In some cases, there is a negative correlation of spiders with bryophytes. This could be again be a habitat need for particular taxa, but it is also possible that there is some chemical interaction that discourages some spider species from nearing the bryophytes. Certainly this is an unanswered question that could lead to some practical uses in deterring some spiders in houses and may warrant investigation. But it is also certain that at least in most cases, not all spiders are deterred.

Invasive Bryophytes

While tracheophytes have numerous invasive species, few invasive species among bryophytes have concerned ecologists. One reason for this is their apparent ability to travel well on their own, hence not often being solely the result of human activities. But some species are indeed invasive and can even be aggressive. In some cases, they may bring their fauna with them, as is true for those used in the horticulture industry, but more recently the moss garden trade has become another possible source. Even bryologists are likely to introduce species, often inadvertently when a bit is pulled from a pocket or by other means escapes its human vector. These invasive species have the potential to create new niches and to outcompete and replace old ones, not to mention introducing a new fauna from their hitch-hikers. One way to get implications for the role of bryophytes in an ecosystem is to compare habitats where mosses have either disappeared or have been introduced.

Schirmel *et al.* (2011) examined the impact of the invasive moss *Campylopus introflexus* (Figure 203) on spider communities of acidic coastal dunes along the Baltic Sea. This moss species can quickly build dense carpets in such habitats, creating new environmental conditions. Schirmel and co-workers chose to examine the carabid beetle and spider communities because of their known indicator value. They compared the spider fauna on non-invaded native, lichen-rich (*Cladonia* spp.) acidic coastal dunes with those that had been invaded by the moss *Campylopus introflexus*, the latter creating a moss-rich community. Using pitfall traps, they found 2682 spiders (66 species). Both activity levels and species richness decreased in the invaded areas. Both web-building and wolf spiders (Lycosidae) were more abundant among the native ground cover. They attributed the change in fauna to differences in vegetation structure, microclimate, and a reduced food supply. It will be interesting to see if the decrease in species richness persists as time permits invasion of species more suited to the new habitat, including appropriate food species.

Schirmel and Buchholz (2013) found that the invasion of *Campylopus introflexus* (Figure 203-Figure 204) in acidic coastal dunes altered the functional diversity of the spider fauna and altered the pattern of life history traits of the faunal community. The invasive moss caused shifts in hunting mode of the spiders, permitting larger individuals than did the native vegetation. Furthermore, the percentages of web-building spiders were reduced while the trait composition of spiders became more heterogeneous with more functional diversity.

Known Associates

It is difficult to put together a list of known associates with any reliability, and after finding hundreds with only limited effort, I decided that publishing a list was beyond the need for this book. Photographs on the web suggest possible relationships, but may be posed or represent only casual association on the way to another location. Additional records, particularly indicating the role of the bryophytes, will be welcomed.

Figure 203. *Campylopus introflexus*, an invasive bryophyte in many parts of the world, including this one in Wales. Photo by Janice Glime.

Summary

In addition to *Sphagnum*, *Polytrichum*, *Hylocomium*, and *Racomitrium* have been cited as habitats where spiders live. But in most cases, the actual bryophyte is not named and the role of the bryophyte is seldom known.

Forest mosses are characterized by **Linyphiidae**, **Lycosidae** (not abundant), **Salticidae**, **Theridiidae**, and **Thomisidae**. Forest rock outcrop bryophyte communities differ from those of the forest floor and of the epiphytic bryophytes, the latter often being quite important in tropical rainforests. Those bryophyte fauna of forested areas are often species with broad habitat distribution.

Many of the same spiders occur in mosses in heathland, mountains, and tundra, with **Linyphiidae** being especially important for both diversity and numbers, but also having **Clubionidae** as a common inhabitant.

Marshes, moist meadows, and swampy places often share common species with each other and with bogs and fens. The **Linyphiidae** is again the predominant family. Grasslands and pastures likewise have **Linyphiidae**, but have a greater representation of the larger **Lycosidae**, a character they share with the tundra, in both cases probably due to greater sunlight and openness. Mountains and the tundra share genera, but often the species are different not only between these two habitats, but also between locations of the same habitat. The **Linyphiidae** predominate among the bryophytes. The **Lycosidae** are more common here than in forests, heath, and marshland.

Hence, the most common family in most habitats is the **Linyphiidae**, with **Walckenaeria** seemingly the most diverse and frequent genus among the mosses.

Lichens seem to share few species with bryophytes and have fewer spider inhabitants, perhaps not offering the moisture available among bryophytes. Some spiders may be seen on bryophytes only because the bryophyte is there and must be crossed to reach a destination. But many species of spiders seem to use bryophytes at least some of the time for moisture, drinking, hiding, and egg sites. When a habitat changes to dominance of one type of vegetation such as grasses to dominance by bryophytes, the types of spiders changes as well and thus the invader may prove to be a detriment to the spider community. Considerable experimental work is needed to determine the importance and role of the bryophytes for the spider community.

Invasive bryophyte species, such as ***Campylopus introflexus***, can change not only the appearance of the vegetation, replacing the lichen-dominated community, but also alter the spider communities associated with the ground vegetation.

Acknowledgments

My co-author, Jørgen Lissner, actually collected data and took numerous photographs to help make the forest portion of this chapter more complete; he also served as a critical reviewer that prompted me to re-organize the chapter. Norm Platnick helped me to find current names for species from older literature. Jeremy Miller provided me with a paper on tropical Erigoninae that included many moss dwellers. John Steel alerted me to the moss-dwelling Malkaridae and provided me with the paper. Many photographers contributed images, as noted in the captions.

CHAPTER 7-4

ARTHROPODS: SPIDERS AND PEATLANDS

Figure 1. A spider's view of *Sphagnum capillifolium*. Photo by Michael Lüth, with permission.

A number of studies have investigated the spider fauna of peat bogs, *e.g.* Villepoux (1990), Kupryjanowicz *et al.* (1998), Koponen (2000), and Scott *et al.* (2006). Some studies have been aimed at ecological aspects such as investigating the spider fauna assemblages of different bog types, others have been aimed at comparing assemblages as a function of shading or assessing spider indicator species of conservation value. Rėlys and Dapkus (2002) demonstrated the high degree of dissimilarity between spiders in pine forests and bogs in southern Lithuania. Few studies dealing directly with spiders and preferred moss species are known to us. Most information is scattered in the literature, and in most instances only relate spider habitats in respect to mosses to higher taxonomical levels such as "among moss" or "in *Sphagnum* bogs" (Figure 1).

Bogs and Fens

The nomenclature used for labelling the various types of bogs and fens has been inconsistent among the continents and even within continents, especially when considered over time. This makes it somewhat difficult to make adequate comparisons between studies when one is not familiar with the specific location. The fact that current

usage is based on water and nutrient source to define these habitats into **bog** (raised bog with only precipitation as water and nutrient input), vs **fen** (nutrients and water sources include ground water) makes it even more difficult to determine the category based on published studies alone. The fen is further divided into **poor**, **intermediate**, and **rich fen**, again based on nutrient levels. These distinctions may influence the spider fauna, but as will be documented in some of the studies below, the flora (usually described by the tracheophytes) may be the more important character for describing the spider habitat.

Many studies have catalogued the spiders in peatlands around the world, but especially in Europe. This even broader term of peatlands can include grasses and sedges with no or few mosses and lacking *Sphagnum* completely. Although authors often did not distinguish the substrate used by the spiders, it is reasonable to surmise that the spiders' presence was because the mosses that dominate the ground surface of the bog or fen provided the conditions needed for their lives (Figure 1), even if that is to provide a habitat suitable for shrubs and trees that the spiders inhabit. *Sphagnum* (Figure 2), especially, plays a large role in creating those conditions.

Figure 2. *Sphagnum subsecundum* showing spider webs. Photo by Michael Lüth, with permission.

