri*). Photo by Buchling, through Creative Commons.

Figure 13. *Fontinalis antipyretica* var. *gracilis*. Photo by Des Callaghan, with permission.

Bohlen (1999) used mosses in 40-liter aquaria to rear the spined loach (*Cobitis taenia*; Figure 14), a common freshwater fish of oxygen-rich water from Europe and Asia (Robotmam 1977). The fish laid their eggs in the most dense moss vegetation available (Bohlen 1999). The eggs lacked adhesion and easily fell through the gauze beneath the moss. Eggs numbering 2905-4282 were laid over a period of 101-120 days and were successfully reared using this method.

One website [Breeding my pencil fish (*Nannostomus beckfordi*; see Figure 15) 2007] provides a video of the golden pencil fish (*Nannostomus beckfordi*) breeding among the Java moss fronds in an aquarium. The pencil fish, widespread in its native South America (Wikipedia: Pencil fish), with a wide distribution in the lower Rio Negro and middle Amazonas river (AquaWorld: *Nannostomus beckfordi* 2011). It prefers slightly acidic water (pH 6.0-7.5), which is likewise suitable for many aquatic bryophytes. Java moss is especially good for scatter

breeders, serving like a safety net to catch the eggs. The moss needs to be kept clean to remain healthy, but this cleaning may be detrimental to the eggs that are housed there, as they, too, may be removed.

Figure 15. *Nannostomus beckfordi*, a genus in which some members deposit eggs among mosses. Photo by Jan Ševčík, through EOL Commons.

The website Aquamoss extols the benefits of **Java moss** for rearing **killifish** (Figure 16-Figure 17), **barbs** (Figure 18), and **characins** (Figure 19). Not only does the moss provide cover, but it helps to keep the aquarium clean by absorbing the nitrogen waste. Eggs among the mosses are protected from predation, and the moss provides a substrate for bacteria, detritus, and other food sources. The author of the site also claims that the young fry grow better when Java moss is in the tank.

Figure 17. *Heterandria formosa*, the least killifish. Photo by Brian Gratwicke, through Creative Commons.

Figure 18. Tin foil barbs (*Cyprinidae*). Photo from Wikimedia Commons.

Figure 19. Red phantom tetra, *Megalamphodus sweglesi* (Characidae). Photo from Wikimedia Commons.

A native southeastern USA fish, *Elassoma evergladei* (Figure 20), the **pygmy sunfish**, is a very skittish fish when it has no cover. In an aquarium, **Java moss** serves well to provide cover for this small fish. In the wild, it seeks shelter among the vegetation and prefers to lay its eggs on *Ceratophyllum demersum*. The cover helps to protect the males against the aggressive behavior of other territorial (especially larger) males.

Java moss (*Taxiphyllum barbieri*; Figure 12) may be the best of the mosses for removing nitrogen in multiple forms (Alghamdi 2003), withstanding the wide chemical range of aquarium water, and doing well at warm temperatures, but other mosses have also been used successfully. Takaki *et al.* (1982) report the use of the mosses *Amblystegium* (*Leptodictyum riparium*; Figure 21), *Fontinalis* spp. (Figure 13), *Platyhypnidium riparioides* (Figure 22), *Rhacopilum*, *Taxiphyllum* spp.

(Figure 12), *Vesicularia* (Figure 23), and the liverworts *Riccia fluitans* (Figure 24), *Ricciocarpos natans* (Figure 25), and *Chiloscyphus* (Figure 26). I have been successful in using *Bryum pseudotriquetrum* (Figure 27) in an aquarium with alkaline water. Beware of dealers selling a club moss as an aquarium plant. It is neither a moss nor an aquatic species. It is a tracheophyte (*Lycopodium obscurum*) that will retain its green color for several months under water. For more information on use of mosses for aquaria, see Chapter 4 (Aquaria) of Volume 5, Uses.

Food

Bowden *et al.* (1999) pointed out that the roles of bryophytes in streams remain largely unexplored. Their role as a food source is one of these relatively unexplored areas. Specifically, they stated that it is "not clear whether fish benefit from an increase in abundance of insects often observed when bryophytes are present in a stream."

Cheney mentioned in 1895 that bryophytes serve as a food source for fish. Richards (1946) reported on the introduction of *Fontinalis antipyretica* into streams in South Africa in an effort to increase invertebrate populations that serve as fish food. Unfortunately, the insects in those streams were adapted to smooth rocks and bottom sediments and did not fare well on the rough structure of the mosses. Hence, their substrate was diminished and their numbers decreased. I know of no follow-up studies to see if this changed, with better adapted species arriving to fill the void.

Bryophytes can serve as a food source in two ways. The most obvious, but rarely used, is as a direct food source – eating the bryophyte. The other is that the bryophytes house numerous insects and other arthropods that serve as food. *Fontinalis* serves as a source of abundant food organisms, particularly chironomid larvae (Figure 10), for fish in the same stream (Mills 1981). Macan and Worthington (1974), in their book "Life in Lakes and Rivers," consider the mosses and liverworts that occur in thick mats to "profoundly influence fauna by providing a foothold for animals which otherwise could be swept away by current."

Brusven *et al.* (1990) examined the importance of stream bryophytes as providers of drifting stream invertebrates that serve as potential fish food. They compared the density, biomass, and drift in various areas of the South Fork Salmon River, Idaho, USA, including areas with and without moss cover of *Fontinalis neomexicana*. Insect densities were 4-18 times as great in moss clumps compared to moss-free areas. Simply being near the moss in mossy areas did not significantly increase invertebrate density compared to areas with no moss. And Brusven *et al.* were unable to determine any advantage to fish feeding in the daytime. It seems that despite the greater number of invertebrates living among the mosses, the daytime drift in that area was no greater than in the moss-free areas. That

does not mean that there would be no differences at night when the greatest drifting occurs. If one assumes that daytime feeders only strike at drifting invertebrates, the mosses may not provide them with a feeding advantage until these invertebrates emerge as adults that fly above the stream within striking distance.

Muotka and Laasonen (2002) made it clear that retention of mosses was an important part of stream restoration in the channellized streams used for hauling out forest harvest, citing that when the mosses were dislodged they were replaced by periphytic algae and that only periphyton feeders increased when streams were restored by the addition of leaf litter that caused further loss of bryophytes.

Nurminen *et al.* (2003) explored the relationships of the rudd (*Scardinius erythrophthalmus*; Figure 28-Figure 29) and found that bryophytes were included among other aquatic macrophytes in their diet. In the period of 15 May to 15 June, bryophytes were more than half the diet by weight (26.2 g per g ww fish) for 6-year-old fish, but less for other ages and time periods. The **omnivorous** (eats plants and animals) common rudd is widely distributed in South America, Europe, and middle Asia (Common Rudd 2010). It prefers clean water of lakes, ponds, large rivers, small streams, and even thermal springs, with lots of plant cover, where they can feed on the plants at warmer temperatures (above 18°C). Early stage larvae start their diet on small algae, then shift to cladocerans and copepods, before including the broad range of immature insects and vegetation that characterize the adult diet.

At least one observation provides definite proof that some fish eat bryophytes. On the Aquamoss website, we are warned not to put the Siamese algae eater, *Crossocheilus siamensis* (Figure 31), in a tank with Taiwan moss (*Taxiphyllum alternans*; Figure 32) because the fish will devour it – quickly! (Figure 32).

Figure 31. Siamese algae eaters (*Crossocheilus siamensis*) nibbling on Taiwan moss (*Taxiphyllum alternans*). Photo from Tan Sze Wei, Aquamoss website <<http://www.aquamoss.net/Articles/Siamese-Algae-Eater-And-Aquatic-Moss.htm>>, with permission.

Jones (1951) discovered that plant material (including algae) was only discernible in the first part of the gut, being digested and amorphous by the more distal portions. In that portion, only impervious parts like chitinous arthropod exoskeletons could be identified. He expressed concern that studies that did not recognize this would give misleading proportions of the food choices.

Frost (1942) recognized the importance of bryophytes in providing a habitat for food organisms of fish. She had already demonstrated that these organisms were important in the diet of brown trout (*Salmo trutta*; Figure 33) at both

Ballysmuttan and Straffan in Ireland (Frost 1939). Young salmon have feeding habits similar to those of trout and similarly consumed a large portion of their food from moss dwellers (Frost & Went 1940). And many of the smaller minnows "cropped" the moss fauna (Frost 1942). Not only do the mosses provide shelter for the immature stages of these food organisms, thus providing food at that stage, but it is likely that some of the consumed aerial adult forms spent their younger aquatic days among the mosses.

Figure 32. Taiwan moss (*Taxiphyllum alternans*). **Upper:** Before the introduction of the Siamese algae eater (*Crossocheilus siamensis*) into the tank. **Lower:** One day after the introduction of the Siamese algae eater. We know that the roach (*Rutilus rutilus*; Figure 34), a common fish in lakes and lowland rivers, spawns in mosses (Mills 1981). From that we can easily deduce that at least some individuals live in places where mosses occur. Roaches consume aquatic insect larvae and molluscs as they grow (Mann 1973), but switch to mostly plant material and algae as they get larger (Hellawell 1972; Mann 1973). It is a natural extension in logic then, to infer that organisms that live among the mosses are potential food organisms, whether it is while they are in the mosses, or only when they venture forth into the open water. So far there seems to be no documentation that the plant material includes mosses, but certainly some of the moss inhabitants must be eaten.

Figure 34. Roach, *Rutilus rutilus*. Photo by Andreas Hartl, through Creative Commons.

Sayre (1936) reports a case in which rainbow trout (*Onchorhynchus mykiss*, formerly *Salmo gairdneri*; Figure 1) actually eats mosses (not *Fontinalis*, apparently). When insects become scarce in streams in autumn, mosses can become part of the diet. A few strands of *Scleropodium obtusifolium* were found in the gut of one of these normally carnivorous individuals in a stream on the western slope of Colorado, USA. Sayre considered that they switched to algae and mosses because other food sources were scarce. It is possible, however, that such invertebrates as Chironomidae were still abundant among the moss leaves. She reported that the moss had lost some color but had not been digested, adding further support to the suggestion that it was only housing the real food.

As one might expect, mosses provide camouflage and cover for potential fish-food organisms. A particularly interesting case is that of the dragonfly *Leucorrhinia dubia* (Odonata) (Henrikson 1993). The naiads of this insect are able to change color to match the brown and green of local *Sphagnum* (Figure 35). They are significantly more abundant among *Sphagnum* and show a preference for this substrate in lab tests. Where lakes have large *Sphagnum* mats, this dragonfly is able to co-exist with fish.

Fish serve as human food, and in Alaska the mosses played an important but misunderstood role in their preservation. The Alaskan natives stored their fish and whale blubber in holes and packed them into holes lined with wood, skins, or leaves and covered them with mosses or leaves (Segal 1992). These were left to ferment for 1-2 months. With the introduction of modern technology, many switched to using plastic bags instead of the natural products. The result was that often the anaerobic

conditions of the bags fostered the growth of *Clostridium botulinum*, resulting in an increase of botulism from 1.2 cases per 100,000 population before 1966 to 15.2 cases per 100,000 by 1992.

Piscicidal Properties

One reason for the refusal of fish to eat bryophytes may be the chemical properties of the mosses. Asakawa *et al.* (1985) found a diterpenedial in the liverwort *Lobatoriccardia yakushimensis* that is potent in killing fish! We know that many bryophytes have secondary compounds that discourage herbivory and it is likely that there are many more than this one that discourage fish from eating the bryophytes. The strongest of these **piscicides** seem to be the (-)-polygodial from the *Porella vernicosa* complex (Figure 36) and sacculatal from *Trichocoleopsis sacculata* (Figure 37) and *Pellia endiviifolia* (Figure 38), *Pallavicinia levieri* (Figure 39), and *Lobatoriccardia yakushimensis*, all liverworts (Asakawa 2007). These two compounds have a hot taste and can kill **killifish** (*Oryzia latipes*; Figure 40) within 2 hours at a concentration of only 0.4 ppm. Sacculatal and 1 β -hydroxysacculatal are lethal to the **killifish** within only 20 minutes at 1 ppm. On the other hand, isopolygodial and isosacculatal from the same liverworts seem to be harmless at concentrations of 10,000 ppm.

Figure 36. *Porella vernicosa*, member of a liverwort complex that produces the piscicide polygodial. Photo by Masanobu Higuchi, with permission.

Figure 37. *Trichocoleopsis sacculata*, a leafy liverwort that produces the piscicide sacculatal. Photo by Rui-Liang Zhu, with permission.

Figure 38. *Pellia endiviifolia* with young capsules. Photo by Michael Lüth, with permission.

Figure 39. *Pallavicinia levieri*, a thallose liverwort that produces sacculatal, a piscicide. Photo by Rui-Liang Zhu, with permission.

Figure 40. *Oryzia latipes*. Photo through Wikimedia Commons.

Among the bryophytes, liverworts have received the most attention regarding piscicidal and other antibiotic activities. This is because liverwort cells have oil bodies that store lipophilic terpenoids and aromatic compounds that serve these purposes (Asakawa 2001).

Cover

The most important role of bryophytes, from a fish perspective, may be that of cover. *Fontinalis* (Figure 41) species, with their long, dangling branches, is especially good at providing cover and rarely is out of water during breeding season.

Figure 41. *Fontinalis antipyretica* forming a dense mat of streamers that can provide cover for eggs and young fish. Photo by Michael Lüth, with permission.

But not all bryophytes are advantageous as cover. In Norway, Heggenes and Salteit (2002) found that juveniles and adults of Atlantic salmon (*Salmo salar*; Figure 42) were less dense in areas where liverworts grew than where that bryophyte had been removed. They suggested that increases in liverwort density actually had a negative effect on the Atlantic salmon. Removal of the brook moss *Fontinalis* (Figure 41) had no significant effect on density of salmon. Brown trout (*Salmo trutta*; Figure 43-Figure 44), on the other hand, had higher densities in association with the *Fontinalis*.

Figure 42. Atlantic salmon (*Salmo salar*). Photo by William Hartley, USFWS, through public domain.

The Atlantic salmon (*Salmo salar*) is one of those anadromous fish that migrate upstream to spawn, then the young fish return to salt water until breeding time (Atlantic Salmon 2010). Once independent of the yolk sack, the

juveniles begin eating tiny invertebrates, but as they become larger they eat small fish. Aquatic insects are a common food, and bryophytes can serve as either direct sources of the insects, or cover for these insects when they are not in open water. In any case, bryophytes generally increase numbers of insects in streams (see later chapter on aquatic insects).

The brown trout (*Salmo trutta*; Figure 43-Figure 44) likewise migrate upstream to spawn, but in this case they are migrating from lakes (Brown trout 2010). While in the streams or rivers, they are major predators on macroinvertebrates – shrimp, corixids, caddisflies, stoneflies, and mayflies. Cover is important protection from predators for them and they seek out submerged rocks, undercut banks, and overhanging vegetation, which could include mosses.

Douglas Burns (2008) tells about his friend who finds successful fishing for bass at strip mine ponds covered with moss. The only problem seems to be finding open water in which to work the lure. The advantage to those fishing is that these ponds are very productive and rarely have other persons fishing.

In Volume 5 on Uses, Chapter 4 (Aquaria), I have discussed the use of bryophytes in aquaria. For example, Tan (2003) reported that the Java moss (mostly *Taxiphyllum barbieri*; Figure 12, Figure 31, Figure 32) is used by fish hobbyists around the world to decorate aquaria and provide cover.

Diversity

With the cover provided by bryophytes, one would assume there would be some correlation between fish communities and bryophyte cover. However, when Paavola (2003) tested this in an Arctic stream, there seemed to be little protective relationship. Rather, fish communities seemed to relate to oxygen levels, depth, and stream size, whereas bryophytes were more related to nutrient levels and in-stream complexity. Species richness did seem to correlate somewhat.

It appears that mosses might be able to help some fish survive drought conditions. McPhail (1999) experimented with the black mudfish (*Neochanna diversus*; Figure 45 - Figure 46) from New Zealand to determine how it might survive both hypoxia and drought. This fish is able to breathe air by rising to the surface and gulping an air bubble that it holds in the buccal cavity while still using its gills to get oxygen to its blood. In McPhail's study, when the water around it dropped to less than 2.5 mg L⁻¹, the fish all gulped air from the surface. At temperatures around 20-22°C, the animals stayed alive on damp mosses for 10 weeks. They lost weight steadily, but all adults recovered upon re-immersion. Two young-of-the-year fish died. The black mudfish is on the IUCN Red List of Threatened Species and was thought to be extinct, but in a 2004 survey in New Zealand, a healthy population was found (World Conservation Monitoring Centre 1996). McPhail (1999) suggested that as a management strategy, mosses could be provided in restoration to help fish survive periods of drought.

Figure 45. Brown mudfish, *Neochanna diversus*. Photo by R. M. McDowell (NIWA), with permission.

Figure 46. Brown mudfish, *Neochanna diversus*, showing its small size. Photo by Vince Kerr, permission pending.

Heino *et al.* (2005) and Paavola *et al.* (2003) found that bryophytes were not a good surrogate for fish diversity. Rather, species richness of this group seems to more related to geographic location, stream size, water color, and acidity. Hence, bryophytes are apparently not useful in predicting fish diversity. Paavola *et al.* (2006) further clarified this poor relationship by examining 101 boreal streams for concordance among fish, macroinvertebrates, and bryophytes. They found that spatial extent of the study was a critical factor in predictability (*i.e.* concordance) and that single river systems provided poor concordance.

Biodiversity of bryophytes can be threatened by fish-harvesting activities (Russell 2006). In the southernmost province of Chile, bryophytes are threatened by fish farming, among other things human activities.

Nutrient Relations

But are the bryophytes really a source of nutrition for the fish?

Sayre (1936) and Bland (1971) state that in Colorado streams rainbow trout will eat mosses when insects become scarce, but when we tried to feed *Fontinalis* to starved laboratory-reared rainbow trout (*Onchorhynchus mykiss*, formerly *Salmo gairdneri*), we were successful only occasionally when our graduate student forced the moss into their mouths (Paulson 1980). In the few cases where he was successful in force-feeding them, they later passed a small, cylindrical package of *Fontinalis* (Figure 47), essentially in tact, at the other end of the digestive tract! If they eat it in nature, it may be to get the insects that invariably live among the leaves.

Figure 47. Package of feces from rainbow trout (*Onchorhynchus mykiss*) containing undigested *Fontinalis* that had been force-fed. Photo by Janice Glime.

There does not seem to be any evidence that fish get nutrients from the bryophytes themselves. On the other hand, bryophytes may get nutrients from the fish! Peterson and Matthews (2009) found that the annual migration of salmon back to their streams can carry nutrients from the ocean to the streams. Using changes in ^{15}N , they measured C:N and C:P ratios in the bryophytes, among other things. When they compared channels with and without decomposing salmon, the bryophytes had lower C:N and C:P ratios in channels with salmon decomposing than in those without. This ratio is the result of higher N and P content, *i.e.*, more nutrients were stored in bryophytes of streams where the salmon returned during migration. Thus, bryophytes contribute to the capture of salmon-derived nutrients in the streams.

Movement of nutrients upstream in fish and ultimate arrival in bryophytes might be predictable, but finding ocean nutrients in **riparian** (banks of a natural water course) bryophytes is a bit of a surprise. Ben-David *et al.* (1998) found salmon-derived nutrients along forest trails near streams. Wilkinson *et al.* (2005) suggested that these nutrients are important contributions to the nutrient input of non-vascular plants. Bryophytes such as *Hylocomium splendens* absorb up to 90% of the dissolved nutrients. Through this pathway, the bryophytes retain nutrients that may later be released to the tracheophytes.

pH and *Sphagnum*

All is not well in *Sphagnum* land as far as fish are concerned. Dunson and Martin (1973) looked at the effects of this moss on downstream communities of fish. They examined the effects of pH on the fish through transplant experiments and distribution data. Brook trout (*Salvelinus fontinalis*; Figure 48 - Figure 49) of various ages were transplanted upstream, near the bog, where the pH was lower. The two adult trout both died within seven days in the zone closest to the bog (pH down to 3.7). For smaller fish (5 cm), half were dead in 4.5 days and all of them after 10 days, while the pH generally remained above 4.4. In a second experiment, the pH generally remained below 4.4 and all 50 fish (5 cm) died within 6.3 days. Although other factors could account for the deaths (differences in flow rate, stress from transplantation, confinement), these data suggest that low pH resulting from *Sphagnum* could be detrimental to some fish populations.

Figure 48. Brook trout, *Salvelinus fontinalis*, a fish sensitive to low pH. Photo by Derek Ramsey, through Wikimedia Commons.

Figure 49. Brook trout (*Salvelinus fontinalis*). Photo through public domain at EPA website.

Hinder *et al.* (1996) found that liming improved the quality of water downstream from peatlands by raising the pH. Brown trout (*Salmo trutta*; Figure 43-Figure 44) survived even after the pH dropped back down to 5.2-5.3.

Table 1. Presence (+) of four fish species at increasing distances and pH downstream from Bear Meadows Bog in Pennsylvania, USA. Data from Dunson & Martin 1973.

	1	2	3	4	5	6	7	tributary

Creek chub (<i>Semotilus atromaculatus</i>)						+	+	+
Blacknose dace (<i>Rhinichthys atratulus</i>)						+	+	+
Lowest pH	3.7	3.7	-	4.0	4.2	4.2	5.1	5.3

Pollution

Mosses are known for their ability to absorb and concentrate heavy metals. Huckabee and Blaylock (1972) demonstrated this mercury. Caines *et al.* (1985) demonstrated that both mosses and liverworts could decrease the metal concentrations in associated water, but that as the H^+ ion concentration increased in the water, the ability of mosses to bind the metal ions decreased. This is consistent with experiments done with *Sphagnum*; flooding that moss with H^+ ions is one way to remove its attached cations. In the Scottish streams, Caines *et al.* found that the metal ions in the mosses remained there as long as the pH remained above 5.5. But if the stream pH drops below that level due to acid rain or drainage from peatlands, it can cause sufficient release of heavy metals to be lethal to fish.

Concentration of the heavy metals by macro-invertebrates can be even higher than that in bryophytes, depending on their position in the food web (Culioli *et al.* 2009). But fish, despite depending on smaller organisms for food, retained the smallest concentrations of arsenic, even lower than that in water. Mersch *et al.* (1993) likewise found that the aquatic moss *Fontinalis antipyretica* had much higher concentrations of heavy metals than did fish. In fact, for fish the concentration depended on the tissue, with copper accumulating in the liver and lead in the kidney. Mouvet *et al.* (1993) reported four different instances in which fish were killed but mosses survived, supporting the notion of using mosses as biomonitors of stream health.

If mosses live and fish die, the mosses need to give some sort of early warning. One such warning is loss of green color. Other symptoms include the discoloration of the terminal bud. And for those willing to do the testing, measuring accumulation of suspected toxins in the moss can indicate the degree of accumulated pollution.

Lithner *et al.* (1995) compared the ability of invertebrates, fish (*Perca fluviatilis*, *Esox lucius*), and *Fontinalis antipyretica* at a location in Sweden to sequester and concentrate heavy metals as a function of pH. They found that when the pH decreased, so did the bioconcentration factor for Zn, Cd, Ni, Co in bryophytes, but the concentrations of Pb and Cu increased in fish with decreasing pH. This emphasizes the fact that bryophytes and other organisms may not be surrogate indicators for the suitability of heavy metal conditions for at least some fish.

A new twist on the use of mosses associated with fish is related to the administration of antibiotics to cattle and fish (Pouliquen *et al.* 2009). Oxolinic acid, florfenicol, flumequine, and oxytetracycline are all used in farming both fish and cattle. These ultimately end up in "freshwater." A study in France reveals the ensuing

scenario. In this case, four fish farms and a sewage plant were located on the main course of the river. The famous mossbags were used, this time in the water. All four of these antibiotics could be measured in the bryophytes and sediments, but not in the water. Both Flumequine and oxytetracycline entered the water from fish farms, animal farms, and possibly human pharmaceutical sources. Accumulations of antibiotics could, through the course of time, alter the flora and fauna of the river. If carried into drinking water, antibiotics could affect the digestive bacteria needed by humans and other animals. And the impact on native mammals that drink from the river could be a concern. Therefore, bryophytes could serve as suitable organisms for testing to determine the levels of antibiotics in the water, particularly when the events of these entering the river are intermittent. The bryophytes, as accumulators, can permit assessment over a lengthy period of time.

Global Warming

The controversial global warming may have an indirect effect on fish that is mediated by changes from planktonic algae to deep-water bryophytes (Felleys 2003). Loss of organic carbon in lakes of the southern boreal forest of Ontario, Canada, previously depleted by acid rain damage, results in clearer water. Lake levels are falling due to declines in rainfall and increased evaporation due to increased temperatures. These factors, and the greater penetration of light, have depressed the planktonic algae in favor of the deep-water (down to 50 m) **bryophytes**. The lakes are now too warm for the cold-loving **trout** that previously lived there. This signals danger for the Arctic lakes that typically remain cold far into the summer. Warming there could seriously affect the fish populations adapted for cold water.

Surrogate Species

Surrogate species are those that can be used to assess the conditions of a habitat in lieu of another species or group. Virtanen *et al.* (2009) attempted to determine the usefulness of **bryophytes** in this role, compared to two groups of insects, the **Chironomidae** (midges) and four orders of insects, **Ephemeroptera**, **Plecoptera**, **Trichoptera** and **Coleoptera**. They found that the bryophytes were not good surrogates for spring insects. On the other hand, there seemed to be relatively good agreement among bryophytes, benthic insects, and fish in boreal headwater streams across a broad scale of water drainage systems, but not at the fine scale of streams in a single drainage system. Such research suggests that bryophytes could be used to assess the likely success rate of introducing fish into streams that have lost portions of their native fauna.

Summary

Bryophytes can provide cover, food, and spawning ground for fish. Although it seems that few fish eat bryophytes, many fish food organisms live there. In those cases where the fish eat the bryophytes, it is not clear whether they gain any nutrition from them. Little fish can take cover in bryophytes. And at least some fish use bryophytes for spawning sites. One variety of stickleback builds a hut in which mosses can be a major constituent. Others simply use the mosses as they are growing. Some liverworts, including streambank species, are known to have **piscicidal** properties, but their ability to use these in habitats where the fish occur is not known.

A number of mosses, especially Java moss (*Taxiphyllum barbieri*), are used in aquaria for cover and spawning beds. Furthermore, Java moss is able to remove the fish nitrogen waste from the water.

Some insects can only survive fish predation when they have cover among mosses, and the naiads of *Leucorrhinia dubia* are able to change color to blend in with the *Sphagnum*.

Sphagnum can acidify lakes and streams, making them uninhabitable for at least some kinds of fish.

Bryophytes can benefit fish as biomonitors, providing early warning signs that the water is contaminated, including more recent contamination with antibiotics. But sometimes the ability of bryophytes to accumulate substances differs from that of the fish.

Acknowledgments

I appreciate the quick responses of Vince Kerr, R. M. McDowell, and Des Callaghan to give me permission to use their photographs. Thank you to all the bryonetters who helped me find the correct names of the piscicidal liverworts and to obtain their images (Rob Gradstein, Rui-Liang Zhu, Li Zhang, Masanobu Higuchi, Michael Lüth). I appreciate those photographers who have put their images in the public domain on the web. And thank you to Rod Morris for correcting my common name of *Neochanna diversus*.

CHAPTER 14-1

AMPHIBIANS: ANURAN ADAPTATIONS

Figure 1. *Dendrobates tinctorius* (Dyeing Poison Frog), perched on a bed of mosses. Many species in the tropics use bryophytes to maintain hydration. This species is named for the use of the poisons in its skin. Its specific name, *tinctorius*, refers to the way indigenous tribes of Amerindians of the Amazon drainage and the Guianas rub the frogs' skin or blood onto the skin of plucked parrots, toxifying the skin and causing the new feathers to develop with a variety of different colors (Métraux 1944). Bryophytes and Amphibians Share Commonalities

In searching for information on bryophytes and their amphibian inhabitants (frogs, toads, salamanders; Figure 1), I ran into Wachman's (2010) interesting question: "In what way are the bryophyte plants and the amphibian animals alike?" Wachman points out that bryophytes have shared the planet with amphibians since the Carboniferous era. Both are transitional organisms from living entirely in water to living at least part of their life cycle on land, a shift that occurred around 360–290 mya. Wachman claims both need a moist environment (I think most bryologists would take exception to that claim, and many treefrogs likewise have found ways around that requirement, although they do use mosses and other moist places to keep their skin moist). While it is true that most amphibians must find water to reproduce, this can be the basin of a bromeliad or tree hole, and a number of them lay their eggs on mosses or other vegetation in trees or on the ground.

Bryophytes need water to maintain the viability of their male gametes (sperm) while they travel to female reproductive organs, taking advantage of rainwater or dew in most cases. Both bryophytes and most amphibians have two distinctive phases of development – bryophytes have haploid leafy gametophytes and diploid sporophytes with a capsule; amphibians have larvae (not always free-living; usually known as tadpoles in frogs and toads) and adults. (But certain salamanders are neotenic in that they stay aquatic and have gills all their lives. Newts have three life phases: larva, then eft, then aquatic adult. They are somewhat able to go back to the eft stage if the standing water disappears – their skin becomes less permeable to water.) And both bryophytes and amphibians thrive best when far from populated areas. But bryophytes seem to be well armed against disease by their secondary compounds, whereas amphibians seem very susceptible to diseases. Since bryophytes are able to grow well in some areas, becoming a major part of the flora, it is to their credit that they provide cover and moisture for the amphibians there.

But in one way, bryophytes differ greatly from amphibians. Bryophytes have tolerance to extreme cold, occupying the northernmost and southernmost locations on the planet, sometimes even surviving on glaciers, whereas amphibians have very poor cold tolerance and most cannot occupy areas with permafrost. In central Alaska, only the Wood Frog (*Lithobates sylvaticus*) and Boreal Toad (*Anaxyrus boreas boreas*) occur, surviving the winter buried in frozen mud (National Park Service 2013).

Anura – Frogs and Toads

The tailless amphibians (Figure 1) are in the order **Anura**, a word that literally means without a tail. These include the frogs and toads. Most of the more familiar temperate frogs were included in the family **Ranidae** in the genus *Rana*. The family occurs on all continents except Antarctica. However, only the Australian Wood Frog (*Hylarana daemeli*) represents this family in Australia, where it is restricted to the far north. The family has been revised and many of the familiar species are no longer in the genus *Rana*.

Standard English names used here are according to Crother (2008) for North American species. **Common names** are local and not at all standardized, whereas the **Standard English names** have legal standing through an official published list (Crother 2007, 2008). Scientific (Latin) names are based on Frost (2011), using classification concepts based largely on recent molecular studies. Where possible, I have tried also to provide the older, more familiar names.

Ranid frogs range in size from the Wood Frog (*Lithobates sylvaticus*, previously *Rana sylvatica*; 2.5-7 cm long; Figure 2) to the Goliath Frog (*Conraua goliath*; up to 45 cm long).

Figure 2. *Lithobates sylvaticus* on a bed of mosses, the smallest of the "true" frogs (Ranidae). Photo © John White, with permission.

Role of Bryophytes for Anurans

Amphibians utilize bryophytes in a variety of ways, from nesting sites to substrata for maintaining or replenishing moisture to perches for calling to winter hibernacula. One of the more amazing discoveries I have

made is to pick up a moss clump in late fall and discover a torpid toad beneath it. Indeed, many herpetologists seek out mossy sites when they are on amphibian hunts, as I well remember from my undergraduate days when I had the privilege to go in the field with a well-known **herpetologist** (one who studies amphibians and reptiles). But often the use of the bryophytes is passive or difficult to perceive. The bryophytes grow in the same sorts of habitats where these amphibians can survive, but does the bryophyte really contribute?

The evidence of bryophyte-amphibian interaction is modest and experiments to demonstrate the importance of the bryophytes are all but non-existent. Most of the reports on anurans only mention bryophytes casually. For example, Bosch and Martínez-Solano (2003) describe the factors that influence the presence of montane frogs in ponds and describe their study area as having moss with underwater caves. In many of the contacts I have made with herpetologists they have commented that the area (especially in the tropics) was covered with bryophytes and that surely the frogs make use of that habitat, but often published documentation is lacking. Nevertheless, it appears that loss of bryophytes could seriously impair many species in this highly vulnerable group of vertebrates that already are disappearing from the planet at an extraordinary rate.

Bryophytes provide a number of possible advantages to the anurans. For the tiny species, the bryophytes may be a full-time or part-time home where they can move about unseen by large predators like birds. As we wend our way through the many species that have been collected among the bryophytes, we will find that they provide mating and nesting sites, cover, calling sites, oxygen under water, and even food sources – both as food themselves and as sites for more traditional food items.

Bryophytes harbor many endangered species whose disappearance will increase with the loss of the bryophyte habitat. Some of these are tiny tropical anuran species that have not even been identified or named. Those that stay within the bryophyte mat are the least likely to have been collected (except perhaps by bryologists ☺). Many occur on the IUCN (2011) list of endangered species.

Safe Sites

Safe sites, sometimes also known as predator-free sites, are important for amphibians, especially when they are calling or hibernating or nesting. Anurans are vulnerable to all sorts of predators, depending on their size. Large ones can suffer a brutal death by ducks that beat them to death on the water surface. Small ones can even become prey to insects, including those that can inhabit bryophytes, both on land (Figure 3) and in the water (Figure 4), or spiders (Figure 5) that lurk on ground and in the trees. Snakes lurk among the branches and leaf litter (Figure 6-Figure 7). For the amphibians, having colors of green, brown, and black can protect them when living among bryophytes, serving as camouflage. Furthermore, a large number of would-be predators are unable to maneuver among the small spaces provided among the bryophyte branches and leaves. Hence, for small frogs and salamanders the bryophytes provide safe sites. And for winter even larger amphibians can hide under them.

Figure 3. *Pristimantis ridens* that has fallen prey to an ant. This tiny frog most likely would have been just as vulnerable to ants within a mat of bryophytes, but would perhaps have been less obvious during its movements. Photo by Tobias Eisenberg, through Creative Commons.

Figure 7. *Craugastor gollmeri*, a species adapted primarily for leaf litter, and resembling leaves. Photo by Brian Gratwicke, through Creative Commons.

Moisture and Temperature Conservation

Frogs and toads must maintain **moisture** without drowning, and mosses can provide that balance. As lung and skin breathers, it is more difficult for most anurans to obtain oxygen in water than in air, but the skin must remain moist to keep the cells functional and pliable. The moisture and temperature of the frogs are also important in attaining maximum jumping distance to avoid predators (Walvoord 2003).

Mosses can provide a moist environment at times when other habitats might be dry, playing a major role in the moisture conservation of many amphibians. Mazerolle (2001) demonstrated that the Wood Frog (*Lithobates sylvaticus*; Figure 2) had more predictable activity, based on weather, near the fragmented edges than in pristine bogs. This greater activity seemed to be more related to the amount of precipitation in the fragments than it was in the bogs, suggesting that the bogs are able to buffer the moisture changes for the frogs living there.

Walvoord (2003) demonstrated that for Cricket Frogs (*Acris crepitans*, **Hylidae**) maximum jumping distance requires maintenance of appropriate interplay between

temperature and hydration. In lab experiments at 30°C, jumping distances of frogs at hydration levels of 85-95% significantly exceeded those at 75%. Furthermore, when the temperature was lowered to 15°C, the frogs had significantly poorer performance. However, at 15°C and 85% hydration, the frogs jumped as well as those at 95% hydration at 30°C. Air temperature was the best predictor of frog body temperature, and sky condition (sunny, cloudy) was the best predictor of hydration. The frogs are able to behaviorally modify their body temperature and their hydration to near optimum by choosing their location, thus permitting them maximal jumping distance and increasing their chances to avoid predators. In the field, the mean body temperature of 55 Cricket Frogs was 28.0°C and hydration was 97.4%. As we shall see, some frogs burrow into mosses during the day or go underground or under mosses, presumably optimizing their temperature and state of hydration.

Calling Sites

In anurans, calling by males is used as a means to attract females. But it also calls attention them by would-be predators (not to mention humans). In the cypress swamps of Georgia, USA, frogs often perch on mounds of moss in summer, using these as locations for breeding calls (Wright 2002), and possibly increasing the distance the call will travel by using an elevated location. But in the tropics, calling sites are often elevated on tree branches and leaves (Figure 8), or even located **within** bryophyte clumps. Presumably, this affords a place to hide while the frog is otherwise making itself more noticeable by calling.

Figure 8. *Eleutherodactylus eileenae* (Eileen's Robber Frog) perched on a tree leaf in Cuba to call during breeding season. Photo by Ariel Rodríguez, with permission.

One of the common genera calling from within mosses is *Bryophryne* (Figure 9). In southern Peru, at elevations of 3800-3850 m asl, Lehr and Catenazzi (2010) found *Bryophryne abramalagae* (Strabomantidae) calling from inside Peruvian feather grass clumps and in mosses at 11:00-13:00 hours. Likewise in Peru, *Bryophryne cophites* (Figure 9) calls from within moss clumps, despite its absence of a **tympanum** (exposed outer surface of ear drum).

Figure 9. *Bryophryne cophites* on a bed of mosses. Note the absence of a tympanum, the external evidence of an ear. Photo by Alessandro Catenazzi, with permission.

In the same location as *Bryophryne abramalagae*, *B. flammiventris* called at 10:00-16:00 hours, again from within large moss mats (Lehr & Catenazzi 2010). Another species of *Bryophryne* (*B. gymnotis*; Figure 10) and a different genus of strabomantid (*Psychophrynella* sp.; Figure 11) also call from moss hideouts. These calls were often heard from the opposite side of the valley, suggesting that the moss cover was likely to be an important safe site during calling, protecting them against detection and possible predation when they were making such loud sounds.

Figure 10. *Bryophryne gymnotis*, a Peruvian frog that calls from within moss mats. Photo by Alessandro Catenazzi, with permission.

In Bolivia, as in Peru, the genus *Psychophrynella* (syn. = *Phrynopus*) (Strabomantidae, formerly in Leptodactylidae) has a number of species that call from mosses (De la Riva 2007). At Cotapata, *P. guillei* begins as the mist rolls over the vegetation, calling from 5-10 cm deep within the mosses. *Psychophrynella iani* calls from under stones and among the mosses. *Psychophrynella iatamasi* (Figure 11) seems to stay in the forest floor mosses for its daytime calling (Aguayo & Harvey 2001). All of the Bolivian páramo *Psychophrynella* species seem to call from secluded places such as mosses, with time of day or night depending on the species. The

páramo (Figure 12) is a misty alpine plateau with stunted trees and wide daily temperature fluctuations, creating a severe habitat. Luteyn (2011) describes the páramo as high, cold, inhospitable, wind and rain swept. I think I would seek shelter too.

Figure 11. *Psychrophrynella* (=Phrynopus) *iatamasi* on a bed of mosses. Photo by Ignacio de la Riva, with permission.

Figure 12. Chingaza páramo in the Eastern Cordillera of the Andes, Colombia. Photo by Andres Baron Lopez, with permission.

Peru seems to be one of the best-studied tropical countries for calling sites. *Gastrotheca pacchamama* (Ayacucho Marsupial Frog, **Hemiphractidae**; see Figure 13) males were found during the day, calling from moss-covered talus (Duellman 1987).

Figure 13. *Gastrotheca testudinea*. Photo by Tiffany Kosch, with permission.

In east of Tanzania, from the moss forests at the summit of Morne Seychellois (1000 m), *Sooglossus* (=Nesomantis) *thomasseti* (**Sooglossidae**; Figure 16) calls

from under objects, on cliff faces and boulders. Naomi Doak (pers. comm. 24 February 2011) reports that the three species of sooglossids that she studied [*Sooglossus sechellensis* (Figure 14), *S. gardineri* (Figure 15), *S. thomasseti* (Figure 16)] call from mosses, and despite sooglossids being ground-dwelling frogs, they sometimes call from mosses on tree trunks.

Figure 14. *Sooglossus sechellensis*, a species that sometimes calls from epiphytic mosses. Photo by Naomi Doak, with permission.

Figure 15. Perhaps the world's tiniest frog, *Sooglossus gardineri* sits on a bed of moss in the Seychelles. Photo by Naomi Doak, with permission.

Figure 16. *Sooglossus thomasseti* sometimes calls from mosses on tree trunks. Photo by Naomi Doak, with permission.

In New Guinea, *Choerophryne* species (**Microhylidae**) call from steep, mossy-covered rocky cliff faces, as well as the forest floor and leaves of shrubs (Kraus & Allison 2001).

In a temperate forest in southern Chile, *Eupsophus emiliopugini* (Figure 17) (**Cycloramphidae**, formerly in Leptodactylidae) and its close relatives excavate burrows in mosses in bogs, from which they make their calls (Penna *et*

al. 2005). This species also calls from burrows hidden in the moss *Racomitrium* (Figure 18-Figure 19) and grasses or ferns on the margins of small streams. Stimuli from calls of nearest neighbors increase the calling intensity, creating a chorus, hence making a larger concentration of frogs that is advantageous for mating.

Figure 17. *Eupsophus emiliopugini* on a bed of mosses, probably *Racomitrium* sp. Photo by Rafael I. Marquez, with permission.

Figure 18. *Racomitrium lanuginosum* in Europe. Photo by Michael Lüth, with permission.

Figure 19. *Racomitrium lanuginosum* showing spaces where tiny frogs can hide while they call. Photo by Michael Lüth, with permission.

Males of *Eupsophus calcaratus* (Figure 20) use cavities within mosses to alter the resonance of their calls (Márquez *et al.* 2005). Hence, the females learn to recognize the resonance characteristics of the mossy burrow-like cavities where the males call. This moss cavity resonance contributes to the recognition by females of the males of their own species in an environment where several species may be calling at the same time.

Figure 20. *Eupsophus calcaratus*, a frog that uses cavities among mosses to modulate its call resonance. Photo © Danté B. Fenolio <www.anotheca.com>, with permission.

It is somewhat of a surprise to find that a Macaya Burrowing Frog (*Eleutherodactylus parapelates*, *Eleutherodactylidae*, formerly in *Leptodactylidae*) was calling from within a large moss clump at 3 m high in a tree at the Massif de la Hotte of the Haitian Tiburon Peninsula, southwestern Haiti (Hedges & Thomas 1987). Many members of this genus call from mosses on the ground or on trees (*e.g.* *E. richmondi*, Figure 21). One must interpret general references to the genus *Eleutherodactylus* with caution. This genus has recently been divided based on molecular evidence and some members now reside in different families and genera.

Even the larger frogs, in *Ranidae*, may call from within moss mats. In southwestern Sulawesi, Indonesia, *Limnonectes* (= *Rana*) *arathooni* calls from 4-10 cm depths within mosses, as well as from leaf litter and rotting roots (Brown & Iskandar 2000).

Figure 21. *Eleutherodactylus richmondi* calling from a bed of mosses. Note the really narrow toes that would be of little help in swimming. Photo by Luis J. Villanueva-Rivera, with permission.

Nesting and Reproduction

Some frogs and toads make use of bryophytes as **nesting sites**. Many more species for which the nesting sites are unknown, especially in the tropics, are likely to make use of bryophytes. Altig and McDiarmid (2007) described the arrangement of deposited eggs in amphibians, stating that semiterrestrial eggs need a source of free water without being submerged. Mosses at the edge of a bog or seepy talus often fulfill this need, where some frogs deposit their eggs in wet moss (McDiarmid & Heyer 1994). When the larvae of these species hatch, they do not feed, and they undergo their development right there in the moss bed.

For example, in the Philippines *Limnonectes* (= *Rana*) *magnus* (**Dicroglossidae**), which is threatened by habitat loss, lays her eggs on rocks and moss (Wells 2007). *Limnonectes* (= *Rana*) *leytensis* (Swamp Frog, **Dicroglossidae**; Figure 22) also occurs in the Philippines, where it is endemic. The female most frequently deposits her eggs on mosses attached to roots or rocks, although she may also use leaves (Alcala 1962). Males call from the nest and guard the nest until the tadpoles hatch. By placing the eggs near the water, the female provides for the tadpoles to be washed into the water by rain – or to scramble there when disturbed.

Figure 22. The Swamp Frog, *Limnonectes leytensis*. Photo by Wouter Beukema, with permission.

Frogs that call from mosses often lay their eggs there as well. Figure 23 shows *Bryophryne cophites* (**Strabomantidae**) tending her eggs on a bed of moss, perhaps at the same place the male has called to her.

Figure 23. *Bryophryne cophites* tending a clutch of eggs laid among mosses. Photos by Alessandro Catenazzi, with permission.

Experimental observations on *Sooglossus gardineri* (**Sooglossidae**; Figure 15), an endemic species from the moss forests of Mahe, Seychelles, suggest that wet substrata may be preferred in that species (Nussbaum 1980). In terraria, all observed **amplexus** (mating stage in which a male amphibian grasps a female with his front legs prior to depositing sperm on her eggs; Figure 24) occurred on damp paper towels or mosses. This is one of the tiniest frogs in the world at 9-12 mm long. This small size suggests that it would easily be at home within the epiphytic and ground bryophytes in the mossy forests where it lives. Fortunately, it is relatively widespread in the Seychelles and is not endangered in the way many of these tiny frogs are.

Figure 24. *Hylarana temporalis* in amplexus. The smaller frog on top is the male. Photo by Sandilya Theuerkauf, through Wikimedia Commons.

Living in a tree has unique environmental problems for young tadpoles that can't escape or change environmental conditions by swimming. Some species, like tree-dwelling *Sooglossus seychelles*, have solved the problem by carrying the tadpoles on their backs (Figure 25). Bryophytes in their habitat may help to maintain their moisture.

Figure 25. *Sooglossus sechellensis* carrying its tadpoles on its back. Photo by Naomi Doak, with permission.

Limnonectes (= *Rana*) *arathooni* (Djikoro Wart Frog, **Dicroglossidae**) in Indonesia, where it is endemic (BioDiversity Hotspots), deposits eggs under 4-10 cm of mosses, leaf litter, and rotting roots (Brown & Iskandar 2000). The male guards the eggs until they hatch and calls from within the nest while sitting on top of the eggs. When disturbed, nearly mature larvae can rapidly emerge from

the eggs and bounce down rocks, banks, etc to reach the nearby stream water. A further advantage of these streamside nest sites is that the splash of water from the stream keeps them humid, a necessity for these eggs and hatchlings. The height above the water protects the eggs from being washed away during high water periods. *Limnonectes poilani* (Figure 26) lives in streams and along their borders in the highlands of central and southern Vietnam and eastern Cambodia. As shown in Figure 26, bryophytes are often common in these habitats.

Figure 26. *Limnonectes poilani* (Dicroglossidae) on bryophytes in a stream, where its coloration matches that of the rocks. This is a member of a genus that often lays eggs among streamside mosses. Photo by W. Djatmiko, through Wikimedia Commons.

A Cuban species of the widespread bryophyte inhabitant *Eleutherodactylus* (*E. rivularis*; Figure 27), laid its eggs, a clutch of 42, 4 m from the edge of the Jibacoa River at Las Mercedes (Díaz *et al.* 2001). These eggs were in a hole that had been excavated, presumably by the frog, under a piece of cloth and "moss sheaths."

Figure 27. *Eleutherodactylus rivularis* calling to attract a female. Photo by Ariel Rodríguez, with permission.

Many tropical treefrogs deposit their eggs in mosses. The extent of these occurrences is not well documented, and almost no experimental evidence exists to demonstrate any preference. *Dendropsophus sarayacuensis* (formerly *Hyla sarayacuensis*; Hylidae) (Shreve's Sarayacu Treefrog; Figure 28) from Bolivia, Brazil, Colombia, Ecuador, Peru, and Venezuela will lay its eggs on either leaves (Figure 29-30) or moss-covered trees (Henzi 1987).

Figure 28. *Dendropsophus sarayacuensis* (Shreve's Sarayacu Treefrog) is adapted by its coloration to sitting on a tree branch and looking like lichens or dying leaves that have insect damage. Nevertheless, it also uses mosses as egg-laying substrate. Photo by Andreas Schlüter, through Wikimedia Commons.

Figure 29. Eggs of *Dendropsophus sarayacuensis* hanging from the underside of a leaf. Note how easily these masses can break and "drip" the froglets to the ground or water beneath. Photo by Andreas Schlüter, through Wikimedia Commons.

Figure 30. *Teratohyla* (formerly *Cochranella*) *spinosa* (Glass Frog) eggs dripping. Photo by Brian Gratwicke, through Creative Commons.

In North America, the east coast of the USA has several terrestrial species. Among these, we know that the Chorus Frog (*Pseudacris feriarum*; Figure 32) (central Pennsylvania inland south to southern Alabama and Georgia) deposits eggs in February to mid-May at the edge of wet patches (ponds and marshes), often on mosses (Livezey & Wright 1947).

Figure 31. *Teratohyla* (formerly *Cochranella*) *spinosa* (Glass Frog) on a leaf covered with lichen and liverwort epiphytes. Epiphytes hold moisture and help to keep the frogs moist. Photo by Brian Gratwicke, through Creative Commons.

Figure 32. *Pseudacris feriarum*, a Chorus Frog that often deposits its eggs on mosses. Photo by John D. Willson, with permission.

The genus *Mantella* (Malagasy Poison Frog, Mantellidae) is endemic to Madagascar. It lays clutches of up to 130 eggs that are deposited under moss layers and other hidden places in their captive terrarium, but nesting behavior in the wild may differ (Glaw et al. 2000). *Mantella laevis* (Figure 33) are **oophages** – they eat tadpole eggs, and these may be delivered to them by adult females, providing a type of parental care. Members of the genus *Mantella* frequently hybridize with each other, suggesting they aren't quite species yet (see Figure 34 for a member of this group).

Figure 33. *Mantella aurantiaca* (golden mantella) on a bed of bryophytes. Photo by Robert Lawton, through Wikimedia Commons.

Overwintering

Many frogs and toads use bryophytes for **cover** from cold and drought, especially in winter or dry weather. It is not uncommon to pick up a moss clump late in the fall and find a hibernating frog or toad under it (personal observation). For some frogs, the bryophytes are a hiding place, and an array of adaptive coloration patterns helps to disguise these amphibians, especially among the tree frogs, as discussed later.

Peatlands may be important temperature mediators for amphibians. Their openness permits warming in the sun, but their branches with air spaces provide a thick insulation from both heat and cold. Toads in north central Alberta, Canada, take advantage of this temperature buffering for hibernation locations (Browne & Paszkowski 2010). In the boreal forest there, 14 out of 21 hibernation sites were in cavities in peat hummocks (Table 1). Other locations were decayed root channels and red squirrel middens (refuse heaps).

Figure 34. *Mantella expectata*, a species known to hybridize with *Mantella laevis*, on a bed of bryophytes. Photo by Paddy Ryan, with permission.

Peatlands in northern areas are known to freeze down to 80 cm. Toads are known to die at temperatures between

-1.5 and -5.2°C (Swanson *et al.* 1996). It is noteworthy that the hibernacula selected by toads in north central Alberta, Canada, rarely or never had temperatures below -5.2°C (Browne & Paszkowski 2010; Table 1). Furthermore, the toads hibernated in communal groups of up to 29 toads, most likely providing further insulation that was not detected by the temperature recorders, although groups of 2-5 were more common. By regularly exchanging positions, they could keep each other from freezing.

The importance of these sites is suggested by their use at distances ranging up to 1020 m from the breeding pond (Browne & Paszkowski 2010). It is likely that the insulation supplied by these peatland sites is crucial for overwintering in these northern sites that mark the limits of tolerance for temperature in *Anaxyrus*. At the boreal forest site, the toads had a significantly higher selection for black spruce/tamarack stands than for other available habitats, with 79% of the toads hibernating there. Thus it appears that the peat/moss configuration of the forest floor provides the most important overwintering habitat in these northern locations.

Table 1. Site temperature characteristics of paired hibernation and reference sites for Western Toads (*Anaxyrus boreas*). Modified from Browne & Paszkowski 2010.

hibernation or reference	shelter type	depth (cm)	min (C)	consecutive days <0C<-1.5C<-5.2C		
hibernation	red squirrel tunnel	45	-2.44	176	0.7	0

reference	peat hummock, cavities	62	-6.31	150	21.7	0.7

Undulating Mosses and *Lithobates* (=Rana) *sylvaticus* (Wood Frog, Ranidae)

Imagine the mosses around you suddenly heaving and rising! The earliest known report of frogs freezing in winter is that of the Arctic explorer, Samuel Hearne (1769 in Hearne 1911). He reported that he frequently saw Wood Frogs, *Lithobates sylvaticus* (Ranidae; formerly placed in *Rana*; Figure 35) that were dug up with the moss when they pitched tents. These seemingly dead frogs could be "brought back to life" by wrapping them in skins and warming them slowly by the fire. For *Lithobates sylvaticus*, the mosses not only ameliorate the temperature fluctuations, but also greatly reduce the water loss (Churchill & Storey 1993). And, these frogs may very well be frozen, only to start hopping around again in the spring! Despite being the smallest ranid, they are the only frog to be found north of the Arctic Circle (Conant & Collins 1998). Unprotected, the frozen frogs could die in 7-9 days from dehydration, so the moss is an important contributor to their survival.

Figure 35. Wood Frog, *Lithobates* (=Rana) *sylvaticus*, among woodland *Polytrichaceae*. Photo by Michael Zahniser, through Wikimedia Commons.

It is not surprising that peatlands are one of the habitats providing a winter home for Wood Frogs. (Wikipedia 2008). Richard Andrus relays "a curious thing I've seen with Wood Frogs in our area (Adirondacks, New York, USA). These critters are explosive breeders in vernal pools for which the eggs and tadpoles are susceptible to predation. So they have a need to find pools that won't support larger frogs and fish. Several years ago I was at a floating mat bog in late April just as the ice was melting. There was ice and snow in the spruce forest around the pond but the mat itself had melted. When we reached the open mat we saw literally 1000's of Wood Frogs all over the mat, in the water, and pouring out of the forest. The reason for this huge number was apparently that the pH of the water (ca 4.0) was too low for fish and Green Frog tadpoles (*Lithobates clamitans*; Figure 36) but not too low for Wood Frogs (*Lithobates sylvaticus*; Figure 35). So this was a huge 'safety zone' for them to breed without these predators. They were coming from the north side as its southern exposure caused this to warm up first. On a hunch, the very next week I went out to another floating *Sphagnum* (Figure 37) mat I knew of and saw exactly the same thing repeated!! So apparently at least this species can escape egg and tadpole predation by using *Sphagnum*-acidified ponds."

Cold Water – *Rana temporaria* (Common Frog, Ranidae)

Despite their **ectothermic** (cold-blooded) nature, many frogs are able to survive winters that take them to below freezing (Koskela & Pasanen 1974). *Rana temporaria* (the European Common Frog; Ranidae; Figure 38-Figure 39) is not freeze-tolerant (Voituron *et al.* 2009a). Instead, as is common in northern Finland, *Rana temporaria* spends its winters under water to avoid freezing (Koskela & Pasanen 1974). From the time these frogs enter their winter habitat until they leave in April (mature individuals) or May (immature frogs), they disappear into the bottom muds or under bottom moss carpets, stones, or other hiding places. They are not in hibernation, and they can become active if disturbed, but they do not feed. When the air temperature exceeds 5°C, the adult frogs emerge to land, with the juveniles emerging 1-3 weeks later. Following mating, a large mass of eggs with up to 2000 individuals is produced (Peatlands 2009). The eggs hatch into tadpoles within a week. In Northern Ireland the species is declining due to loss of peatlands and other wetlands. Hence, the species has been legally protected from capture for sale.

Freeze Tolerance – *Rana arvalis*

In contrast to *Rana temporaria*, *Rana arvalis* (Moor Frog, **Ranidae**; Figure 40) is **freeze-tolerant** (Voituron *et al.* 2009a). It spends the winter not in the water, but in the soil under litter or mosses. The juveniles can survive freezing temperatures for about 72 hours at body temperatures of -3°C (Voituron *et al.* 2009b). In nature, they prepare for this when the temperature drops to the range of 4 to -1°C. In this temperature range, glucose increases 14-fold in the liver and 4-fold in the muscles. **Aerobic** metabolism (using oxygen) persists at a low level, decreasing with temperature, thus preventing the toxic conditions that would arise from **lactate** accumulation. Voituron *et al.* (2009b) suggest that their terrestrial habitat beneath mosses and litter layers provides a temperature regime that shortens the time they spend frozen. Allowance for temperatures to -3°C would permit them to live without freezing under the insulation of snow with the added insulation of the litter, including mosses.

Figure 40. *Rana arvalis* (Moor Frog) on a bed of mosses. Photo by Petr Balej, with permission.

Despite this cold tolerance, *Rana arvalis* (Figure 40) seems to be rare in the Czech Republic (Šandera *et al.*

2008). It requires nearby water with emergent vegetation where it can attach its eggs (Martin Šandera, pers. comm. 20 February 2011). Its breeding period is a short one week, and that is the time it is best to observe it. After that, even if found, it is difficult to identify.

Under Woodland Bryophytes - *Pelophylax* (Ranidae)

Other frogs **hibernate** in woodlands. *Pelophylax lessonae* (Pool Frog; Figure 41) and *P. ridibundus* (Edible Frog; Figure 42-Figure 43), both formerly placed in *Rana*, leave the ponds to prepare for winter (Holenweg & Reyer 2000). *Pelophylax esculentus* (Figure 44) is a hybrid of *Pelophylax lessonae* (Figure 41) and *Pelophylax ridibundus* (Marsh Frog, also formerly included in *Rana*), (Figure 42-Figure 43), but it is no longer recognized as a separate species by Frost (2011). In the woodlands, members of this frog group hibernate 3-7 cm below the surface, often under mosses, fallen leaves, or soil. Interestingly, they change hibernation sites during the winter, sometimes more than once. They seem able to find warmer spots – the hibernation sites had warmer temperatures than other spots that were sampled.

Bryophytes for Food and Food Locations

Strangely enough, Ting (1950) found that *Sphagnum* (Figure 37) mixed with egg yolk could serve as a food source when rearing various species of tadpoles. It has the added advantage of reducing the bacterial growth. Hartmann (1971) discovered that certain mosses produced **neurohormones** that stimulate frog hearts much like the action of **acetylcholine** (and have the same RF value). However, there is no conclusive evidence that mosses serve as an intended food source for adult frogs in nature.

Tadpoles may, however, consume at least some bryophytes in nature. We generally think of tadpoles as being algal and detrital feeders. However, at least in the terrestrial habitat, bryophytes may form part of the diet (Wickramasinghe *et al.* 2007). The semi-terrestrial tadpoles of *Nannophrys ceylonensis* (Ceylon Streamlined Frog, **Dicroglossidae**; Figure 45) in Sri Lanka, like most tadpoles, shift from a scraping food strategy as larvae to catching live prey as adults. During their larval stage, algae are an important part of their diet, with the majority of diatoms being *Selenastrum* (Figure 46). Surprisingly, in

the population studied by Wickramasinghe *et al.*, *Barbula* sp. (*sensu lato*; Figure 47) accounted for most of the moss consumption. As the body size increases, the consumption of mosses decreases significantly, as does the consumption of diatoms. At the same time the mosses and diatoms diminish in the diet, so does the gut size. (Longer guts are needed to absorb nutrients from food organisms with cell walls, like algae and mosses.)

Figure 47. *Barbula convoluta* from Europe, member of a genus that can provide food for frogs. Photo by Michael Lüth, with permission.

Stebbins (1955) found the Tailed Frog *Ascaphus truei* (Figure 48) (Leiopelmatidae) in company of the Olympic Salamander *Rhyacotriton olympicus* under moss-covered rocks along the Pacific coast. Since the seepage where they were found was nearly completely hidden by the mosses, it is not clear that presence of the moss on the rocks was an important habitat consideration or simply that both frogs and mosses preferred the same conditions. But it seems that the two amphibians prefer the same food (Bury 1970). More specifically, young frogs eat a diet similar to that of the salamander. *Ascaphus truei* shifts from having mostly *Collembola* in the diet when young to eating more amphipods at older stages. But even when both are eating the same foods, the abundance of food items among the mosses prevents competition. *Ascaphus truei* climbs on rocks that are covered with mosses and algae, and Noble and Putnam (1931) suggested that these moss-covered rocks might provide a richer food source than locations within the rapid flow of the stream. Bury (1970) indicated that this habitat of *Ascaphus truei* was consistent throughout their range, where they lived in association with "small, water-washed or moss-covered rocks" in running water or along its borders.

Figure 48. Coastal Tailed Frog, *Ascaphus truei*. Photo by James Bettaso, with permission.

Occasional Usage – A Place to Travel

In Panama, aerial frogs like the Banded Horned Treefrogs, *Hemiphractus fasciatus* (formerly *Cerathyla panamensis*; *Hemiphractidae*) (Figure 49-Figure 53) may make indirect or intermittent use of bryophytes. This frog lives among **bromeliads** – those basket-shaped plants that capture water and live in trees (Stejneger 1917). The female *Hemiphractus fasciatus* carries her eggs and her young on her back (Myers 1966; Figure 49-Figure 50), suggesting that desiccation could become a problem. The bromeliads are abundant on both trees and the ground, and mosses are frequently present around them. It is difficult to imagine that these frogs do not take advantage of the cover, camouflage, and moisture of the mosses as they move from place to place. At the very least, one might expect to find these frogs when looking for bryophytic treasure on tropical tree branches. However, it appears that this species does not need to hide from many kinds of predators.

Instead, it rears up, arches its body, and throws up its head (Figure 51). The yellowish-orange tongue and large mouth present an imposing image (Figure 53). If a would-be predator makes contact, the frog has further defense by clamping two sharp tooth-like projections (Figure 53) into the attacker and hanging on with a strong grip (Figure 52), a painful experience that Myers knew all too well. The frog had to be pried loose!

Figure 49. *Hemiphractus fasciatus* female carrying eggs on her back. Photo by Edgardo J. Griffith, El Valle Amphibian Conservation Center (EVACC), Director, with permission.

Figure 50. *Hemiphractus fasciatus* female with juvenile frogs on its back. Eggs are retained in patches until the larvae develop into young adults, then remain for some time with the mother after hatching (Myers 1966). This behavior permits the adult to carry the young to locations with sufficient moisture. Photo by Brian Gratwicke, through Wikimedia Commons.

Adaptations to Bryophyte Habitats

It is interesting that so many species of anurans exist sympatrically (same geographic area) in "mossy" habitats such as the mountain tops of tropical areas. Hofer *et al.* (2004) paraphrased Gause's Rule by stating that "If interspecific competition is a strong structuring force of

communities, ecologically similar species should tend to have spatial ranges at local scale that do not overlap." They used collected data to test the hypothesis and were surprised to find that whereas lizards and birds exhibited adjustments that reduced the potential for interspecific competition, the frogs did the opposite – there was a greater than chance co-occurrence of ecologically similar frog species. They suggested that resource requirements such as breeding sites may be more important for frogs than competition.

With this in mind, we can see that bryophytes can play a role in providing breeding sites that maintain moisture and provide cover that contributes to keeping the eggs safe. They furthermore provide moist respites for travelling anurans, and for many species can provide hiding places. Given this usage of bryophytes to define part of the anuran niche, we should expect adaptations to have evolved that make this bryological life somewhat easier.

An Altered Life Cycle

Alcala (1962) divided the tadpoles of anurans into three environmental categories. Stream dwellers have depressed bodies, strong tail muscles, and reduced body and tail fins (Figure 54); pond tadpoles have subspherical bodies, weak tail muscles, and high body and tail fins (Figure 55). Both of these aquatic larvae come from small eggs laid in large clutches. Larvae with direct development (out of water) have altered larval structures, including abdominal sacs instead of gills, and derive from large eggs in small clutches. A fourth category is those anurans that have no tadpoles at all, but that hatch directly into froglets.

Figure 54. *Atelopus limosus*, showing the flattened body of a stream tadpole. Photo by Brian Gratwicke, through Creative Commons.

Figure 55. *Paracrinia haswelli* (Haswell's Frog) tadpole showing the high body and tail fins typical of pond tadpoles. Photo through Wikimedia Commons.

In the study area of Negros, Philippine Islands, more than 50% of the eggs are laid out of water (Alcala 1962). Among those in the study, some eggs were attached to mosses growing on rocks above a pool in a mountain stream, including *Platymantis dorsalis* (= *Cornufer meyeri*; **Ceratobatrachidae**; Figure 56) whose adults live on the montane forest floor, sometimes under moss mats.

Figure 56. *Platymantis dorsalis*, a frog that seeks refuge under moss mats on the forest floor. Photo by Amir Hamidy, with permission.

Food Capture

Terrestrial adults require different adaptations to capture their food than do the aquatic larvae of their ancestors. One of these adaptations is an extremely fast tongue (O'Reilly & Nishikawa 1995). The anuran tongue is attached at the front, permitting a rapid and extended unfolding.

Escaping Predators and Flying Moss Frogs

When hiding among the mosses is not an option for avoiding predators, then a fast getaway might work. *Ecnomiohyla rabborum* (Rabb's Fringe-limbed Treefrog, Hylidae) is only known from the cloud forest in the mountains near El Valle de Anton, Panama, in the narrow elevational range of 900-1150 m asl (Mendelson *et al.* 2008; Mendelson 2009), where it lives in the canopy. Its large feet (Figure 57) permit it to glide downward from its arboreal habitat, effecting a rapid escape route. It lays its eggs in tree holes, just above the water line. Males remain near the eggs and defend them (Frost 2011). Although I could find no documentation that this species uses mosses, its habitat in the canopy of the cloud forest almost assures that it does.

Figure 57. *Ecnomiohyla rabborum* (Rabb's Fringe-limbed Treefrog, Hylidae), illustrating the large, very webbed feet used for gliding in the Costa Rican forest. Photo by Brian Gratwicke, through Creative Commons.

I thought I had finished adding new species to this chapter when I ran into "moss frogs." None of the names I had seen used this terminology except for the "mossy frogs" that mimicked mosses. But these were a whole new group of frogs, the genus *Arthroleptella* (**Moss Frogs, Pyxicephalidae**; southern Africa) and the family **Rhacophoridae** (Old World Tropics) (Wikipedia 2015a). Well – not quite all were new. *Theleiderma*, the genus of the Vietnamese Mossy Frog, is in the **Rhacophoridae** and will be discussed below.

Of interest is that some members of the genus *Rhacophorus* are known as **Flying Frogs** or **Parachuting Frogs**. *Rhacophorus malabaricus* (**Malabar Flying Frog, Rhacophoridae**; Figure 58-Figure 59) lives in the Western Ghats of India with an altitudinal range of 300-1200 m asl (Biju *et al.* 2004).

Rhacophorus malabaricus lives in tropical moist evergreen and deciduous forests as well as secondary forests and agricultural forests such as coffee plantations (Wikipedia 2011b). It spends its time in the lower canopy or understory and breeds in overhanging vegetation where tadpoles can drop from the foam nests into ponds and pools.

Rhacophorus malabaricus frogs are known as flying frogs because of their ability to glide from their arboreal habitat to the ground. Using their leg and toe spread (Figure 60) and unique morphology, they are able to minimize their descent (falling/gliding) speed and maximize their descent time (Emerson & Koehl 1990). Rather than relying on increasing horizontal travelling distance, their particular maneuverability permits them to actually decrease horizontal distance during descent. These gliding pathways can carry them 9-12 m, about 115 times their length (Wikipedia 2011b). Webbing between the toes further increases their gliding ability.

Figure 58. *Rhacophorus malabaricus* showing its narrow legs. Photo by L. Shyamal, through Wikimedia Commons.

Rhacophorus arboreus (**Japanese Green Treefrog; Kinugasa Flying Frog**; Figure 61-Figure 62) lives in Honshu, Japan, from sea level to 2000 m asl (Chantasirivisal 2011). It is a comparatively large treefrog; adult males are smaller (42-60 mm) than females (59-82 mm). During breeding season, they live in ponds and rice fields. Otherwise, they live in trees and leaf litter. They hibernate through the winter under moss or shallow soil.

Unlike the moss frogs of *Arthroleptella*, *Rhacophorus arboreus* females deposit eggs in a foam nest on vegetation near standing water where the larvae can easily enter the water. To protect the eggs, the female excretes an albumin-based fluid from her cloaca. She creates the foam by beating her hind legs, forming a nest to protect the 300-800 eggs. The male then fertilizes the eggs and the foam hardens, protecting the eggs from water loss and predators.

Figure 62. *Rhacophorus arboreus* (Japanese Green Tree Frog) in its arboreal home. Photo © Danté B. Fenolio <www.anotheca.com>, with permission.

Arthroleptella bicolor (Bainskloof Moss Frog, Pyxicephalidae) lives in fynbos and heathland of Western Cape Province, South Africa at 300-2000 m asl (IUCN 2011). This species breeds in wet mossy areas usually near water, where it lays 8-10 eggs in terrestrial mosses or similar vegetation. Nevertheless, its eggs do not hatch into tadpoles, but develop directly into froglets.

Arthroleptella drewesii (Drewe's Moss Frog, Pyxicephalidae; Figure 63) is endemic to Table Mountain and other mountains, up to 1,000 m asl, in the Cape Peninsula of South Africa (IUCN 2011). It lives in fynbos and heathland, as well as forest. It lays its 5-12 unpigmented eggs in moss or similar vegetation in wet mossy areas similar to those of *A. bicolor*. As in *A. bicolor*, the eggs hatch directly into froglets.

Arthroleptella lightfooti (Lightfoot's Moss Frog or Cape Chirping Frog, Pyxicephalidae) is endemic to Table Mountain and to the other mountains of the Cape Peninsula, South Africa, where it occurs from sea level up to 1000 m asl (Frost 2011). Like the other *Arthroleptella* species thus far, it lives in fynbos, heathland, and forest (IUCN 2011). It lays its 5-12 eggs in mosses or similar vegetation in wet mossy areas, and likewise chooses locations near wet areas and streams (Rose 1929; Livezey & Wright 1947; Frost 2011). It, too, has direct development into froglets. Metamorphosis to adults occurs there on the mosses (Livezey & Wright 1947).

Figure 63. *Arthroleptella drewesii* on a bed of moss. Photo by Robert C. Drewes, with permission.

Arthroleptella villiersi (De Villiers' Moss Frog, Pyxicephalidae) is endemic to the western cape of South Africa, from sea level up to 1,000 m asl (IUCN 2011). It lives in lowland and montane fynbos and heathland, where it breeds in wet mossy areas similar to those of the other *Arthroleptella* species mentioned here. It lays its 10 eggs in moss and similar vegetation.

Anhydrophyrne hewitti (Hewitt's Moss Frog, Pyxicephalidae; Figure 64) lives in forest and dense vegetation in the Drakensberg and midlands of Kwa-Zulu Natal, South Africa (IUCN 2011). Its breeding habitat is in wet mossy areas of riverine bush and forest near waterfalls and rapids. The 14-40 eggs are laid in moss and leaf-litter on edges of streams. Despite its preference for streamside habitats, the eggs develop directly without a larval stage.

Figure 64. *Anhydrophyrne rattrayi*, here blending with the leaf litter, shows the small size of these frogs. Another member of its genus, *A. hewitti*, lays its eggs in wet mossy areas along streams. Photo by Robert C. Drewes, with permission.

But most frogs don't glide. Some can hop quite high. I had a pet **Green Frog** (*Lithobates clamitans*) I soon named Mr. Wanderlust. He lived in my garden room on the main floor of the house, but he would often escape. I found him hopping across the TV room at the other end of the house several times, at the top of the stairs on the second story several times, and once I found him on top of the open door! I watched him jump one time as I saw him on the floor beside me at my desk. Then suddenly, he was on the desk beside me! But despite our usual vision of hopping frogs, many of them spend more time creeping and

climbing (Figure 65). That is how Mr. Wanderlust escaped under the hanging screen to get free from the garden room.

Camouflage and Mimicry

When you make a good dinner, it is helpful to be invisible. A number of species of frogs have disruptive coloration that would make them less conspicuous than a solid color. Greens and browns are common colors among frogs, again providing good camouflage for moss dwellers. But some have disruptive skin surfaces with warts and other extensions, making them blend with the mosses even more.

Importance of Being Still

One reason we know so little about the moss-dwelling frogs is that they do camouflage so well. Cooper *et al.* (2008) noted that camouflaged frogs should limit their movement to avoid detection by disrupting their crypsis. They experimented with *Craugastor fitzingeri* (formerly *Eleutherodactylus fitzingeri*; *Craugastoridae*; Figure 66-Figure 67) and demonstrated that when the frogs were motionless, four humans were able to detect only 60% of them in a 2 m diameter circle within 60 seconds. Over 90% of the individuals of five species of *Craugastor* remained motionless until the potential predator reached them.

Disruptive Coloration - *Boophis*

Vallan *et al.* (1998) reported on a new tree frog in the genus *Boophis* (**Bright-eyed Frogs, Mantellidae**; Figure 68) from Madagascar. This frog was especially adapted to blending with tree bark covered with lichens – it has tubercles and fringes and flattens against the branch when it is disturbed. It can change colors from whitish to brown, thus making it also camouflaged on some bryophytes. This mimicry makes it very different in appearance from other

members of the genus, such as *B. viridis* (**Green Bright-eyed Frog**; Figure 69).

Figure 66. *Craugastor fitzingeri* on mosses. Photo by Brian P. Folt, with permission.

Figure 67. *Craugastor fitzingeri*, with colors that blend with the soil. This one seems to be eyeing an ant, a potential food source. Sitting quietly not only protects it from being preyed upon, but also permits it to lie in wait for food organisms without being noticed. Photo by William Leonard, with permission.

***Ceratophrys ornata*, A Bryophyte Mimic**

Some frogs and toads really play it safe with both disruptive coloration and tubercles, making them look like the light and dark patches of a bryophyte clump. Such is the case for *Ceratophrys ornata* (up to 16.5 cm long), the Argentine Horned Frog, but it appears that this frog typically spends its time in grassland (except in captivity). In fact, moss in a terrarium can cause impaction if the frogs eat it. These frogs are unusual in having teeth and a strong jaw – strong enough to inflict pain on animals that attack them. The mouth is extremely large, and they feed on rodents, small reptiles, large spiders, and insects. Gut analysis of thirty-four specimens from Uruguay included 78.5% anurans, 11.7% passerine birds, 7.7% rodents, and 0.3% snakes, leaving only 1.8% as "other" (Basso 1990). They use a "lie-in-wait" strategy that is facilitated by their similarity to the bryophyte (or other) background. There are several color forms, ranging from mostly green to mostly brown. The larvae are also unusual – these are the only vertebrates to make calls in the larval state.

Tubercles – *Theloderma corticale* (Vietnamese Mossy Frog, Rhacophoridae)

The **Vietnamese Mossy Frog**, *Theloderma corticale* (Figure 72-Figure 73), is one of many moss mimics among the amphibians, and perhaps the most famous. Literally translated from medical terminology, its generic name means nipple skin. Although it resembles a toad, it is not one. This strange animal can mimic both mosses and bird droppings, sometimes in the same animal! (Indraneil Das, pers. comm. 8 January 2012).

Figure 72. **Vietnamese Mossy Frogs**, *Theloderma corticale*. Photo by Milan Kořínek, with permission.

It is an inhabitant of the karst zones of northern Vietnam, where it lives in flooded caves and other deep holes on the banks of mountain streams (Ryboltovsky 1999). Its skin is a mottled black and green that resembles a "bunch of moss." Numerous spines and tubercles add to the disruptive pattern that makes it quite invisible among the dense moss and lichen cover (Figure 73).

These frogs remain quiet in the daytime and hunt at night (Figure 73). When frightened, they will roll into a ball and play dead (Figure 74) (Wikipedia 2015b). They also avoid detection by being ventriloquists – throwing their voice to another location so they cannot be found while calling. This rare frog is now being bred as a terrarium pet. It appears that the starter pair has been

rescued from an area that is rapidly becoming unsuitable as a home. Despite its broad habitat range, it is threatened by habitat loss (Animal Photo Album 2007).

Green and Wet – *Centrolene geckoideum* (Pacific Giant Glass Frog, Centrolenidae)

The Pacific Giant Glass Frog, *Centrolene geckoideum* (Figure 75), lives in tropical and South American cloud forests of Ecuador and Colombia (Glass Frogs: Centrolenidae), especially near waterfalls or rapids, where traversing mossy substrata must surely be a necessity in

some locales. This is the largest of the glass frogs and its coloration of dark green to lime green, and skin covered with tubercles, most likely helps it to be inconspicuous among wet bryophytes and rocks. Clearing of forests for farming and chemical sprays from agriculture have reduced numbers so that this is listed as an IUCN vulnerable species (IUCN 2011).

Figure 75. *Centrolene geckoideum*, the Pacific Giant Glass Frog, from near Tandayapa, Province of Pichincha, Ecuador. Note the tubercles and greenish color that help to camouflage this frog among bryophytes and lichens. Changing Colors – *Platymantis* spp. (Ground Frogs, Ceratobatrachidae)

Platymantis macrosceles (Figure 76), endemic to Papua New Guinea, where it lives in montane forests, is not known for its arboreal behavior. However, when Foufopoulos and Brown (2004) found them in New Britain, two of them were perched on moss-covered branches of shrubs about 1 m above the ground and 2 m from a small stream. Their tubercles, combined with brown spots on green backs, made them all but invisible on their mossy perch. Interestingly, when removed from the mosses, they lost their patterned colors and became a yellowish green color (Figure 76; Johannes Foufopoulos pers. comm. 10 February 2009).

Figure 76. *Platymantis macrosceles*, after losing its color when removed from its mossy perch. Photo by Johannes Foufopoulos, with permission.

Platymantis mamusiorum (Ceratobatrachidae; Figure 77), another little-known frog from the Nakanai Mountains of New Britain, Papua New Guinea, lives in montane rainforests where the ground and logs are thickly covered with moss (Foufopoulos & Brown 2004). It spends resting time on bushes and low branches up to about 1 m from the ground, but its cryptic coloration permits it to remain unseen against a mossy background. It is not as well camouflaged as the former species, lacking the brown spots and tubercles (Johannes Foufopoulos pers. comm. 10 February 2009).

Figure 77. A ground frog, *Platymantis mamusiorum* showing cryptic coloration on a bryophyte-covered perch. Photo by Johannes Foufopoulos, with permission.

Colors Matter

As seen by the foregoing discussion, cryptic and disruptive coloration permit frogs to sit quietly without being seen. But it is not just blending with one particular substrate that provides an advantage. Having multiple color forms within a species increases chances for the species to survive. Forsman and Hagman (2009) demonstrated this in their studies of 194 species of Australian frogs. The polymorphic color patterns afforded larger ranges, more survival habitats, less negative population trends, and less vulnerability to extinction compared to species with non-variable color patterns. Among these, we can assume, is the ability for some color forms to utilize bryophyte habitats to their advantage where they are available. is a good example of multiple color morphs.

Oophaga pumilio has many color morphs (Pröhl & Ostrowski 2011; Figure 78-Figure 81) with estimates of 15-30 different forms (Summers *et al.* 2003). The green morphs typically remain within the moss mats and spend less time foraging compared to the brightly colored morphs that are more active (Pröhl & Ostrowski 2010). This dual strategy in a highly poisonous frog permits two different kinds of adaptations to operate in the same population. The brightly colored morphs advertise their poisonous nature through their warning coloration, whereas the green morphs are less conspicuous to us, to predators, and apparently also to potential mates.

Does Size Matter?

Although some large frogs and toads make use of mosses for nesting and moisture retention, those that live within the mosses terrestrially are typically quite small. Bryophytes, particularly mosses, provide them with small spaces where they can navigate without being seen by hungry predators. But it appears that bryophytes might have had a role in their evolution and size characteristics.

The tiny *Noblella pygmaea* (Noble's Pygmy Frog, **Strabomantidae**; Figure 82) was found for the first time in southern Peru, where it occupied two habitat types, one along the montane ridge and the other in the elfin forest where moss cover was abundant (Lehr & Catenazzi 2009). This frog is the smallest in the Andes (females 12.5 mm, males 10 mm) and one of the smallest in the world. (Note that members of **Leptodactylidae** and related families have many small members and will be discussed later). Having a small size, while beneficial for hiding in mosses, is detrimental for venturing away from the moss during the drying heat of day. As size decreases, the surface area to volume ratio increases, providing relatively more surface area for losing water.

To understand the role of size and other parameters in the evolution of Neotropical amphibians, Gonzalez-Voyer *et al.* (2011) examined the correlates of species richness with habitat parameters and body morphology. They found that a greater age of the clade did not increase richness. Rather, ecological and morphological traits seemed most important. One of these traits that correlated well with greater terrestrialization and ability to live at high altitudes was the presence of greater vascularization in the ventral skin. This, presumably, may aid in moistening the body by ventral contact with moist substrates such as bryophytes.

Figure 82. Adult *Noblella pygmaea* on what appears to be a liverwort. Photo by Alessandro Catenazzi, with permission.

Since being small can also be a problem for eggs, having only two eggs permits *Noblella pygmaea* to make larger eggs with less relative surface area to suffer drying out (Figure 83) (Gonzalez-Voyer *et al.* 2011). The moss cover should help to protect both eggs and adults against water loss as well as provide camouflage, but the preferred egg-laying locations of many of these small species, including *Noblella pygmaea*, are not known.

Figure 83. Adult *Noblella pygmaea* with its two eggs. Photo by Alessandro Catenazzi, with permission.

Although Gonzalez-Voyer *et al.* (2011) found no correlation between latitude and richness, Wiens (2007) and Moore and Donoghue (2007) found greater diversification rates in amphibians in lower latitudes. Amphibians seem to have evolved in contrast to **Bergmann's** (1847) **rule** (species of larger size are found in colder environments; usually applied to endotherms), having greater body size farther from the poles and small size at high elevations in the tropics (Feder *et al.* 1982; Adams & Church 2007; Lehr & Catenazzi 2009). Geist (1987) disagreed with Bergmann's rule and instead claimed that in mammals body size initially increases with latitude, but at latitudes of 53-65°N it reverses, with the result being small body sizes at the lowest and highest latitudes.

But does this relationship apply to ectotherms like anurans? Ashton (2002) found a distinct body size relationship with latitude and elevation in salamanders, with 13 of 18 species being larger in higher latitudes and elevations. But anurans seemed less likely to conform, with only 10 of 16 species showing these trends.

Part of the disagreement lies in what is being compared. The within species comparison of Ashton (2002) is not the same as comparing among species and genera. Blackburn and Hawkins (2004) quote Bergmann as saying that "on the whole. . . larger **species** live farther north and the smaller ones farther south."

For terrestrial frogs, Gonzalez-Voyer *et al.* (2011) found that larger body size correlated only marginally with latitude and elevation. In fact, they suggested that small-bodied species may diversify more than larger ones in the Neotropics, at least in the Andes, because they are able to partition the niches on a finer scale (see also Lomolino 1985; Purvis *et al.* 2003).

The first explanation that comes to mind regarding Bergmann's rule is that a larger body is less susceptible to losing heat due to a smaller surface area to volume ratio. While this is a reasonable explanation for endotherms, there does not seem to be any reason to assume this for ectotherms. In fact, Ashton (2002) found no clear relationship between body size of salamanders and environmental temperature.

One explanation for the ability of small frogs to survive at high altitudes is their ability to make a physiological activity shift in response to lower temperatures (Navas 1996, 2006; Lehr & Catenazzi 2009).

This ability permits them to occupy the "mosaic" of small patches where the habitat is suitable and a food source is available (Hutchinson & MacArthur 1959). These terrestrial frogs have the advantage that they do not need to migrate to water to lay their eggs, and generally their home range is small, sparing them of the dangers of moving among a patchwork of unfavorable habitats. Such small patches would be unsuitable for larger frogs with greater food demands and need for moisture.

Let us consider the genus *Pristimantis*, a genus that includes arboreal bryophyte dwellers, in this discussion. *Pristimantis* (Figure 84) represents the clade with the greatest number of terrestrial species (Gonzalez-Voyer *et al.* 2011). Lynch and Duellman (1997) reported a correlation between small body size and arboreal species richness in this genus. Concomitantly, prey size correlates with body size, a phenomenon which Duellman (2005) suggested might indicate competitive release through resource partitioning, subsequently explaining high local diversity that can reach as high as 139 species in 6.5 km² in the Amazon (Bass *et al.* 2010).

One explanation for the successful niche partitioning is that large amphibians retain water more easily and maintain body heat at a more constant temperature (Shoemaker 1992). The presence of many body sizes permits greater niche partitioning, with each size group locating where moisture and temperature are optimal. In this regard, the variety of bryophyte growth forms available can provide a wide range of niches with different moisture and insulating abilities. Conversely, the divergent niches offered create divergent selection pressures that, coupled with the geographic isolation afforded by ridge and valley topography, provide suitable conditions for speciation (Lynch 1986; Lynch & Duellman 1997).

Figure 84. *Pristimantis bacchus* on a bed of mosses. Photo by Esteban Alzte, through Creative Commons.

One peculiar habit noted for small frogs in marshy areas of Suryamaninagar, Tripura, India, is that they form small groups as rain approaches, effectively becoming a large animal, but after it stops they separate from each other (Acharya 2011). One could hypothesize that this behavior may help to prevent overcooling during the rain, so it would be interesting to know if the same behavior would occur if they were able to sit within the cover of bryophytes.

The Frog or the Egg?

When frogs invaded bryophytes, whether on the ground or in the trees, did they invade because they were small, or did they become smaller as they adapted more and more to terrestrial living and bryophytic habitats? Did the tiny frogs invade first, or did they begin using bryophytes as egg-laying sites, taking advantage of UV protection, moisture, and protection from larger predators? If the latter, did birth among the mosses direct more and more of them to seek shelter there later in life, creating greater survival for those that did, and driving selection toward those with that behavior and miniature size? Did bryophytes drive anuran evolution in the tropics, or were they just convenient co-evolvers in time? In any event, being small permits a wider range of uses of bryophytes by anurans.

Enter the Bryophytes – and *Eleutherodactylus* (Eleutherodactylidae)

The genus *Eleutherodactylus* has many species of very small frogs associated with mosses. Their subtle coloring, often with disruptive patterns, makes them inconspicuous in a variety of habitats, including bryophytes. This is clearly demonstrated for *E. cuneatus* in Figure 85. So far, we do not know much about the moss interactions of this species. Is it pre-adaptive to becoming a moss-dweller when its environment becomes too dry for open exposure? Or is its coloration already an adaptation to the multiple habitats it must cross during its daily activities?

Figure 85. Some frogs, like this Cuban endemic *Eleutherodactylus cuneatus*, blend in well with the mosses they cross by having a disruptive pattern of light and dark browns. This same coloration would serve it well as it crosses forest soil and patchy, decomposing leaf litter. Nevertheless, it is on the IUCN red list. Is it rare because it is disappearing, or only because we seldom see it due to its coloration? Photo by Ansel Fong, with permission.

Being tiny is one adaptation that permits some members of this genus to inhabit mosses. The smallest frogs known in the world are in this genus, measuring only 8.5 mm long (Wikipedia 2011a). The tiny *Eleutherodactylus coqui* (Figure 86) has invaded Hawaii, where it competes with native species (Kreaser *et al.* 2007). Frogs of this small size are likely invaders in the moss

trade, where they can travel unnoticed among the imported moss species. But of even greater concern is the trafficking of these tiny frogs in the plant trade.

Figure 86. *Eleutherodactylus coqui* on a tree bole, surrounded by bryophyte and algae growth. Photo by Alan Cressler, with permission.

One species of *Eleutherodactylus* appears in greenhouses so commonly through plant transport that it has been named the **Greenhouse Frog** (*Eleutherodactylus planirostris*; Figure 87) (Frost 2011). The natural distribution of this species is in Cuba, and the Isla de Juventud (0-720 m asl), Cayman Islands, and Caicos Islands. But they have been introduced into Florida, southern Louisiana, southern Georgia, Oahu, and the island of Hawaii, USA, and to Guam, Jamaica, Honduras, and Veracruz, Mexico. This terrestrial species lives in both mesic and xeric habitats, including forests, caves, beaches, nurseries, gardens, and urban areas (Hedges *et al.* 2004). In the Cayman Islands it has naturalized in bromeliads. No surprise, it is categorized as least concern by the IUCN.

Figure 87. *Eleutherodactylus planirostris* on moss. Photo by Brian Gratwicke, through Creative Commons.

When you are as small as these *Eleutherodactylus* species, even thin mats of bryophytes can help maintain moisture. Note in Figure 88 the wet leafy liverworts that are epiphyllous on the leaf, maintaining a moist location for this tiny *Eleutherodactylus gryllus* (**Cricket Robber Frog**; Figure 88-Figure 89). A native of interior uplands in Puerto Rico from 300-1182 m asl, it is known from only a few localities and is considered endangered (IUCN 2011). Mosses provide daytime retreats in its forest home. It calls from perches in trees and shrubs (Figure 88). Eggs still require water and are laid in basins of bromeliads, but Father Alejandro Sánchez found them under bryophytes (Figure 90). These develop young froglets, with no tadpole stage.

Figure 88. *Eleutherodactylus gryllus* (**Cricket Robber Frog**) calling from a leaf covered with epiphylls. Photo by Luis J. Villanueva-Rivera, USDA, with permission.

Figure 90. Eggs of *Eleutherodactylus* sp. under layer of moss on a tree trunk, El Yunque National Forest, Puerto Rico. Photo by Father Alejandro Sánchez, with permission.

Most of these species don't bear any coloration patterns that distinguish them as bryophyte dwellers. However, *Pristimantis galdi* (formerly *Eleutherodactylus galdi*) (Espada's Robber Frog; Figure 91) has both color patterns and tubercles to render it invisible in the right setting; i.e., it is a moss mimic. This species lives in both secondary and old-growth humid evergreen forests in Peru and the Cordillera of Ecuador from 1000 to 1740 m asl (Frost 2011; Rodríguez *et al.* 2004). It seems to prefer leaves at 1-2 m above the ground (Lynch & Duellman 1980). Its habitat is threatened by livestock farming, agriculture, and logging, classifying it as near threatened (Rodríguez *et al.* 2004).

Summary

Bryophytes and amphibians are both transitional organisms that have adapted to land. Their life cycles are characterized by two phases that have different requirements. Frogs need to maintain moist skin, so bryophytes can provide them with a suitable habitat. Mosses provide moist safe sites from the drying sun during the day and serve as mating and calling sites for many species. *Sphagnum* can offer a moisture refugium for migrating amphibians. The same moisture advantage is offered to eggs. The male Leyte Wart Frogs (*Limnonectes leytensis*) stay under the mosses with their eggs; tadpoles can later be washed into the nearby water by rain. In winter, the bryophytes can provide insulation for hibernating anurans that can become frozen up to 60%, as well as reducing the risk of desiccation. And some bryophytes can serve as food and even sources of oxygen. *Sphagnum*, mixed with egg yolk, can even serve as food for rearing several species of tadpoles. At the very least, mosses provide refuge for a number of invertebrates that are suitable food for the anurans. For some species, using mosses as cover during overwintering may save their lives. In summer, some frogs may even return day after day to the same spot among the mosses.

Some Anura seem to be well adapted for the bryophyte habitat. Small size is an advantage for living among the stems or climbing across epiphytes on branches. Many have disruptive coloration of browns and greens. And some have protuberances that further disrupt the shiny surface, serving as additional camouflage. Some even change their color to blend with their substrate. Altered life cycles are adaptations to land in general, with such modifications as parental care of eggs, carrying eggs on their backs, having large but few eggs, and burying the eggs in mossy nests. Because of these anuran traits, bryophytes offer them **safe sites** against not only environmental conditions, but also against predation.

One means of escape for Moss Frogs and others is "flying." This is actually gliding, and some of these frogs have modified muscle placement that permits them to maneuver to a selected landing spot. Others simply hop or crawl.

Acknowledgments

We are thankful for all the people who don't know us but who graciously gave permission to use their images. Dick Andrus shared his story of emerging *Lithobates sylvaticus*. Chuan Ho, Thien Tam, and Le Thi Thuy Duong helped me get information on *Theloderma corticale*. Johannes Foufopoulos provided comments on a very early draft. Jim Harding provided us with the information needed to update the nomenclature. Jim was helpful in causing us to rethink our organization of the chapter, although we ended up using a different one from either his or our original. Hans Lambers provided references that we had been unable to obtain. And thank you to the many people who put their images in the public domain for use without needing permission. Google's search engine found

the images, email addresses, and literature, making possible wonderful stories that would not have been included otherwise. Without the kind cooperation of many, many people, this chapter could not have been written. The herpetologists have been incredible in encouraging us on the project and in providing images, especially for the tropical frogs. Wikipedia and Wikimedia helped us find biological information and nomenclature synonyms for the included species.

CHAPTER 14-2

ANURAN CONSERVATION ISSUES

Figure 1. *Atelopus certus* in its natural setting, streamside on a mossy rock. This species may soon only exist in captivity and is the object of a rescue operation. Photo by Brian Gratwicke, through Creative Commons.

Conservation Issues and Endangered Species

Many species of anurans, especially in the tropics, are disappearing because their ranges are small, restricted to mountain tops separated by uninhabitable valleys, preventing them from spreading to new locations (Figure 1). For some, extinction is imminent because their small range of habitat is being destroyed. Blaustein *et al.* (1994) suggest that amphibian species may not be able to recolonize areas where they have become extinct because of physiological constraints, low mobility, and site fidelity.

Knutson *et al.* (1999) examined landscape effects and wetland fragmentation on anuran abundance and species richness in Iowa and Wisconsin, USA. They found that there was a negative association with the presence of urban land, but a positive association with emergent wetlands and upland and wetland forests. For these larger species, a complex of habitats including wetlands is the best combination for success of the amphibian populations.

But amphibians are declining at an alarming rate worldwide. Factors of disease, parasites, deforestation, agriculture, heavy metals, herbicides, pesticides, increasing UV radiation, acid rain, fire, and other environmental changes all seem to have contributed to a rapid decline in anuran species.

Although the decline of amphibians is well known throughout the world, the causes are not so clear. It appears that the causes are multiple and that the tadpole stage, in particular, is very sensitive. This helps to explain why amphibians are endangered from pesticides, heavy metals, organic compounds, parasites (Figure 2), and bacteria. Tadpoles of many species are sensitive to low pH (Freda *et al.* 1991). Rising temperatures may play a role by increasing likelihood of bacterial, fungal (Halliday 1998), or parasitic infection (Blaustein & Dobson 2006). The rich diversity of arboreal amphibians in the tropics is particularly at risk, and we know almost nothing about where they place their eggs or how bryophytes may be essential in their life cycle survival. Meanwhile, their habitats are disappearing (Mazerolle 2003).

The anurans are negatively associated with urban development. This group of organisms often requires different habitats for breeding, hibernation, and summer feeding. When one of these habitats disappears or becomes inaccessible, the amphibians will disappear from the others as well. The genus *Lithobates* is a common peatland visitor that exemplifies common characteristics among disappearing anuran species: aquatic habit, montane distribution, and large body size (Lips *et al.* 2003).

Figure 2. *Bufo bufo* infected with parasitic fly larvae. Photo © Henk Wallays, with permission.

The amphibians are further limited by their latitudinal restrictions. While species richness decreases from low to high latitudes for all animal groups but birds and sawflies, the amphibians are nearly absent in the Arctic (Kouki 1999).

One contributing factor to the absence of amphibians at high latitudes, in addition to the short food season and cold temperatures, is the lack of canopy and higher levels of UV. As the ozone in the stratosphere diminishes, more UV-B radiation is able to penetrate the atmosphere and reach the Earth. Several researchers have hypothesized that it is increased levels of UV-B that have precipitated the massive losses of amphibians. This suggestion is in part due to the much greater decline in amphibians than that seen in birds or mammals (Bancroft *et al.* 2008). Bancroft *et al.* showed that UV-B radiation reduced amphibian survival by 1.9-fold compared to controls, with larvae (tadpoles) being more susceptible than embryos. Salamanders were even more susceptible than frogs. They concluded that the UV-B acted synergistically with other environmental stressors, such as those mentioned above. However, the results of multiple studies have been conflicting, with the same species acting differently at different life stages and even at the same life stage in the same population at the same time.

The complicating factor in explaining amphibian decline seems to be that there are multiple causes. For example, the Boreal Toad *Anaxyrus boreas boreas* (Figure 3) suffered total loss of 11 populations in the West Elk Mountains of Colorado between 1974 and 1982 (Carey 1993). In this case, it was the bacterium *Aeromonas hydrophila* that seemed to be the culprit. Carey concluded that stress caused a suppression of the immune system, increasing the sensitivity to infection. Such suppression would make the amphibians more susceptible to fungal, bacterial, viral, and parasite attacks.

Red leg: *Aeromonas hydrophila*

One of the most common infections of frogs in the lab, in my experience, is red leg, caused by a heterotrophic, Gram-negative, rod-shaped bacterium, *Aeromonas hydrophila*. This bacterium travels through the bloodstream to the first available organ, where it produces an Aerolysin Cytotoxic Enterotoxin (ACT) (Wikipedia 2011a). Its very toxic infections are common in fish and amphibians, and can also affect humans. It is most likely to

infect during times of environmental change, stress, temperature change, pollution, or in an otherwise unhealthy animal. One reason for the name of red leg is that the disease can cause internal hemorrhaging, a problem that can lead to death. For the disease to become manifest, both hemolysin and the endotoxin must be present (Rigney *et al.* 1978), resulting in bloating, lesions, hemorrhaging, and other serious problems in the frogs.

Figure 3. *Anaxyrus boreas* on a bed of mosses. Photo by William Flaxington, with permission.

Red leg may be a somewhat seasonal infection. Emerson and Norris (1905) observed more incidence of the disease in the warm weather of September and October, claiming that short periods in the cold chamber would delay death by the disease in infected frogs. But in 14 sites in Minnesota, USA, there were more infections in *Lithobates pipiens* (Leopard Frog; formerly *Rana pipiens*) in March-June than in August-November (Hird *et al.* 1981), suggesting that either these frogs were more stressed early in the season after a winter of little food, or that the disease could grow better under spring conditions, possibly in lower temperatures. In that study, red-leg infections could not account for the declining populations of *Lithobates pipiens* (Hird *et al.* 1981).

Frogs are actually rather well protected from diseases such as those caused by *Aeromonas* species. Glands in their skin produce secretions containing a multitude of peptides with antimicrobial prosperities (Simmaco *et al.* 1998). In *Pelophylax lessonae* (Edible Frog; formerly *Rana esculenta*), 20-30 different peptides are secreted. Although these bacteria can grow freely in the blood of the frog, those in contact with the skin toxins are killed within 10 minutes.

Peatland Conservation

One might argue that the tropics and the peatlands are the two most vulnerable ecosystems under current circumstances. Peatlands are disappearing through mining and draining, and if they are replaced, it is frequently by a different vegetation type and hydrologic regime. But even when peatland pools are retained, lack of suitable habitat for summer retreats may cause amphibian losses (Marsh & Trenham 2001). Baldwin *et al.* (2006) and Bellis (1965) likewise concluded that summer refugia in peatlands were important for the Wood Frog (*Lithobates sylvaticus*; Figure 4), providing shade and moisture-laden *Sphagnum* (Figure 5).

Figure 4. *Lithobates sylvaticus*, a frog with short lifespan and high fecundity. Photo by Bill Peterman, with permission.

Figure 5. Mer Bleue Bog with *Sphagnum* near Ottawa, Canada. Photo through Creative Commons.

Harper *et al.* (2008) concluded that current federal wetland law is inadequate to protect the amphibians, partly because it lacks protection for surrounding areas. They contend that state wetland regulations that protect no more than 30 m from the breeding pool cannot support the terrestrial habitat needs.