Bryophytic Accommodations

Humans need to explain things, being curious and asking why. So we ask here why spiders associate with peatlands and their mosses. An obvious consideration is moisture, but the mosses also provide an escape from the sun (heat and light), a location for food, and a refuge from predation. These are the same characteristics typical of bryophyte interactions for most invertebrates. We will examine just how important they are for spiders in the bog and fen habitats.

Moisture Relationships

Moore and Bellamy (1974) discuss maintaining moisture as being among the adaptations of arachnids in "mire" habitats. Mires, bogs, and the various types of *Sphagnum* (Figure 1) peatlands have an increasing temperature upward and an increasing humidity downward. Nørgaard (1951) presented this gradient for a Danish *Sphagnum* bog (Table 1). Kajak *et al.* (2000) found that moss and litter layers were important for spiders in both natural and drained fens, with mosses causing the soil under them in the sedge-moss community to have the highest water-holding capacity and the greatest moisture stability throughout the year.

Table 1. Gradation of temperature and humidity in a Danish *Sphagnum* bog. From Nørgaard 1951.

	Diurnal Temperature Fluctuation	Relative Humidity
100 cm above surface	26°C	<40%
At mire surface	33°C	<40%
100 cm below surface	5°C	100%

A particularly helpful study is one by Biström and Pajunen (1989) examining the arachnid fauna occurring in association with *Polytrichum commune* (Figure 3), *Sphagnum girgensohnii* (Figure 4), and *S. squarrosum* (Figure 5) during May – October 1988 at two locations in southern Finland. All three of these mosses can occur in light shade with high water content. The life forms of these three mosses differ, with the sun-loving *P. commune* being

slender and upright, forming tall turfs, and sometimes having limited space between the stems, especially for larger spiders; it furthermore has a waxy leaf surface that does less to maintain surface moisture. *Sphagnum girgensohnii* is more shade-loving and provides relatively open spaces among the stems while creating a much greater canopy to intercept light and protect from UV radiation than one would expect from within the *P. commune* turf. *Sphagnum squarrosum* has a similar life form to that of *S. girgensohnii*, but it has larger leaves and a more succulent appearance.

Figure 3. *Polytrichum commune*, illustrating the waxy appearance of the leaves that hold little water compared to *Sphagnum*. Photo by Michael Lüth, with permission.

Figure 4. *Sphagnum girgensohnii*, a treed fen species that provides habitat for spiders. Photos by Janice Glime.

Figure 5. *Sphagnum squarrosum*, a woodland species that harbors spiders. Photo by Janice Glime.

When Biström and Pajunen sieved the mosses they retrieved 1671 arthropod specimens. Among these were 1368 Araneae represented by 77 species, 35 Pseudoscorpionida represented by 1 species, and 157 Opiliones represented by 5 species. Other arthropods included Diplopoda (39/4), Chilopoda (43/3), and Symphyla (9/1). Mites (Acarina) were not included in the study. Our climate in the Keweenaw Peninsula, Michigan, USA, is similar to the climate of Finland, but I (Glime) must confess that I have never found pseudoscorpions or harvestmen among any moss collections. Perhaps I simply was not observant at the right times.

Biström and Pajunen identified three moisture content levels (dry, moist, and wet) among these Finnish mosses and estimated the number of individuals per sample in each of these three conditions. They then estimated the number of individuals of each major spider species per sieved sample in each category (Table 2). Species that tended to occur in drier stands included the **Linyphiidae** *Dicymbium tibiale* and *Tenuiphantes alacris*. Those that seemed to prefer moister mosses included the **Linyphiidae** *Centromerus arcanus*, *Minyriolus pusillus*, and *Tapinocyba pallens*. They found that the spider *Walckenaeria kochi* (Figure 61; **Linyphiidae**) occurred only on *Polytrichum commune*, suggesting a preference for a drier habitat than that afforded by the five *Sphagnum* species present. Palmgren (1975) considered the optimum habitat for *Centromerus arcanus* to be moist spruce forest with a *Sphagnum* (Figure 1) carpet. The only spider community that seemed to differ significantly was that of *Sphagnum girgensohnii*, a grouping that was revealed by cluster analysis.

In addition to the moisture contained within the *Sphagnum* (Figure 1) mat, peatlands can give spiders a convenient access to open water, particularly for amphibious and "aquatic" species. Amphibious spiders that live in bogs are able to run along the surface of the water (Figure 6) until they reach a plant (Figure 7) (Nørgaard 1951). They can then climb down the plant, using the leverage gained from the plant attachment to break through the surface tension and climb down into the water.

Table 2. Abundance (individuals per sample) of widespread spider taxa in each of three moisture categories in Finnish forested boggy areas. From Biström & Pajunen 1989.

	dry	moist	wet
<i>Dicymbium tibiale</i>	0.87	0.39	0.24
<i>Semljicola faustus</i>	0.10	0.14	0.28
<i>Minyriolus pusillus</i>	0.03	0.10	0.23
<i>Tapinocyba pallens</i>	0.05	0.09	0.13
<i>Walckenaeria cuspidata</i>	-	0.04	0.04
<i>Centromerus arcanus</i>	0.82	0.95	1.45
<i>Tenuiphantes alacris</i>	0.48	0.28	0.11
<i>Macargus rufus</i>	0.13	0.12	0.06
<i>Neon reticulatus</i>	0.02	0.04	0.06
<i>Robertus scoticus</i>	0.03	0.18	0.09

But spiders in bogs are not just about water. Rather, this specialized fauna reflects not only the microclimate

and physical factors, but also the lack of disturbance, the age of the habitat, and the surrounding vegetation that may supply new fauna or serve as a refuge during certain times of the year (Bruun & Toft 2004). For the small spiders like the **Linyphiidae**, where long distance travel is difficult, stability is key. And ability to maintain body moisture is part of that.

Regular flooding effectively prevents some species from inhabiting various wetlands. In particular, Bruun and Toft (2004) found that the **Linyphiidae** were absent at Gjesing Mose, Denmark, attributing the absence to frequent flooding. On the other hand, they were present in other locations where the moss was floating, hence avoiding flooding of the spider habitat. Under moderate fluctuations in water level, some spiders are able to retreat upward into the hummocks. Other spiders such as *Maro lepidus* (Figure 38; **Linyphiidae**) take advantage of the water, preferring hollows over hummocks (Koponen 2004). This species was also found by Komposch (2000) in wetlands of Austria.

Kupryjanowicz *et al.* (1998) found a large proportion of **hygrophilous** (water-loving) species in the raised peat bogs of Poland. Humidity and illumination were the major determinants of the spider fauna. In the sunlit areas of the bog, two wolf spiders (**Lycosidae**), *Pardosa sphagnicola* (Figure 8) and *Arctosa alpigena lamperti* (Figure 51) dominated the spider fauna. Since these are larger spiders, it is likely that they are more tolerant of the drying sun because of their lower surface area to volume ratio. Their dominance in peatlands is a shift from the dominance of **Linyphiidae** among mosses in most drier habitats. The somewhat loose arrangement of the *Sphagnum* (Figure 1) branches below the surface might permit them to retreat there when they need to replenish moisture, avoid UV light, or escape from predators.

Figure 8. *Pardosa sphagnicola* female on *Sphagnum*. Photo by Walter Pfliegler, with permission.

The moisture relations of spiders in bogs are reflected in the ability of the bogs to support species that are also common in marshes and other wetlands. For example, in Poland Kupryjanowicz (2003) found some of the most common **sphagnophilous** species, including **Hahniidae**: *Antistea elegans* (Figure 9), **Lycosidae**: *Pardosa sphagnicola* (Figure 8), *Pirata tenuitarsis* (Figure 10), and *P. uliginosus* (Figure 33) in the sedge-moss marshes.