Life span can play a role in amphibian sensitivity, with a short life span and high fecundity, like that of the Wood Frog (*Lithobates sylvaticus*; Figure 4), being most sensitive to habitat loss and isolation. On the other hand, long life and low fecundity, like that of the Spotted Salamander (*Ambystoma maculata*), can lead to greater sensitivity to habitat degradation and lower adult survival. Furthermore, connections between wetlands are needed for recovery after population crashes (Baldwin *et al.* 2006; Harper *et al.* 2008).

Mining

Mining of peat changes the gross morphology of the peatland, removes the more open upper layers where it is easy for frogs and toads to nestle among the stems, and alters the hydrology. Such changes are likely to remove the aspects of peatlands that make these favorable habitats for amphibians.

Mazerolle (2003) demonstrated the negative impact of peat mining on amphibian abundance and diversity. Species richness and numbers of individuals both were lower in bog remnants (after mining) than in unmined bogs. The Wood Frog (*Lithobates sylvaticus*; Figure 4) was most abundant in areas far from the ponds when the area had not been mined. Only *Anaxyrus americanus* (formerly *Bufo americanus*; Figure 6) appeared to benefit from the increase in habitat complexity resulting from mined edges in fragmented peatlands. Knutson *et al.* (2000) suggest that more wetland patches are likely to increase the probability that at least one of those sites will be suitable for amphibian habitation. Mazerolle (2003) contended that amphibians would benefit from a management plan that maintained a complex mosaic of bog ponds, shrubs, and forest patches. Since peatlands are such important habitats for many amphibians, it is essential that we understand the role of their bryophytes in our attempts to restore their fauna along with wetland restoration (Mazerolle *et al.* 2006).

Figure 6. *Anaxyrus americanus* amid mosses and rocks. Photo by John D. Willson, with permission.

We can surmise from the foregoing information that some anurans would suffer from the loss of peatland habitat due to water loss during travels and daytime activity and to loss of egg-laying sites. Bellis (1962) stressed the importance of moisture provided by a spruce and tamarack bog in northern Minnesota, especially for smaller frogs.

But it appears there may be other consequences that result from mined peatlands. Mazerolle (2001) examined effects of fragmented bogs in southeastern New Brunswick, Canada. He found that the Wood Frogs (*Lithobates sylvaticus*; Figure 4) that occurred in fragments were actually larger than those in pristine bogs. Leopard Frogs had a similar size relationship, but only in the 1998 year of study. Mazerolle attributed this relationship to be the result of larger frogs having a better chance of surviving than small frogs in the disturbed habitat of mined peatlands. Larger frogs would have a smaller surface area to volume ratio, thus decreasing their sensitivity to desiccation.

Old-growth Forests

Old-growth forests (Figure 7) with mature trees, continuous canopy, logs, snags, and often well-developed moss beds on the ground, logs, and branches, are likely to represent the third major habitat type where amphibians are rapidly disappearing. Logging and clearing for harvest or

agriculture greatly alters the old-growth habitat, eliminating vast acreage and replacing it with a drier cover with fewer niches.

Figure 7. Old-growth habitat of *Ascaphus truei*. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

Dupuis *et al.* (1995) demonstrated the importance of stand age in providing suitable habitat for amphibians. They found that logging could reduce terrestrial amphibian populations by up to 70% in old-growth forests in Canadian forests. Logging reduced the availability of moist habitats such as snags and logs, reduced shade, and often lost streamside buffer zones. As in peatland studies, they found that having connectivity between patches of suitable habitat was important. Bryophytes can play a role in these connections and in creating microhabitats that are moist and provide protection against UV-B radiation.

One of these disappearing species (the Coastal Tailed Frog, *Ascaphus truei*; **Leiopelmatidae**; Figure 9) has been discussed earlier because it seems to find a rich food source among the streamside mosses. This is an unusual frog that can unlock keys to evolutionary processes. Although it is "tailed," it does not break the anuran rule of no tails because its "tail" lacks bone and is thus not a true tail. This is the only genus of frogs with internal fertilization (California Herps.com 2011).

Figure 8. *Ascaphus truei* tadpole in a stream with leafy liverworts. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

Welsh (1990) found that the Coastal Tailed Frog occurred primarily in old-growth forests – those primeval coniferous forests that are disappearing rapidly from the Pacific Northwest in North America. Younger forests do not offer the needed microclimate required. It is only in the older forests that the preferred cover of the Coastal Tailed Frog (moss, rocks, and organic matter) exists. Their sucker-like mouths permit them to hang onto the rocks,

where they presumably eat the attached algae. The importance of the bryophytes has not been studied experimentally, but Noble and Putnam (1931) suggested that these mossy habitats might provide an enriched food source for them. The tadpoles (Figure 8-Figure 10) occur in fast melt-water streams.

Tropics

There are possibly the greatest numbers of endangered amphibians in the tropics. That is where the smallest of vertebrate species live among bryophytes, lichens, and other epiphytes in the canopy, on tree trunks, and on the ground. Many of the anuran species remain to be described. But this habitat is in great danger of destruction to make way for farming and managed forestry, depleting the sites with bryophyte-covered habitats and replacing them with non-forest or with young trees that do not have established bryophyte cover.

A rapid decline in tropical anurans was first noticed in the 1980's (Bustamante *et al.* 2005; La Marca *et al.* 2005). Bustamante *et al.* noted that 24 anuran species in the Ecuadorian Andes were in decline or had become extinct since the late 1980's. But the decline was not prevalent in

all species. Between 1988 and early 2000's, 56 of 73 species had declines, but 27 had increased in relative abundance. In six of seven localities, fewer species could be located, despite greater capture effort. It is noteworthy that they found greater differences for species with aquatic larvae (reduction from 34 to 17 species) than for those terrestrial species having direct development. For example, the genus *Eleutherodactylus* presented 28 species in both the earlier and recent surveys. Furthermore, six species had expanded their distributions to higher altitudes.

Fong and Hero (2006) explored eastern Cuba in an effort to document the extant anuran species so that losses with habitat destruction could be measured. They cited *Eleutherodactylus cuneatus* (Figure 11) as a species that is at high risk of disappearance if habitat loss were to occur in Cuba (Williams & Hero 1998; Lips *et al.* 2003; Hero *et al.* 2005; Fong & Hero 2006). In the tropics, at least in Latin America, species living close to streams seem to be the most vulnerable (Young *et al.* 2001).

Figure 11. *Eleutherodactylus cuneatus*, a species that is at risk due to limited distribution. Photo by Ansel Fong, with permission.

Despite forest habitat destruction, Lips (1998) had also surmised that it was species with aquatic eggs and larvae that were most vulnerable to decline. Those with direct development such as *Eleutherodactylus* and some salamanders (*Bolitoglossa minutula*), both bryophyte inhabitants, typically arboreal, do not seem to be in decline. Lips further concluded that based on evidence in Australia, Brazil, and Costa Rica, it was an environmental contaminant such as chemicals or biotic pathogens, or a combination of factors that might include climate change. Laurance *et al.* (1996) concluded, based on worldwide spread patterns and presence of the disease in pristine environments that lacked environmental contamination, that the problem was caused by a disease.

Atelopus (Bufonidae)

The genus *Atelopus* (Bufonidae), the Neotropical Harlequin Frog – but actually a toad – seems to be particularly vulnerable. Of the known 113 species, 42 species have been reduced by at least 50% since earlier surveys, and only ten have stable populations (La Marca *et al.* 2005). Many of the species could not be relocated, and 30 have been missing from all previously known localities for at least 8 years. In this case, it seems to be those at higher elevations (above 1000 m) that are most vulnerable, with 75% disappearance, compared to 58% disappearance among lowland *Atelopus* species. Habitat loss did not seem to be the causal factor. Climate change may have

played a role, but environmental contamination, pet trade, and introduction of competitor or predator species did not seem to have any role. Rather, 22 species had disappeared from protected areas! There is some good news, however. *Atelopus varius* (Figure 12) has recently been located in Costa Rica in a mossy stream (Solano Cascante *et al.* 2014).

Figure 12. *Atelopus varius*, known from a mossy stream in Costa Rica. Photo by Brian Gratwicke, through Creative Commons.

Atelopus certus (Darien Stubfoot Toad; Toad Mountain Harlequin Frog; Figure 13-Figure 16) is an endemic to Panama, where it occurs at 500-1150 m asl. This golden-colored frog with spots like a giraffe is disappearing from Panama. It is one of the frogs targeted for a rescue operation to breed the frogs in captivity (Amphibian Rescue and Conservation Project 2011). On an expedition to capture these frogs for rescue, Mark Cheater (2011) reported finding the first few of these frogs on mosses, including a pair in amplexus. The frogs were placed in plastic cups lined with damp moss for transport.

An alarming factor was beginning to emerge. *Batrachochytrium dendrobatidis*, a fungal disease organism that causes **chytridiomycosis** in amphibians and other animals, had arrived. And this fungus was present in populations of nine of the *Atelopus* species that have declined.

Chytridiomycosis

Although loss of cover and moisture will surely have a great impact on the anuran fauna, it appears that another serious threat is the rapid spread of the fungal disease **chytridiomycosis**. Anurans seem to be defenseless against fungi that are causing whole populations to disappear (Thompson 2010).

Catenazzi *et al.* (2011) found that the introduced fungal pathogen *Batrachochytrium dendrobatidis* caused the **chytridiomycosis** that accounted for a large portion of amphibian decline in the Andes of Peru. In its short known history, it has been responsible for both extinctions

and **extirpations** (local extinctions) in Central America. In Peru, the overall number of species declined by 47%. The fungus seems to have a greater effect on aquatic and arboreal species (declined by 55% between 1999 and 2008) than on the terrestrial species. Abundance of frogs also declined during that period, following its discovery by Longcore *et al.* in 1999. The declines correspond with increases in the fungus (Catenazzi *et al.* 2011).

The fungus adheres to the skin of the amphibians, causing it to thicken, thus interfering with respiration (Denton 2008). That thickened skin inhibits the animal's ability to take in water and interferes with the salt-water balance in the body of the frog (Voyles *et al.* 2007). Furthermore, the fungus damages the nervous system (Denton 2008). This causes lethargy and ultimately death.

This fungal disease seems to be associated with a large number of amphibian declines worldwide (Berger *et al.* 1998; Piotrowski *et al.* 2004; Bovero *et al.* 2008; Brodman & Briggler 2008; Byrne *et al.* 2008; Reeves 2008; Gaertner *et al.* 2009), but the greater incidence of the disease could have multiple causes that weaken the amphibian resistance to the disease. Furthermore, it seems clear that chytridiomycosis is not the only cause of the decline (Daszak *et al.* 2003; Di Rosa *et al.* 2007).

In a summit-type meeting of herpetologists regarding the threat of amphibian extinctions in Latin America, 88 Latin American herpetologists and conservationists concluded that "at least 13 countries have experienced declines, and in 40 cases species are now thought to be extinct or extirpated in a country where they once occurred. Declines or extinctions have affected 30 genera and nine families of amphibians. Most declines have occurred in remote highlands, above 500 m in elevation in Central America and above 1000 m in the Andes. ...Climate Change appears to be important at one site and chytrid fungal disease has been identified at sites in three countries." (Young *et al.* 2001). Recognizing the importance of *in situ* studies, they concluded that it would be important to rear species in captivity to avoid imminent extinction.

One species targetted for *in situ* studies is *Atelopus limosus* (Limosa Harlequin Frog; Figure 17-Figure 22), an endemic to Panama, where it lives on stream banks in subtropical or tropical moist lowland forests and rivers (Wikipedia 2011b; Figure 13). Once a thriving species, it is now endangered by chytridiomycosis (Figure 21-Figure 22) as well as habitat destruction (IUCN 2011).

Figure 17. *Atelopus limosus* in its natural habitat. Photo by Brian Gratwicke, through Creative Commons.

Figure 18. A once healthy, reproductive species, *Atelopus limosus* is now endangered due to chytridiomycosis. Here it blends with mosses in its terrestrial habitat. Photo by Brian Gratwicke, through Creative Commons.

Figure 19. *Atelopus limosus* male and female in amplexus. Note the size differences between the male (smaller) and female in this lowland color form. Photo by Brian Gratwicke, through Creative Commons.

The Limosa Harlequin Frog has two color forms, a brown form with yellow nose and finger tips in the lowlands, and a green form with black patches on its back in the uplands (Wikipedia 2011b). The upland form is in the greatest danger, and the Amphibian Rescue and Conservation Project (2011) targeted this species and managed to maintain one upland female in captivity (Estrada 2011). They successfully bred the Limosa Harlequin Frog in captivity – no small feat.

This species, particularly the green and black upland variety, has been described several times as being camouflaged among the mosses and dark rocks (Amphibian Rescue and Conservation Project 2011; Price 2011). This ability to blend makes them difficult to locate, hence making the rescue operation difficult. Typical food for the genus includes beetles, ants, flies, and mites (Durant & Dole 1974), all of which can be found among and near bryophytes.

But they must leave these bryological hiding places during the dry season and return to fast-flowing rainforest streams (Amphibian Rescue and Conservation Project. 2011). It is here that the females lay their eggs. The rapidly moving water helps to protect the eggs from

predation. Once the tadpoles emerge, they cling to the rocks with their suction cup mouths.

A more fundamental question is why this disease has suddenly become so widespread. One might look at acidification as a contributor, with frogs being more vulnerable and fungi typically being favored by a lower pH.

Figure 20. *Atelopus limosus* dead from chytridiomycosis caused by *Batrachochytrium dendrobatidis*. Photo by Brian Gratwicke, through Creative Commons.

Figure 22. Dead *Atelopus limosus*, a typical result of chytridiomycosis. Photo by Brian Gratwicke, through Creative Commons.

The danger from chytridiomycosis has gotten so severe that several scientists travelled to Panama to rescue as many frogs as they could (Goodman 2006; Figure 24-Figure 25). According to models of the spread of the fungus causing chytridiomycosis, attack on these

populations was imminent. So they packed hundreds of frogs into deli containers with wet mosses, placed them in carry-on suitcases, and began their adventure through airport customs back to Atlanta where they would attempt to breed them in captivity.

Diagnosis

When organisms are under stress, whether it be temperature, pollution, or disease, one measure of the severity of that stress is an instability in development (St. Amour *et al.* 2010). The assumption is that it is costly to control symmetry (I am reminded of so many things that develop in a spiral, including at least some protonemata from spores imbedded in agar, and rhizoids before they touch a substrate). Therefore, the greater the evidence of asymmetry, the greater the indication of stress. In their study of asymmetry, St. Amour *et al.* found that *Lithobates clamitans* (Green Frog; Figure 4) had significantly higher levels of fluctuating asymmetry in individuals infected with chytridiomycosis.

A Cure?

One of the first steps in combating chytridiomycosis is to determine what conditions the fungus likes. Puschendorf *et al.* (2011) studied several species of the tree frog *Litoria* (Hylidae). They found that the fungus thrives where the environment is cool and moist, causing the highest outbreaks to occur in such areas. To support this conclusion, they demonstrated that in species with greater elevational ranges, populations disappeared at the higher elevations while surviving in the lowlands. To their surprise, they found a population of *Litoria lorica* and one of *Litoria nannotis* (Figure 26-Figure 27) in a stream at high elevation in a dry sclerophyll forest. In that and six additional surveys, 82.9% of the frogs had *Batrachochytrium dendrobatidis* (Figure 28). Among tadpoles of both species, 100% were infected. BUT none of the individuals had any signs of chytridiomycosis. This site had little canopy cover, low annual precipitation, and a more defined dry season than a nearby rainforest site. In that nearby site, *L. nannotis* was negatively affected by the disease chytridiomycosis. They hypothesized that the open habitat permitted the rocks where the frogs perched to warm up, having negative effects on growth and reproduction of the fungus.

Figure 27. *Litoria nannotis* tadpole. Photo by Jean-Marc Hero, through Wikimedia Commons.

Litoria nannotis (Figure 26-Figure 27) lives in fast streams, waterfalls, and cascades in the rainforest or wet sclerophyll forest of Australia (Liem 1974; McDonald 1992), where it is endemic (Williams & Hero 1998, 2001; Hodgkison & Hero 2001). The tadpoles are specially adapted to living in these torrents, including a streamlined body shape, large sucking mouthparts, and a muscular tail (Liem 1974; Richards 1992). At night, the frogs may venture up to 15 m from the stream in search of food, returning to the stream before dawn (Hodgkison & Hero 2001).

Figure 28. *Batrachochytrium dendrobatidis*, a fungus causing chytridiomycosis. Photo by A. J. Cann, through Creative Commons.

Rowley (2006), and later Searle *et al.* (2011) found that some anuran species may be severely affected by chytridiomycosis while others in the same area are unaffected. Rowley suggested that behavior of the frogs

played a role. Such factors as physical contact between frogs, contact with infected water, and contact with terrestrial substrates that serve as reservoirs all contribute to the likelihood of contracting an infection. In other words, the microenvironment plays a role. As in other studies, Rowley found that at elevations above 400 m asl the populations were more likely to decline due to chytridiomycosis, even while populations of the same species in the lowlands contracted no infection. Among three species of *Litoria*, *L. nannotis* became locally extinct at all known high elevation sites. *Litoria genimaculata* (Figure 29) declined at the high elevation sites, then recovered. The third species, *L. lesueurii* (Stoney Creek Frog; Figure 30), had no known infection at any elevation. Ouellet *et al.* (2005) found similar confounding indications in Quebec, Canada. They examined specimens spanning the years 1895 to 2001 from 25 countries, totalling 3371 specimens. In recent studies, they found no evidence of mortality from chytridiomycosis in amphibians from Québec, despite the presence of the fungus in 17.8% of the amphibians from 1990-2001. Furthermore, epidermal infections were apparently absent in 440 amphibians from 23 other countries. It appears that despite the internal infection in seemingly healthy amphibians from eastern North America, the lethal expression of chytridiomycosis has complex causes that may require a predisposition to contract the disease.

Figure 29. *Litoria genimaculata* showing cryptic coloration and pronounced tubercles that permit it to blend with mosses and lichens. Photo by Jean-Marc Hero, with permission.

Figure 30. *Litoria lesueurii* in its stream home, exhibiting much smaller tubercles than its terrestrial congenics. Photo through Wikimedia Commons.

Rowley (2006) demonstrated that the frequency of contact with other frogs and with water was greatest for *L. nannotis* (Figure 26), intermediate for *L. genimaculata* (Figure 29), and least for *L. lesueurii* (Figure 30), corresponding with the degree of infection mentioned above. Furthermore, *L. lesueurii* travelled farthest from the stream, whereas *L. nannotis* remained in the stream all day, moving only a short distance from the streams. These "travelling" patterns further separated the environment created for the fungus by creating temperature differences. For the most susceptible species, *L. nannotis* (Figure 26), the frogs rarely moved outside the temperature range that was optimum for the fungus. On the other hand, the uninfected species, *L. lesueurii* (Figure 30), were frequently at sites with temperatures above the temperature optimum and even the thermal tolerance for the fungus. *Litoria nannotis* even had the most suitable hydric conditions for development of the fungus. Hence, the "predisposition" seems to be the behavior of these three species. From our bryological perspective, the substrate used by the frogs can also play a role. Dewel *et al.* (1985) found that zoospores of chytrids are common on moss-covered rocks, and Letcher and Powell (2002) suggested that distance from moss could affect the safety of a given substrate where the frogs might sit.

Searle *et al.* (2011) looked at the differences between species somewhat differently, showing that even with the same degree of *Batrachochytrium dendrobatidis*, the mortality rates differed among species. This would eliminate dispersal and contact as causal factors. Temperature seems to be emerging as an important distinction, but the work of Searle *et al.* seems to suggest that there is also a difference in immunity.

The spread of this disease around the world has been rapid. One contributing factor, perhaps the primary one, has been the human factor. Among these has been international trade in aquarium fish (Laurance *et al.* 1996). But even plant trade, with frogs as hitchhikers, contributes to the problem. And if the zoospores survive on mosses, then the moss trade can also spread the disease, either by spreading the zoospores, or by transport of infected frogs.

One interesting aspect of survival of the *Batrachochytrium dendrobatidis* is that rising temperatures, often viewed as a cause for disease increase, may actually improve the resistance of tadpoles to the disease. In experiments on tadpoles of *Rana muscosa* (Mountain Yellow-legged Frog; Figure 31-Figure 32), at 22°C, 50% died within 35 days, while 95% of those maintained at 17°C died (Andre *et al.* 2008). Nevertheless, Piotrowski *et al.* (2004) showed that growth of the chytrid fungus from the zoospores (Figure 33) was maximal in the range of 17-25°C.

There is perhaps some hope for at least some of the amphibians in this chytridiomycosis epidemic. There is strong evidence that some species of amphibians survive because of a co-habiting bacterium, dubbed the **anti-Bd skin bacterium** (Lam *et al.* 2009). The resistance seems to result from antimicrobial skin peptides and these anti-Bd skin bacteria. I have to wonder if any of the bryophyte antibiotic properties might help their inhabitants avoid fungal and other infectious invasions.

Figure 31. *Rana muscosa* (Mountain Yellow-legged Frog), a species whose tadpoles are susceptible to death from chytridiomycosis at temperatures of 17-25°C. Photo by USGS, through public domain.

Figure 32. *Rana muscosa* (Mountain Yellow-legged Frog) that has died from chytridiomycosis. Photo by Vance Vredenburg, NSF.gov website, through public domain.

Figure 33. Zoospores of the fungus *Batrachochytrium dendrobatidis* that causes chytridiomycosis in amphibians and other animals, in this case living on an arthropod. Photo by A. J. Cann, through public domain.

In summary, chytridiomycosis seems to be a major player in the decline of amphibians, but it is not the only cause. Amphibians are sensitive to stress, and stress can

exacerbate chytridiomycosis, but this same stress may be the primary cause. Furthermore, as will become obvious in the rest of this chapter, loss of habitat is a severe problem in parts of the world, particularly the Neotropics. In the Neotropics, it is likely that many species will disappear before they will even be described, and many of these are bryophyte inhabitants.

Moss Use in Captivity

Use of frogs in the pet industry is one of the causes for amphibian decline, but for most species this use may be minor compared to spread of disease and habitat loss. Nevertheless, it appears that the pet industry has helped in the spread of the disease.

Certain frogs have been targetted for rescue from tropical areas where their demise seems imminent (Amphibian Rescue and Conservation Project 2011). In the rescue efforts, bryophytes are often placed in plastic containers to provide a moist environment with cover that helps to keep the amphibians alive, especially during transport (Amphibian Rescue and Conservation Project 2011). In searching for various species and their relationships to mosses, I found many descriptions for preparing terraria for pets, including mosses as part of the habitat. Even biological supply companies often package frogs in mosses, especially *Sphagnum* (Figure 34), for shipping.

Figure 34. *Sphagnum*, suitable packaging for amphibians. Photo by Hermann Schachner, through Wikimedia Commons.

Many species of anurans have suffered the fate of becoming pets. To this end, they are frequently sold along with a species of moss, often *Sphagnum* (Figure 34), to be placed with them in a terrarium or other container. The mosses can help to maintain moisture. *Sphagnum*, in particular, can provide antibiotics that reduce chances of infections like red leg, a bacterial disease caused by any of several genera (*Aeromonas*, *Citrobacter*, *Escherichia coli*, *Proteus*, *Pseudomonas*, *Salmonella*) (Hadfield & Whitaker 2005; PetEducation.com 2011). In the lab, we found presence of *Sphagnum* (Figure 34) in the aquarium/terrarium to prolong the life of the frogs and reduce incidence of red leg. It also reduced the effects of excreted ammonia and gave the frogs a place to get out of the water.

Making a Home – *Scaphiopus holbrookii* (Eastern Spadefoot, Scaphiopidae)

Like the fire-bellied toads, the Eastern Spadefoot (*Scaphiopus holbrookii*), often called the spadefoot toad, is not a member of the toad family Bufonidae. Its English name indicates its habit of using its hind feet to dig a hole in the sandy ground typical of its home, where it escapes the heat and drying atmosphere. My first experience with this unique animal was at a Girl Scout camp on the Eastern Shore of Maryland, USA, where we found it on the outdoor shower floor after dark. We put it in a jar for the night and released it the next day. To our amazement, it immediately dug a hole and disappeared! And its disappearance was rapid. Only a bit of disturbed soil indicated its former presence (Figure 35-Figure 37).

Figure 35. The Eastern Spadefoot Toad, *Scaphiopus holbrookii*, begins to dig a hole in the ground in Maryland, USA. Photo by Janice Glime.

Figure 36. The Eastern Spadefoot Toad, *Scaphiopus holbrookii*, digging a hole in the ground. Photo by Janice Glime.

Figure 37. The Eastern Spadefoot Toad, *Scaphiopus holbrookii*, as it ultimately leaves only a bit of raised, disturbed soil. Photo by Janice Glime.

I don't know of any evidence that the Eastern Spadefoot uses bryophytes in its natural home, but it can make good use of them in captivity. Wright (2002) tells about a pet Eastern Spadefoot (*Scaphiopus holbrookii*; Figure 38) that made the most of the mosses provided for it as a winter home. The first batch of mosses seemed too wet, so Wright provided an additional set of dry ones. The spadefoot immediately began work and arranged the moss into an enclosure. At the rear was a thick pile of mosses, but the front had only a thin film through which the spadefoot could still see. Such instinctive behavior suggests that it may use mosses or similar vegetation structures in nature.

Figure 38. Eastern Spadefoot, *Scaphiopus holbrookii*, on a bed of mosses. Photo © John White, with permission.

In the Aquarium - *Trachycephalus resinifictrix* (Amazon Milk Frog, Hylidae)

In aquaria, mosses such as Java moss serve as nesting substrata and hiding places for tadpoles. In Figure 39, the tadpoles of *Trachycephalus resinifictrix* (Amazon Milk Frog; Hylidae; Figure 40-Figure 42) are in the shelter of aquarium mosses. The milk frog derives its name from its habit of exuding a toxic, milky-white substance when threatened (Amphibian Rescue and Conservation Project 2010). Not only does this substance deter predators, but it helps to keep the frog hydrated, although it would seem to be stealing from itself to do so. This is one of the largest of the South American treefrogs, with males up to 10 cm and females 11.4 cm vent to snout. Their large size and concomitant large vocal sacs permit them to make very loud calls.

Summary

Many of these anurans, especially in the tropics, are on the IUCN protected list, largely due to habitat loss and pollution. Stresses due to habitat changes most likely contribute to the increasing occurrences of the fungal disease **chytridiomycosis**. Most of the tropical anurans lack legal protection because they are so poorly

known, but they may be rapidly disappearing due to habitat loss and pollution. Peatland species may be especially vulnerable as the area of peatlands on the planet continues to diminish and become fragmented. Species in tropical forests may disappear due to habitat destruction before we even know they exist. Our lack of knowledge about the role of bryophytes in the various life stages of amphibians could hinder our ability to preserve these fascinating species.

Since most of these frogs have cryptic coloration that makes them almost invisible among lichens and bryophytes on trees, they are likely to be further endangered by air pollution that causes loss of this cryptogamic flora. Furthermore, in areas of deforestation, it will be many years before new forests develop the kind of epiphytic flora in which they are so well camouflaged. Under these circumstances they are likely to experience the same sorts of selection pressures for loss of some color variants as that seen in the classic example of the peppered moths (*Biston betularia*) due to loss of lichens.

Stresses make the amphibians more susceptible to disease. Among these is red leg, a common bacterial disease caused by *Aeromonas hydrophila*. Its ability to cause hemorrhaging causes the legs to become red.

Chytridiomycosis, a fungal disease caused by *Batrachochytrium dendrobatidis*, has been causing severe declines. In the tropics, it is the higher elevation populations that are most susceptible, offering the optimal temperature conditions. Hence, in these bryologically dense habitats, the anuran inhabitants may disappear. In some habitats, bryophytes may provide a safe resting place for chytrid zoospores that can eventually infect amphibians that journey across them. For frogs that are more mobile, there is more opportunity for contact with infected frogs or with deposits of zoospores on bryophytes and other substrates.

Mosses are used to provide suitable conditions for anurans in captivity. In experiments with spadefoot toads (*Scaphiopus holbrookii*), the toads rearranged the mosses to create their "comfortable" moisture level. Amphibian pet trade accounts for some of the losses of the colorful anurans. Mosses are often used in both transport containers and terraria for keeping these pets.

cooperation of many, many people, this chapter could not have been written. The herpetologists have been incredible in encouraging us on the project and in providing images, especially for the tropical frogs. Wikipedia and Wikimedia helped us find biological information and nomenclature synonyms for the included species.

Acknowledgments

Johannes Foufopoulos provided comments on a very early draft. J. D. Willson gave me full access to his wonderful website with numerous species from around the world. We are thankful for all the people who don't know us but who graciously gave permission to use their images. Jim Harding provided us with the information needed to update the nomenclature. Jim was helpful in causing us to rethink the organization of the chapter, although we ended up using a different one from either his or our original. And thank you to the many people who put their images in the public domain for use without needing permission. Google's search engine found the images, email addresses, and literature, making possible wonderful stories that would not have been included otherwise. Without the kind

CHAPTER 14-3

GROUND-DWELLING ANURANS

Figure 1. *Nannophryne variegata* (previously *Bufo variegatus*) peering from a bed of the dung moss *Tetraplodon mnioides* in southern Chile. This toad is most likely only a casual visitor to the *Tetraplodon*, although the attraction of these moss capsules for flies might make it an attractive feeding location for the toad. Photo by Filipe Osorio, with permission.

Peatland Habitats

Peatland habitats have been considered inhospitable for many species of frogs due to their acidity. Some frogs are tolerant enough to breed in the *Sphagnum* pools, but for others, mortality is too high. However, the *Sphagnum* mat and associated bryophyte serve other roles in the life cycles of these amphibians (Figure 1).

In Australia, the **Sphagnum Frog**, *Philoria sphagnicolus* (Limnodynastidae; Figure 2), has good reason for its name. This frog produces large eggs that are embedded in a foamy jelly (Debavay 1993). The male excavates a shallow burrow in clumps of *Sphagnum* or under stones on the forest floor. The females deposit the eggs in these burrows. The tadpoles complete development into adults within the nest. It is in small numbers

worldwide and is on the IUCN red list of endangered species.

Figure 2. *Philoria sphagnicolus*, the **Sphagnum Frog**. Photo by Evan, through Wikimedia Commons.

Mazerolle (2005) determined that male calling indicated that upland ponds were preferred by frogs over bog ponds, with calls emanating from 75% of the upland ponds, but only from 25% of the bog ponds, supporting the notion that the bog ponds may be too acid. None of the minnow traps in bog ponds caught tadpoles, whereas 58% of the upland ponds had at least one trapped tadpole. Several other studies likewise found few successful attempts of amphibians to breed in peatlands (Saber & Dunson 1978; Dale *et al.* 1985; Karns 1992b).

Furthermore, Mazerolle (2005) found no evidence that frogs moved from the forest to the bog in the summer, suggesting that the bog was not a significant refuge. However, there was back and forth movement between the bog and the upland, suggesting that the bog may provide a site for rehydration at times. Karns (1992a) and Mazerolle (2001), observing a number of amphibians, found that amphibians increased in bogs following the breeding season, so perhaps at least some frogs and other amphibians use them as summer sites.

But, it appears that **Green Frogs** (*Lithobates clamitans*; Figure 3) will use *Sphagnum* for rehydration (Mazerolle 2005). In an experiment where frogs were given the choice of *Sphagnum*, upland sifted sandy loam, and well water with a pH of ~6.5 (upland pond water), the frogs showed no discrimination between the *Sphagnum* and the upland media as a source for rehydration.

Figure 3. *Lithobates clamitans* sitting among *Sphagnum*. Photo by Alexander McKelvy, with permission.

Nevertheless, it appears that *Sphagnum* (Figure 4) peatlands are not as inhospitable to amphibians as formerly thought. In the boreal peatlands of North America, one might find the **Northern Leopard Frog** (*L. pipiens*; Figure 4), **Wood Frog** (*Lithobates sylvaticus*; Figure 5), **Green Frog** (*L. clamitans*; Figure 3), **Mink Frog** (*L. septentrionalis*; Figure 6), **Spring Peeper** (*Pseudacris crucifer*; Figure 7), **Western Chorus Frog** (*P. triseriata*; Figure 8), and **Gray Treefrog** (*Hyla versicolor*; Figure 9-Figure 10) (Desrochers & van Duinen 2006).

In Maine, the **American Bullfrog** (*Lithobates catesbeianus*; Figure 11) and **Pickerel Frog** (*Lithobates palustris*; Figure 12) are often found, as well as **Wood Frog** (*L. sylvaticus*; Figure 5), **Green Frog** (*L. clamitans*; Figure 3), **Northern Leopard Frog** (*L. pipiens*; Figure 4), **Spring Peeper** (*Pseudacris crucifer*; Figure 7), and **Gray Treefrog** (*Hyla versicolor*; Figure 9-Figure 10)

(Desrochers & van Duinen 2006). Stockwell and Hunter (1989) also examined peatland amphibians in Maine, USA, and found twelve amphibian species. Of these, 94% of the captures were anurans. The most abundant of these was *Lithobates sylvaticus* (**Wood Frog**; Figure 5), comprising 59% of the captures. *Lithobates clamitans* (**Green Frog**; Figure 3) was the second most abundant, with 30% of the captures. Despite the presence of both sexes among adults in the Maine peatlands, Stockwell and Hunter concluded that none of the frogs except *Lithobates sylvaticus* (Figure 5) laid eggs in the peatlands. In Minnesota, the **American Toad** (*Anaxyrus americanus*; Figure 14) is added to the previous lists as one of the dominant species (Karns 1992a; Figure 13).

Figure 11. **American Bullfrog**, *Lithobates catesbeianus* (Ranidae). Photo by John D. Willson, with permission.

Figure 12. The **Pickerel Frog**, *Lithobates palustris* (Ranidae), on a bed of terrestrial mosses. Photo by Janice Glime.

Figure 13. Comparison of percentage of **Wood Frogs** (*Lithobates sylvaticus*) with **American Toads** (*Anaxyrus americanus*) and other reptile and amphibian species trapped in various types of Minnesota peatlands. Redrawn from Karns 1992a.

The Tulula Wetlands, North Carolina, USA, have similar species to the boreal peatlands: **American Toad** (*Anaxyrus americanus*; Bufonidae; Figure 14), **Cope's Gray Treefrog** (*Hyla chrysoscelis*; Figure 15), **Green Frog** (*Lithobates clamitans*; Figure 3), **American Bullfrog** (*Lithobates catesbeianus*; Figure 11), **Wood Frog** (*Lithobates sylvaticus*; Figure 5), and **Spring Peeper** (*Pseudacris crucifer*; Figure 7) (Amphibians: Tulula Wetlands 2009). Knutson *et al.* (2000) suggest that the presence of **Pickereel Frog** (*Lithobates palustris*; Figure 12) is the best indicator of habitat quality in cold wetlands. Bog ponds can be especially enticing for amphibians because they harbor numerous insects and other invertebrates that serve as food (Desrochers & van Duinen 2006). Nevertheless, not all bogs seem to hold this attraction; in Estonia, frogs and toads are rare in bogs (H. Strijbosch in Desrochers & van Duinen 2006).

Effects of *Sphagnum* Acidity

Because of its nearly continuous moisture, *Sphagnum* would seem to be an ideal habitat for frogs. But there is a caveat. *Sphagnum* acidifies its environment. And adult frogs typically avoid acidic conditions (Karns 1992a; Vatnick *et al.* 1999). Acidity can interfere with their development (Pough 1985; Leuven *et al.* 1986). Hence, it appears that low pH bog ponds might be of little or no importance in successful breeding and reproduction, but can be detrimental or lethal during tadpole development for most anurans (Gosner & Black 1957).

Rorabaugh (2008) found that the use of New Brunswick peatlands by the juvenile and adult **Northern Leopard Frogs** (*Lithobates pipiens*; Figure 4) peaked in August, a time when juveniles disperse from the breeding ponds (Mazerolle 2001). But pH is a problem for them. Tadpoles were unable to survive at pH less than 4, and even at less than pH 5.6 for more than 24 hours, mortality was high (Rorabaugh 2008).

As already suggested, *Sphagnum* can present problems for frogs because of the low pH conditions it creates. The **Wood Frog**, *Lithobates sylvaticus* (Figure 5), has tolerance to the lowest pH values measured in the New Jersey Pine Barrens, USA (Johnson 1985; Freda & Dunson 1986). In nine Maine bogs, Stockwell and Hunter (1985) found the **Wood Frog** to be the most common of the amphibians (59% of amphibians and reptiles). Karns (1979) never found tadpoles of this species at a pH lower than 5.0, although Johnson (1985) determined that eggs could develop normally at pH 4.0. Freda and Dunson (1985) showed that tadpoles of *L. sylvaticus* experienced lower sodium, chloride, and water concentrations in a low-pH pond (4.05-4.90) than did those from a nearby pond with a pH of 5.74-6.37. Higher sodium efflux occurred in both populations when placed in the lower pH pond, demonstrating the effect of low pH on ionic regulation in the tadpoles. This ability to exist in low pH water gives them an advantage – their predators are unable to survive the low pH, giving the tadpoles a huge advantage (See

discussion of overwintering and the anecdotal story by Dick Andrus).

Mazerolle and Cormier (2003) reported that they had captured **Green Frog** tadpoles in some of the bog ponds. However, they considered these ponds to be marginal, with an average pH of 3.67 (Mazerolle 2005), whereas the LC_{50} (pH at which 50% of frogs died) for **Green Frog** tadpoles in one study was 3.36 (Freda & Taylor 1992). Hence, the habitat was indeed marginal and indicated its importance despite its near-lethal pH. On the other hand, *Lithobates clamitans* (**Green Frog**; Figure 3) was among the most common (29%) of the amphibians and reptiles trapped in nine Maine, USA, bogs (Stockwell & Hunter 1985). In contrast, Brooks *et al.* (1987) found 13 amphibians and reptiles in peatlands of the Pocono Mountain region of Pennsylvania, USA, but none was common. The **Green frog** and *Lithobates sylvaticus* (**Wood Frog**; Figure 5) were not among the most common there. In Minnesota, the **Wood Frog** was the dominant amphibian (47% of all amphibian and reptile captures), but the **Green Frog** was conspicuously absent (Karns 1992a). Rather, in the Minnesota peatlands the **American Toad** (*Anaxyrus americanus*; Figure 14) was among the most common. Karns attributed this to more pools in the Maine peatlands, favoring the more aquatic **Green Frog**.

Not all amphibians are equally susceptible to the effects of low pH. Freda and Dunson (1986) found that in central Pennsylvania and the New Jersey Pine Barrens, USA, the **Jefferson Salamander** (*Ambystoma jeffersonianum*; Ambystomatidae) and **Fowler's toad** (*Anaxyrus fowleri*, formerly *Bufo woodhousei*; Figure 16) were intolerant of water with a low pH. These two species had significantly higher mortality in ponds with low pH. In addition, *Pseudacris triseriata*, *P. crucifer*, *Lithobates pipiens* (Figure 4), *Hyla versicolor* (Figure 9-Figure 10), and *Anaxyrus* (= *Bufo*) *americanus* (Figure 14) were negatively affected by low pH water found in bog lakes. In laboratory experiments, *Anaxyrus fowleri* (Figure 16 and *Hyla andersonii* (**Pine Barren Treefrog**; Figure 17) exhibited significantly slower growth under acidic conditions, perhaps helping to explain the global decline in amphibians under the bombardment of acid rain. Freda and Dunson suggested that the small but erratic fluctuations of pH in the New Jersey ponds could contribute to their demise. They found that a pH change of only 0.2 units could alter hatching success. Contributions from acid rain could alter the pH sufficiently to kill sensitive eggs and larvae if the event were to occur at a critical time. In ponds where *Sphagnum* or other mosses are contributing H^+ ions, this additional input could be lethal.

On the other hand, in these same locations the **Wood Frog** (*Lithobates sylvaticus*; Figure 5) and the **Pine Barrens Treefrog** (*Hyla andersonii*; Figure 17) tadpoles occurred in ponds with the lowest pH values, with the latter hatching at a pH as low as 3.70 (Freda & Dunson 1986). Ling *et al.* (1986) in Marquette County, Michigan, and Karns (1992b) in northern Minnesota, USA, found a similar tolerance for low pH in tadpoles of *Lithobates sylvaticus* (Figure 5). The larvae were seemingly unaffected when reared at pH as low as 3.0 (Ling *et al.* 1986). But further study is needed to explain the survival of *Hyla andersonii* at such low pH levels when the same

authors (Freda & Dunson 1986) have demonstrated that low pH has a negative effect on its growth.

Figure 16. **Fowler's Toad** (*Anaxyrus fowleri*) sitting on *Plagiomnium*. Photo by Twan Leenders, with permission.

Figure 17. **Hyla andersonii** (**Pine Barrens Treefrog**). Photo by Bruce Means, US Fish & Wildlife Service, with permission.

It is perhaps encouraging that proximal populations of *L. sylvaticus* (Figure 5) may differ. Karns (1992b) found that both embryos and larvae of *L. sylvaticus* from northern Minnesota peatlands had a greater tolerance for the low pH of bog water than did those that came from a circumneutral marsh in southern Minnesota. However, Karns concluded that the preference of this species for fen sites (higher pH) was due to being born there and not to avoidance of bog water.

Acid as a Refuge - *Rana arvalis* (Moor Frog, Ranidae)

The Moor Frog (*Rana arvalis*; Figure 18) occurs in many European countries. This frog can be the only frog species in some upland Lithuanian bogs (Direika & Staðaitis 1999). As many as 20 individuals may be found in 0.1 hectare. However, throughout Europe it inhabits a wide range of habitats. In Siberia it occurs primarily in open swamps.

Figure 18. The **Moor Frog**, *Rana arvalis* on *Sphagnum*. Photo by Piet Spaans, through Creative Commons.

This is one of the few species that is able to breed in acid peat bogs (Figure 19) because the acidic water is not suitable for frog egg development in most species (Klaus Weddelling, Bryonet 26 March 2011). Šandera (pers. comm. 20 February 2011) suggested that the frogs may hide in mosses in the summer to maintain moisture. Extensive fishery and agriculture threaten the future of *Rana arvalis* (Figure 18) (Šandera *et al.* 2008).

Figure 19. *Rana arvalis* in amplexus with the male on top. Notice the difference in coloration between the male and female. Photo by Martin Šandera, with permission.

Moisture Refuge

The **Wood Frog** (*Lithobates sylvaticus*; Figure 5) also may use *Sphagnum* as a "refugium" when it is migrating to its summer habitat and during the daytime in forested wetlands (Baldwin *et al.* 2006). The moisture and protection from the sun permit it to survive its trek to its new home. At least in Maine, USA, forested wetlands with *Sphagnum* are important in their migratory success. It is time to let the world know that to save the frogs we may need to save the mosses!

As already discussed, frogs need moisture. Hence, Mazerolle (2005) investigated the use of *Sphagnum* bogs (peatlands) by **Northern Green Frogs**, *Lithobates* (= *Rana*) *clamitans melanota* (Figure 20), in New Brunswick, Canada, to look for indications that the low pH would deter them from use of the moist habitat of the bog.

Figure 20. **Green Frog**, *Lithobates clamitans*. Photo by Tony Swinehart, with permission.

Burrows in the Bog Moss

The **Common Frog** in Europe (*Rana temporaria*; Figure 21) inhabits raised bogs, blanket bogs, and fens (Peatlands 2009). Ida Bruggeman (pers. comm. 5 February 2009) observed them in her own Netherlands garden peatland, where they sometimes would burrow into holes dug by **Green Frogs** (*Pelophylax*). They never seemed to dig their own holes, however. She was able to observe *P. rubicundus* digging a burrow in which it would sit for hours (Figure 22-Figure 24). It would return to the same burrow for several consecutive days.

Figure 25. **European Common Spadefoot Toad (*Pelobates fuscus*)**. Photo by Christian Fischer, through Wikimedia Commons.

Retreats – Mosses Instead of Sand

The **European Common Spadefoot (*Pelobates fuscus*; Pelobatidae; Figure 25)** can occur in *Sphagnum*

peatlands, where its retreat-making behavior might be useful (Stachyra & Tchórzewski 2004). But its typical habitat is farmland, dunes, and pinewoods (Bosman & van den Munckhof 2006). This spadefoot is also known as the garlic toad because of the odor it emits as part of its noxious exudation defense mechanism. Like so many species of amphibians, this one is also disappearing. Its need for a suitable terrestrial habitat is emphasized by its predominantly beetle diet (Nicoară *et al.* 2005).

A Toxic Bog-dweller – *Bombina bombina* (European Fire-bellied Toad, Bombinatoridae)

Native to lowland swamps and wetlands (IUCN 2011), the **European Fire-bellied Toad** is named *Bombina bombina* (Figure 26). [Tautonyms (specific name repeats the generic name) are acceptable in zoological nomenclature, but are cause for rejection in botanical nomenclature and word processor grammar checkers!] *Bombina bombina*, common in eastern and central Europe (IUCN 2011) and from the Balkans across central and eastern Asia (Staniszewski 1998), is one of the amphibians that inhabit the highland and transitional *Sphagnum* peatlands in Poland (Stachyra & Tchórzewski 2004), as well as bogs in other areas. It is not a true toad, but does have a warty skin. Its name derives from its bright red-orange belly that acts as warning coloration against predators, especially as it rears up to expose its bright underbelly. Despite its toxic skin, this and several other species of fire-bellied toads are kept as pets.

When it is time to shed its skin, this slightly toxic (to humans) toad first bloats itself, making a coughing sound, then tears off its skin with its mouth and eats it for added nutrition (Wikipedia 2008). When endangered, it rolls over, exposing its colorful belly, and covers its eyes with its feet (AmphibiaWeb: *Bombina bombina* 1999). In other cases, it may arch its back and expose its brightly colored underside (Wikipedia 2010). Despite its threatening color display and distasteful poison, it still is frequently eaten.

Figure 26. **European Fire-bellied Toad (*Bombina bombina*)**. Photo by Mark Szczepanek, through Wikimedia Commons.

BSTI is a protease in the skin of these frogs that is a trypsin and thrombin inhibitor (Mignogna *et al.* 1996). Mignogna and coworkers suggest that the role of this protease in the skin is to prevent the premature release or breakdown of skin peptides. But it seems likely that the protease may also have toxic properties against predators. Certainly, inhibition of thrombin can cause excessive

bleeding, but the authors did not test this possibility in would-be predators. Despite its use of many kinds of habitats, the disappearance of wetlands is the greatest threat to this species (AmphibiaWeb: *Bombina bombina* 1999).

Ground-Dwellers: Bufonidae (Toads)

Although a number of amphibians have the common name of toad, only members of the Bufonidae are true toads. They differ from all other amphibian families by the presence of a pair of **parotoid glands** (Figure 27) at the back of the head, behind the eyes. Most of the Bufonidae have conspicuous warts, but so do members of many other Anuran species. Otherwise, they generally resemble frogs.

North American toads have recently been moved to a different genus, based on genetics and cladistics (Naish 2009), from the well known genus *Bufo* to *Anaxyrus*, a genus restricted to the North American continent. However, this move is not acceptable to all herpetologists because it makes the remaining genus *Bufo* paraphyletic (Pauly *et al.* 2004, 2009). Furthermore, morphological characters that unite the genus *Anaxyrus* and separate it from *Bufo* have not yet been elaborated. Nevertheless, I shall use *Anaxyrus* for the North American members where it is appropriate, but be aware that other genera have also been split off from *Bufo* as well.

Most of us know the toads from childhood and may have been told that we would get warts from handling them. But toads don't cause warts. They do, however, emit secretions that can be irritants to some people. Toads have a pair of **parotoid glands** (Figure 27) on the backs of their heads. These excrete an alkaloid poison when the animals are stressed. There is a variety of compounds in these, differing among species. The term **bufotoxin** refers to any of these. The most toxic of these is from the Cane Toad, *Rhinella marina* (previously *Bufo marinus*).

Figure 27. Head and thorax of the American Toad, *Anaxyrus americanus*, illustrating the location of the parotoid gland and the tympanum, the external portion of the ear drum. Photo © Jason Gibson, with permission for academic use.

As already seen, toads certainly make use of bryophytes as hibernacula, where they spend the winter under the insulating blanket of clumps and thick mats. Toads spend less time in the water than do the true frogs. Hence, in addition to casual use, as is likely for

Nannophryne variegata (previously *Bufo variegatus*) in Figure 1, we might expect somewhat different uses of the bryophytes than that seen for frogs.

Most toads lay their eggs in paired strings in open water (Figure 28) (Wikipedia 2015b). These eggs hatch into tadpoles except in *Nectophrynoides*, whose eggs hatch directly into tiny toads.

Figure 28. *Rhinella arunco* (Bufonidae) strings of eggs. Photo © Danté B. Fenolio <www.anotheca.com>, with permission.

One of the strangest characteristics for toads is the ability of the male to change sex! These males have a **Bidder's organ** that can become an ovary under the right conditions (Wikipedia 2015b). But apparently this organ only becomes functional as an ovary when the testes are destroyed – an event most likely to occur in the lab (Wikipedia 2014). But it can also become functional when the testes are rendered non-functional by exposure to endocrine-disrupting chemicals. This may be somewhat adaptive in our polluted world.

Anaxyrus americanus (American Toad, Bufonidae)

Among the amphibians of the boreal peatlands in North America (Desrochers & van Duinen 2006) and the Tulula Wetlands in North Carolina, USA (Amphibians: Tulula Wetlands), one can find the widespread American Toad, *Anaxyrus americanus* (Figure 29-Figure 32). In Maine, USA, wetlands this species likewise occurred, but it was not abundant (Desrochers & van Duinen 2006).

It is likely that toads use bryophytes as part of a mosaic habitat. Their mottled browns and grays make them inconspicuous on the intermittent patches of soil. They can burrow under the bryophytes in winter to hibernate or burrow into them in summer to get cool or remain hydrated (Figure 30).