Other peat bog species present in these marshes were the **Gnaphosidae**: *Drassyllus lutetianus* (Figure 11) and *Gnaphosa nigerrima* (Figure 12) – a species mostly restricted to *Sphagnum* carpets of moors in Germany (Platen 2004), and **Salticidae**: *Neon valentulus* (Figure 13). The **Linyphiidae** were also present, represented by *Aphileta misera* (Figure 36), but this family is much more species-rich elsewhere.

Figure 16. *Trochosa robusta* (Lycosidae) female, a species that lives in bogs but is adapted to dry habitats. Photo by Jørgen Lissner, with permission.

On the other hand, it appears that many of the spiders in bogs are actually **xerophiles** (dry-loving), permitting them to survive the dry heat of summer in exposed areas of the bog. For example, *Walckenaeria furcillata* (Figure 14; **Linyphiidae**) is a widespread species that occurs not only under heather and scrub, and among mosses and grasses on acid heathland, but also occurs in deciduous woodlands, calcareous grassland, and fens (Dawson *et al.* in prep). *Synageles hilarulus* (Figure 15; **Salticidae**) is a sub-boreal species (Logunov 1996) that runs about in search of food, but in the Mediterranean region, it occurs in grassland (Telfer *et al.* 2003). *Trochosa robusta* (Figure 16; **Lycosidae**) lives predominately on dry grassland of limestone, but can also be found on the oligotrophic moors (Platen 2004). These spiders can escape excessive moisture by climbing plants or hummocks.

Temperature Relationships

Although it is sometimes difficult to separate the effects of temperature from those of moisture, certainly the *Sphagnum* (Figure 1) mat provides a gradient of both, as seen in Table 1. The surface experiences greater extremes of both (Figure 87), making the mat a suitable refuge for some spider species. The differences between surface

conditions and those within the peat layer can provide adequate niche separations in a short vertical distance. Nørgaard (1951) cites the vertical separation of two members of **Lycosidae**, *Pirata piraticus* (Figure 17) and *Pardosa pullata* (as *Lycosa pullata*; Figure 18-Figure 19), in a Danish *Sphagnum* (Figure 1) bog in relation to temperature and humidity. *Pirata piraticus* lives among the *Sphagnum* stalks (Figure 4) where the relative humidity remains a constant 100% and the temperature varies only about 5°C within a day. At the surface (Figure 1), however, where *Pardosa pullata* lives, the humidity varies between 40 and 100% on a single day with temperature variations up to 30°C within a day. *Pardosa pullata* is physiologically adapted to this fluctuation, with a higher temperature preference and a higher thermal death point than those of *Pirata piraticus*. The latter species also has a greater sensitivity to low humidities. This relationship is described in greater detail later in this subchapter.

Spider Mobility

Perhaps one limiting factor for spiders among bog and fen bryophytes is the problem of mobility. First, they must arrive, so that for restored peatlands, this can be a serious detriment to species diversity and the specialists are likely to be the last to arrive because they must traverse unfriendly territory to get there. Some spiders are highly mobile compared to others. The larger spiders like **Lycosidae** (wolf spiders) are able to run across the surface, and as most of us have witnessed, these can run fairly quickly and traverse considerable distances compared to such spiders as the tiny **Linyphiidae**. Hence, the larger spiders, especially the **Lycosidae**, are more common on peatlands, especially during restoration, than in other bryological habitats. *Gnaphosa nigerrima* [6.7-9.1 mm (Grimm 1985); Figure 12; **Gnaphosidae**] is widespread in northern Europe and Asia, where it is common on *Sphagnum* lawns (Figure 1). Its presence in pitfall traps among *Sphagnum* (Harvey *et al.* 2002) reflects its ability to run about swiftly at night. Nevertheless, it is unable to cross a fragmented landscape to recolonize restored wetlands. This is evident in Denmark, where it only occurs in the very best (undisturbed) bogs. This species demonstrates the importance of broad ecological amplitude in enabling spider dispersal.

Abundance and Dominance

Peatlands seem to have a better commonality of dominant species over widespread geographic areas than some of the other communities. This is especially true for the **Lycosidae**, where the genera *Arctosa*, *Pirata*, *Pardosa*, and *Trochosa* are common and often the most abundant, but species vary geographically. Nevertheless, as large spiders, they can be less abundant in numbers than small spiders like the **Linyphiidae**. Biomass comparisons might tell a different story.

Komposch (2000) used a variety of sampling methods (pitfall traps, light-traps, soil-sifter, hand-collecting) to study the spiders in wetlands at Hörfeld-Moor, Austria. This study assessed the spider fauna of alder forest, willow shrub, hay meadow, moist meadow, sedge swamp, reed bed, meadowsweet fen, floating mat, and raised bog. Surprisingly, the bog had the smallest percentage of red data species (17% endangered) among the habitats sampled. Komposch suggested that the small number of endangered

species in the raised bog may relate to the small size of this habitat in the study area. Fourteen species occurred only in the bog, but were not necessarily bryophyte inhabitants and were often represented by only one or two individuals. The dominant species were members of the **Lycosidae**: *Trochosa terricola* (Figure 20-Figure 21) (30%), *Trochosa spinipalpis* (Figure 22) (22%), and *Pirata hygrophilus* (Figure 23) (10%), all reported elsewhere in this chapter as important species in bogs or fens. *Gnaphosa nigerrima* (Figure 12; **Gnaphosidae**), likewise reported elsewhere in this subchapter, occurred on hummocks (Komposch 2000) in an area where peat was formerly harvested (Rupp 1999).

Kupryjanowicz *et al.* (1998) reported 203 species of spiders in the raised peat bogs of Poland, where *Sphagnum magellanicum* (Figure 24) and *S. rubellum* (Figure 25) dominate the moss layer. The *Sphagnum magellanicum* habitat was dominated by **Lycosidae**: *Pardosa sphagnicola* (Figure 8) (14, 32, and 34% of spiders at three sites) and in the *Vaccinium uliginosum* pinetum, *Pirata uliginosus* (Figure 33) with 19 and 24% at two sites and 39% at another site. *Pardosa sphagnicola* comprised 18% at the latter site. But even rare species were relatively numerous here and in other bogs, especially on more sunlit peat bogs: *Arctosa alpigena lamperti* (Figure 51; **Lycosidae**) (7% in one site), *Gnaphosa microps* (Figure

26; **Gnaphosidae**) (3% in one site), *Pardosa hyperborea* (Figure 52) (3% in one site), *P. maisa* (8% in one site), and *Scotina palliardi* (**Liocranidae**) (3%, 0.03%, 4% in three sites) – a species new to Poland.

Figure 25. *Sphagnum rubellum*. Photo by Michael Lüth, with permission.

Figure 26. *Gnaphosa microps* (Gnaphosidae). Photo by Glenn Halvor Morka, with permission.

In bogs of Geitaknottane Nature Reserve, western Norway, the **Lycosidae** again dominated. *Pirata hygrophilus* (Figure 23) showed the highest activity abundance (49.2%), followed by *Pardosa pullata* (Figure 18-Figure 19) (17.2%); *Notioscopus sarcinatus* (Figure 27; **Linyphiidae**) (3.9%), *Pardosa amentata* (Figure 28) (3.3%), and *Trochosa terricola* (Figure 20-Figure 21; **Lycosidae**) (3.3%) were also among the most abundant (Pommeresche 2002). However, activity can be misleading, with the distance travelled by the tiny **Linyphiidae** being quite short and often confined to the mosses, keeping them out of pitfall traps.

Biström and Pajunen (1989), in their study of two Finnish peatlands, found 23 species with densities of 1 or more individuals per square meter. They found that in the forested boggy areas they studied, the spider fauna was represented by a few very abundant species and many rarely sampled species. Seven species comprised 66% of the total number of spiders. *Centromerus arcanus* (**Linyphiidae**) was the most abundant spider, with 8.7-24.4 individuals per square meter, and tended to be more frequent in *Sphagnum girgenoshnii*. Other **Linyphiidae** included *Dicymbium tibiale* (1.8-11.9) and *Lepthyphantes alacris* (0.7-8.6). Larger spiders such as *Pirata uliginosus* (Figure 33; **Linyphiidae**) are somewhat less dense (1.4), but more easily seen. *Theonoe minutissima* (Figure 29; **Theridiidae**) is small like a linyphiid but was not as abundant (1.1).

Figure 29. *Theonoe minutissima* (**Theridiidae**) female on moss. Photo by Jørgen Lissner, with permission.

Koponen (2002) compared the spider fauna of Sweden, Finland, and northern Norway. He found that spider communities of the southern sites (hemiboreal) differed from the boreal sites of coniferous taiga and those north of the taiga. In the hemiboreal zone, the **Lycosidae** were dominant, led by *Pirata uliginosus* (Figure 33), along with *Pardosa pullata* (Figure 18-Figure 19), whereas the **Lycosidae** *Pardosa sphagnicola* (Figure 8) and *P. hyperborea* (Figure 52) were dominant in the boreal zones. *Hilaira nubigena* (Figure 30; **Linyphiidae**) and *Pardosa atrata* were dominant north of the taiga. No one species

dominated throughout the study area. In Finland, near the northern limit of the hemiboreal zone, the 20 most abundant species were nine **Lycosidae**, nine **Linyphiidae**, one **Hahniidae**, and one **Philodromidae**. The three boreal zones all had *Pardosa sphagnicola* and *P. hyperborea*, both **Lycosidae**, as their two most abundant species. *Arctosa alpigena* (Figure 51; **Lycosidae**) (as *Tricca alpigena*) was also typical there. In the two northernmost zones [palsa (low, often oval, frost heaves occurring in polar and subpolar climates, containing permanently frozen ice lenses) and coastal hemiarctic bogs], *Hilaira nubigena* (Figure 30; **Linyphiidae**) and *Pardosa atrata* were also common.

In a similar study Koponen (1994) found 169 species of spiders in 14 families in the peatlands of Quebec, Canada. Of these, 73 species occurred only in the temperate-boreal region, 58 only in the subarctic-arctic region, and 38 in both regions. The **Linyphiidae** were the most species-rich family (58.3% of species), an interesting observation in a study using pitfall traps. This family was typical of the subarctic region, with the **Erigoninae** being especially important there. The linyphiid *Ceratinella brunnea* occurred in six of the seven study areas. Typical of peatlands, the **Lycosidae** comprised 12.4% of the species, with *Alopecosa aculeata* (Figure 94) and *Pardosa hyperborea* occurring in six of the seven study areas; **Gnaphosidae** comprised 7.1%. The **Hahniidae**, **Dictynidae**, **Salticidae**, **Liocranidae**, and **Theridiidae** were mostly confined to the temperate and to a lesser extent to boreal regions, although *Theonoe stridula* (**Theridiidae**) occurred in six of the seven study areas. Quebec and southern Ontario bogs had 64% of their species in common in the temperate region, whereas only 27% were in common in the subarctic region. The species from bogs in the Manitoba taiga and Quebec were intermediate with 50% of the species in both. About one-third of the spiders in the Quebec bog are Holarctic.

Figure 30. *Hilaira nubigena* (**Linyphiidae**). Photo by Glenn Halvor Morka, with permission.

In Russia, open *Sphagnum* bogs and bog moss pine forests supported 97 species of spiders (Oliger 2004). The most abundant of these was *Pardosa sphagnicola* (Figure 8; **Lycosidae**). The most common families in pitfall traps were **Lycosidae**, **Gnaphosidae**, and **Liocranidae**, whereas the **Linyphiidae** was represented by the most species. It is

possible that the **Linyphiidae** were more abundant than indicated by the pitfall traps. Members of this family of tiny spiders are likely to spend little time venturing outside their moss habitat.

As in most of the other habitats discussed in Chapter 7-2, the linyphiid genus *Walckenaeria* plays an important role in species diversity. This subchapter likewise includes a number of species of *Walckenaeria* from bogs and fens. In addition to these, Millidge (1983) reported several from "boggy areas" in North America and Greenland, including *W. clavicornis* (Figure 63), *W. redneri*, *W. castanea* (Figure 31), and *W. prominens*. Among these, only *W. castanea* was identified as being in a *Sphagnum* bog.

Tyrphobionts

Peus (1928) coined the term **tyrphobiont** to define those species that are confined to living in peat bogs and mires. Following this definition, Casemir (1976) listed eight species of spiders as true tyrphobionts in Europe: *Heliophanus dampfi* (Figure 32; **Salticidae**), *Pirata uliginosus* (Figure 33; **Lycosidae**), *Clubiona norvegica* (Figure 34; **Clubionidae**), *Theonoe minutissima* (Figure 35; **Theridiidae**) – a species listed as rare in Slovakia. Representing the **Linyphiidae**, he found *Aphileta* (as *Hillhousia*) *misera* (Figure 36), *Drepanotylus uncutus* (Figure 37), *Hilaira excisa*, and *Maro lepidus* (Figure 38).

Are these tyrphobiont designations supported by other studies? We find that the suitability of the designation can vary by country. It is interesting that Casemir (1976) considered *Drepanotylus uncatus* (Figure 37; Linyphiidae) and *Maro lepidus* (Figure 38; Linyphiidae) to be tyrphobionts, whereas at Hörfeld-Moor in Austria, these species were present in some habitats, but not in the bog (Komposch 2000). And even in Great Britain, *Clubiona norvegica* (Figure 34; Clubionidae) occurs in wet places of the high moorland in other mosses as well as

Sphagnum (Harvey *et al.* 2002). *Hilaira excisa* (Linyphiidae) is even more puzzling, for we were unable to find any other record of this species from *Sphagnum* bogs, although our search was definitely not comprehensive. In Denmark it occurs in mossy springs with seeping cold groundwater (cold in the summer). Furthermore, in the Tyne Valley, UK, *Hilaira excisa* lives among grass, rushes, and moss in swamps (Jackson 1906).

Neet (1996) hypothesized that the tyrphobionts should serve as indicators of "good-state" peat bogs. However, the analysis was confounded by the strong relationship between peat bog area and number of tyrphobiont species (Kendall's rank correlation $\tau = 0.65$). Neet (1996) showed that the number of tyrphobiont species of seven European peat-bogs increased as the area of the bog increased. He pointed out that in addition to the species-area relationship, insufficient sampling effort, biogeographical effects and isolation, and perturbations causing local extinctions all contribute to absent tyrphobionts. As in the analysis above, Neet (1996) pointed out that later evidence does not support all members of Casemir's (1976) list as tyrphobionts. He found that under conditions where the preferred peatland habitat is scarce, some of these tyrphobionts could occur in other habitats, including *Pirata uliginosus* (Figure 33; Lycosidae) and *Drepanotylus uncatus* (Figure 37; Linyphiidae) (Hänggi 1987; Hänggi *et al.* 1995). I (Lissner) likewise found *Drepanotylus uncatus* in non-peatland habitats in Denmark, but less reliably, among mosses of neutral or alkaline mesotrophic fens. Hence, these are not strict tyrphobionts.

Specialists and Rare Species

Bogs are often the home of rare species, and their rarity increases as more bogs get destroyed. One such example of rarity is *Heliophanus dampfi* (Figure 32; Salticidae). *Heliophanus dampfi* is a rare jumping spider, known in the United Kingdom only from Flanders Moss (Stewart 2001) and two other mires, one each in Wales and Scotland (Harvey *et al.* 2002). Nevertheless, it is known as a bog inhabitant in studies elsewhere [Casemir 1976 (Germany); Kupryjanowicz *et al.* 1998 (Poland)].