Terrestrial mosses may be more important than wetlands for toads. In the late autumn, I have more than once lifted a clump of moss for a collection, only to find a very quiet toad (**American Toad, *Anaxyrus americanus***; Figure 29) under the moss. I presumed that these animals were spending the winter there. It would seem likely that the moss would help to protect them from desiccation and cold during the winter months, and perhaps even lessen evaporative cooling. Kate Frego (personal communication 12 January 2008 and Bryonet 3 February 2009) relays this interesting story from Crepieul Township, northern Ontario (near town of Chapleau), Canada. She was working in an

upland white spruce post-fire forest, ~130 years old, with a thick carpet of *Pleurozium schreberi* (Figure 33). "It was quite startling! I arrived at my site before the snow melted (on purpose) and watched everything come to life. One day the *Pleurozium* carpet around some tree bases was literally pulsating. I was somewhat spooked, and watched for some time, from a distance!! Eventually there was a little break in the moss, and these toad feet 'swam' out, and a great fat **American Toad** pulled itself out of the opening it had made." The toad sat on the moss in the warm sun, then hopped off toward the pond. She estimates that the toad had been about 12 cm below the surface of the mosses. The pond nearby was full of **American Toad** tadpoles every year she was there, suggesting that this was an important breeding and overwintering habitat.

Figure 30. Toad (*Anaxyrus*) burrowed into moss in July in the Adirondacks, eastern USA, perhaps to keep its skin moist. Photo by Sean Robinson, with permission.

To be of use to the toads, breeding habitats must be near water – ditches, pools, even vernal ponds. Eggs are laid in a long string or tube and young are hatched as tadpoles (Figure 34).

Figure 34. Eggs and tadpoles of the common **American Toad** *Anaxyrus americanus* in a shallow pool. Photo by Janice Glime.

***Anaxyrus boreas* (Western Toad, Bufonidae)**

Bartelt *et al.* (2004) used radio transmitters to demonstrate the movement patterns of 18 **Western Toads** (*Anaxyrus boreas*, previously *Bufo boreas*; Figure 35). The toads seemed to move at times and through habitats that maximized moisture conservation and selected moss cover for their movements 1.8% of the time, despite a frequency of this cover type that was near zero. Browne and Paszkowski (2010a) found that in north-central Alberta, Canada, this species used moss-covered peatland, among other habitats, during the foraging period, but they did not report use of mosses for hibernation (Browne 2010; Browne & Paszkowski 2010b).

Figure 35. *Anaxyrus boreas* on the forest floor where moss cover can help to maintain skin moisture. Photo by William Flaxington, with permission.

Bull (2009) found a similar preference by juveniles for mossy areas in Oregon. Young toads dispersed up to 2720 m from their site of birth within only 8 weeks after entering their adult stage. During their movement to their new summer home, they were subject to desiccation, predation (especially by birds), death by car, cattle trampling, and chytridiomycosis infection. Having mosses at 85% of the plots where juveniles occurred, compared to presence of mosses in only 3% of the area may only be a correlation with the need for the water. Mosses may have occurred in wetter areas. Nevertheless, Bull suggested that the mosses helped to provide protection from desiccation.

***Bufo bufo* (European Common Toad, Bufonidae)**

The **European Common Toad** (*Bufo bufo*; Figure 36), which also extends into northern Africa, may be one of the few amphibians to eat bryophytes. Javier Martínez Abaigar (February 2009 pers. comm.) tells of finding bits of leaves of aquatic bryophytes, such as *Fontinalis antipyretica* (Figure 37), *Chiloscyphus polyanthos* (Figure 38), and other unidentified species, in the guts of tadpoles of this toad. Was this truly intended as food? Or did the rasping mouth tear these as it scraped algae from the leaves, or did they enter as detritus among the other edibles nestled among the bryophytes or on the bottom? In any event, I thought this would be worth exploring as a potential dispersal mechanism for the moss, but Javier says the tadpoles are confined to small, quiet pools and would provide no more dispersal than the fragment would have without the help of the tadpole, unless of course, the tadpole gets eaten.

Figure 37. *Fontinalis antipyretica*, shown here exposed out of water in early autumn, is an occasional food source for the **European Common Toad**, *Bufo bufo*. Photo by Janice Glime.

Figure 38. *Chiloscypus polyanthos*, an occasional food source for the **European Common Toad**, *Bufo bufo*. Photo by Des Callaghan, with permission.

This **European Common Toad** excretes a **bufagin** toxin that deters most predators. Unfortunately for the toad, grass snakes and hedgehogs, both predators on toads, are immune to it (Wikipedia 2015a). Females typically return to the pond where they were born to lay eggs in the spring. As adults, they are land-born, eating insects and other small invertebrates, but turnabout is fair play – larger toads may also eat grass snakes. These toads are on the IUCN (2010) red list of endangered species. They are often vulnerable when crossing roads to reach breeding grounds, causing some environmental groups to build tunnels under the road to permit safe crossing (Figure 39). Mazerolle (2005) indicates that drainage ditches may offer similar facilitation for frogs.

Figure 39. Tunnel under road to permit safe passage of the **European Common Toad** *Bufo bufo* to and from its breeding grounds. Photo by Christian Fischer, through Wikimedia Commons.

Incilius coniferus (formerly *Bufo coniferus*, **Evergreen Toad**, Bufonidae)

Incilius coniferus (formerly *Bufo coniferus*; **Evergreen Toad**) (Figure 40) is listed as a species of least concern (IUCN 2011), but it seems to be largely ignored. A Google search found nothing except its occurrence on several species lists. Its known distribution was on both Atlantic and Pacific slopes in east-central Nicaragua, Costa Rica, and Panama and into the Pacific lowlands of Colombia and northern Ecuador (Frost 2011).

Figure 40. *Incilius coniferus* (**Evergreen Toad**) blending with a bed of mosses and liverworts. Photo by Brian Gratwicke, through Creative Commons.

I could find nothing to indicate this species makes use of bryophytes for a habitat element, but the picture shown here (Figure 40) suggests that it might, and that it certainly would have good camouflage if it did. But this is not its only coloration. Most individuals are yellow-green to olive green, or even dull brown or gray, with little mottling, or sometimes with white or dark blotches (Savage 2002). The presence of warts helps to disrupt its coloration and facilitate blending with its environment. This individual seems to have combined these in just the right way to blend with the surrounding bryophytes. These color patterns help it to blend with its humid lowland forest and premontane habitat, where it is known up to 1550 m (Savage 2002). But it most likely also helps make it less conspicuous when it climbs, as much as several meters (Duellman & Schulte 1992; Savage 2002).

A further suggestion, besides its coloration, that bryophytes might be an important part of its habitat is that it eats ants and mites (Toft 1981), both of which can be abundant among bryophytes. Its oviposition doesn't offer any clues – it occurs at the beginning of the wet season, and the frogs place the eggs in temporary pools or depressions (Crump 1989). Tadpoles emerge from the eggs five days later, attesting to its aquatic, rather than terrestrial, affiliations. Is the coloration of *Incilius coniferus* (**Evergreen Toad**; Figure 40) just a co-incidence?

Pseudepidalea viridis (Green Toad, Bufonidae)

The green toad, *Pseudepidalea viridis* (previously *Bufo viridis*) (Figure 41) is a common inhabitant of peatlands in high elevation and transitional peat bogs in Poland (Stachyra & Tchórzewski 2004). This frog breeds over several months, presumably as a mechanism for greater survival in habitats that may dry up before tadpoles mature (Kovács & Sas 2009). When food gets scarce, the tadpoles may become cannibalistic, a phenomenon known in other tadpoles such as *Anaxyrus boreas* (Figure 35) (Jordan *et al.* 2004).

Figure 41. The **Green Toad**, *Pseudepidalea viridis*, a peatland inhabitant. Its coloration suggests it might blend well with the mix of moss tops and dark spaces in the peatland. Photo by © John White, with permission.

Figure 43. Adult **Natterjack Toad**, *Epidalea calamita*, at night. Photo by Christian Fischer, through GNU Free Documentation License.

Epidalea calamita (Natterjack Toad, Bufonidae)

Although this European frog, a close relative of *Pseudepidalea viridis* (Figure 41), inhabits sand dunes and gravel quarries (AmphibiaWeb: *Bufo calamita* 2006), the **Natterjack toad**, *Epidalea calamita* (previously *Bufo calamita*) (Figure 42-Figure 43), is likewise a common inhabitant of peatlands in high elevation and transitional peat bogs in Poland (Stachyra & Tchorzewski 2004). This is the only species of toad native to Ireland, where it lives near pools that stay warm (Wikipedia 2016). In The Netherlands, Strijbosch (1979) found this species selected the most eutrophic sites during its aquatic stage. Elsewhere in Europe it is common in heathlands.

Figure 42. Very young **Natterjack Toad**, *Epidalea calamita* climbing among the mosses. Photo by Piet Spaans, through Creative Commons.

In southern Britain, these toads avoid *Calluna* heaths, but they spend their entire lives in open areas where bare sand or short bryophyte turf dominates the landscape (Banks *et al.* 1993). It is interesting that introducing the cyprinid fish known as **ide** or **orfe** (*Leuciscus idus*; Figure 44) to the breeding pools reduced the predatory invertebrates, increasing survival of the tadpoles. Unfortunately, adults, especially males, fell prey to the grass snake (*Natrix natrix*; Figure 45).

Figure 44, *Leuciscus idus* (**ide** or **orfe**), a fish that reduces predators on the tadpoles of *Epidalea calamita* by eating the predators. Photo through Wikimedia Commons.

Figure 45. *Natrix natrix* (**Grass Snake**), a predator on adult **Natterjack Toads** (*Epidalea calamita*). Photo by Karl Larsaeus, through Wikimedia Commons.

Beebee (1977) attempted to determine the cause of 40 years of decline in this species. It is interesting that it was the inland heaths that had the greater decline, compared to the dunes. Climate change, human activity, and development did not seem to be a problem. Rather, large-scale changes in the heathland flora were responsible. Grazing stopped and forestry activity increased, permitting the invasion by taller vegetation and greater shade. These conditions were unsuitable for the **Natterjack Toad**, but a greater problem was the invasion of its competitor, *Bufo bufo* (Figure 36).

***Leptophryne cruentata* (Indonesia Tree Toad, Bleeding Toad, Bufonidae)**

Leptophryne cruentata (Figure 46-Figure 47) is a true toad distributed in Southeast Asia, primarily Indonesia. Kusrini *et al.* (2007) found fifteen frogs hidden in a crevice covered by mosses in the wall of a waterfall. Its habit of hiding could explain its elusiveness. It is listed as critically endangered, at least partly because of the volcanic eruption of Mount Galunggung in 1982 (Wikipedia: Bleeding Toad 2008) that buried a large part of its range.

Figure 46. Indonesian Tree Toad, *Leptophryne cruentata*, showing a pink-purple variety. Photo by Frank Yuwono, with permission.

Figure 47. *Leptophryne cruentata*, the Indonesian Tree Toad, showing a red and yellow spotted variety. Photo by Georg Moser, with permission.

***Atelopus zeteki* (Panamanian Golden Frog, Bufonidae)**

In tropical wet forest stream habitats, the critically endangered Panamanian Golden Frogs (*Atelopus zeteki*; Figure 48-Figure 49) can be found among mosses (Hong 2007; Lindquist *et al.* 2007). Technically a toad (Bufonidae), these amphibians look more like a tree frog. They may climb as much as 3 m near water falls, where they perch on large moss-covered boulders. But beware of these beautiful frogs. Their skin contains a highly toxic

alkaloid that is an analog of saxitoxin (Fuhrman *et al.* 1969; Brown *et al.* 1977) and has the ability to block sodium channels in the nervous system (Yotsu-Yamashita *et al.* 2004).

Atelopus loettersi (Bufonidae)

This newly described species was located on the Amazonian slopes of southern Peru at 400-1000 m asl (De la Riva *et al.* 2011). Only tiny juveniles could be found, dwelling on mosses covering a large rock wall along a river bank. That appears to be all that is known about this species at this time.

Toads in the Trees: Bufonidae

Rhinella tacana (formerly *Chaunus tacana*, Bufonidae)

First named in 2006 (Padial *et al.* 2006), *Rhinella tacana* (Figure 51) lives in the humid forest at only one known location in Bolivia at 1500 m asl (Frost 2011). It lives in Andean valleys and Amazonian slopes. Within its habitat, it climbs moss-covered tree trunks and rests on leaves or trunks at 1-4 m height (Padial *et al.* 2006). Its reproduction is unknown and too little is known about it for classification in the IUCN redlisting (IUCN 2011).

Figure 51. *Rhinella tacana*, a toad that climbs mossy tree trunks in Bolivia. Photo by Sean Michael Rovito, with permission.

Ansonia latidisca (Borneo Rainbow Toad, Sambas Stream Toad, Bufonidae)

The Sambas Stream Toad (Figure 52) had not been seen since 1924 when Dr. Indraneil Das and his research

team set out in 2011 to find it (Lin 2011). Just imagine the excitement of his graduate student, Pui Yong Min, who discovered it near the border of Indonesia and Malaysia, perched 2 m above ground on a moss-covered branch. But at this time, that is about all we know about it, except that it is a beautiful toad that would be a desirable pet for that reason. Therefore, to protect it, the location will not be published.

Eastern Hemisphere Mossy Habitats

Arthroleptidae

Leptodactylodon albiventris (Whitebelly Egg Frog; see Figure 53) is endemic to Cameroon, Africa, in subtropical and tropical moist lowland forests, moist montane areas, rivers, and rocky areas (Amiet 2004). Living at 300-1000 m asl (Frost 2011), this species calls day and night from hidden locations; it finds a thin layer of water flowing under rocks or other cover and can only be located by removing the rocks, mosses, or looking among submerged roots (De la Riva *et al.* 2001).

Figure 53. *Leptodactylodon* sp. (Whitebelly Egg Frog) on leaf, member of a genus where some species hide under mosses in flowing water. Photo by Ignacio De la Riva, with permission.

Myobatrachidae

Pseudophryne (Myobatrachidae)

Several species in this genus, which is endemic to Australia, are known to be bryophyte inhabitants. Unique

to *Pseudophryne* species among the anurans, part of their defense is accomplished by a class of indolic alkaloids called **pseudophrynamines** (PS's). These compounds appear to be produced internally, either by the frog itself or by symbiotic organisms living within the frog (Smith et al 2002). In addition to these toxic alkaloids, they also possess **pumiliotoxins** (PTX's). The latter are found in all genera worldwide if those anurans (frogs & toads) contain lipophilic alkaloids. The PTX's appear to have a dietary source, with lab-reared animals lacking the compound. It is subsequently incorporated into the skin. An interesting consequence of high levels of this skin toxin is that it seems to inhibit the production of PS.

***Pseudophryne corroboree* & *P. pengilleyi*
(Corroboree Frogs, Myobatrachidae)**

The genus *Pseudophryne* is known only from Australia. The alpine species *Pseudophryne corroboree* (Figure 54) in New South Wales, Australia, has been split into two species with the northern one separated into *P. pengilleyi* (Osborne et al. 1996; Figure 55). Corroboree is the aboriginal name for a group meeting and the name of the frogs refers to the habit of gathering in large groups to form a chorus.

Figure 54. *Pseudophryne corroboree*, an alpine corroboree frog from New South Wales, Australia, shown here in its peat moss (*Sphagnum*) habitat. Its bumblebee coloration is a better warning coloration than a camouflage. Photo by Scott Robinson <www.ifrog.us>, with permission.

Figure 55. The Northern Corroboree Frog, *Pseudophryne pengilleyi*, in its native peatland habitat in northern New South Wales, Australia. Photo by Ken Thomas, with permission.

Both live in peatlands and often deposit their 10-38 eggs there (Pengilley 1973) in locations that become seasonally inundated. The male makes deep burrows in the *Sphagnum* or other substrate and proceeds to call from there to attract females. Males generally stay with the eggs for two-four weeks. Like several other moss-dwelling frogs, females may deposit several clutches of eggs, thus making smaller clutches and increasing the oxygen availability to all the eggs (Woodruff 1976). The southern species, *P. corroboree* (Figure 54), is in danger of extinction (Project Corroboree). Efforts to save the species include captive breeding.

***Pseudophryne semimarmorata* (formerly
Pseudophryne bibroni) (Southern Toadlet,
Myobatrachidae)**

Pseudophryne semimarmorata (Figure 56) occurs in the extreme southeast of South Australia, southern Victoria, and eastern Tasmania, where it enjoys the status of least concern – an unusually safe designation for a small frog (IUCN 2010). It is called a toadlet due to its warty appearance, but it is not a true toad. Its typical habitats are dry forest, woodland, shrubland, grassland, and heath (Frogs of Australia 2011). The frogs hide under leaf litter or other debris (a designation that includes bryophytes) in depressions and other moist areas. They move about in their habitat by walking instead of the familiar hop we typically think of for frogs, but then many (most?) frogs walk or crawl when not trying to escape something.

Figure 56. *Pseudophryne semimarmorata*, a species that hides under mosses in southern Australia. Note the absence of a tympanum behind the eye. Photo by John Wombey, through Creative Commons.

Males call, from burrows that the males construct, in late summer and autumn (FrogsAustralia 2005). But this species lacks any structural hearing organ (Figure 57) (Loftus-Hills 1973b; Parks & Wildlife Service, Tasmania 2010). One hypothesis is that they sense the sounds through the vibrations of the skull bones, a concept supported by the correlation between head width and auditory threshold (Loftus-Hills 1973a). They cease calling if *Crinia victoriana* begins calling nearby, and resume when this competing species stops (Littlejohn & Martin 1969). These two species use the same frequency band (~2500 Hz), so cessation of the call increases the efficiency of their communication.

Figure 57. *Pseudophryne semimarmorata* on a bed of mosses. Note the absence of a tympanum behind the eye. Photo by John Wombey, through Creative Commons.

It has an unusual reproductive behavior that befits its amphibious habitat. The nesting burrows, dug by the males, are located near water or boggy ground (FrogsAustralia 2005). The females lay their large eggs in loose clumps under litter in these shallow burrows (Frogs of Australia 2011). These must be located where they will later be flooded so that the aquatic tadpoles have a place to swim. The unusual aspect is that the eggs of one female may have up to eight different fathers and be placed in as many different nests (O'Brien 2011). These fathers stay with their fertilized eggs until they have developed into tadpoles (O'Brien 2011), a duty that lasts for at least 42 days (Parks & Wildlife Service Tasmania 2010). This promiscuous strategy by the females increases the chances that some of her eggs will be in nests that are suitably positioned for flooding at the right time (O'Brien 2011). If they are flooded too early, the eggs could be washed away, whereas if flooding is too late, the eggs can dry out. Since mosses often grow in such amphibious locations, they may play a role in the "debris" used for nesting and adult habitat.

***Crinia nimbus* & *C. georgiana* (Australian Moss Froglet, Myobatrachidae)**

In Tasmania, you might hear what sounds like a ping-pong ball dropped on wood: took-tok-tok-tok-tok, the call of the endemic **Australian Moss Froglet, *Crinia nimbus***, a cloud forest froglet (Wildlife Management 2014; Figure 58). The call of this common but narrowly distributed frog (southern mountains of Tasmania) is likely to come from its position under mosses or lichens in its nest, thus muffled by the overlying cover (Sopory & Hero 2008).

In *Crinia nimbus*, the larval development time is greatly benefitted by temperatures as they increase from 5 to 15°C (Mitchell & Seymour 2003). It would be interesting to learn whether the dark-colored mosses serve as black bodies to warm the habitat for these larvae in winter. If so, they could significantly increase survival because the larvae do not feed, and at 5°C they can run out of yolk and die before reaching adulthood and food intake.

The **Australian Moss Froglet** requires mosses or lichens to maintain sufficient moisture for the development of its embryos (Mitchell 2002a). The female deposits 4-16 large eggs (Figure 59) in nests made from these in the

subalpine regions of southern Tasmania (Mitchell & Seymour 2000). The frogs spend one year as larvae within any of about 10 species of mosses, lichens, and lycopods (Mitchell 2002b), and in southern Tasmania, this occurs under the snow (Mitchell & Seymour 2000). In laboratory experiments, embryos that experienced more drying than that experienced among the mosses had asymmetrical deformities and lower survivorship (Mitchell 2002a).

Figure 58. The **Australian Moss Froglet, *Crinia nimbus***, a small (up to 30 mm length) Tasmanian endemic that sounds like a ping-pong ball calling from its nest under mosses. Photo by Gerry Marantelli, compliments of the Amphibian Research Centre <<http://www.frogs.org.au/>>, with permission.

Figure 59. **Australian Moss Froglet, *Crinia nimbus***, eggs in their nest under mosses. Photo by Gerry Marantelli, compliments of the Amphibian Research Centre <<http://www.frogs.org.au/>>, with permission.

But moisture is not the only contribution of the moss. The thick gelatinous capsule around the eggs in this species affords further protection from desiccation, but it creates a formidable barrier to the entrance of oxygen (Mitchell & Seymour 2003). Models predict that the frogs should die at temperatures above 5°C due to insufficient oxygen, but in reality, the frogs have an added advantage in the moss layers and rarely die at any of their natural temperatures (Mitchell 2002a). Not only does the moss permit aeration of both lower and upper surfaces, but the photosynthetic

oxygen production further supplements the oxygen available. At night it is safer for the frog to roam away from the protection of the moss. In the daytime, the nest of *Crinia georgiana* (Figure 60) in a moss bed had double the oxygen it had during pre-dawn hours (Seymour *et al.* 2000).

Figure 60. Two frogs of *Crinia georgiana*, looking very much like two humans doing a dance! Photo by Jean-Marc Hero, with permission.

Byrne (2002) found *Crinia georgiana* (Figure 60) breeding in shallow temporary pools by a sloping, moss-covered granite outcrop where it "enjoys" the privilege of having a testes size at least four times that of any other species of *Crinia*. This unusual size may be an adaptation to its habit of multiple matings (1-9) with a single female, creating sperm competition (Birkhead 1995; Byrne 2002).

***Crinia tasmaniensis* (Tasmanian Froglet, Myobatrachidae)**

Crinia tasmaniensis, the **Tasmanian Froglet** (Figure 61), is endemic to Tasmania and must always be near water (ZipcodeZoo.com: *Crinia tasmaniensis* 2009). This requirement takes it to alpine areas, rainforests, bogs, swamps, fens, and peatlands, where mosses are part of its environment. Its call sounds like a bleating sheep.

Figure 61. The **Tasmanian Froglet**, *Crinia tasmaniensis*, an inhabitant of bogs, swamps, and peatlands, among others. Photo through GNU Free Documentation License.

***Geocrinia victoriana* (Victoria Ground Froglet, Myobatrachidae)**

Gollmann and Gollmann (1996) collected *Geocrinia victoriana* (Figure 62) in southwestern Victoria and from 180-1300 m in central Victoria from mosses in a roadside ditch and under grass tussocks. In laboratory experiments they demonstrated that populations from the mountains were larger when they hatched and grew faster than those from the lowland sites, but those from the southwest were similar to their counterparts at higher altitudes in central Victoria.

Summary

Although peatlands provide moist sites for adults to rest, bog ponds are often too acid. Acidification has resulted in extirpation of many species of frogs, interfering with development, but apparently the Wood Frog (*Lithobates sylvaticus*) is more tolerant and thus can inhabit low pH ponds without risk of predation by other amphibians. The tadpoles of the Green Frog (*Lithobates clamitans*) are apparently unsuccessful in surviving the low pH of bog ponds. *Rana arvalis* is one of the few species that is able to breed in acid peat bogs. Nevertheless, many frogs use peatlands in summer. Frogs such as *Rana temporaria* (European Common Frog) and *Pelophylax* spp. (green frogs) often make burrows in *Sphagnum* banks as a resting place in summer; other frogs may use those same burrows or tunnels and burrows made by small mammals. The *Sphagnum* Frog (*Phyllorhina sphagnicolus*) male excavates a nest where the female deposits the eggs; the tadpoles remain in the nest. The destruction of peatlands can result in decreases in both numbers and diversity of anurans.

The **American Toad** (*Anaxyrus americanus*) is common in wetlands, including peatlands, as well as forests. Toads often spend the winter under bryophytes where both temperature and humidity are modulated. The bryophytes may be especially important during migrations. Some toads, such as tadpoles of the European common toad (*Bufo bufo*), may eat bryophytes, but it is possible these bryophyte fragments

come along with bacteria, algae, and other food items being scraped from their surfaces.

The Cloud Froglet Tadpoles (*Crinia* spp.) require the moisture of mosses or lichens for the larvae to develop. The mosses also provide oxygen to the eggs and adults. Panamanian Golden Frogs (*Atelopus zeteki*) perch on mosses near waterfalls to maintain their moisture.

Acknowledgments

Twan Leenders and Tony Swinehart were helpful in providing some of my needed images. J. D. Willson gave us full access to his wonderful website with numerous species from around the world. We are thankful for all the people who don't know us but who graciously gave permission to use their images. Ida Bruggeman offered her story and pictures about her garden frogs. Kate Frego provided her wonderful story of pulsating *Pleurozium*. Javier Martínez Abaigar provided me with his unpublished information on gut analysis. Johannes Foufopoulos provided comments on a very early draft. Jim Harding provided us with the information needed to update the nomenclature. Jim was helpful in causing us to rethink organization of the chapter, although we ended up using a different one from either his or our original. Hans Lambers provided references that we had been unable to obtain. And thank you to the many people who put their images in the public domain for use without needing permission. Google's search engine found the images, email addresses, and literature, making possible wonderful stories that would not have been included otherwise. Without the kind cooperation of many, many people, this chapter could not have been written. The herpetologists have been incredible in encouraging us on the project and in providing images, especially for the tropical frogs. Wikipedia and Wikimedia helped us find biological information and nomenclature synonyms for the included species.

CHAPTER 14-4

ANURANS: WATERFALLS, TREEFROGS, AND MOSSY HABITATS

Figure 1. Honduran cloud forest at Parque Nacional Montana de Santa Barbara at 2180 m asl that is habitat to many tropical anurans. Photo by Josiah Townsend, with permission.

Waterfalls

***Sachatamia ilex* (formerly *Centrolene ilex*) (Limon Giant Glass Frog, Centrolenidae)**

A number of glass frogs are native to Central and South America where they live in streams and in subtropical or tropical moist lowland and moist montane forests. The Limon Giant Glass Frog, *Sachatamia ilex* (Figure 2), is also known as the Ghost Glass Frog and is nocturnal and **arboreal** (lives in trees) (Leenders 2001). It sleeps during the day on the upper surfaces of leaves where its green coloration makes it inconspicuous. Its habitat is in both primary and secondary wet forests where it often occurs in the spray zone of waterfalls and rapids of streams. Its color makes it inconspicuous when it perches on mosses and it may be more common there than observations would indicate.

Figure 2. The **Limon Giant Glass Frog, *Sachatamia ilex*** (formerly *Centrolene ilex*). Its pose here makes one wonder if it is watching for dinner among the mosses, a place where insects often hide. Photo by Twan Leenders, with permission.

Frogs in the Trees

We know that mosses that live in trees must have xerophytic adaptations to survive the periods of no rain. The frogs that live there are most abundant and have the most species in the tropics (as will be seen below), where they share their habitat with epiphytes, including bryophytes (Figure 1). We can presume that bryophytes hold moisture and protect against UV light in these arboreal habitats, permitting at least some species to have a better survival chance than would be possible with no bryophytes.

Espadarana prosoblepon (formerly *Centrolenella prosoblepon*) (Emerald Glass Frog, *Centrolenidae*)

The Emerald Glass Frog, *Espadarana prosoblepon* (= *Centrolenella prosoblepon*) (Figure 3), is an arboreal frog (WWW.WildHerps.Com 2009). It has the coloration needed to blend with the many epiphytes, including bryophytes, on the mossy branches. These frogs take advantage of this coloration in their nest sites and calling locations among mosses and leaves. Jacobson (1985) studied this species at the Gaucimal River in Monteverde, Puntarenas Province, Costa Rica, at an elevation of 1360 m asl. She found that females deposit their eggs on leaf tops, moss-covered rocks, and moss-covered branches, where they attend the eggs immediately after depositing them (Jacobson 1985; Ryan & Lips 2004). Although in some species, attendance of eggs is important for removal of bacteria and fungi, it did not seem to improve larval survival for this species. Jacobson found 50 clutches of eggs, and these demonstrated a choice of moist micro-habitats. Five of the clutches were on constantly wet, mossy rocks on a river bank. Three were in water-laden mosses in forks of tree branches.

Figure 3. The Emerald Glass Frog, *Espadarana prosoblepon* (formerly *Centrolene prosoblepon*), blending in with the light green color of the mosses and liverworts. Photo by Twan Leenders, with permission.

Unlike many of the tropical arboreal frogs, *Sachatamia ilex* and *Espadarana prosoblepon* are not on the IUCN (2015) protected list and are not considered to be endangered (WWW.WildHerps.Com: *Centrolene prosoblepon*, Emerald Glass Frog).

Hylidae: North Temperate Treefrogs

The Britannica Online Encyclopedia defines the treefrogs as any frogs living in trees. Hence, they encompass several families. Among these, the **Hylidae** (Figure 4) are considered to be the "true" treefrogs, a taxonomic distinction rather than an ecological one. We prefer the definition from <dictionary.com> "any arboreal frog of the family Hylidae... They are strong jumpers and have long toes ending in adhesive discs, which assist in climbing," but common names ignore those requirements.

Figure 4. *Hyla arborea* (Hylidae) on moss. Photo by Milan Kořinek, with permission.

While some amphibians are most likely casual visitors, treefrogs in the tropics necessarily encounter bryophytes frequently. In tropical forests, biodiversity can be high, but many of these habitats remain unexplored (Tennesen 1998). Among these seemingly unknown habitats are the arboreal mosses – habitats where new species of frogs can be discovered on nearly every collecting trip to new areas. Each location may act like an island where contact with other such "islands" has been cut off by topography for a long enough period of time for genetic drift, differing selection pressures, and new mutations to create new species or variants. Such tiny frogs as are typical of these arboreal locations most likely don't travel far across open habitats without trees. Much like the human aborigines in some parts of the world, I doubt that they travel to a new mountain range very often.

The ground of many Peruvian forests is covered with wet *Sphagnum*, and epiphytes abound on the trees. Although treefrogs need to maintain moist skin, there seems to be little direct evidence linking them to the use of these bryophytes to maintain moisture in their aerial habitat. Nevertheless, cryptic coloration that blends well with moss- and liverwort-covered branches suggests that such locations may be favorable resting places and may account for the limited observations that have been made of many species. Johannes Foufopoulos tells me he would never have discovered one of the new species in New Guinea (Foufopoulos & Brown 2004) if the frog hadn't called from its mossy perch. He had walked right by it without seeing it. It appears that some, perhaps many, can change colors to blend with their backgrounds or select backgrounds where their colors blend in. They become invisible to most searching eyes, especially those of the herpetologists.

Furthermore, nesting requirements and locations of eggs are virtually unknown in many of these species (e.g. Foufopoulos & Brown 2004). The same moisture advantage is offered to eggs and it is likely that eggs of

many species hide among the bryophytes and litter on the trees and forest floor.

We know that in the tropics, at least some treefrogs lay eggs among the mosses on the trees (Filipe Osorio pers. comm.). In Figure 5 the eggs resemble *Nostoc* balls and may thus be ignored by some carnivores because *Nostoc* has an unpleasant taste or just because they don't look like eggs. The terrestrial young of these species could remain protected from predators and desiccation within the mossy chambers until they develop to a sufficient size to move about easily.

Figure 5. Eggs of frogs on the tropical epiphytic liverwort *Plagiochila* sp. Can you find them in the upper picture? Photos by Filipe Osorio, with permission.

In these forests, animals have evolved reproductive specializations to the plants they live on, often being highly adapted to a single species or group of species. Frogs in particular have some special advantages that permit them to survive in an aerial habitat. Some sit on their eggs to incubate them. Others carry their tadpoles on their backs. And others lay eggs on leaves so that the young will fall into the river when they hatch. Most either have warning colors to threaten predators or have mottled colors that serve as camouflage (Figure 6).

Figure 6. This dart frog is not difficult to see when resting on epiphytic moss, but it is protected by its warning coloration of black and white and its poisonous skin. In some locations, its light and dark patches may hide it among sunflecks. Photo by Nate Warner, with permission.

At Monteverde, Costa Rica, temperatures in a sunlit moss mat or bromeliad basin may exceed the lethal temperature for the endangered tree-dwelling frogs that inhabit them (Pounds *et al.* 2006). Fortunately, these habitats are usually shaded, affording the frogs a safe place to live most of the time.

A variety of breeding niche diversifications, including mouth breeding, permit up to 80 different species of frogs and toads to co-occupy the same small forests in southern Chile, despite the absence of standing water in the treetops (Fogden & Fogden 1989). Their small size and susceptibility to dehydration causes the treefrogs to have narrow distributions, and many are **endemic** [exclusively occurring in just one locale (country, province, mountain, etc)] to a single or small group of mountains. Navas (2006) suggests the long history of amphibians at mid elevations in the Andes has permitted the many populations to adapt independently to the lower temperatures of the higher elevations. But high elevations require adaptations to other stressors as well, including UV radiation, especially for eggs. More recently, the more successful spread of chytridiomycosis in the lower temperatures at higher elevations has further reduced taxa there.

***Hyla chrysoscelis* (Cope's Gray Treefrog, Hylidae)**

The Cope's Gray Treefrog (*Hyla chrysoscelis*; Figure 7-Figure 8) is a native American treefrog that lives on the bole and branches of trees. This species is listed as endangered in New Jersey, USA, but it is not federally listed (Southern Gray Treefrog, *Hyla chrysoscelis* 2011). It can change color from green to gray in only a few seconds to blend with its substrate (Reptiles and Amphibians of Minnesota 2009). It tends to occur in habitats with lots of mosses as ground cover, and moss is a recommended substrate for keeping the species in captivity [Costanzo *et al.* 1992; Girgenrath & Marsh 2003; Pollywog 2009]. Its coloration permits it to blend in with the lichens and mosses on tree bark. Despite its small size, *Hyla chrysoscelis* is able to withstand freezing, but where does it spend the winter? What use does it make of mosses and liverworts during its life cycle?

Figure 7. The Cope's Gray Treefrog, *Hyla chrysoscelis* in its grey coloration. When on a green substrate such as mosses, it can change rapidly to green. Photo by John D. Willson, with permission.

Figure 8. *Hyla chrysoscelis* (Cope's Gray Treefrog) in its greenish coloration, here blending with the bryophytes on the branch. This mossy branch seems to be a good night-calling position. Photo by Kerry Kriger, through SaveTheFrogs.com, for public use only.

Hyla versicolor (Gray Treefrog)

The specific name of *Hyla versicolor* means changing color, a capability of a number of treefrogs. *Hyla versicolor* is a similar species to *H. chrysoscelis*, differing only in its call and its ploidy number, but lives farther north, overlapping with it at the southern end of its range. These species differ not only in range, but also in chromosome number, with *H. chrysoscelis* being diploid and *H. versicolor* being tetraploid (Ptacek *et al.* 1994). Like *H. chrysoscelis*, it blends with the mosses of its tree bark environment (Rhode Island Vernal Ponds 2009; Figure 9). The AnimalsandEarth (2011) website describes *Hyla versicolor* as camouflaged on a moss-covered tree.

Figure 9. *Hyla versicolor* on a bed of moss. Photo by Brian Gratwicke, through Creative Commons.

Hyla arborea (Common Treefrog, Hylidae)

Hyla arborea, the Common Treefrog (Figure 10-Figure 11), typically occurs in open forests and open areas in Europe (Wikipedia: European Treefrog 2008). However, in Poland it is one of the species to be found in high elevational and transition bogs (Stachyra & Tchórzewski 2004). It is the only indigenous treefrog in mainland Europe and is endangered due to habitat loss and pollution (Wikipedia 2008).

Figure 10. Young *Hyla arborea*, the Common Tree Frog, on a finger, demonstrating its tiny size. Photo by Christian Fischer, through Wikimedia Commons.

Figure 11. *Hyla arborea* on a bed of moss. Photo by Milan Kořinek, with permission.

Hyla gratiosa (Barking Treefrog, Hylidae)

Hyla gratiosa (Figure 12) is one of the larger hylids and is known from southeastern USA (Frost 2011). Wright (2002) reported it from a "moss-laden" black gum (*Nyssa sylvatica*) tree in Okefinokee Swamp, Georgia, USA.

Figure 12. *Hyla gratiosa*, the Barking Treefrog, on a bed of bryophytes, where it sometimes calls to attract females. Photo by Brian Gratwicke, through Creative Commons.

Hylidae: Tropical Treefrogs

Ptychohyla dendrophasma (formerly *Hyla dendrophasma*) and *Ecnomiohyla mineria* (formerly *Hyla mineria*) (Fringe-Limbed Treefrogs, Hylidae)

The trunks of tropical cloud forest trees are typically covered with bryophytes. There hide numerous

inconspicuous frogs, still unknown to the world. Among these, *Ptychohyla dendrophasma* (formerly *Hyla dendrophasma* (a name meaning tree ghost) was discovered in 2000 from the Sierra Los Cuchumatanes in northwestern Guatemala (Campbell *et al.* 2000). This is a surprisingly large frog (84.1 mm) for bryophyte habitation, but it was hanging from a moss-covered tree branch about 1.2 m above a stream. At the same location, *Ecnomiohyla minera* spends its nights on the sides of moss-covered tree trunks and on branches. Duellman (1970) suggested that the resistance to desiccation and arboreal lifestyle of the Central American *Ecnomiohyla miliaria* (Figure 13) are evidence that its home is in the forest canopy. Its coloration would help to camouflage it among the canopy mosses. The large toe pads and scallops along the legs help it to maintain its hold in the canopy.

Figure 13. *Ecnomiohyla miliaria* blending with the multicolored bark of the branch. It occurs in humid rainforests and wet forested highlands of Colombia, Costa Rica, Nicaragua, and Panama. Note the fringes on the legs that may be helpful in holding onto branches, where it flattens itself against the substrate. Or perhaps they help it to glide. Photo by Joseph H. Townsend, through Wikimedia Commons.

Isthmohyla lancasteri (formerly *Hyla lancasteri*) (Lancaster's Treefrog, Hylidae) – Why Have Tubercles?

As noted earlier, the brown splotchy pattern on the green-colored *Isthmohyla lancasteri* (formerly *Hyla lancasteri*; Figure 14) should serve it well as camouflage among the mosses. But as elevation levels increase (to 1920 m asl in Panama), so do the elevations on the frog. That is, instead of the smooth skin seen at elevations between 650 and 910 m in Panama and Costa Rica (Figure 14), this higher elevation frog gets dorsal warts that are increasingly greater in size as elevation rises (Figure 15; Trueb 1968). It looks a bit like a miniature field of volcanoes.

One can only speculate on the selection pressure behind retention of such an innovation. Why should higher elevations favor conservation of larger tubercles? One might consider camouflage amid the moss or perhaps added protection against UV radiation. Or might it be a deterrent to would-be predators? Trueb (1968) seems to think that the protuberances provide cryptic coloration: "At 1920 m on Cerro Pando, the frogs were perched on branches covered with deep moss. The frogs were difficult to see because of their **tuberculate** skin and cryptic coloration – green, white, and brown mottling. At 1450 m,

less moss is present and the frogs are correspondingly less tuberculate. Moss is less common at lower elevations, and frogs have fewer and less prominent protuberances and more subtle dorsal mottling. At elevations less than 910 m, the frogs are smooth, and the dorsal mottling is replaced by blotches on a unicolor background; these frogs are typically found on or near the ground, perched on leaves, branches, and stones." But Trueb also suggests that the protuberances on the legs and feet may help the frogs to hold onto the slippery branches. One might also speculate that they would help to keep a slippery, sleeping frog from falling through the mosses to the ground.

Figure 14. *Isthmohyla lancasteri* showing the low elevation (550 m asl) morph at Guayacan, Limon Province, Costa Rica. Note the color splotches and almost no tubercles. Photo by Brian Kubicki, with permission.

Figure 15. This is a higher elevation form of *Isthmohyla lancasteri* showing prominent tubercles. The photo was taken in Panama at Bocas del Toro Province, Parque Internacional La Amistad Caribbean side, Cerro Frío, at 1000 m asl. Photo by Angel Solís, with permission.

Agalychnis (Hylidae)

Agalychnis saltator (Misfit Leaf Frog; Figure 16- Figure 17) is one of those adorable green frogs with red eyes and large suction pads on its toes. It can be found in the Caribbean lowlands of northeastern Honduras, Nicaragua, and east-central Costa Rica at 15-1300 m asl. Pictures of frogs like this one frequently adorn ads, calendars, and other decorative positions. Bryophytes can provide a suitable substrate for laying its eggs, spread in a layer over the bryophyte mat (Figure 18). This species adds to its charm by **parachuting** (a free-fall descent that is less than 45° from the vertical) (Roberts 1994)!

Parachuting frogs display a tropical novelty that is part of the breeding activity. Males and females of *Agalychnis saltator* (Figure 16) gather in breeding aggregations on **lianas** (vines) above temporary swamps (Roberts 1994). From there, both genders parachute to the ground to join breeding aggregations there. They return to the canopy rapidly by a hand-over-hand movement up the **lianas** (vines). They lay grey eggs during the daylight hours, packed into the mosses that surround the lianas. Their eggs are vulnerable to mortality caused by desiccation, submergence in water, and predation by ants, snakes, and birds. Roberts suggests that the parachuting behavior, followed by walking, may permit these frogs to live in the canopy where they are widely dispersed, then to gather in a short burst to breed in large numbers in isolated ponds.

Figure 18. Eggs of *Agalychnis saltator* on leaf. Photo by Peter Janzen, with permission.

The related species *Agalychnis spurrelli* only occasionally lays eggs among the mosses (Gomez-Mestre & Warkentin 2007). These are laid in an irregular X shape only one layer deep (rarely in 2 layers). The tadpoles (Figure 19) drop into the water when they hatch. The eggs are subject to predation by egg-eating snakes. Tadpoles may be eaten by fish.

Figure 19. *Agalychnis callidryas* eggs – a treefrog that does not use mosses for oviposition. Photo by Geoff Gallice, through Creative Commons.

***Charadrahyla nephila* (Oaxacan Cloud-forest Treefrog, Hylidae)**

Charadrahyla nephila (Figure 20) is endemic to Mexico, where it lives in subtropical or tropical moist lowland forests and moist montanes (cloud forests), and rivers at 680-2256 m asl, habitats that are all being destroyed, thus threatening its existence (Santos-Barrera & Canseco-Márquez 2004). It seems further to be suffering from **chytridiomycosis**, a fungal disease caused by *Batrachochytrium dendrobatidis*, as suggested by the loss of keratinized mouthparts in tadpoles of southern Mexico. (See subchapter 14-2 for a discussion of this fungus disease.)

Figure 20. *Charadrahyla nephila* (Oaxacan Cloud-forest Treefrog) clinging to a tree and surrounded by bryophytes at La Chinantla, Oaxaca, Mexico. Photo by Omar Hernandez-Ordoñez, with permission.

***Anothea spinosa* (Spine-headed Tree Frog, Hylidae)**

Anothea is a **monotypic** hylid genus. That is, there is only one species in the genus, *Anothea spinosa* (Spine-headed Tree Frog, Figure 21). It is distributed in Costa Rica, Honduras, Mexico, and Panama in subtropical or tropical moist lowland forest and montane regions (Santos-Barrera *et al.* 2004) where it lives in cloud forests (Duellman 1970). It is active year-round, requiring it to choose habitats where it can maintain moisture through dry seasons. Unlike the tiny *Eleutherodactylus*, this relatively large 80 mm species lays an average of 158 eggs per clutch (Jungfer 1996), keeping them wet in the basin of a bromeliad or a tree hole. The female stays with her eggs, and when she feels the tadpoles swimming against her, she releases a second set of eggs that serve as nutrient sources for the tadpoles.

The branches that hold these bromeliads in a cloud forest are typically covered with bryophytes, so being adapted to sit among them is beneficial. The bryophytes are most likely important in providing both camouflage and in maintaining moisture. For some they might provide sites for eggs that are adapted to the terrestrial environment. And the bryophytes hold numerous arthropods that serve as potential food items.

Figure 21. *Anothea spinosa* (Spine-headed Tree Frog), shown here amid bryophytes on a tree at La Chinantla, Oaxaca, Mexico. It appears that looking like a leaf or bark is useful when bryophytes are sparse. Photo by Omar Hernandez-Ordoñez, with permission.

***Litoria serrata* (Green-eyed Treefrog, Hylidae)**

Litoria serrata (Figure 22-Figure 23) lives in northeastern Queensland, Australia. Ross Alford (pers. comm. 28 March 2011) states that this species looks quite inconspicuous when it rests on mosses, which it often does in its natural habitat. This is facilitated by its tubercles and its brown-grey-green coloring.

Figure 22. *Litoria serrata* in its brown and green camouflage form. Photo by Jean-Marc Hero, with permission.

Figure 23. *Litoria serrata* in its lichen/moss camouflage form. Note the fringe projections on the legs that help hold it in place on tree branches and trunks. Photo by Jean-Marc Hero, with permission.

***Ecnomiohyla miliaria* (Cope's Brown Treefrog, Hylidae)**

Ecnomiohyla miliaria (Figure 24) lives in rainforests in humid lowlands and premontane slopes from eastern Honduras and southeastern Nicaragua and central Colombia (Duellman 1970) to southeastern Costa Rica on the Atlantic slope (20-900 m) and on the Pacific slope in humid premontane areas of southwestern Costa Rica and western Panama at 600-1300 m asl (Frost 2011).

Figure 24. *Ecnomiohyla miliaria*, demonstrating the flattened position that helps to make it inconspicuous. Its coloration helps to hide it among the lichens and mosses. Its large toes and fringes on the legs help it to clasp its arboreal substrate. Photo by Josiah H. Townsend, through Creative Commons.

Its actual habitat is unknown, although its thick, roughened skin, large toe suction pads, and fringes on the legs, as well as its ability to flatten its body, suggest that it is an arboreal species (Schoville 2000). Its coloration and tubercles suggest that it would blend well among bryophytes. It is listed as vulnerable because it is distributed over less than 20,000 km², its distribution is severely fragmented, and the extent and quality of its forest habitat in Nicaragua, Costa Rica, and Panama are in continued decline (IUCN 2010).

***Smilisca sila* (Panama Cross-banded Treefrog, Hylidae)**

This Panama Cross-banded Treefrog lives in Colombia, Costa Rica, and Panama in subtropical or tropical moist lowland forests, rivers, and freshwater marshes (Frost 2011). These include mossy habitats, where it often traverses the bryophytes on the soil and trees (Figure 27). But its actual use of these substrata and their importance to its habitat have not been investigated. Habitat loss threatens its existence, so it is important to understand if this if bryophytes are a vital part of its niche.

Mantellidae

***Spinomantis aglavei* (Anamalozoatra Madagascar Frog, Mantellidae)**

Spinomantis aglavei (Figure 25-Figure 26) is known from the Andringitra Mountains and eastern forests of Madagascar (Frost 2011). It occurs from sea level to 1500 m asl in slow-flowing streams, swamps, and fast-flowing streams of the rainforest, but does not tolerate secondary forests (Nussbaum & Vallan 2008). It is medium-sized (40-50 mm), greenish brown, and resembles tree bark with epiphytes (Glaw & Vences 2007). Its calls are emitted from the canopy, 1.5-3 m above ground, necessitating its travel up the tree where its coloration serves as camouflage. It deposits 30-38 eggs on leaves above streams and the hatching tadpoles drop into the streams to complete their development. Adults rest on the tree trunks during the day, relying on their cryptic coloration and skin fringes to hide them from harm. It is listed as a species of least concern because it is widely distributed and presumed to have a large population (IUCN 2010). It is likely that other species in this genus also use mosses (Figure 27).

Figure 25. *Spinomantis aglavei*, showing the large toe suction pads and leg fringes typical of frogs living high in trees. Photo by Jörn Köhler, with permission.

Cloud Forests and Other Mossy Habitats

As I worked on this chapter, I discovered an interesting co-incidence that may actually reveal evolutionary adaptations. Based on concerns by an anuran systematist who was not accustomed to seeing my included taxa arranged in non-phylogenetic order, I rearranged

everything to a semblance of their current phylogenetic positions. I later decided this did not accomplish the ecological purpose of the book and began grouping the stories by habitat. By the time I finished the frogs and toads and was wrapping up the **Hylidae**, I realized that this chapter was mostly in habitat order already. Hence, as we end the discussion of the **Hylidae** and their close relatives, which are mostly tree-dwellers, (arboreal) we begin a group of families associated with bryophytes on the ground, rocks, or low branches (<2 m), but in "mossy" habitats they occur on trees as well. Note that I refer to bryophytes here and not just mosses because I believe that liverworts are often the substrate as well. However, most folks studying anurans are not bryophyte taxonomists and do not take note of the distinction, hence, I suspect, grouping the leafy liverworts into the broad category of mosses. Thus, as you read "mosses" below, keep in mind that they may include liverworts.

In tropical cloud forests, biodiversity can be high, but many of these habitats remain unexplored (Tennesen 1998). Many of the species are known from only one or two collections, and information on their biology and ecological preferences is extremely limited.

Cape Horn, South America

In her visit to the Cape Horn area, Blanka Shaw observed frogs among the very mossy habitats there (Figure 28-Figure 30). It's too bad we don't have joint herpetological and bryological field trips so that we can describe the habitats of these frogs more completely and so bryologists can be more familiar with the roles that bryophytes play in many mossy ecosystems.

Figure 28. Habitat for small frogs among liverworts in *Nothofagus betuloides* forest at Fjord Agostini, Provincia Magallanes, Chile. Photo by Blanka Shaw, with permission.

Microhylidae

The Microhylidae is a large family in the tropics and spans both eastern and western hemispheres. The species frequent mossy forests, among other habitats.