In a study of the *Sphagnum* (Figure 1) habitats of northwest Russia, Oliger (2004) reported that *Antistea elegans* (Figure 9; Hahniidae), *Arctosa alpigena* (Figure 51; Lycosidae) (as *Tricca alpigena*), and *Gnaphosa nigerrima* (Figure 12; Gnaphosidae), all species reported for bogs elsewhere in this subchapter, were numerous in bogs but rare in forests. Biström and Pajunen (1989) considered that the hahniid *Antistea elegans* (Figure 9) might be a bog specialist, with 1.4 individuals per square meter in one site in Finland, but Kupryjanowicz (2003) has reported it from marshes in Poland.

In England, the rare *Maro lepidus* (Figure 38; Linyphiidae) is only known from acid mires, generally with abundant *Sphagnum* (Boyce 2004). *Erigone psychrophila* (Figure 39; Linyphiidae), *E. dentigera* (as *E. capra*), and *Semljicola faustus* (as *Latithorax faustus*) (Figure 40; Linyphiidae) similarly are bog specialists in upland blanket mires in England, living in saturated *Sphagnum* at the margins of pools. But *Semljicola faustus* is known from mosses among heather in the Faroe Islands (Bengtson & Hauge 1979; Holm 1980) and from peat bogs

as well as among stony debris in North Bohemia (Růžicka & Hajer 1996). *Glyphesis cottonae* (Figure 41; Linyphiidae) and *Centromerus levitarsis* (Figure 42; Linyphiidae) are specialists among *Sphagnum* in acid mires; Dawson *et al.* (in prep.) report *C. levitarsis* from *Sphagnum* in damp woodlands and moors in Great Britain.

Figure 41. *Glyphesis cottonae* (Linyphiidae) on *Sphagnum*. Photo by Jørgen Lissner, with permission.

Figure 42. *Centromerus levitarsis*. Photo by Jørgen Lissner, with permission.

Later Boyce (2011) explored the invertebrate fauna of Dartmoor, UK, bogs. He considered *Walckenaeria nodosa* (Figure 43) to be frequent in bogs and wet heaths. And like others, he found the Linyphiidae to be well represented. He considered the linyphiid *Aphileta misera* (Figure 36) to be a specialist in acid mires. *Bolyphantes luteolus* (Figure 44) is likewise an obligate acid mire associate, occurring in litter and mosses of blanket bogs. It is "scarce" in the UK. *Meioneta mossica* (Figure 45) occurs exclusively on *Sphagnum* (Figure 1) lawns where adults build small webs among upper parts of moss cushions. This species requires abundant bog mosses to make suitable homes. *Araeoncus crassiceps* (Figure 46), *Drepanotylus uncatus* (Figure 37), and *Pirata uliginosus* (Figure 33) live in litter and moss in blanket bogs.

Figure 43. *Walckenaeria nodosa*, a species of bogs and wet heaths. Photo by Rudolf Macek, with permission.

Figure 44. *Bolyphantes luteolus*, an obligate acid mire associate Rudolf Macek, with permission.

Figure 46. *Araeoncus crassiceps*, a species that lives among litter and mosses in blanket bogs. Photo by Jørgen Lissner, with permission.

Erigone welchi (Figure 47; **Linyphiidae**) lives in saturated *Sphagnum*, making its webs in the moss cushions just above the water surface (Boyce 2004). *Meioneta mossica* (**Linyphiidae**) builds small webs among the upper layers of the moss cushions in open *Sphagnum* lawns. *Pirata piscatorius* (Figure 48; **Lycosidae**) lives in very wet areas of *Sphagnum* bogs, where the females build a vertical silken tube in the moss, leading down beneath the water surface and providing an escape when the spider is disturbed.

Figure 47. *Erigone welchi* (**Linyphiidae**). Photo by Marko Mutanen, through Creative Commons.

Figure 48. *Pirata piscatorius* (**Lycosidae**) female with egg sac. Photo by Jørgen Lissner, with permission.

Komposch (2000) demonstrated the uniqueness of spider **coenoses** of bogs in the wetlands of Austria. He used pitfall traps, light traps, soil sifters, and hand collections to assess the spider fauna of alder forest, willow shrub, hay meadow, moist meadow, sedge swamp, reed bed, meadowsweet fen, floating mat, and raised bog. The dendrogram of communities showed the greatest separation of the bog spiders from those of all other habitats in the study. Nevertheless, the three dominant species were not specialists. *Pirata hygrophilus* (Figure 49; **Lycosidae**) was the most frequent species in the area, but it has a widespread habitat range, including the ground layer of damp woodlands, raised bogs, lowland heaths, marshy grassland, but especially associated with open water (Harvey *et al.* 2002). *Trochosa terricola* (Figure 20-Figure 21; **Lycosidae**) was the most abundant and is known from woodland, grassland, heathland and industrial sites, hiding under stones and logs; it prefers dry, heathy conditions to bogs and marshes (Harvey *et al.* 2002). Only *T. spinipalpis* (Figure 22) among these abundant spiders prefers damp places, but even it occurs widely in bogs, wet heath, damp meadows, fens, and marshland. On the Austrian raised bogs, *Trochosa terricola* (Figure 20-Figure 21) and *T. spinipalpis* were **sympatric** (have overlapping distributions) and formed the spider coenosis there. The floating mat bog seemed to be the preferred habitat for *Pirata piscatorius* (Figure 48).

Figure 49. *Pirata hygrophilus* (**Lycosidae**) female with egg sac. Photo by Jørgen Lissner, with permission.

Stewart (2001) sheds light on the niche questions for some of these bog species from Flanders Moss, Scotland. Species that were common in some areas seemed to be absent in many others. This is the case for *Clubiona diversa* (Figure 50; **Clubionidae**), a common bog dweller in Scotland, but preferring drier sites in southern England (Stewart 2001); in Denmark it is common in wet and dry heathland, but not in places with a peat layer. But what is it that causes these spiders to inhabit such disparate habitats in different places?

In Poland, Kupryjanowicz *et al.* (1998) found that the rarest species and those that could be labelled tyrophobionts were present on the more sunlit peat bogs. Among the most numerous of these rare species were **Gnaphosidae**: *Gnaphosa microps* (Figure 26); **Linyphiidae**: *Glyphesis cottonae* (Figure 41) and *Meioneta mossica*; **Liocranidae**: *Scotina palliardi*; **Lycosidae**: *Arctosa alpigena lamperti* (Figure 51), *Pardosa hyperborea* (Figure 52), and *P. maisa* [also from *Sphagnum* in poor pine fens (Itaemies & Jarva 1983)]; **Salticidae**: *Heliophanus dampfi* (Figure 32) and *Cobanus cambridgei*? (as *Talavera westringi*; see Platnick 2013); and **Theridiidae**: *Theonoe minutissima* (Figure 35). But in the mountains of the UK, *Arctosa alpigena* lives both in and under the moss *Racomitrium lanuginosum*. And *Theonoe minutissima* occurs among mosses in woods of the Tyne Valley, UK (Jackson 1906) and in peat bogs as well as among stony debris in North Bohemia (Růžička & Jaher 1996). Other rare species in Poland bogs included **Clubionidae**: *Clubiona norvegica* (Figure 34 – also in moorland in the UK); **Gnaphosidae**: *Haplodrassus moderatus* (Figure 53 – also in mosses of forests in Denmark) and *Zelotes aeneus* (Figure 54); **Linyphiidae**: *Aphileta misera* (Figure 36 – also in marshes in the UK), *Centromerus semiater* (Figure 55), and *Ceraticelus bulbosus* (as *Ceraticelus sibiricus*) (Figure 56); **Lycosidae**: *Pirata insularis*, *P. tenuitarsis* (Figure 10 – also in marshes in Poland), and *Zora armillata* (Figure 57); and **Mimetidae**: *Ero cambridgei* (Figure 58-Figure 59). The percentage of rare species ranged from 3.5% to 18.3%.

Mosses as Spider Habitats in Bogs and Fens

Is *Sphagnum* Special?

One factor that creates tyrphobionts is having a special requirement. For example, *Pirata hygrophilus* (Figure 23;

Lycosidae is a prominent species in a number of European bogs (Casemir 1976; van Helsdingen 1976; Almquist 1984; Kupryjanowicz *et al.* 1998; Svaton & Pridavka 2000). Unlike the sun-loving rare species described by Kupryjanowicz *et al.* (1998), *Pirata hygrophilus* seems to occur only in areas of shaded *Sphagnum* (Nørgaard 1952). *Pirata piscatorius* (Figure 48) also seems to be confined to the *Sphagnum* area of the habitat (Bruun & Toft 2004).

Some species seem to require the bogs for their winter retreat (Boyce 2004). For example, *Sitticus floricola* (Figure 38; **Salticidae**) spends the winter deep in the *Sphagnum* hummocks (Harvey *et al.* 2002; Boyce 2004).

Boyce (2004) found that for some species, the acid nature of the habitat seemed to be important, but was it the pH (acidity) or the vegetation associated with it? For example, *Hilaira pervicax* (Figure 62; **Linyphiidae**) is an acid mire dweller among *Sphagnum* and rushes in acid flushes and blanket mires (Boyce 2004). *Hilaira nubigena* (Figure 30) lives above 400 m and is likewise associated with *Sphagnum* and rushes in acid flushes and blanket mires. *Semljicola caliginosus* (**Linyphiidae**) lives in *Sphagnum* and wet litter on blanket mires. *Clubiona norvegica* (Figure 34; **Clubionidae**), *Walckenaeria kochi*, (Figure 61) and *W. clavicornis* (Figure 63; **Linyphiidae**) are primarily known from acid (*Sphagnum*) mires in Britain, but they are not restricted to this habitat (see Chapter 7-2). *Pirata tenuitarsis* (Figure 10; **Lycosidae**) usually lives among *Sphagnum* near bog pools. Do they require this habitat, or do they benefit from lack of a predator or competing species?

Figure 63. *Walckenaeria clavicornis* (**Linyphiidae**) on moss. Photo by Jørgen Lissner, with permission.

On the other hand, some spider species prefer *Sphagnum* habitats, but are not necessarily confined to bogs. At the Lesni Lom Quarry (Brno-Hady) in the Czech Republic, *Zelotes clivicola* (Figure 64; **Gnaphosidae**) was abundant among mosses in peat bogs, but it also occurred under stones in peat bogs and among mosses in pine and birch forests (Hula & Štátna 2010).

Figure 64. *Zelotes clivicola* (**Gnaphosidae**) male. Photo by Jørgen Lissner, with permission.

Maelfait *et al.* (1995) found that *Gongylidiellum latebricola* (Figure 65; **Linyphiidae**) was one such species, with its presence correlating with the presence of *Sphagnum* in riverine forests in Flanders, Belgium. But what is the role of *Sphagnum* in such habitats? Is it a winter retreat? Or could it be a moist refuge in the heat or drought of summer? I (Lissner) have found it commonly among *Hypnum* mats in forests in Denmark and about equally common from acidic fens (with or without *Sphagnum*). Hence, whatever role *Sphagnum* has for this species, it is apparently not unique. Furthermore, not all *Sphagnum* species are equal, with some occurring in forests in shallow turfs, some submerged, and others at varying water levels in the open.

In Russia, two members of **Lycosidae**, *Pardosa atrata* and *Pirata piscatorius* (Figure 48), occur commonly in bogs, but are absent from forests (Oliger 2004). *Antistea elegans* (Figure 9; **Hahniidae**), *Gnaphosa nigerrima* (Figure 12; **Gnaphosidae**), and *Arctosa alpigena* (Figure 51; **Lycosidae**) (as *Tricca alpigena*) were numerous in bogs, rare in forests. On the other hand, four **Lycosidae** were dominant in both bogs (48%) and forests (52%) in this study: *Alopecosa pulverulenta* (Figure 66), *Pardosa sphagnicola* (Figure 8), *P. hyperborea* (Figure 52), and *Pirata uliginosus* (Figure 33).

Figure 66. *Alopecosa pulverulenta* (**Lycosidae**) with spiderlings on moss. Photo by Walter Pfliegler, with permission.

Pommeresche (2002) found that bog spider communities in Norway had more species in common with the open *Calluna*-pine forests than with other types of forests, perhaps indicating an acid preference. **Lycosidae**, **Liocranidae**, and **Tetragnathidae**, for example, dominated both bogs and *Calluna*-pine forests. Some species indicated open areas: *Trochosa terricola* (Figure 20-Figure 21; **Lycosidae**), *Gonatium rubens* (Figure 67; **Linyphiidae**), and *Pardosa pullata* (Figure 18-Figure 19; **Lycosidae**). *Pirata hygrophilus* (Figure 23; **Lycosidae**) was an indicator species for bogs. *Pirata hygrophilus* and *Notioscopus sarcinatus* (Figure 27; **Linyphiidae**) (in wet *Sphagnum* and *Polytrichum* under scrub) only occurred in the bogs, whereas elsewhere in Europe *P. hygrophilus* frequently occurs in humid forests (Maelfait *et al.* 1995; Thaler 1997) and *Notioscopus sarcinatus* (Figure 68) occurs in fens (Boyce 2004), supporting the observation that the preferred habitat may differ geographically.

Figure 67. *Gonatium rubens* (**Linyphiidae**). Photo by James K. Lindsey, with permission.

Figure 68. *Notioscopus sarcinatus* on moss. Photo by Jørgen Lissner, with permission.

Heathlands, another acid habitat, have some species exclusively in common with the bog habitats. For example, *Hypselistes jacksoni* (Figure 69; **Linyphiidae**) and *Trochosa spinipalpis* (Figure 22; **Lycosidae**) occur almost exclusively in bogs and wet heaths in Great Britain (Boyce 2004).

Figure 69. *Hypselistes jacksoni* (Linyphiidae) on moss. Photo by Jørgen Lissner, with permission.

As might be expected, marshlands can have similar species to those of bogs. *Gnaphosa nigerrima* (Figure 12; Gnaphosidae) occurs in *Sphagnum* lawns (Boyce 2004) as well as in marshes (Kupryjanowicz 2003). On the other hand, *Carorita limnaea* (Figure 70; Linyphiidae) not only lives in very wet acid *Sphagnum* mires (Boyce 2004), but also in mixed coniferous woods (Pickavance & Dondale 2005), another typically acid habitat.

Figure 70. *Carorita limnaea* (Linyphiidae) suspended from moss. Photo by Jørgen Lissner, with permission.

The foregoing studies imply the importance of the vegetation structure, at least as a complement to the niche provided by *Sphagnum*. But how do we explain that some spider species occur in what appear to be very different habitats? For example, *Satlatlas britteni* (Linyphiidae) lives in *Sphagnum* bogs and salt marshes (Boyce 2004). In the Faroe Islands, *Centromerita bicolor* (Figure 71; Linyphiidae) not only occurs in *Sphagnum* wetlands, but also on a sand dune, as well as many other habitat types (Lissner 2011). Clearly some of these are generalists, but some, like *Satlatlas britteni* occupy only two very different habitats.

Figure 71. *Centromerita bicolor* on moss. Photo by Arno Grabolle <www.arnograbolle.de>, with permission.