Albericus valkuriarum (Microhylidae)

Albericus valkuriarum inhabits the mid-montane rainforest and forest edge (Richards & Allison 2004) above 2000 m asl in Papua New Guinea (Frost 2011). Habitat degradation usually results in its disappearance (Richards & Allison 2004). Its breeding is unknown, but Richards and Allison suggest that it probably lays its eggs on the ground or in mosses on tree trunks. Richards and Zweifel (2004) make a similar statement about *Albericus jafniri*.

Cophixalus (Rainforest Frog, Microhylidae)

With a name like **Microhylidae**, one would expect the tiny members of this family to be among the bryophyte fauna, taking advantage of the bryophyte moisture buffering to conserve moisture in the tiny animals with their large surface area to volume ratio.

Cophixalus sphagnicola lives in moss and leaf litter (Zweifel & Allison 1982; Kraus & Allison 2000) in very mossy rainforests near Wau, Morobe Province, Papua New Guinea. In Australia, *Cophixalus ornatus* (Figure 29) is an **arboreal** (tree-dwelling) frog that lives under logs and leaf litter in its New Guinea rainforest home. However, it often lays its eggs in moss (Figure 30) (Online Field Guide: Ornate Nursery Frog; Hoskin 2004). In one observation in Australia, the male attending the eggs began moving them when disturbed (Hoskin 2004). However, before moving them, he consumed some of them, then moved about half of those remaining to a more moist location. Those left behind failed to hatch. The male attendants apparently feed on ants that threaten survival of the eggs. The clutch size of this species is the largest of any known for Australian microhylids, with up to 22 eggs recorded.

Figure 29. *Cophixalus ornatus*, a species wherein some females lay their eggs among mosses. The male is shown here in calling mode with an inflated vocal sac. Its relative, *Cophixalus sphagnicola*, lives among the mosses. Photo by Jean-Marc Hero, with permission.

Figure 30. Leafy liverwort *Lepicolea* on bole at Tierra del Fuego, Peninsula Edwards, Cape Horn, Chile. This dense cover of epiphytic bryophytes provides ideal habitat where small frogs can hide. Photo by Blanka Shaw, with permission.

***Choerophryne* (Microhylidae)**

Species of *Choerophryne* (Torricelli Mountain Frogs), a genus endemic to New Guinea, live on the forest floor and on leaves of shrubs, but also among mosses on steep rocky cliff faces, where they can be heard calling (Kraus & Allison 2001).

***Dyscophus guineti* (Sambava Tomato Frog, Microhylidae)**

Dyscophus guineti (Figure 31-Figure 32) is broadly distributed beside slow-moving streams in the eastern rainforest belt of Madagascar from 150 to 900 m asl (Nussbaum *et al.* 2008). This is a very secretive species, making it difficult to locate. These are somewhat easier to find at night when they travel about on the forest floor. They lay hundreds of sticky eggs that are deposited in ponds (Glaw & Vences 2007), rendering sharp contrast to the single-digit egg clutches of terrestrial egg-layers.

Evans and Brodie (1994) used this frog (and others) in experiments to determine the ability of the surface secretions to slow down predators by creating a glue. But for our purposes, this is more interesting because these secretions make the frog sticky, permitting it to be a dispersal agent of bryophytes. In their discussion of the adhesive strength of these secretions, Evans and Brodie (1994) stated that they first washed the amphibians in their study to remove soil, debris, mosses, and other adhering

substances. In this experiment, *Dyscophus antongilii* and *D. guineti* had the strongest glue among the eleven amphibians tested. The Common Garter Snake, *Thamnophis sirtalis*, was able to free itself from secretions by *Dyscophus* in 7-39 seconds, a sufficient time for the frog to achieve some distance from its predator.

In an email discussion with Butch Brodie, he stated that he had not paid attention to bryophyte adherence in the field; the experiments were in the lab. But this sticky surface can indeed glue substances to the frogs, permitting such things as bryophytes to travel with the frog and potentially get dropped off elsewhere (see image of *Ceuthomantis smaragdinus*, Figure 37). In my garden room, my Green Frog (*Lithobates clamitans*) was usually covered with bird seed shells because it spent much time under the bird feeder where fermenting seed shells nourished fruit flies.

Figure 31. *Dyscophus guineti* (Sambava Tomato Frog) male showing its duller coloration compared to the female. Photo by Franco Andreone, through Wikimedia Commons.

Figure 32. *Dyscophus guineti* female peering out from a seclusive spot among bryophytes. Photo by Tim Vickers, through Public Domain.

While getting these secretions on the belly of a snake in a place where it might be glued down seems a bit of a stretch, these secretions can be useful tactics against some animals. When encountering these frogs, the Lesser Hedgehog Tenrec, a mammal (*Echinops telfairi*) got its lips glued together and one eye and its toes were stuck together for the full thirty minutes of the trial (Evans & Brodie 1994). Furthermore, contact with the secretion caused the tenrec to turn in circles, snuffling and salivating profusely and rubbing the substrate with its head.

It appears that part of the strange behavior that permits *Dyscophus guineti* to escape predators could be the result of a trypsin inhibitor in the skin secretions (Conlon & Kim 2002). This differs from the α -helical antimicrobial peptides used by many frogs as a defense strategy, so Conlon and Kim speculated that it may be part of an alternative strategy of defense against microorganisms. But could it be part of a strategy against predators?

***Platypelis grandis* (Boulenger's Giant Treefrog, Microhylidae)**

Platypelis grandis (Figure 33) lives in eastern and northwestern Madagascar (Frost 2011). Its habitat is subtropical or tropical moist lowland forests and moist montanes where it is threatened by habitat loss. It is usually arboreal, although it is occasionally found on the ground (IUCN 2010). It needs mature forest and breeds in tree holes. Its coloration and tubercles provide camouflage that help to protect it as it climbs on tree trunks and branches.

Figure 33. *Platypelis grandis* on tree bark with bryophytes and lichens. Photo by Jörn Köhler, with permission.

***Hypopachus barberi* (Barber's Sheep Frog, Microhylidae)**

Hypopachus barberi (Figure 34) lives at 1470-2070 asl in the tropical countries of El Salvador, Guatemala, Honduras, and Mexico (Frost 2011). Its limited distribution is threatened by habitat loss in its native habitats of subtropical and tropical moist montane areas and freshwater marshes, although it is also able to live in plantations and rural gardens (Wikipedia 2011b).

Figure 34. *Hypopachus barberi* on a bed of moss where it is able to maintain hydration. Photos by Josiah Townsend, through Wikimedia Commons.

Figure 35. *Hypopachus barberi* from Guisayote Honduras on a bed of moss where it is able to maintain hydration. Photos by Josiah Townsend, through Wikimedia Commons.

***Xenorhina* (Snouted Frog, Microhylidae)**

From the North Coast Ranges of Papua New Guinea, *Xenorhina arboricola* (Figure 36) is unique among members of *Xenorhina* there in being **arboreal** (tree-dwelling) (Allison & Kraus 2000). It lives among leaf litter collected in *Asplenium* (bird's nest fern) and in the mosses that surround the trees and epiphytes. Allison and Kraus found one frog guarding a clutch of 11 eggs that were "connected together by a single filament into a pearl-like string." *Xenorhina zweifeli* (formerly *Xenobatrachus zweifeli*) lives in the same North Coast range, where trees are covered with mosses (Kraus & Allison 2002). Like many of the frogs in that area, the extent of its use of mosses is unknown.

Ceuthomantidae

Ceuthomantis duellmani

New records of tiny, moss-dwelling frogs are common in the less-explored portions of the world. In 2010, Barrio-Amorós described a new species of *Ceuthomantis* from Sarisariñama Tepui, southern Venezuela. This species occurred in a dwarf forest that was completely covered by mosses and other epiphytes. *Ceuthomantis duellmani* called from within holes and hiding places in tree buttresses, undoubtedly taking advantage of the mosses as cover. It would be interesting to determine the density of these frogs within the moss mats during the daytime when moisture may be a problem elsewhere.

Figure 36. *Xenorhina arboricola* from New Guinea, a species that often lives among epiphytic mosses. Photo from Bishop Museum, with permission from Barbara Kennedy.

Ceuthomantis smaragdinus

Ceuthomantis smaragdinus (Figure 37) occurs at 1490-1540 m asl in Guyana (Heinicke *et al.* 2009). Its cloud forest habitat has broad-leafed trees up to 12 m tall, shrubs, and small tree ferns. These are covered with epiphytic bryophytes and bromeliads. Little is known about this frog, but it lives in a mossy habitat where it is likely to encounter bryophytes during its daily activities.

Figure 37. *Ceuthomantis smaragdinus* transporting what appear to be pieces of mosses. See discussion above on *Dyscophus guineti*. Photo by D. Bruce Means, through Public Domain.

Hemiphractidae

***Gastrotheca pacchamama* (Ayacucho Marsupial Frog, Hemiphractidae)**

Gastrotheca pacchamama (cf. Figure 38) is an endemic found along the Amazonian slopes of the Andes, known from three different areas: Machu Picchu, San Luis, and San Pedro in southern Peru (Frost 2011). It is known from 2000-3000 m asl. It is one of the **marsupial** frogs (direct-developing frogs that carry their developing eggs on their backs in a pouch until the eggs hatch) (Wikipedia 2015). The marsupial method in frogs is an adaptation to living in a terrestrial habitat. This species was found under rocks in wet grassland at Abra Tapuna in Peru (Duellman 1987). During the day, some of the males were calling from moss-covered talus. Presumably, the moss reduced the moisture loss and possibly provided camouflage.

Figure 38. Female *Gastrotheca cornuta*, showing eggs in pouches on her back. Photo © Danté Fenolio <www.anotheca.com>, with permission.

***Gastrotheca excubitor* (Abra Acanacu Marsupial Frog, Hemiphractidae)**

Gastrotheca excubitor (Figure 39) lives on the Amazonian slopes of the Andes in southern Peru at 2000-3000 m asl. It exhibits a green and brown pattern that would help make it less conspicuous among mosses, but there seems to be no verification that it lives among the mosses, where it may only be a casual visitor.

Figure 39. *Gastrotheca excubitor* on a bed of moss. The coloration would make this frog less conspicuous to its flying predators. Photo by Alessandro Catenazzi, with permission.

***Stefania* (Stefania Treefrogs, Hemiphractidae)**

There are a number of records of collections of *Stefania* from mossy habitats in the tropics and subtropics. *Stefania evansi* (Figure 40) occurs in Guyana in tropical and subtropical moist lowland forests or moist montane forests up to 1400 m asl and in rivers (Wikipedia 2010). It carries its eggs on its back, and likewise carries the tadpoles, hence providing parental care. In Guyana, MacCulloch and Lathrop (2002) found several species of *Stefania* at night, sitting on moss-covered branches 1-4 m above the ground. Others were found in bromeliads, and one was collected from a mossy tree trunk. At the summit of Cerro Autana, Estado Amazonas, Venezuela, Barrio-Amorós and Fuentes (2003) found *Stefania ginesi*, *S. satelles*, and *S. schuberti*, mossy inhabitants of the high summits of Tepui from 1750-2600 m. In addition to mossy habitats, these species occur along creeks, under rocks, and in bromeliads (*Brocchinia*) (Duellman & Hoogmoed 1984; Gorzula & Señaris 1998; Señaris *et al.* 1996).

Figure 40. *Stefania evansi* from Guyana carrying its eggs on its back. This is a strategy practiced by a number of arboreal frogs and permits them to move to places with sufficient moisture for the eggs. Photo by Philippe Kok, with permission.

Dendrobatidae

Oophaga pumilio (formerly *Dendrobates pumilio*) (Strawberry Poison-dart Frog, Dendrobatidae)

The Strawberry Poison Dart Frog is a small frog (17.5-22 mm) from Central America, where it lives in humid lowlands and premontane forest (Savage 2002; Wikipedia 2011c).

Frogs can be territorial over their personal patch of *Sphagnum* (or other substrate). The Strawberry Poison-dart Frog *Oophaga pumilio* (Figure 41-Figure 43) even exhibited dominance over intruders when it was placed into a new aquarium with the *Sphagnum* it had inhabited in its previous captive home (Figure 42; Baugh & Forester 1994), suggesting chemical markers were left in the moss. An earlier experiment (Forester & Wisnieski 1991) had demonstrated that, given a choice, these frogs exhibited a preference for their home aquarium, which had been lined with *Sphagnum* and contained a bromeliad. On Isla Colón, Bocas del Toro archipelago, Panama, this brightly colored frog can hide inconspicuously within the moss mat covering the trees (Sirota 2011). The males often use tree bases as calling places, likewise often being inconspicuous among the mosses (Pröhl & Ostrowski 2010).

Figure 41. The Strawberry Poison-dart Frog, *Oophaga pumilio* on a bed of *Selaginella*. Photo by Jason Folt, through Creative Commons.

Figure 42. Strawberry Poison-dart Frog, *Oophaga pumilio*, in a chamber with *Sphagnum* where it had been previously, showing aggression toward the newcomer frog. Photo by Don Forester, with permission.

Figure 43. Strawberry Poison-dart Frog, *Oophaga pumilio*, sitting on a tree trunk with bryophytes. Photo by John D. Willson, with permission.

The female Strawberry Poison-dart Frog deposits her tadpoles singly at each location and expends a great deal of energy to care for them (Savage, 2002; Wikipedia 2011c). She visits each tadpole every few days and deposits several of her unfertilized eggs to serve as food. This seems to be an essential food, as no other food form seems to work. The male contributes by transporting water in his **cloaca** (combined cavity used to release both excretory and genital products in amphibians, reptiles, fish, birds, and a few other groups) and watering the eggs to keep them hydrated (Wikipedia 2011c). Even so, success of the tadpoles is only 5-12%. The tadpoles take about one month to develop into young adults, but remain near their water sources a few more days while they absorb what remains of their tails.

These day-active Strawberry Poison-dart Frogs derive their poison from their diet of beetles and ants, primarily formicine ants (Daly & Myers 1967). Thus, the frog is harmless if its diet is confined to other foods, such as that of the ones kept for pets (Wikipedia 2010c).

This species has 15-30 color morphs, as discussed in Chapter 14-1 on adaptations. Among these, the green morphs typically remain within the moss mats and spend less time foraging compared to the more active, brightly colored morphs that advertise their poisons with their warning coloration (Pröhl & Ostrowski 2010).

Phylllobates (Poison-arrow Frog, Dendrobatidae)

Other wet forest frogs that may spend some of their time on or in mosses are even more poisonous [*Phylllobates terribilis* (Golden Poison Frog; Figure 44-Figure 45), *P. bicolor*, *P. aurotaenia*] (Dumbacher *et al.* 2000). Among these, *P. terribilis* (Figure 44) is the most poisonous; natives that use poison darts need only touch a dart to this frog to make it poisonous for a year! (Wikipedia: Golden Poison Frog 2011). Even touching the frog can be lethal for humans (Daly & Witkop 1971; Wikipedia: Golden Poison Frog 2011).

Figure 44. *Phyllobates terribilis*, a very poisonous tree frog that has been used to make poison darts. Photo by Milan Kořinek, with permission.

Phyllobates terribilis lives in rainforests with 5 m or more rainfall! (Wikimedia 2011a). They occur at 100-200 m asl where the temperature is at least 26°C and relative humidity 80-90%. A large portion of the diet consists of ground-dwelling ants in the genera *Brachymyrmex* and *Paratrechina*, contributing to their poisons. These frogs live in social groups of up to six individuals, perhaps protecting each other through their severe poisons. Surely only one would be eaten.

Figure 45. *Phyllobates terribilis* from the Pacific Coast of Colombia showing a color morph that serves as a warning color. Photo by Wilfried Berns, through Wikimedia Commons.

***Silverstoneia flotalator* (Rainforest Rocket Frog, Dendrobatidae)**

The tiny Rainforest Rocket Frog (Figure 46-Figure 48) lives in lowland rainforests and semideciduous forests in Panama and Costa Rica at elevations of 10-865 m asl. It is diurnal and hides among the leaf litter, but must often traverse bryophyte-covered areas to move around. The adults tend to hang out on the rocky sections of forest streams, but they deposit their eggs in leaf litter (Solís *et al.* 2004). The males transport the hatchling tadpoles to the streams where these young develop into adults (Figure 48).

Leptodactylidae

This was once a much larger family that included the huge genus *Eleutherodactylus* (now in Eleutherodactylidae). Current thinking has divided the family and its largest genus.

Within the Leptodactylidae, some members make foam nests for their eggs, an adaptation to terrestrial life. Tadpoles remain in this frothy mass without eating, not exiting until they have completed metamorphosis. Their **development is direct** and they hatch into miniature frogs. That is, they have no tadpole stage.

In Brazil, the Marbled Tropical Bullfrog, *Leptodactylus marmoratus* (Leptodactylidae; Figure 49),

used mosses as cover for a foam nest on a road cut (Wassersug & Heyer 1988). However, nothing else is known that relates this frog to mosses (Mauro Teixeira pers. comm. 8 February 2009).

Figure 49. The Marbled Tropical Bullfrog, *Leptodactylus marmoratus*, a frog known to nest under mosses. Photo © Mauro Teixeira Jr, with permission.

Eleutherodactylidae

This family lives in the tropics and subtropics of the western hemisphere. The genus *Eleutherodactylus* (Robber Frogs, Figure 50; **Eleutherodactylidae**) was the largest genus of frogs. However, many of the species have been placed in other genera and some in other families. It is interesting to see how many of these have gone back to the generic distinctions recognized in the 1800's. Our genetic information seems to have taken us full circle in many cases. What wonderful powers of observation those early herpetologists must have had!

Figure 50. *Eleutherodactylus limbatus* amid lichens and mosses on a tree branch at Gran Piedra, Cuba. Photo by Ariel Rodriguez, for educational use.

This family abounds from the ground to the treetops. The tiny size of the members of Eleutherodactylidae permits these species to live among mosses, especially in the canopy and on tree trunks. Some call from a perch on mosses (Figure 51). Many more may exist there unknown because many surveys don't seem to include searching among the bryophytes. Others seem only to lump the bryophytes into vegetation. When the habitat is a cloud forest, it is usually safe to assume that bryophytes are abundant.

Figure 51. *Eleutherodactylus richmondi* calling from a perch on mosses. Photo by Luis J. Villanueva-Rivera, with permission.

The Burrowing Frog (*Eleutherodactylus parapelates*, **Eleutherodactylidae**, formerly in Leptodactylidae), despite being a ground frog, was calling from within a large moss clump at 3 m high in a tree at the Massif de la Hotte of the Haitian Tiburon Peninsula, southwestern Haiti (Hedges & Thomas 1987).

Eleutherodactylus dolomedes (Figure 52) (Hedge's Robber Frog, Hispaniolan Ventriloquial Frog), likewise from Haiti, is difficult to locate, even when it is calling. It is a ventriloquist! Its 7-note call sounds a bit like a chirping bird and the ability of this frog to make it sound like the call is coming from somewhere else makes it difficult to locate the frog; its original finders spent an hour locating one calling specimen (Hedges & Thomas 1992).

Figure 52. *Eleutherodactylus dolomedes*, the Hispaniolan Ventriloquial Frog, sitting on a fern frond in the mountains of Haiti. Photo from mongabay.com © Robin MooreLCP, for educational use.

It is endemic to the high-elevation (1120 m asl) cloud forest of Massif de la Hotte, Haiti (Frost 2011) and had not been seen since 1991. But it was discovered again in 2010 in the mountains of southern Haiti (Burton 2011). Nevertheless, it is critically endangered. The IUCN report projects a population decline of greater than 80% over the next ten years because of the severe degradation of habitat in Haiti (IUCN 2010). Only 2% of the rainforest there remains.

While it has been recorded from forest edge, this is probably not suitable habitat (IUCN 2010). Eggs are laid on the ground, and it breeds by direct development.

The arguably smallest frog in the world (males 9.6-9.8 mm long, females 10.5 mm long) (Endangered Species

International: The World's Smallest Frog 2011), *Eleutherodactylus iberia* (Figure 53), was first discovered in 1996 in Monte Iberia, Cuba (Wikipedia 2010a). It seems to be the smallest known frog in the Northern Hemisphere, whereas the smallest in the Southern Hemisphere is the Gold Frog [*Brachycephalus didactylus* (formerly *Psyllophryne didactyla*)] from Brazil (Allaboutfrogs.org 2011). Together they are tied for smallest frog and smallest tetrapod in the world. *Brachycephalus didactylus* may actually be smaller, with known males averaging 8-9 mm (Estrada & Hedges 1996).

Figure 53. *Eleutherodactylus iberia*, the smallest known frog in the northern hemisphere, on a leaf. Photograph by Thomas Brown, through Wikimedia Commons.

Eleutherodactylus iberia (Figure 53) lives on the forest floor and requires a high humidity, so it stands to reason that habitats (rainforests) suitable for bryophytes in Cuba are also suitable for this frog (Allaboutfrogs.org). Only two populations are known, both in Holguín Province of eastern Cuba at elevations less than 600 m (Wikipedia 2010), making it critically endangered (Endangered Species International: The World's Smallest Frog 2011). One female has been found guarding a single egg. A small clutch size is common in the tiny frogs (Estrada & Hedges 1996), permitting more energy to be stored in each. It appears that the female of *Eleutherodactylus iberia* guards the eggs and may care for the young. Although the young are unknown, Estrada and Hedges (1996) suggest that the young may be as small as those in *Stumpffia* (*Microhylidae*), *i.e.* only 3 mm long!

The saga of this frog and its adaptations don't end with being small and inconspicuous. Did you wonder why it has the coloration of a bee or wasp (and a number of other poisonous beings)? This condition, known as **aposematism**, is the familiar warning coloration that a number of poisonous, often unrelated, organisms share. Once a predator learns to recognize the color mix through a bad experience, it will avoid other potential prey items with that same color mix, just as we avoid several kinds of bees by recognizing the array of black mixed with yellow, orange, or red. It is noteworthy that this color combination prevails from tiny mites to large snakes. But some animals are **mimics**, displaying the colors without the poison or bad taste, thus taking advantage of the bad experiences with the truly nasty ones. These mimics must be in smaller numbers

than their **models** (the ones with the real poison/bad taste) so that the predator is more likely to encounter the **model** first. Thus, the black, yellow, and white *Eleutherodactylus iberia* (Figure 53) could be a nasty model or an edible mimic.

A slight alkaloid odor among the collected *E. iberia* (Figure 53) frogs led Rodriguez *et al.* (2010) to test them and their close relatives in the area for poisonous alkaloids. They discovered that the skin of these frogs is endowed with a variety of poisonous alkaloids. They hypothesized that the poisons might originate from their diet, a convenient way to save your own energy and let someone else make your poisons. Indeed, they found that the diet consisted primarily of mites, ants, and springtails (*Collembola*). Among the 62 prey items in the gut, 71% were mites. Mites are known to contribute toxins used by other amphibians as skin toxins.

It appears that miniaturization in many of these frogs has been accompanied by a diet where mites play a major role (Caldwell 1996; Vences *et al.* 1998; Saporito *et al.* 2004; Rodriguez *et al.* 2010). Becoming smaller means the food items must also be smaller, and a smaller tongue can't reach as far to catch things. This switch to mites has resulted in the source of the sequestered alkaloids. Given the primary sources of food for *E. iberia* (Figure 53) – mites, ants, *Collembola* – one would expect these frogs to find bryophytes a particularly suitable foraging location because bryophytes often serve as a habitat for large numbers of these food items. Hence, tiny frogs most likely eat tiny mites that live among the tiniest of plants, the bryophytes.

This still very large genus of very tiny frogs in the **Eleutherodactylidae** extends from the ground to the treetops. The morphological variations also change through this vertical range, as shown by the ground to treetop array of *Eleutherodactylus unicolor unicolor*, *Eleutherodactylus wightmanae*, *E. brittoni*, *E. richmondi*, *E. locustus*, *E. antillensis*, *E. portoricensis*, *E. coqui*, *E. cochranae*, *E. gryllus*, and *E. hedricki* (Figure 54), with toe pads becoming larger as the height in the tree increases (pers. comm. Father Alejandro Sanchez, 24 February 2011). Although the moss often becomes dry and brittle, it serves as a suitably moist site for eggs in their season in the cloud forest.

In the Luquillo Experimental Forest of Puerto Rico, the well-known Coqui (*Eleutherodactylus coqui*; Figure 55-Figure 59) does a daily migration that must itself be a significant feat as they attempt to avoid predation by the whip scorpion *Phrynosoma gervaisii* (= *Phrynosoma palmatus*) (Formanowicz *et al.* 1981), tarantulas, snakes, screech owls, and other birds (Stewart 1985). At dusk the Coqui climb the tree trunks to search for food in the canopy. Often within minutes of peak climbing, the arachnid predators make their appearance. During this time, most adult male **Coqui** remain on understory call sites, but the others typically engage in this migration. At daybreak, the frogs return to the ground quickly by parachuting downward. A dry atmosphere reduces the number of frogs making this nightly migration. It appears that mosses contribute to the choice of climbing trees: those with more than 10 climbing frogs had either rough bark or the bark was covered with mosses. Could this correlation be due to hiding advantages, greater moisture, or both?

The Coqui, in turn, contribute to the nutrient dynamics of the forest. Beard *et al.* (2002) experimented with these frogs by using cubic meter enclosures and exclosures of the frogs. When Coqui were excluded, leaf washes had 83% less dissolved organic C, 71% less NH_4^+ , 33% less NO_3^- , 60% less dissolved organic N, and 60-100% less Ca, Fe, Mg, Mn, P, K, and Zn. Exclusion of the Coqui had no

effect on the foliar chemistry of plants transplanted into the exclosures. However, it did decrease nutrients available from decomposing leaf litter by 12% for K and 14% for P. C:N ratios increased by 13% in the litter. These changes appear to result from Coqui waste products, resulting from the conversion of their insect diet into nutrient forms that are more accessible for microbes and plants.

Figure 54. Toe pad sizes as they increase from ground level (top left) to treetop (bottom right) in the *Eleutherodactylus*, a genus whose members commonly lay their eggs among the bryophytes.

Figure 59. *Eleutherodactylus coqui* eggs with a fully formed frog emerging from an egg. Photo by Father Alejandro Sanchez, with permission.

In a different Puerto Rican study, Drewry and Rand (1953) reported members of *Eleutherodactylus* (*sensu lato*; Figure 60-Figure 61) in high elevation mossy forests and the upper montane forest just below it. In Haiti, *Eleutherodactylus limbensis* spent the night on the wall of a ravine where there was a lush growth of moss (Lynn 1958).

Eleutherodactylus longipes (Figure 60) is endemic to Mexico. Its natural habitats are temperate, subtropical, or tropical dry pine-oak forests, subtropical or tropical moist montanes, and caves from 650-2000 m asl (Santos-Barrera & Canseco-Márquez 2010). It is threatened by habitat loss.

Eleutherodactylus gryllus (Cricket Coqui) is endemic to Puerto Rico. It lives in forest edge habitats or openings of subtropical or tropical moist lowland forests and subtropical or tropical moist montanes at 300-1182 m asl (Hedges & Rios-López 2008). During the day it hides in bromeliads or under mosses or rocks. Males call from bromeliads, most intensely at dawn (Villanueva-Rivera 2005), and eggs are laid in bromeliad basins, but development is direct into hatching froglets (Hedges & Rios-López 2008).

Figure 60. *Eleutherodactylus longipes* from ca. 2590 m on the N side of Cerro Pena Nevada near the community of Dulces Nombres in SE Nuevo Leon, Mexico (pers. comm. from Timothy Burkhardt, 17 February 2011). This frog may be taking advantage of the damp moss while blending in with the white lichens. Photo by Timothy Burkhardt <www.mexico-herps.com>, with permission.

Figure 61. *Eleutherodactylus gryllus* (Cricket Coqui) from El Yunque National Forest, Puerto Rico, sitting on a leaf covered with epiphyllous bryophytes. Such leaves are likely to maintain higher moisture levels than leaves without epiphyllous bryophytes. And these epiphylls are almost certainly liverworts. Photo by Luis J. Villanueva-Rivera, with permission.

To many people, *Eleutherodactylus planirostris* (Greenhouse Frog; Figure 62) is best known as an alien in greenhouses, where it was introduced in potted plants. *Eleutherodactylus planirostris* occurs in Cuba, the Bahamas, Grand Cayman, and Cayman Brac (AmphibiaWeb 2011). It has been introduced to Jamaica, and to Florida, Alabama, Georgia (Winn *et al.* 1999), Louisiana (Platt & Fontenot 1993), and Hawaii (Kraus *et al.* 1999), USA, and to Guam (Christy *et al.* 2007). Its altitudinal range is from sea level up to 727 m asl (AmphibiaWeb: *Eleutherodactylus planirostris* 2011).

Figure 62. *Eleutherodactylus planirostris* (Greenhouse Frog) on moss. Photo by Brian Gratwicke, through Creative Commons.

In Gainesville, Florida, USA, males of *E. planirostris* (Figure 62) call from April–September; breeding occurs under moist cover from late May to late September, peaking in July (Carr 1940; Goin 1947). Its 3–16 eggs are laid in moist depressions in the earth or in moist debris (Goin 1947; Lazell 1989; Bartlett & Bartlett 1999). These experience direct development and hatch as miniature froglets (Lazell 1989; Bartlett & Bartlett 1999) in June in Gainesville (Goin 1947) and from late May to early June in Key West, Florida (Lazell 1989). The adults are secretive

and nocturnal except on warm, overcast, or rainy days (Carr 1940; Bartlett & Bartlett 1999). Their food depends on availability. In Florida they eat ants, beetles, and roaches, as well as other types of small invertebrates (Goin 1947; Duellman & Schwartz 1958; Lazell 1989). In Jamaica, they did not eat roaches, but instead ate numerous ants, mites, spiders, and harvestmen (Stewart 1979). In Hawaii, with densities in places of 12,500 frogs ha⁻¹, they have been known to consume up 129,000 invertebrates ha⁻¹ night⁻¹ (Olson *et al.* 2011).

Diasporus hylaeformis (Pico Blanco Robber Frog; Figure 63), previously known as *Eleutherodactylus hylaeformis*, is a nocturnal species that lives at 1,500–2,500 m, where it can be found among the mosses and low vegetation in its native Costa Rica and Panama (Savage 2002). It includes mosses as egg-laying sites. Unlike most of the small bryophyte-dwelling frogs in the tropics, this one is relatively abundant and not endangered.

Summary

Little seems to be known about treefrogs and their use of bryophytes, but it seems likely that bryophytes provide moisture and safe sites in an otherwise dry arboreal habitat. Life cycles are modified to accommodate the terrestrial habitat, including caring for eggs, carrying the eggs, supplying new eggs to tadpoles for food, and emergence of fully formed frogs from the eggs. Many of the tree frogs are tiny (including the smallest tetrapods) and produce only one to a few large eggs. Most have cryptic coloration that makes them nearly invisible among the bryophytes. Tubercles seem to aid some in camouflage. Some, however, have bright colors that advertise that they are poisonous (aposematism), a result of their diet of ants, beetles, and/or mites that live on the ground or among the bryophytes.

Arboreal frogs have special behavioral and morphological adaptations to their lofty habitat. Females may sit on their eggs or carry them on their backs. Some lay eggs on low leaves where the young can fall into the river. Toe pads in *Eleutherodactylus*, and probably other genera, increase in size as the habitat becomes more arboreal.

Cloud forests and other mossy habitats, especially in the tropics, house a large number of species of small to medium frogs. Some frogs hide deep within mosses to make their mating calls. Many lay their eggs on mosses. Like the treefrogs, these are poorly known and their relationships to mosses are often just speculation. They, like the treefrogs, have adaptations in their life cycles that conserve moisture for the eggs and tadpoles, including live birth of froglets or carrying tadpoles on their backs.

Acknowledgments

Twan Leenders was helpful in providing some of our needed images. J. D. Willson gave us full access to his wonderful website with numerous species from around the world. Johannes Foufopoulos provided us with images and additional information on his finds in New Guinea. Filipe Osorio took pictures of frog eggs on mosses and sent them to us. Don Forester provided us with the story and images about chemical recognition of "home." Father Alejandro J. Sánchez Muñoz was generous in allowing us to use many of his images that were not available elsewhere. We are thankful for all the people who don't know us but who graciously gave us permission to use their images (see credits under the images). And thank you to the many people who put their images in the public domain for use without needing permission.

CHAPTER 14-5

ANURANS: CENTRAL AND SOUTH AMERICAN MOSSY HABITATS

Figure 1. Waterfalls at Quebrada Cataguana Honduras, home to many disappearing anurans. Photo by Josiah Townsend, with permission.

Central and South American mossy habitats provide good places for tiny frogs. Some of these frogs are primarily stream dwellers that go ashore to feed as adults (Figure 1). Others live on the forest floor of mossy forests, or in the Páramo. But the most elusive are the ones that live in trees where mosses provide cover and moisture, as well as protection from UV light.

Strabomantidae

The giant genus *Eleutherodactylus* has been divided not only into a number of smaller genera, but also into several families. One of these is the **Strabomantidae**.

Bryophryne abramalagae (Strabomantidae)

Bryophryne species inhabit the cloud forests in Peru, on the eastern slopes of the Andes (Leandro 2011). *Bryophryne abramalagae* is primarily known from its type locality of Abra Málaga at 4000 m asl, in the puna, Provincia de La Convención, Región Cusco, Peru (Lehr & Catenazzi 2010). The males call from inside moss, maintaining their cover during this vulnerable time. The mosses also provide a reproductive site for members of the genus.

Bryophryne flammiventris (Strabomantidae)

This species occurs along the road between Vilcabamba and Pampaconas, Provincia de La Convención, Región Cusco, Peru, at 3800-3850 m asl (Lehr & Catenazzi 2010). There is some suggestion that *B. flammiventris* was adapted to the habitat by having coloration on the ventral side similar to that of the tree roots where the mosses were providing habitats. The male calls, made at 10:00-16:00 hours, were made from within the moss clumps and could be heard on the other side of the valley.

Bryophryne bustamantei (Strabomantidae)

Bryophryne bustamantei (Figure 2) inhabits the transitional zone from the cloud forest to the humid grassy puna in the Umasbamba Valley, Provincia de La Convención, Peru, at 3555-3950 m asl (Lehr & Catenazzi 2008; Frost 2011). The frogs are active in both the rainy and dry seasons, living under stones, in bushes and grass, and under mosses (Chaparro *et al.* 2007; Lehr & Catenazzi 2008). They lack a tympanum, separating them from several members of the genus (Lehr & Catenazzi 2008). Despite the lack of this special hearing organ, the males

call from bushes (Chaparro 2008), suggesting they are still able to hear. Like many other terrestrial anurans, their development is presumed to be direct, lacking a tadpole stage. The species is endangered due to encroachment of human activities in its narrow habitat range.

Figure 2. *Bryophryne bustamantei* on a leaf. Note the absence of a tympanum. Photo by Alessandro Catenazzi, with permission.

***Bryophryne zonalis* (Strabomantidae)**

Bryophryne zonalis (Figure 3) lives in the upper Marcapata valley, at elevations of 3129-3285 m asl along the road from Huallahuala to Quincemil, Quispicanchis, Peru (Frost 2011). This frog lays her eggs in moist habitats such as under mosses (Leandro 2011). The embryos do not become tadpoles, but rather become minute terrestrial froglets. The female remains nearby the eggs to tend them, protecting them from predation and desiccation. The 18-25 eggs are only 4-5 mm in diameter, with the hatchlings measuring about 5 mm snout to vent.

Figure 3. *Bryophryne zonalis* on a leaf. Photo by Alessandro Catenazzi, with permission.

***Bryophryne gymnotis* (Strabomantidae)**

Bryophryne gymnotis (Figure 4) is known only from the montane cloud forest in its type locality, San Luis, at 3272-3354 m asl, Provincia de La Convención, Región Cusco, Peru (IUCN 2013). Its habitat is mossy and it calls from mosses, like other members of its genus (Lehr &

Catenazzi 2010). Leandro (2011) reported that it is the only member of the genus with a tympanum. And like *B. zonalis*, the female tends the eggs, which hatch into froglets, often among mosses (Leandro 2011).

Figure 4. *Bryophryne gymnotis*. Photo by Alessandro Catenazzi, with permission.

***Bryophryne cophites* (formerly *Phrynopus cophites*) (Cuzco Andes Frog, Strabomantidae)**

In the species *Bryophryne cophites*, the name *cophites* means "deaf" and refers to the absence of the middle and external ear (tympanum) in this species (Figure 5), separating it from several other members of the genus.

Figure 5. *Bryophryne cophites* on bark, showing the absence of a tympanum. Photo by Tiffany Kosch, with permission.

The species is endemic to its type locality in the Páramo and elfin forest habitats on both north and south slopes of the Abra Acanacu on the northwestern end of the Cordillera Carabaya, Peru, at 3400-3450 m asl (Frost 2011). Mosses serve as a substrate for the eggs. Its narrow distribution and continuing decline of its Peruvian Andes habitat cause it to be classified as endangered (IUCN 2010).

Catenazzi *et al.* (2011) found that the introduced fungal pathogen *Batrachochytrium dendrobatidis* (see Chapter 14-1) caused **chytridiomycosis**, which accounted for a large portion of amphibian decline in the Andes of Peru, further endangering this species.

***Bryophryne hanssaueri* (Strabomantidae)**

The endemic species *Bryophryne hanssaueri* (Figure 6) is known only from the immediate vicinity of the type

locality (Acjanaco, Manu National Park, Paucartambo, Peru) at 3266-3430 m asl (Frost 2011). The female tends her eggs (Figure 7), which develop directly into froglets (Figure 8). It lives in mossy habitats but, like many of these tropical species, its use of the moss remains a matter of speculation.

Figure 6. *Bryophryne hanssaueri*, an endemic species from cloud forests in southeastern Peru. Photo by Alessandro Catenazzi, with permission.

Figure 7. *Bryophryne hanssaueri* female tending her eggs. Photo by Alessandro Catenazzi, with permission.

Figure 8. *Bryophryne hanssaueri* hatching froglet. Photo by Alessandro Catenazzi, with permission.

***Bryophryne nubilosus* (Strabomantidae)**

Bryophryne nubilosus (Figure 9) lives in the mossy montane cloud forest and montane scrub at 2350-3215 m asl in the vicinity of Esperanza, in the Cosñipata Valley, Provincia de Paucartambo, Región Cusco, Peru (Frost 2011). Its relationship to mosses needs to be verified, but it seems to be sitting on a liverwort in the picture by Alessandro Catenazzi (Figure 9).

Figure 9. *Bryophryne nubilosus*. Photo by Alessandro Catenazzi, with permission.

***Noblella pygmaea* (Noble's Pygmy Frog, Strabomantidae)**

Noble's Pygmy Frog (Figure 10) has already been discussed in Chapter 14-1. This tiny frog is known only from its type locality in the Cusco Region, Peru, 3100 m asl (Frost 2011). It has not yet been rated by the IUCN (2012), but it is certainly endangered with such a small distribution. However, its tiny size and presence among mosses (Lehr & Catenazzi 2009) suggest it might be more widespread but not yet detected.

Figure 10. *Noblella pygmaea* (Noble's Pygmy Frog), a tiny moss-dweller. Photo by Alessandro Catenazzi, with permission.

***Psychrophrynella* (formerly *Phrynopus*) (Andes Frogs, Strabomantidae)**

This genus has already been discussed because many of its species call from bryophytes, often from within the moss mat. The eggs are laid under mosses and stones, where they are seldom found. They presumably undergo direct development.

The **páramo** occurs at high elevations from about 2000 m asl (the upper forest line) to 5000 m (the permanent snow line), creating a uniquely harsh environment. In the páramo at Cotapata, Bolivia, members of *Psychrophrynella* (**Strabomantidae**), formerly members of *Phrynopis* live under stones or among the grasses and mosses (De la Riva 2007). For example, *P. condoriri* spends the day under stones in a humid area of the páramo that has abundant mosses; *P. illimani* lives at the border of the elfin forest and wet páramo where both the ground and rocks are covered with mosses; *P. katantika* was even found among mosses and ferns on old walls and ruins. Likewise at Cotapata, *P. guillei* calls from deep within moss clumps and *P. iani* calls from under stones and among mosses. But *P. iatamasi* stays in the forest floor mosses, calling from there during the day (Aguayo & Harvey 2001). This genus deposits its eggs under mosses and stones, but these are rarely found (De la Riva 2007). As noted earlier, the mosses provide cover for calling males, who call day or night or both.

Psychrophrynella kempffi (Figure 11) usually occurs among the mosses or under stones and logs of the cloud forest. The latter species calls with a short whistle and is difficult to locate (De la Riva 1992), perhaps because it is hidden by the mosses.

Figure 11. *Psychrophrynella kempffi*. Photo by Ignacio De la Riva, with permission.

***Psychrophrynella usurpator* (Strabomantidae)**

Psychrophrynella usurpator (Figure 12) is another tropical frog, known only from the vicinity of Abra Acjanacu Peru at 3270-3539 m asl, a high pass in the Cordillera de Paucartambo, which is the easternmost Andean range facing the Amazonian lowlands in Departamento Cusco, Peru (Frost 2011).

Figure 12. *Psychrophrynella usurpator* on a bed of mosses. Photo by Alessandro Catenazzi, with permission.

***Pristimantis* (South American Rain Frogs; Strabomantidae)**

If you do your searching in the daytime, you might miss some of the moss dwellers. At elevations of 2500-3275 m in the Cordillera Oriental of the central Peruvian Departamentos Huainuco, Junin and Pasco, Lehr *et al.* (2006) found *Pristimantis platydactylus* (formerly *Eleutherodactylus platydactylus*) (**Strabomantidae**) on low vegetation and moist moss at night. However, during the day they were under dry leaves on the ground or in terrestrial bromeliads. In western Ecuador, *Pristimantis quinquagesimus* (previously *Eleutherodactylus quinquagesimus*) has been seen at night on leaves and mossy branches less than 2 m above the ground in cloud forests between 2000 and 2700 m asl in Provincias Imbabura and Pichincha (Lynch & Trueb 1980). Many of these frogs are nocturnal, as witnessed by their night-time calling.

One adult female of *Pristimantis vanadise* (formerly *Eleutherodactylus vanadise*) (**Strabomantidae**) was captured on mosses on the walls of a creek canyon in the cloud forest of the mountains of Merida, western Venezuela (La Marca 1984). All the males and some juvenile females, on the other hand, were found among the litter on the forest floor, possibly including mosses, but not near the stream.

In Ecuador, *Pristimantis simonbolivari* (formerly *Eleutherodactylus simonbolivari*) spends the daytime under mosses on logs as well as in leaf litter and under rotten logs (Wiens & Coloma 1992). Near a small creek, *Pristimantis appendiculatus* (formerly *Eleutherodactylus appendiculatus*) (Figure 13) sits on moss-covered stems or exposed fern fronds at the edge of the road at night (Miyata 1980).

Figure 13. *Pristimantis appendiculatus* (Pacific Robber Frog) on a moss-covered tree trunk. Photo by William Duellman, courtesy of Biodiversity Institute, University of Kansas.

Some species rest on leaves that have **epiphylls** (plants living on leaves), including bryophytes, especially leafy liverworts in the **Lejeuneaceae**. The ability of epiphylls to hold moisture may provide a moist niche for some frogs. *Pristimantis ridens* (Figure 14) is a tiny frog that spends time on epiphyll-covered leaves in Costa Rica, Honduras, and Colombia from sea level to 1600 m asl (Solís *et al.* 2010a).

Figure 14. *Pristimantis ridens* with epiphylls on a palm leaf. Photo by Jason Folt, through Creative Commons.

Duellman and Hedges (2005) found *Pristimantis stictogaster* (formerly *Eleutherodactylus stictogaster*) on the western slopes of the Cordillera Yanachago in central Peru nestled under a moss on the ground. *Pristimantis aniptopalmatus* (formerly *Eleutherodactylus aniptopalmatus*) occurred at 2300-2600 m, also on the western slopes, where it is known only from under moss on tree trunks and under moss on the ground in the cloud forest.

The **Santa Cecilia Robber Frog** (*Pristimantis croceoinguinis*; Figure 15) is a nocturnal frog that lives in the eastern Amazonian lowland rainforest of Ecuador and central Peru (Panguana, 200 m asl, Huanuco, southern Peru; Pakitza, 350 m asl (Madre de Dios); and Tavara (Puno) (Castro *et al.* 2004b). In Colombia it occurs mostly in the Departamento de Putumayo at 400 m asl, but also is able to survive in the low cloud forest at the base of the Pastaza trench. Although its primary habitat is the lowland primary rainforest, it is able to invade low cloud forests as well. Typically, it occurs on low vegetation 0.5-1.5 m from the ground. Its development is unknown, but it is most likely directly into tiny frogs with no free-living tadpole stage.

Figure 15. *Pristimantis croceoinguinis* (Santa Cecilia Robber Frog) in a bed of mosses. Photo by Andreas Nöllert, with permission.

In Panama, *Pristimantis museosus* (Robber Frog; Figure 16-Figure 18) is a moss-dweller whose name (*museosus*) means mossy. Also named the Vanishing Frog, it is a moss mimic, with disruptive warts, green body, and disruptive patches of darker green and brown (Figure 16-Figure 17). I suspect it can vanish in plain view among the

bryophytes. It lives among low vegetation, including the mossy forest floor of humid montane forests (IUCN 2010) of the Cordillera Central of Panama at 700-1000 m asl (Frost 2011). Its egg deposition niche is unknown. This unique frog is on the IUCN endangered list due to a fragmented habitat and narrow distribution (IUCN 2010).

Figure 16. *Pristimantis museosus*, a Panamanian moss mimic. Photo by Justin Touchon, Smithsonian Tropical Research Institute, through Public Domain.

Figure 17. *Pristimantis museosus* on a twig, exposing the white ventral side. If this works as it is supposed to in birds, it would make the frog less conspicuous when viewed from below against a light-colored sky, while maintaining camouflage above against moss-covered bark. Photo by Marcos Guerra, Smithsonian Tropical Research Institute, through public domain.

Figure 18. *Pristimantis museosus* head, showing the tubercles and color patterning that provide it with good camouflage among the bryophytes. Photo by Justin Touchon, Smithsonian Tropical Research Institute, through public domain.

Pristimantis nervicus (Figure 19) lives in extreme southeastern Costa Rica to eastern Panama, and central Colombia from 20 to 200 m asl (Savage 2002). It maintains its moisture by being night-active and living in primary humid lowland and secondary forest. Adults live under surface debris (presumably including bryophytes) and in leaf litter, often near or in caves and rocky streambanks. Its development is directly from egg to froglet.

Figure 19. *Pristimantis nervicus* among mosses (*Thuidium* sp.). Photo by Rafael Marquez, with permission.

Pristimantis gaigei (Fort Randolph Robber Frog; Figure 20) lives in drainage lowlands in extreme southeastern Costa Rica to Panama and central Colombia (Frost 2011) from 20-200 m asl (Savage 2002). This nocturnal species occupies humid lowland and secondary forests under surface debris and leaf litter near rocky stream banks where it is likely to encounter bryophytes.

Figure 20. *Pristimantis gaigei* (Fort Randolph Robber Frog). Photo by Esteban Alzate, through Creative Commons.

Pristimantis cerasinus (Limon Robber Frog; Figure 21-Figure 22) lives in Atlantic lowlands and premontane slopes of Nicaragua, Costa Rica, and Panama, western and central Panama, and northeastern Honduras at 19-1500 m asl (Savage 2002; Frost 2011). The adults live among the leaf litter in the daytime, but at night they roam among the vegetation, most likely including bryophytes (Pounds *et al.* 2004). They deposit their eggs on this low vegetation.

Figure 21. *Pristimantis cerasinus* (Limon Robber Frog). Is that a bryophyte or a fern under it? Photo by Jason Folt, through Creative Commons.

Figure 22. *Pristimantis cerasinus* (Limon Robber Frog). Photo by Brian Gratwicke, through Creative Commons.

Pristimantis bacchus (Wine Robber Frog; Figure 23) lives in Colombia at 1740-2300 m asl. This rare species was last seen in 2002 (Castro *et al.* 2004a). Its home among ground vegetation of cloud forests makes it difficult to locate. It is unlikely that it can avoid travelling among bryophytes in this habitat, but its further use is not known.

Figure 23. *Pristimantis bacchus* (Wine Robber Frog) on a thick moss bed. Photo by Esteban Alzate, through Creative Commons.

***Pristimantis mutabilis* (Strabomantidae) – A new kind of camouflage**

This unusual frog stumped its collectors. They found it among mosses in the Ecuadorian Andes and brought it back to the house in a cup (Quenqua 2015). It was unusual in having tubercles that helped it blend in with its mossy habitat (Figure 24). But when they next looked in the cup, the tubercles were gone (Figure 25) and they at first thought they had collected the wrong frog. But when they added some mosses to the cup, the tubercles returned.

Figure 24. *Pristimantis mutabilis* on mosses, showing the protruding tubercles. Photo by Tim Krynak, with permission.

Figure 25. *Pristimantis mutabilis* on a leaf, showing the disappearance of tubercles. Photo by Tim Krynak, with permission.

Ranging 17-23 mm, this frog was a new species and an interesting anomaly (Guayasamin 2015). But the researchers wondered if this anomaly occurred elsewhere. Hence, they re-examined *Pristimantis sobetes*, a member of a different species group. And there were the tubercles when the frog sat among mosses, but gone they were on other types of substrata. Might there be other moss mimics with this peculiar behavior?

Both species live in montane cloud forests that have abundant epiphytes and bryophytes.

***Yunganastes ashkapara* (Strabomantidae)**

In Peru and Bolivia, *Yunganastes ashkapara* (formerly *Eleutherodactylus ashkapara*; **Strabomantidae**; Figure 26) in the *Yunganastes fraudator* group is a **nocturnal arboreal** species that apparently finds some advantage other than moisture among the mosses. This

species calls from 2.5-10 m height during the rainy season, sitting inside mosses of the cloud forest canopy (Köhler 2000; Padial *et al.* 2007). Little information seems to be available on *Y. pluvicanorus* (Figure 27), but it appears to occupy similar mossy habitats.

Figure 26. *Yunganastes ashkapara* on a bed of mosses. This species calls from within thick moss mats. Photo by Jörn Köhler, with permission.

Craugastoridae

Other members of the former *Eleutherodactylus* genus, such as *Craugastor catalinae* (formerly *Eleutherodactylus catalinae*) (**Craugastoridae**) in Middle America (Panama to Mexico), may conserve their moisture when they sit at night on moss-covered boulders midstream where a rapid retreat into the water is possible (Campbell & Savage 2000).

Figure 27. *Yunganastes pluvicanorus* on a bed of mosses. This species calls from within thick moss mats. Photo by Jörn Köhler, with permission.

Craugastor lineatus (**Montane Robber Frog**; Figure 28) has been recorded from elevations of 300-2000 m asl on the Atlantic side from Guerrero, Oaxaca, and Chiapas, Mexico, southeast to Guatemala. On the Pacific side it occurs from eastern Oaxaca through Chiapas to the southwestern highlands of Guatemala, at elevations of 300-2000 m asl (Santos-Barrera *et al.* 2004). It occupies lower montane evergreen forests and requires nearby streams for development. Unfortunately, it is rapidly declining in

Mexico, probably due to the fungal infection **chytridiomycosis**. Habitat loss through agriculture, logging, and urbanization also threaten its survival.

Figure 28. *Craugastor lineatus* sitting on a bed of *Sphagnum* at La Chinantla, Oaxaca, Mexico. Photo by Omar Hernandez-Ordoñez, with permission.

Craugastor noblei (Noble's Robber Frog; Figure 29) lives in lowland and premontane evergreen forests of extreme eastern Honduras, through Nicaragua and Costa Rica, both slopes in central Panama, and in the lower portion of the premontane zone of southwestern Costa Rica, at 4-1200 m asl (Frost 2011). With its diurnal habit (Solís *et al.* 2010b) and brown color, it is dangerously visible on bryophytes, although its shape makes it look like a leaf.

Figure 29. *Craugastor noblei* (Noble's Robber Frog) on a mat of mosses in Costa Rica. Photo by Andrew J. Crawford, through Creative Commons.

Craugastor bransfordii (Bransford's Robber Frog; Figure 30-Figure 31) lives in humid lowlands and adjacent premontane slopes on the Atlantic mountainside from eastern Honduras and Nicaragua to central Costa Rica, 60-880 m asl (Frost 2011). It is a forest floor species, where it typically lives among leaf litter. However, as seen in

Figure 30-Figure 31, it can traverse bryophytes and most likely finds a moist resting spot there.

Figure 30. *Craugastor bransfordii* (Bransford's Robber Frog) on a bed of mosses. Photo by Jason Folt, through Creative Commons.

Figure 31. *Craugastor bransfordii* (Bransford's Robber Frog) on a bed of mosses. Photo by Brian Gratwicke, through Creative Commons.

Craugastor crassidigitus (Isla Bonita Robber Frog; Figure 32) lives in northern Costa Rica, through Panama to the extreme northwestern border of Colombia, at 10-2000 m asl (Frost 2011). Its habitat is the humid lowland and premontane forests (Solís *et al.* 2004a).

Figure 32. *Craugastor crassidigitus* (Isla Bonita Robber Frog) on a bed of mosses. Photo by Sean Michael Rovito, through Creative Commons.

Craugastor gollmeri (Evergreen Robber Frog; Figure 33-Figure 35) lives in the lowland and premontane humid forests of Panama at 10-850 m asl and in eastern Costa Rica at 10-1520 m asl (Savage 2002). It lives among the leaf litter (Solís *et al.* 2004b), but where bryophytes are present they too can serve as cover or substrate during travels. Females attend the nest in this genus, but nesting sites of this species are not known.

Cycloramphidae

Alsodes vittatus (Cycloramphidae)

It appears that some genera of **Cycloramphidae** in La Picada, Chile, may be dependent on mosses. *Alsodes vittatus* (formerly *Eupsophus vittatus*) (Malleco Spiny-chest Frog; see Figure 36) and *Eupsophus roseus* (Cycloramphidae; Figure 37) can be found under mosses, predominantly *Hygroamblystegium* (Figure 38; Formas & Vera 1980). The males of *Alsodes vittatus* (Cycloramphidae) occur under *Sphagnum* in water-filled cavities. Tadpoles were collected in water-filled cavities (pH 5.0) under *Hygroamblystegium* at the edge of a stream, with fifty tadpoles in one and sixteen in another cavity (Formas & Pugin 1978). Two clutches of eggs were found in similar *Sphagnum*-covered water-filled cavities. Formas and Vera (1980) considered these two species to be derived from pond breeders, with the deposition of eggs and development of tadpoles in water-filled cavities under mosses as a derived character.

Figure 38. *Hygroamblystegium tenax* from a dry streambed in a north-temperate stream. Photo by Janice Glime.

***Eupsophus* (Cycloramphidae)**

In a temperate forest in southern Chile, *Eupsophus emiliopugini* calls from within clumps of the moss *Racomitrium* (Figure 39), and in bogs they excavate burrows where they can make their calls without being seen (Penna *et al.* 2005).

Figure 39. *Racomitrium canescens* in Iceland, demonstrating the types of mounds it can make – suitable for frogs to hide and call. Photo by Janice Glime.

***Rhinoderma darwinii* (Darwin's Frog, Cycloramphidae)**

Protection of eggs from desiccation seems to have been one of the primary drivers in the evolution of terrestrial frogs. One of the strangest egg incubation techniques is that of the Darwin's Frog (*Rhinoderma darwinii*; Figure 40-Figure 46), a vulnerable species from Argentina and Chile. In southern Chile, these frogs live in the beech forests (Fogden & Fogden 1989). The female lays her eggs where it is somewhat damp, under litter or mosses. She abandons the eggs and several males take over the care for about 20 days (Vocal Sac-Brooding Frogs: Rhinodermatidae 2011), an unusual trait in itself. The

males then each put a few eggs into their vocal sacs. Since calling season is over, the vocal sac is no longer needed for calling, so it makes a moist incubation pouch. The larvae feed on their own yolk (Jorquera 1982), but Goicoechea *et al.* (1986) used tracers to demonstrate that there is also a transfer of substances from the male to the developing larvae. In the sac for the next 50-70 days, these eggs hatch and the tadpoles complete their juvenile development (talk about a tickle in your throat!), leaving the males' mouths as froglets! (Vocal Sac-Brooding Frogs: Rhinodermatidae 2011). The males may gather a few eggs from several different clutches and not all the young will be at the same developmental stage. Meanwhile, the presence of the developing frogs makes the male look as if he is pregnant! (Figure 40).

The **Darwin's Frog** is a prey organism to birds, rodents, and snakes (Wikipedia 2011). It is protected from such attacks by camouflage. It comes in many combinations of greens and browns, typically looking like a leaf fallen on a moss, or just a leaf (Figure 46). Crump (2002) demonstrated that it selected substrate color based on its own color. Brown frogs selected brown substrata significantly more often than they selected green, and bicolored frogs likewise selected substrata that matched their color patterns. Green **Darwin's Frogs** (Figure 41), however, actually occurred less often on a green substrate, perhaps gaining an advantage by looking like a fallen green leaf or a plant on soil or other brown surface. Brooding males appeared on warmer surfaces than did non-brooding males or females.

Figure 40. Male **Darwin's Frog** (*Rhinoderma darwinii*) carrying developing tadpoles in its vocal sac, hence appearing to be pregnant. Photo by Claudio Soto-Azat, with permission.

Figure 41. Green variant of *Rhinoderma darwinii*, blending in with the mosses and liverworts. Photo © Danté B. Fenolio <www.anotheca.com>, with permission.

This camouflage serves a second purpose. These frogs are ambush hunters, so they are able to sit undetected among the bryophytes to watch and wait for their own dinner (Figure 42).

One might ask why so many different patterns are necessary, but perhaps the predator would be able to learn a pattern if only one existed. If the frog is detected, it rolls over on its back and plays dead (Figure 43). The underside is black with white spots, a pattern recognized as warning coloration. If water is nearby, the frog jumps into the water, then floats downstream – on its back!

Figure 42. Darwin's frog (*Rhinoderma darwinii*) sitting on damp mosses in Chile. While this animal "leaf" sits still, an insect may land, unaware of the danger. At the same time, its predators often pass it by without noticing that it is a frog. Photo by Filipe Osorio, with permission.

Ceratophryidae

In Peru and Bolivia, *Telmatobius timens* (Ceratophryidae; similar species in Figure 44-Figure 45) lives in the páramo, where it spends the night sitting on rocks, on the ground, or in crevices and under mats of mosses along streams (Riva *et al.* 2005).

The specific name *timens* means frightened, scared, or alarmed (timid) and refers to the possible arrival of the

infectious fungal disease **chytridiomycosis** to Bolivia (Riva *et al.* 2005). This disease has already devastated many amphibian species, including *Telmatobius* in Ecuador and Peru.

Summary

Bryophytes offer opportunities for anurans to live in places where they might not otherwise survive. Among these are waterfalls where bryophytes provide a foothold and place to deposit eggs.

Pristimantis mutabilis is especially adapted to living among mosses by projecting tubercles that help it blend in with mosses, but withdrawing them when it is on a smooth substrate. In the cloud forests, genera such as *Bryophryne*, *Noblella*, *Psychrophrynella*, *Pristimantis*, *Yunganastes* use bryophytes for egg-laying, calling sites, and cover. *Craugastor* is more common in lowland and premontane forests where bryophytes can be common ground cover, providing moisture during travels. *Alsodes vittatus* lives under *Sphagnum* in water-filled cavities. *Eusophus* species call from within clumps of mosses in temperate forests in Chile. Darwin's Frog (*Rhinoderma darwinii*) has multiple color phases that permit the species to blend with a wide range of habitats, including bryophytes. In the páramo, *Telmatobius timens* finds refuge under moss mats.

In Australia, the Darwin's Frog (*Rhinoderma darwinii*) lays eggs in the mosses, then leaves them for the male to incubate, which they do in their vocal sacs after about a week of maternal care.

Acknowledgments

Thank you to Filipe Osorio for thinking of us and getting the pictures of eggs and Darwin's frog. Claudio Soto-Azat provided us with many photos of Darwin's frog and helped us to understand its biology and to obtain some of the literature. We are thankful for all the people who don't know us but who graciously gave permission to use their images (see credits under the images). And thank you to the many people who put their images in the public domain for use without needing permission.

CHAPTER 14-6

SALAMANDERS AND ADAPTATIONS

Figure 1. **Four-toed Salamander** (*Hemidactylium scutatum*), predominantly a moss dweller, in a bed of mosses. Photo by John D. Willson, with permission.

Caudata (Urodela) – Salamanders

The term Caudata refers to having a tail (Figure 1), so the Caudata are the amphibians with tails. Caudata have four legs positioned at right angles to the body, and moist, smooth skin (except in newts). Some live entirely in the water, some live part of their life cycle in water and part on land, and others are entirely terrestrial or **arboreal** (in trees). Newts are salamanders that spend part of their adult life on land and part in the water.

Many salamanders live among bryophytes, and many live in areas where bryophytes form a dominant feature of the landscape. Others live in places where bryophytes are present, but scattered. Casual observations include finding salamanders in bryophyte collections, but we seldom know if this is a casual/accidental association, or if salamanders actually prefer the bryophyte habitat. Does the bryophyte offer any advantage to the salamander? There is no collection of data on the broad role of bryophytes, and most information is observational, thus not providing preferences or causality. The salamander sub-chapters represent an attempt to challenge researchers to make detailed studies on the relationships between bryophytes and salamanders.

In an attempt to be consistent with a worldwide fauna, Latin nomenclature in this chapter follows Frost (2011). English names are mostly based on the SSAR names list (Crother 2008) for North America north of Mexico, and

AmphibiaWeb (Sandmeier 2010) or Frost (2011) for species that do not occur in North America north of Mexico. The order of families follows proposed phylogeny presented by Pearson and Pearson (2010), but the species presented do not, but rather one of related habitats and of convenience.

Distribution

The majority of species of salamanders occur in North America, with the largest family, Plethodontidae, being almost restricted to the western hemisphere. Of the ten families, only the Plethodontidae have a significant number of species that live in areas outside the temperate regions, *i.e.*, in the Neotropics.

If you live in the North Temperate Zone of North America, it is difficult to imagine that large parts of the world do not have salamanders. As somewhat late arrivals on the tree of life, salamanders are absent in Australia (Marc P. Hayes, pers. comm. 26 March 2011; Stan A. Orchard, pers. comm. 27 March 2011; Frost 2011) and in most of India, South America, Africa (Marc P. Hayes, pers. comm. 26 March 2011), and parts of Southeast Asia [Edmund (Butch) Brodie, Jr., pers. comm. 7 June 2011] and of course Antarctica (Frost 2011). The most species-rich areas are the Appalachian and Ozark Mountains, USA,

the Pacific coast of North America, western Europe, Japan, and China (Wake 2011). Only the Salamandridae extend into Northern Africa, southern foothills of the Himalayas, northern Vietnam, and southern islands of Japan.

The largest concentration of salamander species is in the Appalachian Mountains in eastern North America. Perhaps more striking is the distribution of the Plethodontidae, containing 70% of all salamander species. This large family is restricted to the USA, southern Canada, Mediterranean Europe, and the Korean Peninsula (1 species!). In Europe and Asia, the only plethodontids present are the limestone cave dwellers in the genus *Speleomantes*, and only one of these (*S. supramontis*) is known to be associated with a mossy habitat. So, salamanders do not have worldwide distribution, and my North American bias in this presentation is justified.

Descriptions of salamander habitats often seem to lack detail. This is partly justifiable in that often a single individual represents the species when it is described for the first time. Even in surveys, it is typical to describe the general habitat and mention logs and rocks, but omit any mention of bryophytes. Salamanders that hide under bryophytes in the soil are treated as soil organisms and the bryophytes may or may not be mentioned. Epiphytic bryophytes that must be crossed to traverse the arboreal habitat are likewise often not mentioned. In some cases, these omissions are probably true representations of absence, but often they are in old-growth forests, cloud forests, and rainforests where this is unlikely to be the case.

I found it encouraging that Bryce A. Maxell (2005) of the Wildlife Biology Program, University of Montana, Missoula, MT, USA, not only recommended looking on and under bryophyte mats for amphibians, but the sample data sheet for *Plethodon idahoensis* specifically listed it among the habitats to record:

under wood/vegetation
under 4-20cm rock fragments
under >20cm rock fragments
under bryophyte mat
on bryophyte mat
in rock fracture
other_____

This list would insure that habitat information on the bryophytes would be included in any survey using the form. On the other hand, encouraging searching of bryophytes could be seriously destructive to the bryophyte habitat. This seems to be a tricky problem.

Adaptations to Bryophytes

If you have to move through moss mats, it doesn't hurt to be shaped like a worm (Figure 2). For a salamander, that includes having short legs on an elongate body (Figure 2). Your diet necessarily changes to the mites, ants, beetles, and other small invertebrates (mostly arthropods) available. And if you wiggle and move, you attract attention, so your color should either blend in with the bryophytes or you should warn predators to beware by having bright colors that suggest you are poisonous. And if you fail to blend

and someone grabs your tail, disengaging your tail while you run off can confuse your predator (Figure 3-Figure 5) (Wikipedia 2011a), especially if the detached tail continues to wiggle.

Figure 2. *Oedipina pacificensis* showing its small size, reduced appendages, and wormlike body that adapt it to maneuvering among mosses. Photo by Vide Ohlin, with permission for education.

Of these adaptations, most are adaptations to terrestrial living in general. Small size, short limbs, and cryptic (camouflage) coloration are the most bryological. Need for moisture is not an adaptation, but it increases the utility of the bryophytes in some habitats.

Tail Autotomy

Tail autotomy is the ability to drop the tail. Often if the salamander tail is simply dropped, it can continue to move and wiggle (Figure 3), providing a distraction that might permit the rest of the body to escape (Jim McCormac, pers. comm. April 2011). Not only that, but apparently some predators prefer the tail; consumption of the disengaged tail permits the remainder of the body more time for escape (Beneski 1989).

Figure 3. The Greenmountain Slender Salamander, *Batrachoseps altasierrae*, with a waving disarticulated tail on the left and the escaping body in the upper left of the photo. Photo by Gary Nafis, © Gary Nafis at CaliforniaHerps.com, with permission.

And it doesn't hurt to be able to regenerate lost parts. But regeneration requires energy, and this apparently results in loss of reproductive capacity, at least in the salamander *Batrachoseps attenuatus* (California Slender Salamander; Maiorana 1977). On the other hand, Smits and Brodie (1995) demonstrated that in the moss-dwelling *Oedipina uniformis* (Cienega Colorado Worm Salamander) it does not appear to cause any increase in

respiratory cost. They measured respiration before and after activity of this salamander with and without an autotomized tail. Results suggest that the tail accomplishes the oxygen exchange/respiration the tail needs, but the tail is not needed to supply the rest of the salamander.

Figure 4. *Bolitoglossa lincolni*, Lincoln's Mushroomtongue Salamander, with a complete tail. Note the constriction at the base of the tail that permits it to release. Photo by Sean Michael Rovito, with permission.

Salamanders have remarkable abilities to regenerate lost tissues (Figure 5), including other limbs as well as the tail (Endo *et al.* 2007; Keim 2009; Garza-García 2010). The exposed tissue after losing a tail is undoubtedly subject to bacterial infection, but following this self-amputation (**autotomy**), epidermal tissue migrates within 12 hours to cover the remaining stump (Mullen *et al.* 1996; Bryant, *et al.* 2002). In as little as twelve weeks after tail loss, some salamanders are able to achieve coordinated swimming behavior with their newly developing tails (Davis *et al.* 1990). It appears that the only serious price is loss of reproduction.

Figure 5. *Bolitoglossa lincolni* with short tail, suggesting it has been attacked by a predator and lost its tail, which is now regenerating. Photo by Sean Michael Rovito, with permission.

Toxicity

Living on land can often make salamanders more vulnerable to predation. They are more easily seen and more easily caught by small mammals, birds, and snakes than those in water where glares, shadows, and silt can make visibility poor. The salamanders have varying degrees of being poisonous through glands in their skin, and many either have no poison or it is too weak to be effective [Edmund (Butch) Brodie, Jr., pers. comm. 22 April 2011]. Fortunately for herpetologists, the poison is

not a contact poison, but must be eaten to become noxious or dangerous. But when a snake flicks its tongue against this would-be dinner, it feels the effects of the poison from the more toxic ones.

Unfortunately for the salamander, it appears that not every snake is affected by the poison. In some cases, one or more species occurring in the same range, and with historically overlapping habitats to the salamander, have evolved immunity to the poison (Brodie *et al.* 2002; Williams *et al.* 2003; Ridenhour *et al.* 2004). For example, the garter snake (*Thamnophis* spp.) has developed resistance to the neurotoxin **tetrodotoxin** (TTX). This resistance seems to have evolved independently in both related and unrelated snakes. The Sierra Gartersnake, *Thamnophis couchii*, has elevated resistance to TTX, a toxin present in the **sympatric** (having overlapping distribution) newt *Taricha torosa* (California Newt, Salamandridae; Brodie *et al.* 2005). But the distantly related *Thamnophis sirtalis* (Common Gartersnake) also coevolved with its very poisonous sympatric newt prey, *Taricha granulosa*, **Rough-skinned Newt**. These multiple predator-prey co-evolutions in *Thamnophis* seem to result from the simplicity of the genetic structure of TTX resistance in that genus, permitting the evolution of "extreme phenotypes" (Feldman *et al.* 2010), in this case, TTX resistance.

Not only does the *Thamnophis* snake with immunity have a broadened diet that includes newts, it becomes endowed with a bit of protection of its own! Some of these highly resistant snakes are able to ingest multiple newts safely in one meal (Williams *et al.* 2004). Williams *et al.* (2010) found that after consuming only one newt of *Taricha granulosa*, the **Common Gartersnake** *Thamnophis sirtalis* retained significant amounts of active TTX in its liver for one month or more. The 42 µg in the liver that remained after three weeks is sufficient to incapacitate or even kill avian predators, and possibly also mammalian predators (Williams *et al.* 2010). Hence, the bryophytes in the ecosystem, through their housing of newts, could increase the number of snakes in the area through these interactions. *Taricha torosa*, and all *Taricha* species, can dwell in bryophytes [Edmund (Butch) Brodie, pers. comm. 7 June 2011]. It is likely that other bryophyte-dwelling salamanders could be victims or promulgators of similar, as yet unexplored, relationships.

Several authors have attempted to determine the origin of the poison TTX. Possible sources include diet of poisonous arthropods, bacteria that manufacture the poison within the salamander, and manufacture by the salamander itself.

Some arthropods living among mosses are poisonous when eaten, especially mites and ants, and we know these can impart their poisons to some of the poisonous frogs that consume them (Daly & Myers 1967). Although Cardiff (2011) states that the same is true for salamanders, few salamanders eat the beetles, mites, or ants that are poisonous (David Wake, pers. comm. 21 April 2011), and no peer-reviewed study seems to be published to support this poison transfer claim.

Lehman *et al.* (2004) examined the possibility of bacterial origin of the poison TTX. Using PCR primers that amplify 16S rRNA genes, they were unable to detect any bacterial DNA in skin samples from the toxic *Taricha*

granulosa. This provides a strong suggestion that bacteria are not involved.

Hanifin *et al.* (2002) examined the ability of *Taricha granulosa* to manufacture its own TTX by maintaining the newts in captivity. These newts were fed non-toxic earthworms, *Tubifex* worms, and crickets weekly. The levels of TTX actually increased by 20.7% after one year. Since none of these food items is poisonous, these results suggest that the newts manufacture their own poisons. Cardall *et al.* (2004) supported this view by stimulating the release of TTX in *Taricha granulosa* with a mild electric stimulation. Following reductions of 21-90% in TTX levels, these newts regenerated their original TTX levels in the skin during the next nine months in captivity.

It appears that toxins may be rare among the members of the largest family of salamanders, the Plethodontidae. Brandon and Huheey (1981) were the first to identify the composition of a skin toxin in the family Plethodontidae, a family with many bryophyte-dwelling species. This toxin, identified by them in *Pseudotriton ruber* (Figure 13) and *P. montanus*, occurs in the skin and some organs but is most concentrated on the **dorsal** (back) surface. They determined this to be a **pseudotritontoxin**, a proteinaceous **neurotoxin**. When they experimented with its effects on mice, the mice responded by exhibiting hyperextension of their hind legs and lower back, having severe **hypothermia** (body temperature below normal), prolonged debility, coma, and death usually in 12 to 48 hours. Larger doses caused convulsions and death within as little as one hour. Young chickens, perhaps a closer model for their natural predators of reptiles and birds, had convulsions and death within minutes.

But reports of toxins in other plethodontid salamanders are rare. These salamanders are not as easy to experiment with as newts because of their small size, and for many tropical species, rarity. Brodie *et al.* (1991) have found toxicity in *Bolitoglossa huehuetenanguensis* (formerly *B. rostrata*), and *B. subpalmata* (Figure 6-Figure 7), so poisons may exist elsewhere.

Bolitoglossa subpalmata not only produces toxins, but also has behavioral responses to predators (snakes) that deter the predator (Brodie 1977; Ducey & Brodie 1991). In this case, the salamander rolls onto its back. Those salamanders from alpine areas where there were no snakes were less likely to respond with this behavior when making contact with a snake tongue.

Figure 6. *Bolitoglossa subpalmata* on its back in a defensive posture. Photo by Edmund (Butch) Brodie, with permission.

Predator Avoidance

There is some suggestion that some sort of chemical cues may exist that warn other salamanders because at least some members of the family Plethodontidae are sensitive to skin chemicals from other salamanders, both their own species and others in their genus, that have been attacked. These are not documented as being poisonous, but rather elicit avoidance behavior in those salamanders sensing this danger signal (Lutterschmidt *et al.* 1994). Lutterschmidt *et al.* (1994) demonstrated this response for *Desmognathus ochrophaeus* (sometimes a moss-dweller) toward other *D. ochrophaeus* and also to others in its genus, but not to *Plethodon richmondi* skin extracts. This chemical does not seem to be present in the viscera of the salamanders or in damaged mealworms. Recognition of the released chemical from attacked individuals signals the nearby salamanders to flee or take cover.

Warning Coloration and Mimicry

A type of mimicry known as **disruptive coloration** helps to hide organisms in plain view and involves having a color pattern that resembles their surroundings. This is well known in the clothing worn by soldiers who need to blend with their surroundings. You probably noticed that the colors changed when the soldiers started fighting in desert habitats with little vegetation. Greens were replaced by grays.

For bryophyte-dwelling salamanders mimicry can involve resembling the bryophytes that surround them. Disruptive patterns of green, brown, and black give them the appearance of the bryophytes (Figure 8), at least from a distance. Nevertheless, most bryophyte-dwelling salamanders do not seem to mimic bryophytes. Instead, the non-colorful ones are typically shades of brown, instead mimicking the soil, bark, or a stick. This is perhaps reasonable since they could move within moss mats with little visibility, but would be conspicuous on the soil or bark where catching dinner may dictate surface movement. And brown salamanders on green moss do resemble a stick from a distance. I have not located any information to indicate that any salamanders have outgrowths that resemble moss or lichen growths, such as those seen on some frogs.

Figure 8. *Aneides aeneus* (Green Salamander) juvenile somewhat resembling its mossy habitat. However, one could argue that the blackish and yellow colors are also warning colors. Photo by Bill Peterman, with permission.

Some salamanders take advantage of camouflage on top so they are not noticed from a distance, but if a predator draws near, they can rear up and show a bright warning color on the ventral (lower) side, such as that seen for *Taricha granulosa* in Figure 9, or roll over onto their backs (Figure 10-Figure 11). If the predator has had a bad experience with that color combination, it is likely to retreat.

Müllerian mimicry is common among salamanders. **Müllerian mimicry** permits species that look like each other to protect each other through similar warning coloration. Less or non-poisonous species enjoy less predation because they look like a species that is highly poisonous. Thus a predator has a higher probability of encountering the highly poisonous common species first and learns to avoid things that look like it, including the less common weakly poisonous or non-poisonous species. Both relatively common, highly poisonous species and slightly poisonous species with small numbers can have varying degrees of red, yellow, and black warning color combinations. Interestingly, the same color combinations are prevalent among hurtful and toxic species elsewhere in the animal kingdom, including snakes, bees, and frogs.

Howard and Brodie (1971) first demonstrated the **Batesian mimetic** relationships of two toxic salamander species in the area at Highlands, North Carolina, USA. **Batesian mimicry** is the case where there is a toxic model and a non-toxic mimic that gains benefit by looking like a toxic species. It works best when the model is abundant and the mimic at least less abundant so that the predator is more likely to experience the model first. In the experiments by Howard and Brodie (1971), the highly toxic red eft (immature) stage of the **Eastern Newt**, *Notophthalmus viridescens viridescens* (Figure 12), a common moss visitor and a species that is both noxious and toxic, served as a model for the **Red Salamander**, *Pseudotriton ruber schencki* (Figure 13-Figure 15), a moss hibernator. After experiencing a noxious red eft, previously inexperienced chickens avoided the **Red Salamander** as well as the red eft. They still readily ate non-toxic species of *Desmognathus*. Brandon and Huheey (1981) suggested that a **Müllerian mimicry** complex exists that has a variety of palatability levels. In **Müllerian mimicry**, a number of species, often unrelated, resemble each other and thus gain predation protection when a predator experiences another member of the group. This enhances the effectiveness of **Batesian mimics** as well because it increases the size of the pool of models. In the study by Brandon and Huheey, the poisonous (Müllerian) group includes the red eft of the **Eastern Newt** and at least some members of the **Red Salamander**; the non-poisonous Batesian species include such moss dwellers as the **Spring Salamander**, *Gyrinophilus porphyriticus* (Figure 16).

If you have no warning coloration and you are edible, it is not a good idea to advertise your presence. Instead, being still works well. And if the predator gets too close, try to look bigger or more dangerous – or drop your tail and run!

Locomotion

Locomotion provides an interesting story for bryophyte-dwelling salamanders. Limbs provide means of climbing trees and running across rocks, with arboreal species at times having large footpads that help them to cling to slippery surfaces (Wake 2011). But they also use sinuous body movements for rapid locomotion. For example, the genera *Batrachoseps*, *Oedipina*, *Pseudoeurycea* (formerly in *Lineatriton*), and *Phaeognathus* have bryophyte-dwelling members with reduced limbs, and they use body movements for rapid locomotion. Some members of the often bryophyte-dwelling genus *Bolitoglossa* have highly webbed feet with nearly fused toes (Figure 17) that permit them to move across wet leaves and other smooth surfaces like bark. *Aneides*, *Chiropterotriton* (Figure 18), *Dendrotriton*, *Nyctanolis* (Figure 19), and *Pseudoeurycea* have bryophyte-dwelling species that are arboreal and use their long legs and toes with expanded tips to climb, but they are also aided by **prehensile tails** (tails that can be used to grasp, like that of a monkey) (Figure 18).

Life Cycle

Having a life cycle with no aquatic stage is critical for tree dwellers, but many other species are restricted to living near water where they can lay their eggs (Figure 20-Figure 21). This is particularly true for the larger salamanders (newts) in the Salamandridae. For completely terrestrial species, having eggs that hatch into young salamanders (**direct development**) instead of tadpoles (Figure 22) facilitates this terrestrial transition. Others lay eggs near water where the larvae can easily drop or slither in.

Role of Bryophytes

“One does not know whether a man killing an elephant or setting fire to the grassland is harming others until one knows the total system in which his act appears.” Whereas this quote from Hardin (1968) was intended to illustrate the folly of our exploitations against whole ecosystems, it also characterizes our knowledge about the interaction of bryophytes with other members of the ecosystem. The salamanders are a group of organisms that is rapidly disappearing from the planet. As I researched this chapter, it became clear to me that for salamanders in particular, there is a huge gap in our knowledge. Many species live in “mossy” habitats, but little seems to be known about their use of the bryophytes.

Pictures of salamanders on bryophytes abound on the web. But beware! Bryophytes are a favorite substrate for the photographers who often take these animals to the lab to be photographed. The bryophyte in the picture does not necessarily indicate that it is a preference for the salamander.

It is difficult to find documentation that salamanders actually depend on bryophytes, even when they are often found on or among mosses and liverworts (Figure 1). Others hide there in trees or peatlands. For example, Wilson (1992) reported finding one immature salamander

under a bryophyte mat at the base of a rock face in Idaho, USA. What does that really mean? Nevertheless, there is evidence that mosses can be beneficial to salamanders for maintaining moisture, camouflage, cover during hibernation and aestivation, nests, and in a few cases foraging sites.

Moisture

Salamanders have mucous-secreting glands that help to moisten and lubricate the skin. But these are insufficient to keep the skin moist in drier habitats, and not all salamanders are equally endowed with these glands.

The need of salamanders for moisture suggests that the bryophytes might play a vital role, albeit in a spurious way. When the soil is moist and the air is cool, bryophytes may simply be there, occasionally stepped on, and probably more often avoided because the soil and litter are easier to traverse. But when conditions begin to dry, the bryophyte offers a place to replenish moisture or a wetter place to take cover. Even for those species living in the soil, a bryophyte reduces water loss, making the soil more hospitable.

Almost no experiments exist to support the role of bryophytes in the habitat of salamanders. Using the **California Newt *Taricha torosa*** (Figure 23-Figure 25), Brown and Brown (1980) demonstrated the usefulness of mosses in hydrating salamanders. This animal can be up to 20 cm long (Wikipedia 2011b), and water maintenance is important, as it is to all salamanders. In their experiments, Brown and Brown (1980) found that water uptake from wet moss equalled 66% of that in fully submersed members of the species. Furthermore, external movement of water occurred along skin channels from the ventral (lower) to the dorsal (upper) surface, suggesting that a damp substrate such as moss could hydrate an animal resting on it or walking across it (Figure 23-Figure 25).

Figure 23. Adult **California Newt (*Taricha torosa*)** posed on a bed of mosses. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

Figure 24. Front view of adult **California Newt (*Taricha torosa*)** posed on a bed of mosses. Note its low profile, permitting the abdomen to contact the moss as it moves. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

Despite the wonderful pictures above by Gary Nafis, it appears that ***Taricha torosa*** often lives in habitats lacking bryophytes. David Wake (pers. comm. 31 March 2011) concurs. Nevertheless, some ***T. torosa*** and ***T. granulosa*** do indeed live where the forest is humid and epiphytic mosses are common. In these locations, this newt lives among the mosses (Gary Nafis, pers. comm. 27 April 2011; Edmund (Butch) Brodie, pers. comm. 7 June 2011). In general, however, it appears that ***Taricha torosa*** prefers less humid climates than many of the other newt species (Wikipedia 2011b). Too bad – there has been a lot of research on this species. ***Taricha torosa*** further conserves water by storing it in the bladder (Brown & Brown 1980).

Figure 25. Adult **California Newt (*Taricha torosa*)** posed on a bed of mosses where it is able to replenish its water supply. Note the rough skin. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

This research on an animal of relatively dry habitats suggests that mosses could be critically important rehydration sources for other salamander taxa with higher moisture requirements. It is interesting that for their experiments Brown and Brown (1980) chose this species, which rarely encounters bryophytes in its California coastline and in the Sierra Nevada, USA, habitats. One must wonder if the species living in habitats with bryophytes have even better ability to make use of damp bryophytes for moisture regulation. Hopefully someone will investigate this role for salamanders in the "mossy" habitats occupied by amphibians, especially in the Neotropics.

Nesting Sites

Salamander nests are common among mosses, as well as grasses, sedges, and rotting logs (Wood 1955; Salthe 1967; Harris & Gill 1980). Studlar (Bryonet 8 September 2004) shared her observations that lungless salamanders (**Plethodontidae**) may lay their eggs in moss mats in the Appalachian Mountains, USA. Bryophytes help to maintain moisture as well as to provide cover that decreases visibility of the eggs. I wonder if they provide any antibiotic service? This could be especially helpful in preventing molds from developing on the eggs since many, perhaps most, bryophytes produce secondary compounds that have antibiotic properties. On the other hand, large areas of the eggs would not be in direct contact with the bryophytes and may, therefore, derive no antibiotic benefit from their bryological neighbors.

Food Source

As you will see later in this chapter, mosses are at least occasionally consumed by a few salamanders. But are they consumed as food, or merely ingested along with invertebrates or other food matter associated with them? No experimental work seems to be available to address this question.

On the other hand, bryophytes can be home to a number of food organisms, both in the water and on land. In peatlands, one attraction for salamanders in that mossy habitat is the presence of pools that harbor numerous insects, hence providing food (Desrochers & van Duinen 2006). Searching for the food available in the terrestrial bryophytes may impart cover as protection for them during foraging. Their predators may include reptiles, fish, birds, small mammals, and even spiders, with all but the latter being prevented from entering the small spaces within moss clumps.

Hibernation and Aestivation

When one considers **hibernation** (animal state of inactivity and metabolic depression, characterized by lower body temperature and slower breathing; used for passing winter) and **aestivation** (cessation or slowing of activity during summer, especially slowing of metabolism during a hot or dry period) sites, it appears that even less is known. Some salamanders in cooler climates hibernate in the winter and may seek the shelter of bryophytes for that purpose. However, as will be seen in the table at the end of this chapter, there seems to be documentation of this use for only a few species of salamanders. In many cases, the hibernation site is simply unknown.

Most salamander species are night-active. Some may spend the day among bryophytes, where they are less likely to be detected and where moisture is greater than on rocks or even in soil. In habitats where the summer is hot and dry most of the time, aestivation can occur. This likewise is not well documented, but at least a few species are known to use mosses as a summer refuge.

Bryophytes can help to buffer the temperature, maintaining a safer range for the salamanders. Vial (1968) found that *Sphagnum* in the mountains of Costa Rica maintained a relatively low range of stable temperatures (9.8-16°C). Peatland mosses, in particular, may help to cool the habitat through evaporative cooling. Gnaedinger and Reed (1948) found a temperature of 1.2°C under mosses while the air temperature was -3.3°C. The mosses apparently kept the soil from freezing, although the mosses themselves were frozen to a depth of 1 cm, as was the soil where mosses were absent.

This subchapter and the next will necessarily include a lot of anecdotal information and speculation in the hope that the information will stimulate further study. I hope in the following pages to suggest species that are worthy of further investigation to determine the role that bryophytes play in their life cycle – as hibernation sites, aestivation sites, remoistening sites, cover, and nesting sites.

Summary

Newts and salamanders are known as Caudata, a term referring to their tails. The majority are distributed in the Western Hemisphere. Lungless species (**Plethodontidae**) are almost completely restricted to North America and the Neotropics.

Salamander Adaptations: Arboreal bryophyte-dwelling salamanders tend to be small, shaped like a worm, with an elongate body and short legs. Their movements are often sinuous – they slither through a moss like a snake. And some have **prehensile tails** like a monkey, adding a fifth appendage for climbing, hanging, or clinging. Their colors are typically brown with various patterns of other colors (including **disruptive coloration**), and the ventral surface may be endowed with warning coloration. Hence, their defensive behavior may be to rear up or roll on their backs, exposing the **warning colors**. Some species are poisonous and colorful, and other species living in the same area may mimic their warning coloration (**Müllerian mimicry**). When attacked on the tail, salamanders can disarticulate the tail, which may continue wiggling, distracting the predator. They typically feed on ants, beetles, mites, and other small invertebrates. Their life cycle is either fully terrestrial, often with eggs hatching into young salamanders instead of tadpoles (**direct development**), or females locate their eggs near water where the larvae can easily drop or slither into the water when they hatch. Females often defend and tend the eggs, rotating them or cleaning them to reduce bacterial and fungal infection.

Role of Bryophytes: Bryophytes are important moisture reservoirs for salamanders, and at least some have channels in the skin that direct water, gained from bryophytes, upward to their backs. The plethodontid salamanders often lay eggs in mosses, thus satisfying their need for a wet or at least moist incubation environment. Some species use bryophytes exclusively for egg laying and are true **bryobionts**. Some use mosses for winter **hibernacula**, whereas others use them as summer retreats for aestivation. Thick bryophyte mats can buffer the temperature, providing soil that is frost-free longer, or cooled by evaporative cooling and shading. At least a few use the bryophytes as foraging sites.

Specific uses are often unknown, but the co-occurrence of certain salamanders with bryophytes in most of their known habitats suggests that the bryophytes may play an important role in their lives. At the very least, they can serve as indicators of the likely presence of salamanders.

Acknowledgments

I thank Michael Graziano for helping me get images and information on amphibians. Jill Cooper put me in contact with Marc Hayes, who gave me a great summary of salamander distribution and bryophyte relationships on the other side of the ocean. David Wake helped me find other herpetologists with specific expertise I needed. Butch

Brodie kindly reviewed the two salamander sub-chapters and offered many suggestions and references. Gary Nafis not only gave me permission for use of numerous of his images, but he also suggested additional species I had not yet found. The CalPhoto and CaliforniaHerps websites have been invaluable for finding images **and** email addresses of the photographers, permitting me to gain permission and make contacts with the wonderfully helpful community of herpetologists. Wikipedia, AmphibiaWeb, and the IUCN websites have been invaluable for general habitat and distribution summaries and often for life history and other biological information as well, not to mention Google's fantastic search engine for both websites and published literature to verify the website information. Bryonettters, as usual, have been very helpful in seeking out other scientists and sending me anecdotal information that have made this and the succeeding subchapter as complete as they are. Others who gave permission for images are credited under the pictures. Not only have these people been helpful in providing pictures, but they have been very encouraging in the overall endeavor of these amphibian chapters. I appreciate all the individuals who placed images in the public domain where permission was not required.

CHAPTER 14-7

HYNOBIIDAE, AMBYSTOMATIDAE, AND PLETHODONTIDAE

Figure 1. *Desmognathus wrighti* on a bed of moss, probably *Hypnum* sp. Photo by Bill Peterman, with permission.

Hynobiidae

This is a family of ca 36 species of medium-sized (to ~250 mm) terrestrial and semi-aquatic salamanders (Wake 2011). They occur in parts of Asia, south to Japan, and European Russia (Wikipedia 2011a). I could, however, find little information on their associations with bryophytes.

Hynobius tokyoensis (Tokyo Salamander)

Google made a link between *Hynobius tokyoensis* (Tokyo Salamander; Figure 2-Figure 3) and mosses, stating that when this species occurs on the forest floor, it can be found at the entrance of burrows, and under decayed logs, rocks, leaf litter, and moss mats (Kusano & Miyashita 1984). The eggs are deposited in water and the larvae are aquatic. The adults disperse up to 100 m from their breeding site by the time they are 4 years old, suggesting the importance of a suitable forest floor within that proximity.

This species has two completely disjunct distributions in Japan: Fukushima Prefecture southwestward to Kanagawa Prefecture and Aichi Prefecture of the Chubu District of Honshu (Matsui & Nishikawa 2001). It may be, however, that the Aichi population is actually *Hynobius nebulosus* (Matsui *et al.* 2001). This discontinuous distribution pattern is related to their need for areas kept moist by underground water oozing to the surface, a habitat

found only in hills or small mountains (Ihara 2002). Its limited distribution makes it vulnerable to extinction (IUCN 2010).

Figure 2. *Hynobius tokyoensis* on a bed of moss. Photo by Henk Wallays, through Creative Commons.

Figure 3. *Hynobius tokyoensis* on a bed of moss. Photos © Henk Wallays, through Creative Commons.

***Salamandrella keyserlingii* (Siberian Salamander, Hynobiidae)**

The **Siberian Salamander** seems to be the one Asian representative that has a notable association with bryophytes. It is distributed in northern Asia from Northern Hokkaido, Japan, and Sakhalin and Kurile Islands, Russia, from Kamchatka to eastern European Russia (to 45° E), south to northern Mongolia, northeastern China, and northern and northwestern Korea (Frost 2011).

It is an inhabitant of wet coniferous forests and mixed deciduous forests of the taiga, as well as riparian groves of the tundra and forest steppe (Kuzmin 1999).

This is one of the few amphibians to survive the cold of northernmost habitats. However, some salamanders do take advantage of mosses to provide their winter **hibernacula**. The **Siberian Salamanders** (*Salamandrella keyserlingii*; Figure 4), also known as Dybowski's Salamander, Manchurian Salamander, and Siberian Newt, are among the most cold-tolerant species (Potapov 1993). They can freeze for many years in the permafrost, then thaw out and go merrily on their way. Some may have been frozen for 10,000 years (Meat on the Web 2008)! This unusual animal can survive temperatures down to -50°C, and they have been found preserved in ice with the woolly mammoth. However, there is no scientific evidence to support that ancient age for the salamanders. Rather, they probably fell into a crevasse.

Figure 4. *Salamandrella keyserlingii*, the **Siberian Salamander**. Photo by Milòs Anděra, with permission.

The young **Siberian Salamanders** seek out vegetation where the temperature remains above -15°C, but adults spend the winter in moss cushions near ponds and seldom

experience temperatures below -3°C (Potapov 1993). Nonetheless, adults can actually survive several weeks of temperatures below -50°C. Amphibians use such cryoprotectants as glucose and glycerol, but the mechanism in this salamander is unknown. The nearness to ponds is critical when they do thaw because a moist salamander, caught in the freezing temperatures, is likely to die as ice crystals draw water out of the body. Nearness to the pond permits it to seek the safety of the water.

In summer, refugia under cover are important to modulate the temperature and maintain humidity (Hasumi *et al.* 2009). For example, at Shaamar, Mongolia, humidity under logs was 85.5% while the ambient air temperature was 48.3%. Light intensity in burrows and under logs was 27 lux compared to 17,000 lux at the surface. Some of these salamanders take cover in moss mats where they are seldom found by collectors. When captured and kept in the lab, *Sphagnum* will help to prevent desiccation.

Ambystomatidae (Mole Salamanders)

***Ambystoma laterale* (Blue-spotted Salamander)**

This species is distributed from southern Canada and Alaska, USA, south to the southern edge of the Mexican Plateau. It lives under logs, mosses, and damp leaves or in burrows (LeClere 2011; NatureWorks 2011). The species migrates from wetlands to the forest floor where it spends the winter in underground retreats (Douglas & Monroe 1981). The migrants typically must travel 250 m or more to these sites.

The **Blue-spotted Salamander**, *Ambystoma laterale*, also known as Lateral Salamander, Slender Salamander, Silvery Salamander, and Tremblay's Salamander (Figure 5), occurs in central and eastern North America, but it has become endangered in the lower part of its range (Ohio, Iowa) and is listed as a species of special concern in Indiana (Center for Reptile and Amphibian Conservation and Management). However, the IUCN (2010) lists it as a species of least concern. Clearcutting has been a major contributor to its increasing rarity, but acid precipitation also contributes to embryo mortality (Pough 1976). In northeastern North America it is threatened by acid rain (DeGraaf & Rudis 1983; Knox 1999). Not only is the pH detrimental to its development, but larval activity is lowered at pH levels less than 4.5-5.0, causing larvae to be preyed upon more easily (Brodman 1993; Kutka 1994).

Figure 5. The **Blue-spotted Salamander**, *Ambystoma laterale*. Photo by Tony Swinehart, with permission.

***Ambystoma maculatum* (Spotted Salamander)**

The **Spotted Salamander** occurs from Nova Scotia and Gaspé Peninsula west to central Ontario, Canada, and south through the eastern USA from Wisconsin to eastern Texas and east to southern Georgia, excluding the peninsula of Florida (Frost 2011).

The **Spotted Salamander**, *Ambystoma maculatum* (Figure 6-Figure 7), also known as Brown-spotted Salamander, Violet-colored Salamander, Yellow-spotted Salamander, Spotted Eft, Large Spotted Salamander is common in peatlands (Amphibians). Their typical home is in the deciduous forest, but they need vernal pools or ponds with no fish so that their eggs can avoid predation (Wikipedia: Spotted Salamander 2008; Figure 7). Oxygen is often a problem for salamander eggs, but *A. maculatum* has solved this problem by having a partner (Orr 1888; Gilbert 1944; Anderson 1971).

Figure 6. *Ambystoma maculatum* on mosses. Photo by John D. Willson, with permission.

Figure 7. Eggs of the Spotted Salamander, *Ambystoma maculatum*. Photo by John D. Willson, with permission.

The salamander's eggs have a jelly coat that protects the eggs from drying out. However, this coating interferes with oxygen diffusion to the developing embryo. The salamander can solve the problem by partnering with the green alga *Oophila amblystomatis* (Figure 8-Figure 9) (name meaning "loves salamander eggs") (Hammen 1962; Bachmann *et al.* 1986). Through photosynthesis of the alga, the eggs obtain oxygen. The salamander returns the favor by providing the alga with much-needed CO₂ for photosynthesis (Figure 10). Ryan Kerney of Dalhousie University in Halifax, Nova Scotia, Canada, carried this

story further, demonstrating that the algae were actually within the cells of the embryos, closely associated with the mitochondria, and that they benefitted from the nitrogen-rich waste produced by the embryos (Petherick 2010; Thoughtnomics 2011).

Researchers have questioned how these algae become associated and enter the cells, particularly in view of the typical immune response known for vertebrates. Kerney found that the algae could be present in the oviducts of adult females, the place where the jelly sacs that surround the embryos form. This suggests the possibility that the algae are passed to the embryos by the mother, but it does not explain how they enter the cells or what prevents the immune system from attacking them. Perhaps they, like the salamanders' own cells, are recognized as part of self at the time the embryo begins to form – an hypothesis that if true could be of tremendous benefit in our understanding of immunity.

Figure 8. Embryos of *Ambystoma maculatum* that have symbiotic algae, *Oophila amblystomatis*, living with them. Photo by Renn Tumilson, with permission.

Figure 9. Embryo of *Ambystoma maculatum* showing the symbiotic algae, *Oophila amblystomatis*, living within its egg. Photo by Renn Tumilson, with permission.

Figure 10. Comparison of embryos of *Ambystoma maculatum* that have symbiotic algae, *Oophila amblystomatis*, on the **left** and no symbionts on the **right**. Photo by Renn Tumilson, with permission.

Embryos that were raised in continuous light hatched synchronously and at somewhat earlier developmental stages than those in either 12- or 24-hour darkness per day (Tattersall & Spiegelhaar 2008). Those embryos without algae or in the dark moved more frequently than those with symbionts in the light. However, in later developmental stages, those in the light had more movements, suggesting that perhaps those without supplemental oxygen were conserving energy by not moving as much.

Like the frogs, larvae of salamanders are sensitive to low pH water. *Ambystoma maculatum* from three ponds in Marquette County, Michigan, USA, were raised at pH 3, 4, and 5 and in pond water pH (Ling *et al.* 1986). It took only 12 hours for the larvae to die at pH 3. At 4 and 5 the rates of development were significantly slower than those raised at pH above 5. Ling *et al.* (1986) found that 42% of the ponds in their study had pH levels below 5.5. Some of these were surrounded by a mat of *Sphagnum*. In the pond with a central *Sphagnum* mat, and the lowest mean pH at 4.6, the researchers observed a slower rate of development. It is possible that under the stresses of laboratory conditions they were less tolerant of the lower pH than in their native ponds.

***Ambystoma jeffersonianum* (Jefferson Salamander)**

The **Jefferson Salamander** (Figure 11) extends from central New Hampshire, USA, and southern Quebec, Canada, southwest to southern Indiana, and east to central Kentucky, western Virginia and West Virginia, USA (Frost 2011). Through a large part of this range it is able to hybridize with *A. laterale*, complicating identification.