The Bog and Fen Habitat

Hummocks and Hollows

Topogenous *Sphagnum*-dominated, acidic fens are frequently developed into a topographic mosaic of hollows and hummocks. Hollows only provide a thin layer of non-flooded moss as habitat and may become seasonally flooded. Hummocks provide a deeper layer of moss/peat, including subsurface air spaces that spiders may occupy. Not surprisingly, a higher number of spider species is associated with the hummocks than in the surrounding hollows, at least when it comes to spiders living within the moss layer (Koponen 2004). Hummocks are less susceptible to flooding and provide more stable environments than the hollows. The structures of hummocks are more complex due to the thickness of the moss layer and the presence of a higher number of moss and plant species. Thus, they offer lots of hiding and hunting places per unit of area. They may also exhibit a more uniform climate internally except for the upper few centimeters. Ant colonies (e.g. *Formica*, *Myrmica* spp.) are common features of hummocks and the activities of ants may diversify habitats, providing internal runways, and increasing the number of spider species sustained by the hummocks. According to Lesica and Kannowski (1998) the activities of ants may provide an environment for plants that has better aeration and is warmer, as well as nutrient-enriched, allowing more plant species to colonize the hummock. This undoubtedly affects the properties of the spider habitats. Cavities produced by ants may be exploited by web-building spiders, e.g. the small comb-footed spider, *Theonoe minutissima* (Figure 35; Theridiidae), a spider mostly found within hummocks. Densities in moist hollows, low hummocks, and higher *Sphagnum fuscum* hummocks are 1.7-2.1- fold higher than in wet hollows (Koponen 2004). *Drepanotylus uncatus* and *Pardosa sphagnicola* were more abundant in moist hollows in southern Finland and *Robertus arundineti* in hummocks.

Indirect Association with *Sphagnum*

Many spiders found in bogs and fens are indirectly associated with mosses. For example the stunted trees sometimes found on open or scarcely wooded ombrogenous bogs or on poor fens provide microhabitats suitable for spiders (Figure 72). Usually they contain plenty of loose bark and rotten wood, much preferred

hiding places for many spider species. The orb weaver *Araneus marmoreus* (Figure 73-Figure 75; **Araneidae**) is frequently found in wooded wetlands, constructing its web usually at heights above 1.5 m (Harvey *et al.* 2002). The long-jawed orb weaver, *Tetragnatha nigrita* (Figure 76; **Tetragnathidae**), is largely confined to branches of birch and other trees growing on *Sphagnum* bogs and fens, and is only rarely found on the same tree species growing outside bogs and fens. The spider fauna associated with the herb layer of bogs and fens is also distinctly different from that of the herb layer of nearby drier places. For example, the jumping spider *Heliophanus dampfi* (Figure 32; **Salticidae**) can be swept from the herb layer and from tree saplings in *Sphagnum* bogs, but is very rare in other types of wetlands.

Differences among Bogs and Fens

Individual **ombrogenous** (dependent on rain for its formation) bogs as well as poor fens seem to possess rather different spider assemblages even if located relatively close to one another. Many moss-associated spider species of the bogs appear to have a very scattered distribution, being found only in a few widely separated bogs, e.g. *Robertus unguis* (Figure 77; **Theridiidae**), *Clubiona norvegica* (Figure 34; **Clubionidae**), *Glyphesis cottonae* (Figure 41; **Linyphiidae**), and *Carorita linnaea* (Figure 70; **Linyphiidae**). This is puzzling since the dispersal capacity usually is high for spiders. Perhaps this is a combination of low dispersal capacity, inhospitable land between sites, and local extinction exceeding recolonization.

Figure 77. *Robertus unguis* male on moss. Photo by Jørgen Lissner, with permission.

One of the spiders that seems to prefer the *Sphagnum* habitat is *Pardosa sphagnicola* (Figure 79-Figure 81; **Lycosidae**; Oliger 2004). In the Lake Ladoga region of Russia, this species is the most abundant and is nearly ubiquitous among the peatlands. Oliger found that there was significant similarity in the taxa of spiders in peatlands in NW Russia, Finland, and Lithuania. These especially included **Lycosidae**, **Gnaphosidae**, and **Liocranidae**. The latter were frequently encountered in pitfall traps.

Niche Separation – Lycosidae

Nørgaard (1951) reported on the common lycosid spiders *Pardosa pullata* (as *Lycosa pullata*; Figure 82; **Lycosidae**) and *Pirata piraticus* (Figure 83; **Lycosidae**) in Danish *Sphagnum* bogs. These two spiders live in close proximity to each other, but their microdistribution

vertically is very different. *Pardosa pullata* (4-6 mm length) prefers moist habitats, where it runs about on the surface of the closely knit *Sphagnum* capitula (plant tops; Figure 1), although in Great Britain the maritime climate permits it to be quite ubiquitous. In Denmark, Nørgaard found a mean of 12 individuals per square meter on the surface of the *Sphagnum* carpet in mid July. *Pirata piraticus* (up to 9 mm long; Figure 83) likewise prefers moist habitats. Stewart (2001) considers *Pirata piraticus* to be the commonest wolf spider of wet, marshy areas with *Sphagnum* moss, where it dwells beneath the surface among the much more open realm of *Sphagnum* stems (Nørgaard 1951). Nevertheless, it stays close to a free water surface (Nørgaard 1951). As discussed above, temperature can account for the separation of these two species. In the topographic depression bog used for this study, daily air temperatures vary widely from 6°C at night (due to cold air masses streaming down from higher ground) to 32°C in the daytime sun (Figure 84). At the *Sphagnum* surface it is even higher, reaching 39°C. Such wide variation is not, however, the case among the stems within the *Sphagnum* mat. During the same time period, temperatures ranged only 17 to 22°C at 10 cm below the surface.

Figure 84. Daily fluctuations in temperature during mid summer in a *Sphagnum* bog in Denmark at 10 cm below surface (---), surface (—), and 100 cm above surface (.....). Redrawn from Nørgaard 1951.

Further separation of the two species is provided by the differences in relative humidity, especially in summer. During the three days at the end of July when the temperature was measured, the humidity at the surface where *Pardosa pullata* (Figure 82) resides dropped to as low as 40% in the daytime (Nørgaard 1951). On the other hand, the stem layer habitat of *Pirata piraticus* (Figure 83) remained a constant 100%. In experiments, Nørgaard demonstrated that *P. pullata* has a greater tolerance for low humidity than does *P. piraticus*. The former species had 100% survival for the 8 hours of the experiment at $\geq 85\%$ humidity in the temperature range of 20-35°C, whereas *P. piraticus* survived only 2.5 hours at 85% humidity. At lower humidity levels (64 & 43%), *P. piraticus* generally did not survive for 8 hours at any of these temperatures.

For these two spider species, the life cycle is closely tuned to the conditions of the bog (Nørgaard 1951). Both species hibernate while they are still immature. *Pardosa pullata* (Figure 82) hibernates in tussocks of rush, sedge, and *Polytrichum* turfs (Figure 85). These locations keep it safely above the water surface even during winter floods. In spring the female carries its egg cocoon attached to its spinnerets. This species spends its days running about the *Sphagnum* surface, particularly while the sun is shining. It can hide from enemies among the irregularities of the carpet and hunches up between the capitula at night and during cold spells, never entering the stalk layer. Both males and females have disappeared by mid September.

Figure 85. Bog with *Polytrichum* cushions. Photo by James K. Lindsey, with permission.

Pirata piraticus (Figure 83) actually survives in an active state through the winter (Figure 86) and must face some severe conditions. Nørgaard (1951) observed young *P. piraticus* under the frozen *Sphagnum* capitula (Figure 86). Although their movements when disturbed in the field were sluggish, they became quite active when the clumps of moss were thawed in the lab. In this species, the female spider builds a retreat tube vertically in the stem layer (Figure 87). This tube is 6-8 cm tall and open at both ends. The upper end opens at the surface of the *Sphagnum* carpet. The eggs are deposited in the tube and wrapped in a spherical dirty-white cocoon, still attached to the spinnerets. The female takes advantage of the upper opening to position her attached eggs at the surface on sunny days. Disturbance causes the visible cocoons to disappear into the retreat as the female responds to the motion. If they are further persecuted, they exit the tube at the lower end and run on the water surface until they can find a stem to climb down below the water surface.