The **Jefferson Salamander** (*Ambystoma jeffersonianum*; Figure 11), also known as Granulated Salamander, Jefferson's Salamander, Plumbeous Salamander, and Brown Salamander, is among the many amphibians sensitive to conditions of low pH. In a study in central Pennsylvania and New Jersey Pine Barrens, USA, eggs could not hatch at pH below 4.5 (Freda & Dunson 1986). Those ponds with the lowest pH levels typically had abundant *Sphagnum*. *Sphagnum* lowers the pH of the environment around it through cation exchange, releasing H⁺ ions in exchange for cations such as Ca⁺⁺ and Mg⁺⁺ (Clymo 1963). In transplant experiments with embryos,

mortality of *A. jeffersonianum* increased significantly as pond pH declined (Freda & Dunson 1986). The sensitivity helps to explain amphibian decline in the many sensitive species living with acid rain. A change of only 0.2 pH units can determine whether hatching occurs, making timing of the life cycle crucial for survival of the species.

Figure 11. *Ambystoma jeffersonianum*. Photo by Todd Pierson, with permission.

Plethodontidae (Lungless Salamanders)

This large family is distributed on both sides of the Atlantic, from southern Alaska, USA, and Nova Scotia, Canada, south to eastern Brazil and central Bolivia, and in southern Europe and Korea (Frost 2011). But North America has most of the species. The family comprises 70% of the world's salamanders. These are known as **lungless salamanders** because they lack lungs and breathe through their skin. Most members of the large genus *Plethodon* prefer moist substrates (Taub 1961; Sugalski & Claussen 1997; Moore *et al.* 2001), hence making mosses near streams an ideal location for them. Nevertheless, in the tropics many species are land breeders, including many arboreal species. Bryophytes often play a role in keeping them moist as well as providing cover that hides them from predators. Their need for moisture is likely to be one reason for the preponderance of **nocturnal** (nighttime) activity among the plethodontid species.

***Plethodon teyahalee*, formerly *Plethodon oconaluftee* (Southern Appalachian Salamander)**

Both *Plethodon teyahalee* (**Southern Appalachian Salamander**; also known as Teyahalee Salamander, Southern Appalachian Slimy Salamander, Balsam Mountains Salamander; Figure 12) and *P. serratus* (**Southern Red-backed Salamander**; Figure 13) may occur in peatlands (Amphibians: Tulula Wetlands 2009). *Plethodon teyahalee* is endemic to the United States, where it occurs at high elevations in the southern Appalachians, eastern USA, in other habitats as well as peatlands. Ash (1997) suggests that adults of the species may move into dry, clearcut areas to avoid competition with the smaller, immature salamanders of the same and other species in the more moist forest sites.

Figure 12. **Southern Appalachian Salamander (*Plethodon teyahalee*)**. Photo by U. S. Geological Survey, through public domain.

***Plethodon serratus* (Southern Red-backed Salamander)**

This species is also known as Ouachita Red-backed Salamander, Southern Redback Salamander, and Georgia Red-backed Salamander. The **Southern Red-backed Salamander** (Figure 13) is scattered into **disjunct** (disconnected) populations throughout southeastern USA (Frost 2011) where it hides under moss, as well as rocks and rotten logs, and migrates to seeps and springs during dry periods (Aardema 1999).

Figure 13. **Southern Red-backed Salamander (*Plethodon serratus*)**. Photo by Henk Wallays, through Creative Commons.

***Plethodon nettingi* (Cheat Mountain Salamander)**

The endangered relict **Cheat Mountain Salamander** (*Plethodon nettingi*, Plethodontidae; Figure 14), an **endemic** in the Appalachian Mountains, West Virginia, USA, depends on bryophytes, especially the leafy liverwort *Bazzania trilobata* (Figure 15) (NationMaster 2008; Pauley 1985). While in the bryophyte mats, these amphibians feed on small invertebrates. Their territories are small and they seldom move more than a few meters in their lifetimes. Brooks (1945, 1948) reported finding 33 individuals on Cheat Mountain, crawling on moss-covered logs in dense stands of sapling and pole red spruce, sometimes with birch mixed in. On Bickle's Knob, West Virginia, these salamanders began appearing from mosses and under logs just after twilight (Brooks 1945).

Figure 15. Branches of *Bazzania trilobata*, home to the **Cheat Mountain Salamander**. Photo by Michael Lüth, with permission.

***Plethodon cinereus* (Eastern Red-backed Salamander, Plethodontidae)**

The **Eastern Red-backed Salamander** (Figure 16) occurs in the northeastern USA and southeastern Canada, south through northeastern Wisconsin to southern Indiana, southern Ohio, and east of the Appalachian Divide south to northern North Carolina.

Plethodon cinereus poses a danger to the **Cheat Mountain Salamander** through competition with this much more widespread **Eastern Red-backed Salamander** (NationMaster 2008). The widespread distribution of *Plethodon cinereus* is reflected in having 18 English names listed by Frost (2011). This common salamander includes bogs among its habitats, where it can sometimes be found attempting to rob the pitcher plant leaves of their inhabitants (Hughes *et al.* unpubl.). Analysis of gut contents indicate a diet of midge larvae, ants, mites, and other small invertebrates that live in the bogs. I wonder if this diet makes it poisonous? The red-backed salamander can often be found under a clump of moss such as *Leucobryum glaucum* (Figure 17). At Cap des Rosiers, eastern Quebec, Canada, this salamander was mostly under stones and logs, but one specimen was under moss on a vertical limestone cliff face (Trapido & Clausen 1938).

Figure 16. *Plethodon cinereus*, the **Eastern Red-backed Salamander**. Photo by Tony Swinehart, with permission.

Figure 17. *Leucobryum glaucum* cushions that provide suitable shelters for the **Eastern Red-backed Salamander**. Photo by Michael Lüth, with permission.

In this species, adults typically defend the territories surrounding their offspring. However, it appears that mothers cannot recognize their own offspring, nor could the offspring recognize their mothers (Gibbons *et al.* 2003). The young salamander offspring did not distinguish between mosses scented by their mothers and those with no scent or with scents of unfamiliar females. On the other hand, females chose unrelated offspring significantly more often over their own for acts of cannibalism.

***Plethodon dorsalis* (Northern Zigzag Salamander)**

This salamander (Figure 18) often poses in a Z formation, hence its name. Other English names include Ashy Lizard, Zigzag Salamander, and Eastern Zigzag Salamander. It occurs in lower Midwestern USA from southern Indiana and southern and eastern Illinois to western Kentucky, central Tennessee, northern and western Alabama, and northeastern Mississippi (Frost 2011). Although Brode (1957) found it under sandstone slabs, Ferguson (1961) reported it from the bases of cliffs in Tishomingo County, Mississippi, USA, where it was under moist mosses, or from leaf litter.

Figure 18. *Plethodon dorsalis*. Photo by Todd Pierson, with permission.

***Plethodon welleri* (Weller's Salamander)**

Other English names for *Plethodon welleri* (Figure 19) include Spot-bellied Salamander and Spotbelly Salamander. **Weller's Salamander** occurs at higher elevations in Tennessee, north to mountains in Virginia (Frost 2011).

Organ (1960) reported eight nests of this salamander, located from mid-August to early September between the upper rotting surfaces of conifer logs and the mat of 5-10 cm of mosses.

Figure 19. *Plethodon welleri* on a bed of mosses. Photo by Todd Pierson, with permission.

***Plethodon elongatus* (Del Norte Salamander)**

In southwestern Oregon and northwestern California, USA, the **Del Norte Salamander** (*Plethodon elongatus*; Figure 20) is restricted to old-growth forests (Welsh 1990) and may require the moss cover that develops there. These forests range up to 560 years old and have more favorable microclimates than do the young forests. The **Del Norte Salamander** (*Plethodon elongatus*) rarely occurs in open water and seems to require the moisture of mosses, rocks, and organic matter. In northwestern California, Welsh and Lind (1995) sampled 57 sites and found a mean of 20 individuals at sites with moss as ground cover, but only 6.9 individuals at sites with none. The need for mosses meant that these salamanders also needed late successional stage forests where mosses had had time to develop significant cover. These habitats tended to be cooler with more moist microclimates among the mosses.

Figure 20. The **Del Norte Salamander**, *Plethodon elongatus*. Photo by Henk Wallays, through Creative Commons.

***Plethodon idahoensis* (Coeur d'Alene Salamander)**

Plethodon idahoensis (formerly *Plethodon vandykei idahoensis*), the **Coeur d'Alene Salamander** (Figure 21), lives further east in the drainage areas of the Selway River

of northern Idaho and the Bitterroot River of extreme western Montana, USA, as well as in the Duncan and Columbia River drainages of southeastern British Columbia, Canada (Frost 2011). The **Coeur d'Alene Salamander**, *Plethodon idahoensis*, is the only plethodontid in the northern Rocky Mountains (AmphibiaWeb 2004).

This salamander can be found in springs, seepages, streamside, or spray zones of waterfalls (Discover Life 2012; Figure 21-Figure 22). These habitats often have bryophytes and the **Coeur d'Alene Salamander** can most likely be found on and under these bryophytes. Wilson (1990) reports one such case under bryophyte mats on cobbles along a stream at ~540 m in the Nez Perce National Forest, Idaho, USA.

The eggs of the **Coeur d'Alene Salamander** are produced in grapelike clusters, and larvae of this species develop within the eggs; thus, no tadpoles exist (Wikipedia 2011b).

Figure 21. The **Coeur d'Alene Salamander**, *Plethodon idahoensis*. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

At Beauty Bay on Coeur d'Alene Lake, Idaho, USA, Dumas (1957) found two females and two immatures under moist moss on a stable talus slope. In the following year he found another immature under wet moss in a small seepage area on the south shore of the Chatcolet Lake.

***Plethodon vandykei* complex (Van Dyke's Salamander)**

The **Van Dyke's Salamander** (Figure 23), also known as Van Dyke Salamander and Washington Salamander, occurs on the Olympic Peninsula and in the southern Cascade Range of western Washington, USA, at 0-1550 m asl (Frost 2011). This species, along with other members of its species complex, is frequent under moss mats (Slater 1933). *Plethodon vandykei, sensu stricto*, is most common near streams, where it uses the mosses and moist slabs of bark at tree bases for cover.

During the day these salamanders are typically found under stones and mosses within streams, but when they search for food after dark they wander out of the water and hunt streamside. McIntyre *et al.* (2006) suggested that *P. vandykei* (Figure 23) is most common in habitats that are able to maintain both cool and hydric conditions; this species is sensitive to both heat and desiccation. Mosses provide such habitats, particularly in seeps. McIntyre and coworkers hypothesized that this would result in a positive association of this species with early successional stages that were dominated by bryophytes and graminoids, while having a negative association with leaf litter. Typically, in the Cascade Range of Washington State, USA, the mosses were associated with bedrock and small cobble, not soil. Surroundings of moist bryophytes would permit this and other members of the genus to absorb water directly through their skin (Spotila 1972). Seeps typically provide these ideal habitats by providing stability of both temperature and moisture (Hynes 1970; Huheey & Brandon 1973).

Figure 23. **Van Dyke's Salamander**, *Plethodon vandykei* on a log covered with mosses. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

***Plethodon larselli* (Larch Mountain Salamander)**

The **Larch Mountain Salamander**, *Plethodon larselli* (formerly *Plethodon vandykei larselli*; Figure 24), occurs in the Lower Columbia River Gorge of Oregon and Washington, USA (Frost 2011). It inhabits the lava talus slopes, and Burns (1962) found it among mosses on the side of a steep **andesite** (dark grey fine-grained volcanic rock) cliff.

Figure 24. *Plethodon larselli*, the **Larch Mountain Salamander**. Photo © Henk Wallays, through Creative Commons.

***Plethodon glutinosus* (Northern Slimy Salamander)**

The **Northern Slimy Salamander** (Figure 25) is a large (11.5-20.5 cm total length) terrestrial salamander (Virginia Department of Game and Inland Fisheries 2011a) that lives mostly in bottomland and wet hardwood forests of eastern USA (Beamer & Lannoo 2011a). This species lives under logs, rocks, and in tunnels in the soil; there seems to be no documentation that it lives among bryophytes. At night it traverses the forest floor, hunting for food. At that time, mosses may aid in rehydration, but this theory has not been tested. However, it does at times deposit eggs under mosses (Virginia Department of Game and Inland Fisheries 2011a). The eggs are a creamy white with an average of 5.5 mm diameter.

When handled, the **Northern Slimy Salamander** secretes a noxious sticky substance from its tail, a protection against predators (Virginia Department of Game and Inland Fisheries 2011a). Brodie *et al.* (1979) found that this secretion deterred shrews, causing them to avoid the salamander or to spend more time to kill it, resulting in less predation than that on the non-noxious *Desmognathus ochrophaeus*. As an added deterrent it lashes its tail, further exposing the secreting glands.

Figure 25. *Plethodon glutinosus* on mosses. Photo by Henk Wallays, through Creative Commons.

***Plethodon richmondi* (Southern Ravine Salamander)**

This salamander can be found in parts of Pennsylvania, Ohio, Kentucky, Indiana, and West Virginia (Pauley & Watson 2011). It is restricted to woodlands (Duellman 1954). Sexual maturity requires three years in males and four years in females (Nagel 1979). The Virginia Department of Game and Inland Fisheries (2011b) reports that this species has a spring courtship, followed by laying its eggs in damp logs and mosses in the early summer. On the other hand, Nagel (1979) found that in northeastern Tennessee, mating occurred from November to March, with a mean of 8.3 eggs deposited in May.

***Plethodon metcalfi*, formerly *Plethodon jordani metcalfi* (Southern Gray-cheeked Salamander)**

The **Southern Gray-cheeked Salamander**, *Plethodon metcalfi* (Figure 26), is also known as Unspotted Salamander, Metcalf's Salamander, Clemson's Salamander, Clemson Salamander, Highland's Salamander, Highlands Salamander, Rabun Bald Salamander, Rabun Salamander, Frosted Salamander, and Southern Graycheek Salamander. It is surprising to have so many English names for a salamander that ranges only from the southwestern corner of North Carolina and extreme northwestern South Carolina into extreme northeastern Georgia, USA (Frost 2011). Organ (1958) found a courting pair on moss of the forest floor in mid August, but little else seems to be known of its relationship with bryophytes. The food of this species (snails, mites, spiders, insect larvae, springtails, millipedes, and centipedes) suggest that it could subsist on organisms found among bryophytes, making them potential hunting grounds (Whitaker & Rubin 1971).

Figure 26. *Plethodon metcalfi*, the **Southern Gray-cheeked Salamander**, on a bed of mosses. Photo by Bill Peterman, with permission.

***Plethodon jordani* (Red-cheeked Salamander; Jordan's Salamander)**

In the higher elevations of the Great Smoky Mountains, this species (Figure 27-Figure 28) is most abundant in the red spruce-Fraser's fir forest where the forest floor is covered with a heavy layer of mosses and little soil (King 1939). Its greater abundance in forests with a predominant bryophyte cover suggests that bryophytes may be important in maintaining the moisture required in its niche.

Although its range is somewhat small, it is widespread within that range and does not appear to be endangered (Beamer & Lannoo 2011b). Nevertheless, despite its protection within the Great Smoky Mountain National Forest, it could be endangered by the infestation of the balsam woolly adelgid beetle (*Adelges piceae*, Adelgidae, Hemiptera) that has caused considerable canopy changes. As new openings impact the bryophytes (Stehn *et al.* 2010a, b) by creating more light, potentially reducing their cover, this species could lose considerable habitat.

***Plethodon shermani* (Red-legged Salamander)**

Richard Bruce is an avid salamander hunter and has become interested in their mossy habitats. He has just sent me another picture, this time of *Plethodon shermani*, adding another species to the list of bryophyte dwellers. The salamander was living in a species of *Hypnum* on a slope above the Nantahala River, North Carolina, USA. The species is mainly found under logs in daytime, and emerges on humid and rainy nights to forage on the forest floor (Richard Bruce, pers. comm. 4 November 2020). They are only occasionally found under moss cushions (unlike *Desmognathus aeneus* which is a moss specialist, and which co-occurs in forests with *P. shermani*).

Figure 29. ***Plethodon shermani*** crawling on the moss *Hypnum* sp. where it lives. Photo courtesy of Richard Bruce.

***Plethodon stormi* (Siskiyou Mountains Salamander)**

The **Siskiyou Mountains Salamander** (Figure 30) has a narrow distribution in southwestern Jackson County, Oregon, and northern Siskiyou County, California, USA (Frost 2011). Its narrow distribution and loss of habitat cause it to be listed as endangered (IUCN 2010). It is associated with moss-covered rocks (Gary Nafis, pers. comm. 28 April 2011). It appears that nothing is known about nests, eggs, or young (see Bury & Welsh 2011). Adults sit quietly and wait for their prey of collembolans, termites, beetles, moths, spiders, and mites (Nussbaum *et al.* 1983). They dart out from whatever cover they are using, so it is likely that some take advantages of the humidity and cooling ability of the mosses that abound in some of their talus habitats, using them as cover and re-moistening sites.

Figure 30. ***Plethodon stormi***. on a rock with mossy patches. Spotted coloration blends somewhat with the rock, but not with the moss. Photo © Gary Nafis through CaliforniaHerps.com, with permission.

***Plethodon asupak* (Scott Bar Salamander)**

Like the previous species, the **Scott Bar Salamander** (Figure 31-Figure 32) is associated with moss-covered talus rocks (Figure 33; Gary Nafis, pers. comm. 28 April 2011), and it likewise has a restricted distribution, occurring in the Siskiyou Mountains (700-1300 m asl) at Muck-a-Muck Creek above Scott Bar, Siskiyou County, California, USA. *Plethodon asupak* is listed only as vulnerable (IUCN 2010),

being threatened by habitat loss (Lu 2009). It prefers north-facing slopes with closed canopy and talus rock (Lu 2009).

***Gyrinophilus porphyriticus*, formerly *Pseudotriton porphyriticus* (Spring Salamander)**

This common species (Figure 34) has 25 English names in the 2011 list of Frost, even though its range is in just one area of North America: eastern USA from Canada

to Georgia-Mississippi (Frost 2011). The most common alternative name among these is Blue Ridge Spring Salamander. The number may not be so surprising when one recognizes that there have been 34 Latin synonyms – it seems to be rather misunderstood. In Tishomingo County, Mississippi, Ferguson (1961) found a single salamander "resting" on a mat of mosses by a spring at the base of an over-hanging cliff. Scott LaGrecca (pers. comm. 11 August 2014) found "a couple" of them among *Fontinalis* in a stream in the Berkshires, Massachusetts, USA.

Figure 34. *Gyrinophilus porphyriticus*, the **Blue Ridge Spring Salamander**, on a bed of mixed mosses. Photo by Bill Peterman, with permission.

***Pseudotriton ruber* (Red Salamander)**

The **Red Salamander** (Figure 35) occurs from southern New York to northwestern Florida and west to eastern Ohio, central Kentucky and southeastern Louisiana, USA. Burger (1933) found a single adult in torpor under mosses of a drying bog in Pennsylvania in mid-summer. Bishop (1941) also observed adults under mats of *Sphagnum*. As discussed earlier, this salamander has a complex of mimics that take advantage of its poisonous skin secretions.

Figure 35. The **Red Salamander**, *Pseudotriton ruber*, on a bed of terrestrial mosses. Photo by John White, with permission.

***Hemidactylium scutatum* (Four-toed Salamander)**

This seems to be the most famous of salamanders for dependence on mosses. Whenever I ask a North American herpetologist about salamanders associated with mosses, this species is mentioned, usually first. The **Four-toed Salamander** (Figure 36) is also known as Scaly Salamander, Scaly Lizard, and Eastern Four-toed Salamander. Its distribution is fairly continuous from

extreme southern Maine, USA, and extreme southern Quebec and Ontario, Canada, west to northern Wisconsin, USA, south to the **fall line** [area where an upland region (continental bedrock) and a coastal plain (coastal alluvia) meet; an unconformity] in North Carolina, South Carolina, Georgia, Alabama, and Tennessee, USA (Frost 2011). There may be additional disjunct populations in nearby areas.

Figure 36. *Hemidactylium scutatum* (Four-toed Salamander) on a bed of mosses. Photo by John D. Willson, with permission.

The **Four-toed Salamander** (*Hemidactylium scutatum*, Plethodontidae; Figure 37) is one of the best known of the amphibian moss inhabitants. Blanchard (1923) reported that all of his finds near Ann Arbor, Michigan, USA, were among *Sphagnum* clumps of woody bog shrubs within 15 cm above the water surface. The need for deep moss may be explained by the critical temperature maximum (CTM) for this species. In experiments, Hutchinson (1961) found the CTM to be 36.74°C, a temperature easily exceeded at the moss surface on a sunny day, but not likely to be achieved 15 cm below. The **Four-toed Salamander**, *Hemidactylium scutatum* (Figure 36), had a CTM of 36.7 ± 0.11 C.

But, as early as 1918, Wright reported that this species was disappearing from New York due to draining of wetlands. Today the species is listed as endangered or rare in a number of states (Harris 2011), but is listed as a species of least concern on the 2010 IUCN Red List.

Fowler (1942) found a single adult under a *Sphagnum* mat in a shoreline bog of a lake in a Maine coniferous forest. King (1944) found it on fallen tree trunks and logs in a gum swamp in the Great Smoky Mountains National Park. Burger (1933) found two inactive individuals during the last week of March in Pennsylvania, again in swampy conditions. But apparently it has a broader habitat than just boggy or swampy land. Blanchard (1928) reported one adult male in *Sphagnum* in Reese's Bog, northern Michigan, USA, and argued that the apparent scarcity of the species may be due to its secretive habit of hiding among the *Sphagnum*.

Habitat Characteristics

Bleakney (1953) revealed the role that mosses could play in the distribution of this species: "The first record for

the province dates back to 1934 when the Arthur Dean's Nursery in Halifax sent a specimen to the Nova Scotia Museum of Science in Halifax. The salamander was correctly identified, but, because the northern limit of its range was believed to be southern Maine, the occurrence of this specimen was credited to introduction via ship's cargo. However, when in 1951 the nursery records were consulted, it was revealed that this **Four-toed Salamander** (Figure 36) had actually come from a load of moss gathered for the nursery from just outside the city."

Because so little was known of the habitat use of this species, Chalmers and Loftin (2006) investigated these relationships in order to build a predictive model of habitat. Among the predictors, a shoreline of *Sphagnum* species was important, along with wood substrate, water flow, and several plants. Interestingly, the shrub sheep laurel (*Kalmia angustifolia*) was a negative predictor, as was deciduous forest canopy. In Canaan Valley, West Virginia, USA, this species is likewise common in pond habitats with mosses, typically *Sphagnum*, or loose bark on logs that can provide nest cover (Pauley 2007). After breeding season, the **Four-toed Salamanders** (Figure 36) leave the aquatic habitat to forage among the forest litter.

Mating

The species mates in late summer and into fall or even early winter. Courtship is an entertaining set of activities and responses, often occurring on peat mosses. The story reminds me of what we as children called Eskimo kisses. The male rubs his nose on the female's nose (Harding 1997; Petranks 1998). Then he circles her with his tail bent at a sharp right angle. If he is lucky, the female straddles his tail and presses her snout on the base of his tail. After a time, the male begins to move forward, tail undulating, and starts to deposit spermatophores. The female follows close behind, picking up the sticky spermatophores. With her snout still against the male's tail, she deposits the spermatophores in her **cloaca** (posterior opening for the intestinal, reproductive, and urinary tracts) while doing a straddle walk. After about 20 minutes the mating and fertilization are completed. It is not until spring that the female searches for a suitable nesting site to lay her eggs.

Figure 37. *Hemidactylium scutatum* (Four-toed Salamander) on mosses, ventral view. Flipping onto its back is one mechanism of responding to potential predators. Photo by John D. Willson, with permission.

Nest Sites

Numerous studies indicate that mosses are preferred nest sites for laying eggs. Wahl *et al.* (2008) found that when choices of moss, grasses, and sedges were available 89% of the nests at three montane pond sites in Virginia, USA, were in clumps of *Sphagnum*. These sites had steeper banks, lower pH, and faced north more often than expected by chance. These three factors were correlated with embryonic survival. North-facing nests were cooler than those facing south.

The female typically lays her eggs among mosses at the edge of forest ponds and water holes (David Taylor, Bryonet 3 February 2009) where spaces will allow the larvae to wiggle down to the water (Linton & Gascho Landis 2005). Headstrom (1970) tells us that this salamander makes a simple cavity in *Sphagnum* (Figure 38-Figure 39), sometimes making use of a natural opening. Each cavity takes several minutes to construct, and it may take hours to provide for the entire clutch (Gates 2002). It is usually not far from open water and may be along the sides of a moss-covered rock that projects into the water. The eggs are sticky and adhere to the mosses. They have an added advantage – the eggs are unpalatable to insects, giving them protection in the mossy habitat that often houses insects (Hess & Harris 2000).

As already suggested, this species is best known for its occurrence among mosses in bogs and poor fens. Bleakney and Cook (1957) reported two females in Nova Scotia with eggs under *Sphagnum* mosses on logs. The logs hung over a stream and the two egg clutches had 36 eggs. It appears that the number of eggs in the clutch may be diminishing. Bishop (in Gilbert 1941) considered clutch sizes to range 40-60, with an average of 50 per female. But Cornell researchers found that after 1920 the averages were less than 50.

Figure 38. Female **Four-toed Salamander** (*Hemidactylium scutatum*) guarding her eggs in her nest of *Sphagnum*. The *Sphagnum* has been parted so that the picture could be taken. Photo from Minnesota DNR, through public domain.

The females typically lay their eggs in such mosses as *Sphagnum* and *Thuidium* spp. (Wood 1955; Harris 2005). Chalmers (2004) found 238 nests in 36 wetlands in Maine, a state where the species is listed as one of Special Concern, along with eleven other states. Furthermore, it is listed as Threatened in Illinois and as Endangered in Indiana. Chalmers was able to locate these 36 new sites by using the predictive ability of shorelines with *Sphagnum*. The nests

were more common on shorelines with steeper slopes and deeper nesting vegetation, especially with moss and *Ilex verticillata* (winterberry), but were negatively associated with *Spiraea alba*, *Chamaedaphne calyculata*, and *Kalmia angustifolia* when they were within 1 m of the shoreline.

Figure 39. Eggs of *Hemidactylium scutatum* among non-*Sphagnum* mosses. Photo by Jim McCormac <<http://jimccormac.blogspot.com>>, with permission.

Wood (1955) reported that the **Four-toed Salamander** surrounds its nest with liverworts, as well as many species of *Sphagnum*. *Sphagnum* is an important nest material (Wallace 1984), where the female deposits its eggs in mossy hummocks above the waterline where the eggs remain moist but don't drown (NJ Division of Fish & Wildlife 2009; Richard Andrus, pers. comm.; David Taylor, Bryonet 3 February 2009). Although many herpetologists assume that *Sphagnum* is preferred for nesting (Figure 38), females also deposit eggs under other species such as those of *Atrichum* (Figure 40) (David Taylor, Bryonet 3 February 2009), *Sphagnum palustre* (David Taylor, pers. comm. 25 October 2011), *Thuidium* (Figure 41), *Mnium* (probably now *Plagiomnium* or *Rhizomnium*), *Climacium* (Gilbert 1941; Wood 1955; Easterla 1971; Petranka 1998; Harris 2009), *Thamnobryum alleghaniense*, *Hypnum* sp., and in, as well as under, *Aulacomnium palustre* (Figure 42) (David Taylor, Bryonet 3 February 2009). In fact, in Kentucky, USA, John MacGregor (pers. comm. 4 February 2009) finds that most of the nests are under *Thuidium* (Figure 41). Many taxa of both mosses and liverworts surround the nests, contributing to the content of the nests (Harris 2009). The female often remains with the eggs until they hatch (Figure 40).

Figure 40. Female **Four-toed Salamander** (*Hemidactylium scutatum*) guarding her eggs in her nest amid the moss *Atrichum* sp. Photo by John D. Willson, with permission.

Figure 42. *Aulacomnium palustre*, a suitable moss for egg deposition by the **Four-toed Salamander**. Photo by Janice Glime.

Despite the numerous reports on eggs of this species in *Sphagnum*, Wood (1953) found greater mortality for eggs in *Sphagnum* than for those laid on other genera. Overcrowding in large nests resulted in more dead eggs than for loosely placed eggs of small nests. Breitenbach (1982) found that solitary brooding was more likely to occur when there were abundant suitable nesting sites. In a Michigan study, only 12% of 109 nests were communal, with 13 of 14 nests in *Sphagnum* (Breitenbach 1982). Hence, greater reproductive success is likely to occur when there is more moss habitat available for cover. Nest disturbance can cause desertion of the nest, so nests hidden among mosses are less likely to be abandoned.

Wood (1955) found that the salamanders preferred thick mosses that contained many natural crevices where eggs could be placed, compared to shallow, thin mosses lacking such depressions. Gilbert (1941) similarly found that dense mosses such as those at tree bases and stumps or around hummocks did not seem to be desirable, whereas 27 out of 32 nests were in loose mosses along logs.

Hmmm...It appears that the habitat may alter the preferences for growth form and species. Gilbert (1941) found only five of these nests in *Sphagnum*. He described the mosses being used as "loose and fluffy." But another factor could be temperature. Wood (1955) found that nest temperatures were warmer in the two *Sphagnum* habitats than in the seven *Thuidium* hummocks.

Gilbert (1941) found that the logs were located where water was within 7-10 cm. No nests were found where the water had completely dried up. Boyle (1914) found this species in Long Island, New York, by tearing mosses apart at the bases of dead trees at the edge of a pool. Green (1941) found a nest of 12 eggs in Kentucky, covered by a moss mat where a constant drip from a cliff face kept it continuously wet. These collections indicate that bogs are not essential for this species, but mosses apparently are.

Humphrey (1928) actually observed the female laying eggs in captivity. She had available to her *Sphagnum* in a dish. She actually turned upside down to lay the eggs on the overlying *Sphagnum*. On a North Carolina, USA, coastal plain, three out of twenty **Four-toed Salamanders** laid their eggs on the underside of "sheet" moss (Schwartz & Etheridge 1954). Typically, the female repeatedly turns onto her back before laying eggs, perhaps to ensure the eggs are attached to the mosses instead of the underlying substrate (Noble & Richards 1932; Bishop 1941).

One problem that could further endanger such diminishing species as *Hemidactylium scutatum* is predation by inhabitants of the moss. Hess and Harris (2000) experimented with palatability of eggs and found that carabid beetles from the pond did not eat the eggs, but beetles from a stream punctured the eggs. However, they ate few of them. As noted earlier, Hess and Harris suggested that the eggs might contain a toxic or noxious chemical in their gelatinous layer. This avoidance of egg predation helps to explain the lack of nest defense and desertion of nests by this species. However, we have seen that the females seem to stay with the eggs at least some of the time.

***Stereochilus marginatus* (Many-lined Salamander, Plethodontidae)**

The **Many-lined Salamander** (Figure 43), also known as Margined Triton and Margined Salamander, occurs on the Atlantic coastal plain from southeastern Virginia to northeastern Florida, USA (Frost 2011). Gerhardt (1967) found this species in a cypress swamp in Georgia, USA, among the *Sphagnum* in pine flatwoods, where it cohabited in the mosses with the **Broad-striped Dwarf Siren** (*Pseudobranchius striatus*), **Carpenter Frog** (*Lithobates virgatipes*) larvae, **Easter Lesser Siren** (*Siren intermedia*), and the **Mud Snake** (*Farancia abacura*).

Hatching can be fun to watch for both the **Four-toed Salamander** *Hemidactylium scutatum* and **Many-lined Salamander** *Stereochilus marginatus* (Figure 43) (both **Plethodontidae**) when they make their nests in *Sphagnum* or rotting wood (Blanchard 1934; Duellman & Trueb 1986). When the larvae hatch, they wriggle down the moss to the water. These larvae need to beware of cohabiting newts that like to have them for dinner (Wells & Harris 2001).

Adults of *Stereochilus marginatus* are somewhat safer than the larvae due to several anti-predator mechanisms. They secrete a glandular substance from the dorsal part of the tail, "threaten" by raising and undulating the tail, flip

over to expose the yellow venter with black spots (warning colors), secrete noxious substances from the skin, and lose their tails. The tail is lost when the salamander is attacked, even if the salamander has not been captured (Brodie 1977). The tail continues to wiggle after it has been detached (Gates 2002), possibly attracting the attention of the would-be predator.

Figure 43. The **Many-lined Salamander**, *Stereochilus marginatus*. Photo by Michael Graziano, with permission.

In the Dismal Swamp, Virginia, where *Sphagnum* spp. are common, females seem to prefer laying their eggs on the brook moss *Fontinalis* sp. (Figure 44) (Wood & Rageot 1963; Rabb 1966). Bruce (1971) reported that females of *Stereochilus marginatus* in the Croatan National Forest in eastern North Carolina, USA, laid eggs underwater or just above the surface, with those underwater being laid singly or in small groups attached to stems of mosses.

Figure 44. *Fontinalis antipyretica* in a dry stream bed. During seasons of good flow, this is a suitable site for eggs of the **Many-lined Salamander**. Photo by Janice Glime.

***Desmognathus fuscus* (Northern Dusky Salamander)**

The well-known salamander *Desmognathus fuscus* (Figure 45-Figure 47) occurs in Southern New Brunswick and southern Quebec, Canada, south of the Great Lakes to southeastern Indiana, western Kentucky, eastern Tennessee, and northeastern Georgia (excluding the coastal plain of North Carolina and South Carolina), USA.

Figure 45. The **Northern Dusky Salamander**, *Desmognathus fuscus*. Photo by John D. Willson, with permission.

Figure 46. *Desmognathus fuscus*. Photo by Todd Pierson, with permission.

The genus *Desmognathus* seems to be a common one under bryophytes. Adults may be located under mats of moss and other cover (Hom 1987). Their typical strategy when disturbed is to disappear into the mud (Tilley 1981). In New York, the Northern Dusky Salamander was the most common salamander species when Bishop compiled his list in 1922 (Bishop 1923). But lack of suitable sites may limit breeding and population growth throughout much of its range.

Figure 47. *Desmognathus fuscus*. Photo by Bill Peterman, with permission.

In Tennessee, USA, Hom (1987) found nests mostly on the banks of streams (Figure 48) in moist soil under mosses [*Atrichum undulatum* (Figure 51), *Mnium affine*, *Thuidium delicatulum* (Figure 41)] and the leafy liverwort *Trichocolea tomentella*, accounting for 85-95% of the observations over a three-year period.

Unlike many amphibians, most *Desmognathus* species do not have a larval stage, but instead begin life as miniature adults (Chippindale & Wiens 2005); *i.e.*, they have **direct development**. It appears that the most advanced forms have a larval stage that may have secondarily returned to the water, as in the Northern Dusky Salamander. The **Northern Dusky Salamander**, *Desmognathus fuscus* (Figure 47), selects sites in advance for laying eggs (Hom 1988). Burger (1933) found a cluster of eleven eggs under moss on a mountain slope in Lebanon County, Pennsylvania, USA, during the first week of September. These larvae were just ready to emerge, and when disturbed several did break through the egg membrane.

Females can occur in clusters, such as the three females hiding with their egg clusters under a 20-cm square of moss covering mucky soil of a springy swamp (Bishop 1923). Females of the species tended to brood their egg clutches under mosses (Hom 1987). Montague (1977) showed experimentally that *Sphagnum* served as a sufficiently moist site for a clutch of eggs in an environmental chamber at 14°C. Eggs are deposited in moist soil under mosses (Figure 49), rotting logs, rocks, and leaf litter (Dennis 1962; Snodgrass *et al.* 2007). Clutch size typically ranges 5-34 with a mean in the mid 20's (Means 2011). Hatching requires 45-60 days, and the female remains with the eggs during this time (Snodgrass *et al.* 2007). Females seem to recognize tradeoffs in parental care (Forester *et al.* 2005). In an experiment where eggs of several clutches were divided and placed at 13 and 21°C, those at the higher temperature developed faster. When the female was introduced to her two sets of eggs, she spent most of her time caring for those that were further developed. But when the young hatch, she leaves them to fend for themselves.

***Desmognathus ochrophaeus* (Allegheny Mountain Dusky Salamander, Plethodontidae)**

The **Allegheny Mountain Dusky Salamander** (Figure 50) occurs from the mountains of southeastern Kentucky, through the Adirondack Mountains, USA, to southern Quebec, Canada.

As for many salamanders, seeps provide this species with both moisture and temperature stability (Huheey & Brandon 1973). This is true even on rock faces, where they are able to maintain moisture among mosses. But this highly variable species also inhabits forest streambanks where it lives among mosses, under rocks, leaves, bark, and logs, and in rock crevices (Tilley 1972; Mushinsky 1976). Experiments indicate that the adults will select some habitats based on the one in which they experienced early development.

Figure 50. *Desmognathus ochrophaeus* (Allegheny Mountain Dusky Salamander) on a bed of *Atrichum* sp. Photo by John White, with permission.

Bruce (1990) tried to explain the selection pressures accounting for size differences between *D. ochrophaeus* and *D. monticola* (Seal Salamander). The more aquatic *D. monticola* is larger than *D. ochrophaeus*. Bruce located most of the egg clutches under mosses at Wolf Creek in the Appalachian Mountains. Eggs of *D. ochrophaeus* were significantly smaller than those of *D. monticola* and also experienced earlier maturation, making them smaller as adults. Bruce suggested that the decrease in age at maturation in *D. ochrophaeus* accompanied the shift to a terrestrial habitat. The selection pressure could be competition or predation – or both.

Whereas Bruce suggests that the smaller size leads to greater predation, Forester (1979a) suggests that the predation is reduced by greater parental care of egg clutches in this species. Furthermore, those clutches unprotected by females were more susceptible to phycomycete fungi, in as little as 12 days after they were deposited. It appears that the female uses her head and mouth to remove infected eggs and to gently oscillate them through movements of the throat (**gular**) region; mechanically vibrated clutches likewise had a higher percentage of survival than non-vibrated controls. Females were able to defend their eggs against other members of their own species and against ground beetles, but were not so successful against larger salamanders or **Ringneck Snakes** (*Diadophis punctatus*). Nests often occurred under mats of the mosses *Thuidium delicatulum* (Figure 41), *Atrichum undulatum* (Figure 51), and *Plagiomnium ciliare* (Figure 52).

Figure 51. *Atrichum undulatum*, a moss that provides a nesting site for several species of salamanders, including *Desmognathus ochrophaeus*. Photo by Michael Lüth, with permission.

Figure 52. *Plagiomnium ciliare*, a moss that is often home to eggs of *Desmognathus ochrophaeus*. Photo by Annie Martin, Mountain Moss Enterprises, with permission.

Females in this species have a homing instinct for their own nests, at least over short distances (Forester 1974, 1979b). When 117 females were moved 2 m from their nests, 78% returned to their nests within 24 hours. They were attracted to unattended eggs, but were able to distinguish their own nests from others with unattended eggs, only occasionally selecting the eggs of another female in preference to their own. For example, seven females were nesting on a single moss-covered rock. When they were marked and moved, five of the seven

returned to their own eggs. Females typically remain with their eggs and do not forage while attending them.

In an experiment, females were offered sites with depressions in soil, but only half of them were covered with moss (Forester 1979b). Females preferred holes with moss cover in all arrangements tested. That is some of the best evidence I have found indicating preference for bryophytes.

This species is known to avoid predation by early detection of a nearby predator. Chemicals released by wounded members of its own species and others in the genus serve as a warning to take cover (Lutterschmidt *et al.* 1994).

***Desmognathus monticola* (Seal Salamander)**

This species (Figure 53) ranges from the central and southern Appalachians of western Pennsylvania to central Alabama (Camp & Tilley 2011) and is more aquatic than is *Desmognathus ochrophaeus* (Bruce 1990). It is typically found among mosses on rocks in streams (LeGrand *et al.* 2001). It lays its eggs in rapid streams where they are sometimes placed under mosses (Camp & Tilley 2011).

Figure 53. *Desmognathus monticola* on a bed of streamside mosses. Photo by Bill Peterman, with permission.

***Desmognathus santeetlah* (Santeetlah Dusky Salamander, Plethodontidae)**

The **Santeetlah Dusky Salamander** (Figure 54) is restricted to the Great Smoky, Great Balsam, and Unicoi Mountains of the southwestern Blue Ridge Mountains in Tennessee and North Carolina, USA. *Desmognathus santeetlah* (Figure 54) is a higher elevation segregate of the **Northern Dusky Salamander** (*Desmognathus fuscus*) in the southern Appalachians, USA. One of the factors that maintains it as a separate species is that it has a different larval environment (Beachy 1993). This species broods its ca 20 eggs under mosses on logs and rocks at the edges of headwater streams (Jones 1986; Tilley 1988; Beachy 1993), compared to the soil depository under mosses, logs, and rocks for eggs of *Desmognathus fuscus* (Tilley 1973).

Instead of scurrying into the mud to hide, like *D. ochrophaeus* (**Allegheny Mountain Dusky Salamander**; Figure 50), this one remains motionless (Tilley 1981). Both *D. santeetlah* and *D. ochrophaeus* occur in the Southern Appalachians (Tilley 1973) and both seem to prefer brooding sites under mosses on logs or rocks. In some locations, only *D. santeetlah* nesting sites can be found (Tilley *et al.* 1978), but in others both species occur, suggesting that under some conditions there may be competition for suitable nesting sites. However, *D.*

santeetlah oviposits mostly under mosses on rocks or logs in seepage areas.

Figure 54. *Desmognathus santeetlah* (Santeetlah Dusky Salamander), a high elevation salamander from the southern Appalachians. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

Desmognathus aeneus (Seepage Salamander)

Also known as the Cherokee Salamander and Alabama Salamander, the **Seepage Salamander** (Figure 55) occurs from extreme southwestern North Carolina, adjacent Tennessee, and southwestward through northern Georgia (Figure 56) to north central Alabama, USA. In Georgia, Martof and Humphries (1955) found it under leaves, mosses, and stones, especially near seepages and other places of high humidity (Figure 56).

The 11-14 eggs of *D. aeneus* are deposited under mosses, as well as under logs, leaf litter, and mats of roots in seepage or wet areas near streams (Figure 56) (Bishop & Valentine 1950; Valentine 1963; Harrison 1967; Jones 1981; Collazo & Marks 1994). Females remain with the eggs during incubation (Brown & Bishop 1948; Bishop & Valentine 1950). Although this species is not considered a climber, Wilson (1984) observed them jumping from branch to branch in bushes and climbing up grasses. They feed mostly on insects, but their diet also includes nematodes, earthworms, land snails, isopods, amphipods, centipedes, arachnids, and millipedes, all items that can be found among mosses as well as leaf litter (Folkerts 1968; Donovan & Folkerts 1972; Jones 1981).

Figure 55. **Seepage Salamander**, *Desmognathus aeneus* on *Atrichum*. Photo by Todd Pierson, with permission.

Figure 56. Habitat of the **Seepage Salamander** *Desmognathus aeneus* in Georgia, USA. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

Desmognathus wrighti (Pygmy Salamander)

Known as the **Pigmy Salamander** (Figure 57), this small species occurs in woodland areas, especially above 1400 m asl within the southern Appalachians, including the Great Smoky Mountains of North Carolina and Tennessee, the Plott Balsam Mountains and Great Balsam Mountains of North Carolina, USA; it is also common between 950 m and 1400 m asl within the Cowee Mountains, Nantahala Mountains, and Unicoi Mountains of North Carolina, USA.

In the southern Nantahala Mountains, North Carolina, USA, *Desmognathus aeneus* (Seepage Salamander; Figure 55) and *D. wrighti* (Pygmy Salamander; Figure 57- Figure 58) are **sympatric** (ranges overlap) in high elevations (Hining & Bruce 2005). Both occupy clumps of moss, damp leaf litter, or shelter under stones or logs near streams and seepages in the deciduous forest during the spring (Figure 56). *Desmognathus wrighti* not only occupies wet areas, but can also be found up to two meters high in a tree on its leaves (Hairston, 1949; Organ, 1961). The two species manage to remain distinct by having different oviposition times, early May for *D. aeneus* and early August for *D. wrighti* (Harrison 2009).

Figure 57. **Pygmy Salamander**, *Desmognathus wrighti*. Photo by Michael Graziano, with permission.

Richard Bruce (pers. comm. 10 August 2019; Bruce 2019) describes his experience with the Pygmy Salamanders: "I find the salamanders under moss cushions (especially *Thuidium delicatulum*; Figure 58) on the soil but also in the mosses among the rhizoids, stems, and leaves. I find them in loosely organized mosses with a lot

of internal space, as opposed to more compact mosses. But the salamanders also occur in leaf litter and under logs. Of the 3 miniaturized species of *Desmognathus*, *D. aeneus* seems to have the greatest affinity for moss, but the other two also occur frequently in mosses. Mosses provide shelter and moisture, but also an abundance of food, especially oribatid mites, as well as other mites, springtails, and other tiny arthropods. A recent paper by Bruckner *et al.* (1918), based on research in a German forest, reported that oribatids were more abundant in moss than in either leaf litter or dead wood. Pore size (spaces within the moss clump) can be an important factor in mobility as well as moisture retention.

Figure 58. *Desmognathus wrighti* that lives within the mats of *Thuidium delicatulum* and *Atrichum* sp. seen here. Photo courtesy of Richard Bruce.

***Desmognathus quadramaculatus* (Black-bellied Salamander)**

From Monroe County, West Virginia eastward to Henry County, Virginia, and southward through eastern Tennessee, western North and South Carolina to northeastern Georgia, in the Appalachian Mountains, USA. Peatlands are good habitats for salamanders, and *Desmognathus* is certainly represented there. In the *Sphagnum* habitat of the Tulula Wetland, North Carolina, USA, one can find *Desmognathus quadramaculatus* (Black-bellied Salamander; Figure 59), typically in streams (Amphibians: Tulula Wetlands 2009). In North Carolina, it is known from among mosses in streams (LeGrand *et al.* 2001).

This species has a somewhat longer development time than some of the other *Desmognathus* species, requiring six years in males and seven in females to reach first reproduction in the southern Blue Ridge Mountains (Bruce 1988).

Beachy (1997) reported that *D. quadramaculatus* co-occurred with the salamander *Eurycea wilderae*, another bryophyte dweller. Unfortunately for *E. wilderae*, it provides dinner for *D. quadramaculatus*. Larval growth rates of *E. wilderae* differed with different predator densities, but survivorship did not differ, suggesting that provided no advantage in the low productivity of Appalachian streams.

Figure 59. *Desmognathus quadramaculatus* (Black-bellied Salamander). Photo by Bill Peterman.

***Desmognathus ocoee* (Ocoee Salamander)**

The **Ocoee Salamander** (Figure 60) occurs in two **allopatric** (non-overlapping) units, one in the Appalachian Plateau of northeastern Alabama and adjacent Tennessee, and the other in the southwestern Blue Ridge Physiographic Province of western North Carolina, eastern Tennessee, extreme western South Carolina, and northern Georgia, south of the Pigeon River (Balsam, Blue Ridge, Cowee, Great Smoky, Nantahala, Snowbird, Tusquitee, and Unicoi Mountains), USA (Frost 2011).

Along with *D. quadramaculatus*, one can find *D. ocoee* in the *Sphagnum* habitat of the Tulula Wetland, North Carolina, USA (Amphibians: Tulula Wetlands 2009), where their typical habitat is streams. Petranks *et al.* (1993) estimated that timber-harvesting rates of the 1980's and early 1990's caused an annual loss of at least 14 million salamanders of all species in western North Carolina, increasing the importance of peatland refugia.

Typical predators on *D. ocoee* include beetles, but Hess and Harris (2000) showed that pond beetles did not eat their eggs. However, beetles from a stream punctured and consumed a large number of *D. ocoee* eggs.

Figure 60. *Desmognathus ocoee* (Ocoee Salamander). Photo by John D. Willson, with permission.

In Macon County, North Carolina, eggs were mostly in nests embedded in mosses growing on rocks on the stream

bank or in the stream (Hess & Harris 2000). Bruce (1996) likewise found that most of the eggs of this species were located under moss on logs, soil, or rocks at the edges of streams, where females care for the eggs.

***Phaeognathus hubrichti* (Red Hills Salamander)**

The **Red Hills Salamanders** (Figure 61) occur in the wooded Alabama Coastal Plain, southern edge of the Red Hills region, USA (Frost 2011). They generally stay in burrows where the humidity is high (Dodd 2011), but when they leave the burrows to forage they can encounter mosses in their habitat and may use them as foraging sites. Their diet of mostly land snails, ants, beetles, and spiders are all likely moss dwellers and perhaps account for the mosses found in some fecal pellets (Gunzburger 1999).

Figure 61. *Phaeognathus hubrichti*. Photo by John P. Clare, through Creative Commons.

***Ensatina eschscholtzii* (Monterey Ensatina)**

When I was teaching species concepts, this was always one of my favorite examples. Armed with a film loop that showed the morphs and their habitats, I could introduce the difficulty in defining species in any practical way. At that time, several species were recognized, as suggested by breeding incompatibility between some populations, but now they are listed by Frost (2011) as a single species, *Ensatina eschscholtzii* (Figure 62), and, like Christopher (2005), Frost treats them as seven distinct subspecies.

The distribution of this superspecies is in Southwestern British Columbia and Vancouver Island, Canada, south through mesic Washington, Oregon, and California, USA, to northern Baja California, Mexico, in the Sierra San Pedro Martír and Sierra Juárez. Its distribution around the mountain range in western USA led to its designation as a **Rassenkreis**, a circle of races (Figure 70).

Hence, current thinking is that there is only one species within the genus. The subspecies are distributed up the Pacific coast of the USA, across the northern Central Valley, and south through the Sierras. The coastal and Sierran subspecies meet in the mountains of southern California and they behave as separate species. Nevertheless, although some of these subspecies look quite different in the pictures that follow, adjacent salamanders recognize each other and can hybridize. For example,

Ensatina eschscholtzii eschscholtzii hybridizes with *E. e. xanthoptica* and *E. e. klauberi*.

Figure 71 demonstrates the habitat of *Ensatina eschscholtzii oregonensis*. The recognized variants of *Ensatina eschscholtzii*, not including hybrids, are:

- Ensatina eschscholtzii eschscholtzii* (Figure 62)
- Ensatina eschscholtzii klauberi* (Figure 64)
- Ensatina eschscholtzii xanthoptica* (Figure 63)
- Ensatina eschscholtzii picta* (Figure 65)
- Ensatina eschscholtzii oregonensis* (Figure 66-Figure 67)
- Ensatina eschscholtzii platensis* (Figure 68)
- Ensatina eschscholtzii croceator* (Figure 69)

Figure 71. *Ensatina eschscholtzii oregonensis* habitat. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

Gnaedinger and Reed (1948) pointed out that the importance of the moss habitat for *Ensatina eschscholtzii* had apparently been overlooked. At that time, several species were recognized, and when we combine them we need to recognize that the former species did not all have the same habitat, hence requiring caution in applying species habitat descriptions. Gnaedinger and Reed reported the salamander to occur between the moss and the ground, easily visible when the moss was removed. Such moss cover was found in 31.5% of their observations, exceeded only by the grouping of leaves, grass, and twigs. Relative numbers of those individuals found under mosses were 52.4% young, 16.7% juvenile, and 13.6% adults. This suggests that eggs may be laid on or in moss patches. The mosses may have been important in temperature regulation. The young were active under mosses at 1.2°C when the air temperature was -3.3°C, suggesting an insulating effect. The ground where salamanders were located was not frozen, apparently due to the protective cover of mosses. Unprotected soil, leaf litter, and surface of the mosses were frozen to a depth of about 1 cm and almost to the depth where the salamanders were active.

***Hydromantes brunus* (Limestone Salamander)**

This species is known only from the area along the Merced River and North Fork Merced River, Mariposa County, California, USA, at 300-760 m asl (Frost 2011). The type was found under a moss-covered rock in Mariposa County, California, USA (Gorman 1954).

***Hydromantes shastae* (Shasta Salamander)**

This species (Figure 72) is an endemic to the limestone substrates south of Mount Shasta near the Shasta Reservoir, Shasta County, California, USA at 300-910 m asl (Frost 2011). The type specimen was found under a small mossy log at a cave entrance (Gorman & Camp 1953). Eggs are terrestrial and have only been found in caves.

Road construction, quarrying, and changes in water levels cause this species to be vulnerable (IUCN 2010).

Figure 72. *Hydromantes shastae* on mosses. Photo by Henk Wallays, through Creative Commons.

Hydromantes ambrosii

Andreas Nöllert kindly sent me images of two subspecies of this salamander from mossy habitats. He

found both in northwestern Italy. *Hydromantes ambrosii ambrosii* was living on a mossy cliff and *H. a. blanchii* was living in a mossy forest.

Figure 73. *Hydromantes ambrosii ambrosii*, a cliff dweller. Photo by Andreas Nöllert, with permission.

Summary

The Hynobiidae is a small family in Asia and Europe, with *Hynobius tokyoensis* migrating to the forest floor where mosses are among its hiding places. *Salamandrella keyserlingii* is also Asian and European and is one of the most cold-tolerant species of salamanders, spending winter in moss **hibernacula** and even surviving freezing in the permafrost for many years.

The Ambystomatidae extend from southern Canada to Mexico, living under mosses, among other forest floor habitats. Some species (e.g. *Ambystoma maculatum*) are common in peatlands. This species provides oxygen to its jelly-coated eggs by partnering them with the green alga *Oophila amblystomatis*.

In the Western Hemisphere, the Plethodontidae, including the large genus *Plethodon*, is a large family of temperate zone salamanders. Many of these are bryophyte dwellers. The **Cheat Mountain Salamander** (*Plethodon nettingi*) is usually associated with the leafy liverwort *Bazzania trilobata*, a rare example of a salamander associated with a specific bryophyte other than the genus *Sphagnum*. *Plethodon cinereus* often lives in *Sphagnum* peat, where it attempts to rob the pitcher plant leaves of the invertebrates living there. But it can also live under forest floor mosses such as *Leucobryum glaucum*. *Desmognathus* is found with mosses both in peatlands and in old-growth forests.

Peatlands are especially important for some species, such as members of *Plethodon* and *Ambystoma*. Nevertheless, *Sphagnum* and associated ponds are typically too acid for most salamanders.

Hemidactylum scutatum (Four-toed Salamander) apparently uses *Sphagnum*. The **Four-toed Salamander** is the best known of the bryophyte dwellers, depositing its eggs under a variety of bryophytes, especially *Thuidium* and *Sphagnum*. Mosses appear to be critical in its habitat, and loss of wetlands is a threat to its existence.

Stereochilus marginatus lays its eggs underwater on the moss *Fontinalis*. *Desmognathus fuscus* lays eggs in the moist soil of stream banks, under mosses; a number of *Desmognathus* species use mosses for egg-laying sites.

Ensatina eschscholtzii subspecies form a **Rassenkreis** in California, USA, and mosses are often an important niche, where they can be found on the soil surface just under the moss.

Unknown species like *Hydromantes brunus* are likely to be living among mosses, invisible to the collector.

Acknowledgments

I thank Michael Graziano and Tony Swinehart for helping me get images and information on amphibians. David Wake helped me find other herpetologists with specific expertise I needed. Butch Brodie kindly reviewed the salamander sub-chapters and offered many suggestions and references. Andreas Nöllert gave me permission to use his images, then sent me additional ones when he found a species I had not reported from bryophytes. Gary Nafis not only gave me permission for use of numerous of his images, but he also suggested additional species I had not yet found. The CalPhoto and CaliforniaHerps websites have been invaluable for finding images and email addresses of the photographers, permitting me to gain permission and make contacts with the wonderfully helpful community of herpetologists. Wikipedia, AmphibiaWeb, and the IUCN websites have been invaluable for general habitat and distribution summaries and often for life history and other biological information as well, not to mention Google's fantastic search engine for both websites and published literature to verify the website information. Bryonettters, as usual, have been very helpful in seeking out other scientists and sending me anecdotal information that have made this and the succeeding subchapter as complete as they are. Others who gave permission for images are credited under the pictures. Not only have these people been helpful in providing pictures, but they have been very encouraging in the overall endeavor of creating these amphibian chapters. I appreciate all the individuals who placed images in the public domain where permission was not required. And thank you to Ralph Lutts for calling my attention to an error on the header.

CHAPTER 14-8

SALAMANDER MOSSY HABITATS

Figure 1. *Bolitoglossa rostrata* on the moss *Thuidium* sp. Photo by Sean Michael Rovito, with permission.

There are a number of habitats where bryophytes dominate either the ground cover (Figure 1) or the arboreal portion. In these, traversing bryophytes by salamanders is unavoidable. Since the Plethodontidae bryophyte inhabitants are too numerous for one subchapter of downloadable size, I have chosen to subdivide them into the mosses present vs mosses dominant and discuss them in these habitats. Please keep in mind that reference to "mosses" might actually include liverworts as well because the collectors were not trained to recognize the difference.

Tropical Mossy Habitats - Plethodontidae

The Neotropics provide a wide array of niches for bryophytes in trees, and elfin cloud forests literally look as if they have been draped by a bryophytic mat. The epiphytic bryophytes provide moisture-holding capacity that enables bromeliads and other epiphytes to be successful there. This arboreal system is home to a myriad of salamander species that use bryophytes for homes, cover, nests, moisture, and foraging sites. Small size and limited mobility have contributed to the evolution of many related species on mountains separated by valleys that prohibit their interbreeding, resulting in numerous microspecies and more conspicuous species.

Rich salamander fauna is associated with bryophyte mats in cloud forests of Talamancan central America, where they can sometimes be very abundant in the cloud forests. In Costa Rica salamanders use moss mats more commonly than do salamanders farther north and west. This is especially true for *Nototriton* and *Oedipina*. Fossorial *Lineatriton* (now *Pseudoeurycea*) and *Oedipina*

occur only below the lower elevational limit of cloud forests in Veracruz, Mexico, and in Nuclear Central America. On the other hand, in cloud forests of Costa Rica and Panama, elongate members of *Oedipina* are common in moss mats covering soil banks, downed logs, and stumps at elevations up to at least 2000 m. Likewise, in Costa Rica *Nototriton* species, as well as at least two species of *Bolitoglossa* (Figure 1), occur among cloud forest mosses. The mid-elevational cloud forest locations tend to have the most salamanders, and at that elevation, mosses are the more commonly used habitat.

Terrestrial and Arboreal Adaptations

Wake (1987) considers mid-elevation cloud forests to have been critical in the evolution of Neotropical salamanders. Salamanders in the arboreal habitat of the Neotropics represent the epitome of adaptations for salamanders living on land. Wake (1987) considers the epiphytic habitat for tropical salamanders to have diverged into two habitat groups: mosses and bromeliads (Figure 3). The epiphytic bryophyte habitat is actually a composite including roots, club mosses, stems, ferns, and small flowering plants. Altig and McDiarmid (2007) summarized the terrestrial adaptations, which are largely coincidental to adaptations for living among terrestrial bryophytes, especially in the arboreal habitat. Epiphytic bryophyte-dwelling salamanders are not as easy to characterize as the bromeliad dwellers (Wake 1987). They are typically slender with short legs, presumably making movement within the moss mat easier. But living on land, especially in trees, made life cycle adaptations essential.

Nests need to be placed where they have both cover/camouflage and moisture maintenance. Bryophytes can provide both, so their use in arboreal habitats, especially for live-bearers, is a viable option for those not using bromeliad basins.

Eggs (Figure 2) cannot move about to adjust to the changes in their environment, hence they exhibit some of the most important of the terrestrial adaptations. They require tradeoffs among need for gas exchange, need for mechanical support, same-species sperm attraction, other species sperm avoidance, heat conservation or cooling, predator defense, moisture retention, UV light protection, prevention of polyspermy (multiple fertilizations by sperm), and protection from bacteria and the water molds *Saprolegnia* and *Achlys* (Altig & McDiarmid 2007). Together, these needs influence the number of layers, thickness, and physical characteristics of the layers of the eggs. Salthe (1963) suggests that having 8 jelly layers is the primitive condition and that changes in number of layers can occur through the loss of the most external layers (e.g. *Ambystomatidae*), loss of more internal layers (especially *Plethodontidae*), or having eggs with three layers for which we do not understand the homologies. Salthe further suggested that loss of layers of terrestrial eggs in *Plethodontidae* results from changes of internal layers whereas the tough outer layer remains for protection.

Figure 2. *Bolitoglossa hartwegi*, a moss dweller, tending its eggs. Photo by Bill Peterman, with permission.

Figure 3. Bromeliads and mosses on the floor of the cloud forest in Puerto Rico, illustrating the types of habitats available to small salamanders such as *Nototriton* species. Photo by Janice Glime.

Important adaptive features of the jelly layer include elasticity, stickiness, toughness, turgidity, and wateriness. Those eggs laid in the water are typically spherical in the water but sag on surfaces in the air. Terrestrial eggs typically have jelly that is turgid and retains its spherical shape in air. Terrestrial salamanders and frogs that experience direct development to adults lay eggs that have a tough outer jelly that permits proper development, oxygenation, and protection from trampling by the parents. Pigmentation has received insufficient study. However, there is evidence that those eggs laid in the open have melanic pigments at the animal pole (Altig & McDiarmid 2007). Buried eggs usually are pale or lack pigmentation. Pigments can absorb heat and increase rate of development, protect against heat, and protect against specific wavelengths (Barrio 1965; Jones 1967; Hassinger 1970).

Egg placement (Figure 2) necessarily must protect eggs from desiccation. The semiterrestrial eggs have not yet abandoned their aquatic history. These are usually deposited adjacent to a water source, not submerged, where hatchlings can easily move or drop into the water (Altig & McDiarmid 2007). They frequently are laid among mosses in seeps or beside bog ponds.

Development and hatching of eggs is often modified from that of aquatic species. Females of many terrestrial species care for the eggs, cleaning and turning them – an activity that seems to reduce the bacterial and fungal colonization. Some species are **viviparous** (have live birth). Some have embryos that develop directly into young salamanders with no larval stage. But some still require water for development of their larvae and therefore lay their eggs near water where larvae have easy access.

Hatching is similar among most salamanders, using an enzyme to break through the jelly, but in some terrestrial salamanders there is an egg tooth similar to that in birds.

***Bolitoglossa* (Tropical Climbing Salamanders, Plethodontidae)**

Sean Rovito has told me about finding several species of tropical climbing salamanders (*Bolitoglossa*; Figure 4) in the páramo in the Cordillera de Talamanca, Costa Rica, under thick mats of moss. Wake (1987) reported that members of this genus use mats of vegetation, including mosses and liverworts surrounding tree branches and twigs.

Species in this genus are able to propel themselves forward by an "explosive tail flip" that carries them off the vegetation – a protective device when in danger during its daylight resting hours (Leenders & Watkins-Colwell 2003). Another protective behavior is to raise its tail as an offering to a predator. If the tail is grabbed, the salamander can **disarticulate** and run off, leaving the predator with only the tail (Lee 2000).

Figure 4. **La Loma Salamander**, also known as the Ridge-headed Salamander, *Bolitoglossa colonnea* occurs in Costa Rica and Panama. Photo by Twan Leenders, with permission.

Arboreal adaptations include elongated fingers, contrasting with webbing used by aquatic species to move through water, and increased efficiency of the suction cups (Wikipedia 2011a). The arboreal body size is smaller, making it easier to cling (and easier to move through moss mats).

***Bolitoglossa diaphora* (Plethodontidae)**

Although *Bolitoglossa diaphora* (Figure 5) was described by McCranie and Wilson in 1995, it still has no English name (Frost 2011). It is known from 1470-2200 m asl in cloud forests of the Sierra de Omoa on the Atlantic side of the mountains of northwestern Honduras. It was described as a species based on a specimen at Cerro Jilincó at 2200 m asl from under a moss mat in a small hole. Its decreasing population is listed as critically endangered (IUCN 2010b).

Figure 5. *Bolitoglossa diaphora* on a fern. Photo by Josiah Townsend, with permission.

***Bolitoglossa diminuta* (Quebrada Valverde Salamander, Plethodontidae)**

This is a tiny (35 mm) bryophyte-mat-inhabiting Costa Rican salamander, known only from the type locality of lower montane rain forest, near Quebrada Valverde, Cartago Province, on the Atlantic slope of Costa Rica at 1300-1650 m asl. For a long time the only known adult was collected with its egg mass in a mat of liverworts (Robinson 1976; Wake 1987). Wake (pers. comm. 31 March 2011) says that this species specializes in living in balls of mosses attached to vines suspended far from the ground or the trees to which the vines are attached. Eggs are typically laid in these moss balls. This salamander is considered vulnerable because it is known from only one location (IUCN 2010b).

***Bolitoglossa hartwegi* (Hartweg's Mushroomtongue Salamander, Plethodontidae)**

Bolitoglossa hartwegi (Figure 2, Figure 6-Figure 7) lives in Guatemala and Mexico in subtropical and tropical moist montane forests (IUCN 2010b; Frost 2011), 1200-2800 m asl (Encyclopedia of Life 2011). It is also able to live in heavily degraded forests, but loss of habitat still renders it threatened. Its presence in moist montane forests suggests that it might be an occasional moss dweller, or use them at moist sites.

Figure 6. *Bolitoglossa cf. hartwegi* on a bed of *Thuidium*. Photos by Sean Michael Rovito, with permission.

Figure 7. *Bolitoglossa cf. hartwegi* blending with mosses and lichens on a rock. Photos by Sean Michael Rovito, with permission.

***Bolitoglossa helmrichi* (Plethodontidae)**

The tiny *Bolitoglossa helmrichi* (Figure 8-Figure 9) is near threatened in its arboreal home in the cloud forests of Guatemala (IUCN 2010b). Its scarcity accounts for the little information we have on it, but its small size and habitat suggest it spends at least part of its time among mosses.

Figure 8. *Bolitoglossa helmrichi* resting on a leaf. Photo by Todd Pierson, with permission.

Figure 9. *Bolitoglossa helmrichi*. The lower photo shows how small these salamanders are. Photo by Todd Pierson, with permission.

Figure 11. *Bolitoglossa jugivagans* exhibiting its nighttime coloration while sitting on a solid-colored leaf. Photo by Andreas Hertz, with permission.

***Bolitoglossa jugivagans* (Plethodontidae)**

The species *Bolitoglossa jugivagans* (Figure 10-Figure 11) causes one to ask about potential adaptations among these mossy habitat salamanders. This is a newly described species from Panama, where it lives in a mossy habitat (Hertz *et al.* 2013). Its life habits are poorly known, but it has one habit that offers possibilities as an adaptation to its mossy neighborhood – it changes from a highly patterned coloration during the day (Figure 10) to a more uniform coloration at night (Figure 11). Andreas Hertz (pers. comm. 14 January 2016) tells me that the trigger(s) for its change in coloration are currently unknown, but other salamanders are known to respond to changes in light, background coloration, temperature, and stress. Such ability could provide adaptations for salamanders living within bryophyte mats or running about and resting on top of them. He pointed out that while we know about mechanisms for these changes in only a few species, we know that these mechanisms do differ among species.

Figure 10. *Bolitoglossa jugivagans* exhibiting its daytime coloration while sitting on a moss. Photo by Andreas Hertz, with permission.

***Bolitoglossa lincolni* (Lincoln's Mushroomtongue Salamander, Plethodontidae)**

Bolitoglossa lincolni (Figure 12) is known from the central plateau of the Chiapas, Mexico, and mountainous areas of western Guatemala at 1200-3000 m asl (IUCN 2010b). It lives in low vegetation (probably including mosses), under bark, and in bromeliads, with a broad enough habitat that its populations are not declining. However, due to destruction of habitat, it is listed as a species near threatened on the IUCN list.

Figure 12. *Bolitoglossa lincolni* (Lincoln's Mushroomtongue Salamander). Photo by Bill Peterman, with permission.

***Bolitoglossa longissima* (Plethodontidae)**

Bolitoglossa longissima is restricted to intermediate elevations (1840-2240 m asl) on the Atlantic side of Pico La Picucha in the Sierra de Agalta, Honduras (Frost 2011) where it is critically endangered (IUCN 2010b). This species is known from under leaves and moss on the ground and from moss-covered tree trunks at ~2.0-3.5 m above the ground (McCranie & Cruz 1996).

***Bolitoglossa marmorea* (Crater Salamander, Plethodontidae)**

This species (Figure 13) is distributed in Costa Rica and Panama, where it lives in subtropical or tropical moist

montane regions and areas where the forest has been highly degraded (Wikipedia 2011b) at 1,920-3,444 m asl (IUCN 2010b). It hides under rocks in the daytime, but climbs over moss mats on tree trunks and branches at night (Wake *et al.* 1973). It is moderately sized – large for a moss dweller (adults range 128-134 mm in total length), and has long limbs (AmphibiaWeb 2009c). Habitat loss and degradation due to agricultural expansion threaten its existence, causing it to be listed as endangered (IUCN 2010b).

Figure 13. *Bolitoglossa marmorea*, a species that traverses mosses on tree trunks at night in the Neotropics. Photo from Division of Herpetology, University of Kansas, permission through Rafe Brown.

***Bolitoglossa mexicana* (Mexican Mushroomtongue Salamander, Plethodontidae)**

Bolitoglossa mexicana (Figure 14) occurs from the Chiapas, Mexico, to the Honduras (IUCN 2010b). It primarily lives in trees where it hangs out in bromeliads and other epiphytes, presumably including bryophytes. Their broad distribution and abundance cause them to be classified as a species of least concern.

Figure 14. *Bolitoglossa mexicana* on mossy bark at Selva Lacandona, Chiapas, Mexico. Photo by Omar Hernandez-Ordoñez, with permission.

***Bolitoglossa obscura* (Tapantí Giant Salamander, Plethodontidae)**

Hanken *et al.* (2005) examined the members of *Bolitoglossa* in Costa Rica and Panama in an effort to understand the taxonomy there. They found that *Bolitoglossa obscura*, known only from the type locality in the Parque Nacional Tapanti, Provincia Cartago, Costa

Rica., is **sympatric** (having overlapped distributions) with two other tiny (35 mm) moss-mat-inhabiting plethodontid species, *B. diminuta* (Quebrada Valverde Salamander) and *Nototriton picadoi* (discussed below). The existence of *Bolitoglossa obscura* is vulnerable, but its population trend is unknown (IUCN 2010b).

***Bolitoglossa robusta* (Robust Mushroomtongue Salamander, Plethodontidae)**

The **Robust Mushroomtongue Salamander** (Figure 15), also known as the Ringtail Salamander, occupies humid premontane and lower montane areas in the mountains of north-central and eastern Costa Rica at 500-2048 m asl and in Bocas del Toro Province, Panama at 50-2100 m asl (Frost 2011). It is often found under fallen logs, in thick leaf litter, or under mosses (Hanken *et al.* 2005). Although its populations are decreasing, it is still listed as a species of least concern (IUCN 2010b).

Figure 15. *Bolitoglossa robusta*. Photos by Eduardo Bozo, with permission.

***Bolitoglossa rostrata* (Longnose Mushroomtongue Salamander, Plethodontidae)**

The species *Bolitoglossa rostrata* (Figure 16) of Guatemala and Mexico occurs in high elevation forests and is often arboreal (Raffaëlli 2011a). One could expect to find it among epiphytic bryophytes since the genus is well adapted to the small spaces provided by them. The species is vulnerable and decreasing in population size (IUCN 2010b).

Figure 16. *Bolitoglossa rostrata* on *Thuidium*. Photo by Sean Michael Rovito, with permission.

***Bolitoglossa rufescens* (Northern Banana Salamander, Plethodontidae)**

Bolitoglossa rufescens (Figure 17) is distributed from Mexico to Honduras (Frost 2011) where it occupies rainforests in lowlands (sea level to 1500 m asl) (McCoy 1990). It is arboreal and night active (McCoy 1990), living mostly in bromeliads (Frost 2011). The bryophytes in its habitat most likely contribute to keeping it hydrated when it moves about in search of food. Ants are the most important food source (Anderson & Mathis 1999), thus we should expect it to venture away from the bromeliads to find them. It is listed as a species of least concern (IUCN 2010b). It defends itself by flicking its tail, a behavior that distracts the predator, usually a snake, from the more vulnerable parts of the body (Brodie *et al.* 1991). If deemed necessary, it will **disarticulate** its tail (Lee 2000). Unlike *B. palmata* and *B. rostrata*, this species is not noxious to snakes. In one case, Bутtenhoff (1995) observed an attack by the mantid *Choeradodis strumaria* (see Figure 18) on an adult *B. rufescens*. Although mantids would not seem to have much connection to bryophytes, some are excellent bryophyte mimics and hang out among the arboreal bryophytes.

Figure 17. *Bolitoglossa rufescens* on a bed of mosses. Photo by Sean Michael Rovito, with permission.

Figure 18. *Choeradodis strumaria*, a mantid predator on *Bolitoglossa rufescens*. Photo by C. Horwitz through Creative Commons.

***Bolitoglossa sombra* (Shadowy Web-footed Salamander, Plethodontidae)**

Bolitoglossa sombra (Figure 19) occurs on Pacific slopes of the Cordillera de Talamanca of Costa Rica and extreme western Panama at 1500-2300 m asl (Frost 2011) and is found on moss-covered tree trunks, under mosses on tree trunks, and on stumps at 0.6-2.0 m above the ground, but was also found on a concrete structure providing access to an underground aqueduct and between mossy buttresses of a tree on top of leaf litter (Hanken *et al.* 2005). Like most of the tropical amphibians, it is red-listed, but is listed only as vulnerable (IUCN 2010b).

Figure 19. *Bolitoglossa sombra*, a bryophyte dweller in the tropics. Photo © 2013 Don Filipiak, through online permission.

***Bolitoglossa subpalmato* (La Palma Salamander, Plethodontidae)**

The **La Palma Salamander** (Figure 20) occurs in humid lower montane and montane zones, marginally into the premontane belt on both slopes of the Cordillera de Guanacaste, Cordillera de Tilarán, Cordillera Central to central and northern Costa Rica at 1245-2900 m asl (Frost 2011). Its habitat is subtropical or tropical moist montane regions, pastureland, plantations, rural gardens, and heavily degraded former forests (Wikipedia 2011c), where its habitat is threatened by habitat loss and fragmentation due to the encroachment of agriculture, causing it to be listed as endangered by the IUCN (IUCN 2010b).

Figure 20. *Bolitoglossa subpalmata* on a leaf. Photo by Ira Richling, <www.helicina.de>, with permission.

This species enjoys one of the most extensive studies done on tropical salamanders. Vial (1968) found that its niche changes with elevation in Costa Rica. In the middle portion of its elevational range (2400-2700 m asl), its most frequent microhabitat is in the dense carpet of *Sphagnum* (Figure 21) and club mosses, where it is able to maintain its hydration. These salamanders are not active when the humidity is less than 51%. The mossy habitats also afford a relatively low, stable temperature (9.8-16°C).

Figure 21. *Sphagnum balticum* from Costa Rica, home for a variety of salamanders. Photo from Biopix, through Creative Commons.

The species is nocturnal, spending the day under rocks, mosses, and plant debris where these are either deeply imbedded in the soil or have well-developed borders of lichens and mosses (Vial 1968). At night they may climb branches of moss-covered trees to 2 m above ground. They nest under well-imbedded rocks or in decaying logs. Adults attend the eggs (Houck 1977). When the nest is disturbed, the adults abandon the eggs and development ceases. They require a site that has been undisturbed for several years, permitting it to develop a good cover of lichens and mosses. Mosses clearly play a role in maintaining the species in at least the middle elevations of its range.

This species seems to be ideal prey for small snakes, but it has an effective defense mechanism (Wikipedia: *Bolitoglossa* 2011). It, and *B. subpalmata*, are poisonous. The skin secretes a toxin that is effective on particular snake species. The initial contact causes the snake to

become immobile and unable to respond to its prey. The salamander remains still, taking advantage of the behavior of the snake to contact the salamander when the snake flicks its tongue. This contact paralyzes the snake and permits the salamander to run.

Bolitoglossa suchitanensis (Plethodontidae)

The type specimen of *Bolitoglossa suchitanensis* (Figure 22), buried in moss on a log, was collected in Guatemala in 1999 (Campbell *et al.* 2010). However, it was not named and described until 2010. Subsequent collections came from tree trunks and under logs, but not in mosses. Its known habitat is a humid deciduous forest with abundant mosses and epiphytes. It lacks an IUCN status evaluation (IUCN 2010b).

Figure 22. *Bolitoglossa suchitanensis*, an inhabitant of mossy logs and forests. Photo by Sean Michael Rovito, through Creative Commons.

Bolitoglossa xibalba (Plethodontidae)

Campbell *et al.* (2010) reported that most of the individuals of *Bolitoglossa xibalba* (Figure 23) were taken from under loose bark or mosses at bases of rotting tree trunks. These were found at 1980-2760 m asl in wet montane forests of Guatemala. Little seems to be known about the species, and it lacks an IUCN status evaluation (IUCN 2010b).

Figure 23. *Bolitoglossa xibalba*. Note the webbing of the feet. Photo © Jonathan Campbell, with permission.

***Chiropterotriton* (Splayfoot Salamanders, Plethodontidae)**

This genus of twelve species is known from West-central Tamaulipas in the north to the mountains of northern Oaxaca in the south, Mexico (Frost 2011). Tim Burkhardt (pers. comm. 17 February 2011) found an unidentified member of *Chiropterotriton* (Figure 24) at 2440 m asl on the NW slope of Cerro Cofre de Perote, Veracruz, Mexico. It was beneath a mat of mosses on the rocky wall of a ravine.

Figure 24. *Chiropterotriton* sp. from the wall of a ravine where it was beneath sheets of moss on Cerro Cofre de Perote, Veracruz, Mexico. Photo by Timothy Burkhardt <www.mexico-herps.com>, with permission.

***Chiropterotriton chiropterus* (Common Splayfoot Salamander, Plethodontidae)**

Chiropterotriton chiropterus (Figure 25) is known only from central Veracruz, near Huatusco, Mexico, at 1000-1200 m asl (IUCN 2010b). Its niche includes mosses and bromeliads and it has direct development. IUCN lists it as critically endangered and possibly extinct, although it was once abundant. It seems unable to live in degraded habitats.

Figure 25. *Chiropterotriton chiropterus*, a moss dweller in Mexico. Photo by César L. Barrio Amorós, with online permission for educational use.

***Cryptotriton alvarezdeltoroi* (Alvarez del Toro's Salamander, Plethodontidae)**

Timothy Burkhardt (pers. comm. 17 February 2011) suggested to me that the salamanders in *Nototriton* and *Cryptotriton* are the ones most closely associated with mosses. *Cryptotriton* is a recent segregate of the genus *Nototriton*.

In Mexico, *Cryptotriton* (formerly *Nototriton*) *alvarezdeltoroi* (Alvarez del Toro's Salamander; Figure 26), a salamander of ~2.6 cm length (Raffaëlli 2011b), was found at 1200-1550 m asl in the cloud forest of the Chiapas, climbing up a moss bank at night (Papenfuss & Wake 1987). It is known only from this type locality. The IUCN Red List of this species has been changed from endangered (2004) to vulnerable (2008) (IUCN 2010b). This change is because it is now known in less than 20,000 km², all individuals are known in fewer than five locations, and there is continuing decline in the extent and quality of its habitat in Chiapas, Mexico. Its known habitat is restricted to the cloud forest, where it seems to require microhabitats with very high humidity. Like many terrestrial salamanders, it has direct development into froglets that hatch from the eggs.

Figure 26. *Cryptotriton alvarezdeltoroi*, a species that occurs among mosses in the cloud forest of Mexico. Photo by Sean Michael Rovito, through Creative Commons.

***Cryptotriton monzoni* (Monzon's Hidden Salamander, Plethodontidae)**

This little fellow, *Cryptotriton monzoni* (Figure 27), measures only 2.2 cm (Whittaker 2010) and is listed as critically endangered by the IUCN Red List (IUCN 2010b). It is known only from its type locality at 1570 m asl in Zacapa, Guatemala, thus occurring in less than 100 km² and fewer than five localities, while suffering from a continuing decline in its habitat, especially due to deforestation. Its known habitat is in the cloud forest, and it may occur in additional, unexplored sites of cloud forest. The type specimen was found in a bromeliad and its use of mosses is unknown. Most likely they contribute to keeping it moist while it is foraging.

Figure 27. *Cryptotriton monzoni*, known only from lower montane wet forest at its type locality in lower montane wet forest, near La Unión, Zacapa, Guatemala, at 1570 m asl. Photo by Sean Michael Rovito, with permission.

***Dendrotriton cuchumatanus* (Forest Bromeliad Salamander, Plethodontidae)**

In Guatemala, *Dendrotriton cuchumatanus* (also known as Cuchumatanas Bromeliad Salamander; Figure 28-Figure 29) lives under moss mats on oak trees (Sean Michael Rovito pers. comm. 7 February 2009). It is endemic to its type locality in Guatemala (Acevedo & Wake 2004) at Sierra de los Cuchumatanes southwest of San Juan Ixcay (Frost 2011). Despite its common name, it is not known to inhabit bromeliads, but does live both in moss banks and under mosses on fallen trees (ZipcodeZoo.Com 2008a).

Figure 28. Cuchumatanas Bromeliad Salamander, *Dendrotriton cuchumatanus* on a leaf covered with epiphyllous algae and bryophytes. Photo © Jonathan Campbell, with permission.

Figure 29. *Dendrotriton cuchumatanus* on a mossy log. Photo by Sean Michael Rovito, with permission.

***Nototriton* (Moss Salamanders)**

In Costa Rica, and other neotropical countries, a genus of tiny **Moss Salamanders** (*Nototriton*; Figure 30) lives among mosses on trees as well as among leaf litter on the ground (Good & Wake 1993; García-París *et al.* 2000a). Seven species of **Moss Salamanders** have been discovered among the mossy habitats in diversity hotspots in Costa Rica (ZipcodeZoo.Com 2008d). In the cloud forest they can be abundant in moss clumps (Taylor 1954), where they are difficult to find (Good & Wake). In other Neotropical countries, most of the species live in bromeliads (Good & Wake 1993). Some species of *Nototriton* are so small that young ones can fit completely on a man's thumbnail (National Geographic News 2009)! The long, thin bodies maximize surface area for oxygen exchange in this lungless salamander (Edge 2009).

Figure 30. **Santa Barbara Moss Salamander, *Nototriton limnospectator***, a moss salamander of lower montane wet forests of the Parque Nacional Santa Barbara. It occurs at intermediate elevations (1640-1980 m asl) of the Montaña de Santa Bárbara on the Atlantic side of western Honduras where it is threatened by habitat loss. That, plus its limited distribution, cause it to be listed as endangered (IUCN 2010b). Its use of mosses is unknown. Photo by Sean Michael Rovito, with permission.

This genus, as currently configured, is the result of an evolutionary radiation of bolitoglossine salamanders (**Plethodontidae**) that has tremendous diversification of both form and ecology (García-París & Wake 2000). They range from the large, robust terrestrial taxa such as *Pseudoeurycea bellii* to the much smaller moss dwellers of *Nototriton* such as *N. abscondens* (Figure 31).

The genus *Nototriton* is small and slender, with a long tail and moderately long to short legs, with moss dwellers having short legs (García-París & Wake 2000). The feet are small, especially in the arboreal moss dwellers. This is an interesting contrast to the tree-dwelling frogs, where the foot pads are larger with increasing elevation above the ground, providing better suction for holding on. One can assume that such suction ability is not needed for wormlike salamanders that live within the moss mat.

This genus differs from many of the terrestrial plethodontid salamanders in its care of the eggs. Instead of guarding them, the females deposit the eggs in clumps of bryophytes in trees and abandon them (McCranie & Wilson 1992; Good & Wake 1993). This suggests that the bryophytes provide sufficient moisture. But does this suggest that the bryophytes afford such good protection that parental care is unnecessary? Might the bryophytes provide antibiotics that keep the eggs safe from disease?

The larvae of *Nototriton* develop completely within the eggs, and the eggs hatch into small salamanders, not tadpoles. Papenfuss and Wake (1987) describe members of this diverse genus as "rare, secretive, and poorly known." *Nototriton* is characterized by a delicate pattern of colors that are quite beautiful under the dissecting microscope, but to the unaided eye, these colors usually blend to create a dull brown (Figure 37). Wake suggests that miniaturization in this genus permits its members to occupy habitats not available to other species. For some, the habitat appears to be the spaces among bryophytes (see Figure 3).

***Nototriton abscondens* (Plethodontidae)**

Like many of the moss-dwelling salamanders that have been seen only a few times, *Nototriton abscondens* (Figure 31) has no English name. It is known from sub-humid and humid premontane and humid montane forests of the Cordillera de Tilarán and Cordillera Central of Costa Rica, 960-2050 m asl (Good & Wake 1993). This one has been known longer than most, with Taylor (1954) reporting them from moss mats hanging from trees and bushes, occasionally horizontal limbs, and mosses that cover dirt banks, large boulders, or stumps. They also seem to be common in lightly disturbed areas along trails and roads, again in clumps of moss. Good and Wake (1993) found them again in these habitats, but also in mosses on tree trunks and branches in the cloud forest and on mosses on logs. They consider this to be a species that specializes on mosses (**bryobiont**).

Figure 31. *Nototriton abscondens*. Photo by Eduardo Boza Oviedo, with permission.

***Nototriton barbouri* (Yoro Salamander, Plethodontidae)**

Nototriton barbouri (Figure 32) is an endemic living at moderate and intermediate elevations (860-1990 m asl) on the Atlantic mountainside from northwestern to north-central Honduras (Frost 2011). This species occurs in an area of less than 5000 km², has fewer than ten known locations, and suffers from continuous decline of its habitat, making it an endangered species on the IUCN Red List (IUCN 2010b). In this lower montane forest, it lives among moss, low vegetation, on the forest floor, and on tree trunks (ZipcodeZoo.Com 2008b). Its clutch size of 5-19 eggs is a bit larger than that of *Nototriton picadoi* (McCranie & Wilson 2002).

Figure 32. *Nototriton barbouri* on mosses covering decaying wood. Photo by Josiah Townsend, with permission.

***Nototriton gamezi* (Monteverde Moss Salamander, Plethodontidae)**

This species (Figure 33) lives in the premontane and lower montane rainforests of the Reserva Biológica Monteverde, Cordillera de Tilarán, Costa Rica, at 1550-1650 m asl. The species is listed as vulnerable, but stable (IUCN 2010b).

Figure 33. *Nototriton gamezi*. Photo by Sean Michael Rovito, with permission.

Two specimens of *Nototriton gamezi* (Monteverde Moss Salamander, Figure 33-Figure 36) were collected in thick mats of moss in Monteverde Cloud Forest Reserve, Costa Rica, in August, 1987, in forest openings near the divide (García-París & Wake 2000). The type specimen and one other were collected nearby from mosses growing on a tree. García-París and Wake (2000) found specimens by searching through heavy moss mats in openings in the forest. The temperatures within the mats ranged 20.0-21.5°C.

Figure 34. *Nototriton gamezi* on a bed of mosses. Photo by Sean Michael Rovito, with permission.

Figure 35. *Nototriton gamezi*. Photo by Sean Michael Rovito, with permission.

Figure 36. *Nototriton gamezi*. Photo by Eduardo Boza Oviedo, with permission.

***Nototriton guanacaste* (Guanacaste Moss Salamander, Plethodontidae)**

Nototriton guanacaste (also known as Volcan Cacao moss salamander) is known primarily from collections of moss from tree trunks and branches, up to 4 m from the ground, in the cloud forests and premontane rainforests of Costa Rica (Tosi 1969; Good & Wake 1993). It is known only from humid, lower montane moss-laden, low-stature forests near the summits of Volcán Orosí and Cerro Cacao, in the Cordillera de Guanacaste, Province of Guanacaste, northwestern Costa Rica, at 1420 and 1580 m asl (Frost 2011). It has a narrow temperature activity range of 17.1-18.1°C (Good & Wake 1993), suggesting that the bryophytes may serve to buffer its temperature climate, or at least provide a safe haven during inactivity.

Figure 37. *Nototriton guanacaste*. Photo by Javier Sunyer, with permission.

***Nototriton picadoi* (Picado's Moss Salamander, Plethodontidae)**

Nototriton picadoi (Picado's Moss Salamander) is restricted to premontane and lower montane wet forest (in the northern end of the Cordillera de Talamanca in cloud forest, Costa Rica, at 1200-2200 m asl (Frost 2011). Although a few individuals have been found in moss balls up to 8 m high, associated with vines (Wake 1987; David Wake, pers. comm. 31 March 2011), most *Nototriton picadoi* seem to be almost restricted to hanging mosses on tree limbs and tree trunks, but they have also been collected in bromeliads (Good & Wake 1993; Savage 2002). Bruce (1999) considers the species to be a "specialist on moss." In a collecting trip to Tapanti, Bruce was able to locate only 38 individuals in 270 person hours. Of these, three were in moss mats on the ground and 35 were above ground to about 8 cm, all but one being in mosses.

Eggs of *Nototriton picadoi* have been found only in and under mosses in the same habitats where adults are known (Good & Wake 1993; Savage 2002). Nevertheless, it appears that the adults do not attend their eggs (Bruce 1998), an unusual behavioral omission for terrestrial salamanders (Duellman & Trueb 1994). Bruce (1998) suggests that this lack of care may represent a tradeoff with other adaptations that minimize desiccation, predation, and fungal infections in the eggs. Like the tiny frogs, this species has few eggs (1-8), permitting eggs to be larger and more protected. The eggs are laid over an extended period of several months that begins with the wet season in May. All hatching is completed before the dry season, ending in December. Development of the embryos requires 2.5-3 months.

***Nototriton richardi* (Richard's Salamander, Plethodontidae)**

Nototriton richardi (Figure 38-Figure 39) lives in moss banks (Wake 1987) and leaf litter of the humid lower montane rainforest and to a lesser degree in upper premontane rainforest of higher altitudes (1370-1800 m asl) on the Atlantic slopes of the Cordillera Central of Costa Rica (Good & Wake 1993; ZipcodeZoo.Com 2008c; Frost 2011). Good and Wake (1993) also found it among mosses covering tree trunks and stumps in Costa Rica. It is listed as near threatened on the IUCN red list (IUCN 2010b).

Figure 38. *Nototriton richardi*. Photo by Eduardo Boza Oviedo, with permission.

Figure 39. *Nototriton richardi*. Photo by Eduardo Boza Oviedo, with permission.

***Nototriton saslaya* (Plethodontidae)**

Nototriton saslaya (Figure 40) is an endemic known only from the cloud forest near its type locality on the south slope of Cerro Saslaya, Atlántico, Nicaragua, at 1280-1370 m asl (Köhler 2002; IUCN 2010a; Frost 2011). The cloud forest is characterized by an abundant bryophyte cover, so it is almost inevitable that the salamanders will traverse them. They would make ideal safe spots for eggs, but the location of eggs has not been documented. The species is listed as vulnerable (IUCN 2010b).

The species *Nototriton saslaya* not only lives in moss, but the eggs hatch there and juveniles develop there; *i.e.*, they are not dependent upon submersion as are eggs of many salamanders (ZipcodeZoo.Com 2008d).

Figure 40. *Nototriton saslaya* on leaf. Photo by Gunther Koehler, with permission.

***Nototriton tapanti* (Tapanti Moss Salamander, Plethodontidae)**

This species is known only from its type locality, the humid premontane Atlantic slope forest near Tapanti, Costa Rica, where it lives in the humid premontane Atlantic slope at the north end of the Cordillera de Talamanca (Frost 2011). It lives among mosses that cover tree trunks and stumps, on road banks, and probably in leaf litter in the Oroquieta River Valley (Savage 2002). This and other recent species in Costa Rica suggest that a number of species have evolved there through miniaturization, a good adaptation to living among mosses (Good & Wake 1993). In other locations, the species of *Nototriton* are primarily bromeliad dwellers. This species is currently listed as endangered on the IUCN Red List due to its very restricted distribution and may possibly be critically endangered due to continued

habitat loss (Bolaños *et al.* 2004, 2008). However, lack of data makes it hard to assess its status.

***Nyctanolis pernix* (Nimble Long-limbed Salamander, Plethodontidae)**

Nyctanolis pernix (Figure 41) occurs in Guatemala and Mexico in subtropical or tropical moist montanes (IUCN 2010b) at 1200-1610 m asl (Frost 2011). It is listed as endangered due to its small distribution and threatened habitat (IUCN 2010b). It is not found in disturbed habitats. Its habitat is humid pine-oak forests and cloud forests, where it lives under moss and bark and is most active on rainy evenings (Elias & Wake 1983; Stuart *et al.* 2008), suggesting it has high sensitivity to moisture loss. Breeding is direct with no tadpole stage.

Figure 41. *Nyctanolis pernix* on a leaf. Photo by Sean Michael Rovito, with permission.

***Oedipina* (Plethodontidae)**

The genus *Oedipina* has also been segregated from the genus *Nototriton*, based on both molecular and morphological characteristics (García-París *et al.* 2000b).

This genus has fifteen recognized species and is the most specialized genus in the Plethodontidae (Brame 1968). It seems to have evolved around Costa Rica and western Panama, then extended southward from Estado de Chiapas, Mexico, southward through western Colombia to extreme northwestern Ecuador. It occurs primarily in lowlands or low montane areas up to 2286 m asl. The genus is primarily **fossorial** (adapted to digging and living underground) and is often found under very wet mosses along road cuts or in and under rotting logs in pastures of forested areas.

Species of *Oedipina* at intermediate altitudes occur in cloud forests, typically in moss mats covering downed vegetation and soil banks (Wake 1987).

***Oedipina carablanca* (Los Diamantes Worm Salamander, Plethodontidae)**

In Guayacán, Limón Province, Costa Rica, this species occurs in humid Atlantic lowlands (Frost 2011) in places like rotting logs and under moss mats (Kubiki 2011). It is barely known and its population status is known. IUCN (2010b) lists it as endangered.

***Oedipina elongata* (Central American Worm Salamander, Plethodontidae)**

Oedipina elongata (Figure 42-Figure 43), also known as Galliwasps and White-crowned Worm Salamander, occurs at low and moderate elevations from north-central Chiapas, Mexico, and near the Caribbean coast of eastern Belize, across the Guatemalan Atlantic foothills to the Montañas del Mico and into adjacent northwestern Honduras (Townsend *et al.* 2006; Frost 2011). It is known from elevations up to 1035 m asl in Honduras, where it occupies channels within logs, termite nests, leaf litter, and tree stumps (IUCN 2010b). Its preference for moist microhabitats suggests that one should also seek it in mosses. Its development is direct. This lucky salamander is listed by IUCN as one of "least concern" (IUCN 2010b). Nevertheless, like its sister species, it is threatened by deforestation. Fortunately, it does tolerate modest disturbance.

Figure 42. *Oedipina elongata* (Central American Worm Salamander), shown here on a log at Selva Lacandona, Chis, Mexico. Photo by Omar Hernandez-Ordoñez, with permission.

Figure 43. *Oedipina elongata* (Central American Worm Salamander). Photo by Edmund (Butch) Brodie, with permission.

***Oedipina gracilis* (Long-tailed Worm Salamander, Plethodontidae)**

Oedipina gracilis (Figure 44) lives in low to moderately high elevation (3-710 m asl) in Costa Rica along the Caribbean coast and into Panama (Savage 2002; Guyer & Donnelly 2005). Habitat destruction is causing populations to decrease and it is listed as endangered (IUCN 2010b).

Figure 44. *Oedipina gracilis* (Long-tailed Worm Salamander) on *Monoclea*, probably *M. gottschei*. Photo by William Leonard, with permission.

Oedipina gracilis (Figure 44) is nocturnal (Bruce 2003) and inhabits predominantly moist, hidden environments, such as leaf litter, burrows made by insects, and underneath or near rotting logs (Leenders 2001). It finds these habitats in humid Atlantic lowlands of Costa Rica and extreme northwestern Panama (Frost 2011). The eggs occur in the same places as adults, but degree of parental care is unknown (Bruce 2003). Its use of bryophytes is unknown, but likely.

***Oedipina pacificensis* (Plethodontidae)**

Oedipina pacificensis (Figure 45-Figure 46) is known from the humid lowlands and premontane slopes of southwestern Costa Rica and adjacent southwestern Panama at 5-730 m asl (Frost 2011). The pictures below demonstrate its tiny diameter (Figure 45-Figure 46). Its wormlike morphology is suitable for its habit of burrowing underground, sometimes going under mats of wet moss or rotten logs (Höbel 2008).

Figure 45. *Oedipina pacificensis* showing its small size. Photo by Angel Solis, with permission.

Figure 46. Close view of *Oedipina pacificensis*. Photo by Angel Solis, with permission.

***Oedipina poelzi* (Quarry Worm Salamander, Plethodontidae)**

Oedipina poelzi (Quarry Worm Salamander; Figure 47) occurs in the Cordillera de Tilarán, Cordillera Central, and Cordillera de Talamanca of Costa Rica at 775-2050 m asl (Frost 2011). Individuals were taken from moss and lichen mats covering the road cuts near the falls where water seepage was constant (Wake 1987). This species occurs in subtropical or tropical moist montanes, rivers, and previously forested land (Frost 2011). It is threatened by habitat loss.

Figure 47. *Oedipina poelzi*, a moss dweller in Costa Rica. Photo from Division of Herpetology at University of Kansas Biodiversity Institute, with permission through Rafe Brown.

***Oedipina pseudouniformis* (Plethodontidae)**

Oedipina pseudouniformis lives in humid lowland and premontane areas of the Atlantic slope of central Costa Rica and on both slopes in northern Costa Rica at 19-1213 m asl, and in Nicaragua at 730-945 m asl (Frost 2011). It was described from a salamander taken from moss growing beneath bushes on a steep, sloping hill about 0.25 km north of a swamp (Brame 1968). Wake (1987) lists it as an arboreal moss dweller. Additional specimens of *O. pseudouniformis*, in large numbers, were in or under moss covering the east facing slopes, north of the swamp, or under logs in the deep woods to the northwest of the swamp. Its small population size and human activity have caused its populations to grow even smaller, causing it to be listed as endangered (IUCN 2010b).

***Oedipina uniformis* (Cienega Colorado Worm Salamander, Plethodontidae)**

This worm salamander lives in the mountains and lowlands of central Costa Rica (Volcan Tenorio, Meseta Central) to the Panama border at 750-2150 m asl. It is an arboreal moss dweller (Wake 1987) that is decreasing in population size and is near threatened (IUCN 2010b).

***Pseudoeurycea juarezi* (Juarez Salamander, Plethodontidae)**

The **Juarez Salamander** (Figure 48) occurs in the cloud forests of the Sierra Juárez and Sierra Mixe, Oaxaca, Mexico at 2400-3000 m asl (IUCN 2010b). It inhabits pristine moist forests under loose bark, under fallen trees, and under mosses on rocks and logs. Its development is direct, with no tadpoles. Logging, agricultural expansion, and human settlement threaten it with habitat loss. Parra-Olea *et al.* (2008) suggest that it has declined by 80% in the last ten years, and the IUCN has listed it as critically endangered (IUCN 2010b).

Figure 48. This *Pseudoeurycea juarezi* was located by lifting the moss at Sierra de Juarez Oaxaca, Mexico. Photo by Omar Hernandez-Ordoñez, with permission.

***Pseudoeurycea rex* (Royal False Brook Salamander, Plethodontidae)**

Pseudoeurycea rex (Figure 49) lives in the high elevations (2450-4000 m asl) of western Guatemala (Frost 2011) and Mexico (although that may prove to be a different species) and is known to live predominantly in arboreal mosses (Wake 1987). This species has direct development and therefore does not depend upon open water for larval development.

Although it was formerly listed as a species of least concern by IUCN (Wikipedia 2011f), it is threatened by habitat loss. But the whole cause of its decline is unknown; it is declining or disappearing even in areas that still maintain the habitat of former populations. It was once considered to be the most abundant species in Guatemala, but now it is extremely rare, with its population size dropping by 80% in ten years, and its status has been changed to that of critically endangered (IUCN 2010b).