Figure 86. *Sphagnum squarrosum* showing frosted branches during early winter. Photo by Michael Lüth, with permission.

It appears that the location of the tube among the *Sphagnum* stems is ideal for the female spider to incubate her eggs. Nørgaard (1951) experimented with the temperature preferences of newly captured *Pirata piraticus* (Figure 83) and found that both males and females without cocoons preferred temperatures of 18-24°C. However, when the females had egg cocoons, their temperature preference changed to 26°-32°C. By positioning themselves upside down in the tube with the egg cocoon at the surface of the *Sphagnum*, the females could maintain a comfortable body temperature while keeping the eggs at their needed higher temperature. Nørgaard also determined that the temperature was more important than the humidity. In a strong temperature gradient, the spiders would go to 21°C in a moist area or a dry area, depending on where that temperature was available. By contrast, *Pardosa pullata* (Figure 82) does not change its temperature preference when carrying egg cocoons and prefers temperatures of 28°-36°C, making the surface of the *Sphagnum* its location of choice.

Temperature further plays a role in mortality. In the experiments by Nørgaard (1951), *Pirata piraticus* (Figure 83) suffered heat stupor at 35°-36°C, whereas *Pardosa pullata* (Figure 82) experienced heat stupor at 43°C. It is interesting that *Pardosa pullata* females with cocoons began normal movements at 12-14°C, whereas *Pirata piraticus* began at 14-19°C. Clearly the spaces among

Sphagnum stems provide the buffered temperature range that is necessary for the life cycle of *Pirata piraticus*. Nørgaard suggests that construction of the tube permits *Pirata piraticus* to move more quickly to the deeper, cooler part of the mat than would movement through the capitulum layer from the surface of the *Sphagnum* mat when the temperature at the surface approaches the spider's lethal temperature. Even though adults in this family may be too large to move easily among bryophytes, juveniles may find this habitat ideal.

Figure 87. Comparison of temperature niches of two Lycosidae spiders from Danish *Sphagnum* bogs. Based on Nørgaard 1951.

Bryophytes and Trap-door Spiders

Bog habitats are also home to some trap-door spiders (Ctenizidae) that lie in wait for their prey. They make themselves inconspicuous by hiding in a burrow with a trap-door opening (Cloudsley-Thompson 1989). These trap doors are often further camouflaged by bits of lichen or moss incorporated into them.

Bryophytes Hide New Species

Reports describing new species can provide additional species that live in boggy habitats, sometimes giving more detailed habitat information. Efimik and Eshunin (1996) described *Walckenaeria korobeinikovi* (Figure 88; Linyphiidae) as a new species from a boggy habitat in the Urals. Palmgren (1982) described the ecology of *Walckenaeria alticeps* (Figure 89) as new to Finland, where it is restricted to very wet, deep *Sphagnum* or wet debris in areas with some canopy cover. We should expect to find more species as researchers look more carefully at the multiple layers of the bryophytes in bogs and fens.

Figure 88. *Walckenaeria korobeinikovi* (Linyphiidae). Photo by Gergin Glagoev through Bold Systems, through Creative Commons.

Figure 89. *Walckenaeria alticeps* (Linyphiidae) male on *Sphagnum*. Photo by Jørgen Lissner, with permission.

It appears that a *Racomitrium* hummock in the middle of a *Sphagnum* bog can afford a different habitat from its surroundings. For example, *Micaria alpina* (Figure 90; Gnaphosidae) occurs among grass, moss, and under stones above 750 m in Great Britain, but it also is known from a *Racomitrium* hummock (Figure 91) in the middle of a *Sphagnum* bog (Harvey *et al.* 2002).

Conservation Issues

When peatlands are endangered, so are their spiders. The spider species are as unique as those of the plants (Bruun & Toft 2004). Scott *et al.* (2006) found that the number of spider bog indicator species can serve as a surrogate for conservation value of the total invertebrate fauna of bogs. They used three parameters to assess their indicator value: naturalness index, species quality, and species rarity curve. The **naturalness index** has a scale of 1-10, with 0 being totally artificial (Machado 2004). The **species quality index** requires assigning a numerical score to all species present according to their rarity. The index is equal to the sum of the quality scores divided by the number of species. Scott *et al.* used the Red Data Book classification as indicated in Harvey *et al.* (2002) to develop those assignments. These categories were assigned as follows: Common = 1, Local = 2, Notable B = 4, Notable A = 8, RDB3 = 16, RDB2 = 32 and RDB1 = 64. For example, *Heliophanus dampfi* (Figure 32; Salticidae) was assigned 32 points and *Gnaphosa nigerrima* (Figure 12; Gnaphosidae), the rarest species, 64 points (Harvey *et al.* 2002). The **species-area curve** indicates the steepness of the curve as each species is added to the list. In developing their criteria for indicator species, they considered that three criteria must be met to indicate a good indicator species of a good peatland site:

1. the naturalness index exceeds 0.5
2. the species quality is greater than 2.8
3. the indicator species-area relationship is above the trend line (see Figure 92).

Hence, tracking spider fluctuations can serve as a warning system for peatlands in decline.

Figure 92. Species-area curve for spiders from 32 bogs in western Britain. Redrawn from Scott *et al.* 2006.

Platen (2004) demonstrated that spider communities can be used to assess the state of degradation of oligotrophic moors. DECORANA demonstrated differences between the lowest and highest stages of degradation, but failed to distinguish the four stages between those. Platen attributed this to the predominance of eurytopic species occurring in the middle stages. However, the Kruskal-Wallis test did discriminate among all the stages. Forest species increased with increasing degradation. Typical species of oligotrophic moors (less hygrophilic) had the greatest abundance at medium stages of degradation.

Peatland Fire Communities

Studies indicate that loss of peatlands can precipitate a serious loss of spider species. As seen above, a number of rare species occur in bogs and fens. In the following example, fire destroyed the peatland of Sudas Bog in Latvia and this study examined the spider fauna the first season afterwards (Spuðgis *et al.* 2005). A surprisingly large number of species (48), compared to 40 in the unburned areas, occupied the peatlands after this short time. The invading community was somewhat different from the previous peatland community. The dominant colonizers were *Agroeca proxima* (Figure 93; **Liocranidae**), a species typical of pine bogs (Koponen *et al.* 2001; Rēlys *et al.* 2002), and *Alopecosa aculeata* (Figure 94; **Lycosidae**), two species with good mobility. Nevertheless, most of the species were typical of the original pine bog. Activity levels likewise were similar to those on the unburned bog. It is possible that some of these species were able to survive the fire from deep within the moss layer, but many colonized from the surrounding bog habitats, possibly travelling up to 120 m.

One interesting phenomenon was that the spiders, even though they were the same species, were darker in color in the burned over bog (Spuðgis *et al.* 2005). This was especially true in *Ozyptila trux* (Figure 95; **Linyphiidae**), a slow-moving spider (Stewart 2001) that probably survived the fire. Spuðgis and coworkers suggested that this darker color was in response to the dark color of the burned peat, perhaps due to greater predation on more visible light-colored individuals. It is also possible that more dark-colored individuals survived the increased exposure to UV light better.

Figure 95. *Ozyptila trux* (**Linyphiidae**) male among mosses. This species is darker in burned areas. Photo by Jørgen Lissner, with permission.

The **Gnaphosidae**, with *Drassyllus pusillus* (Figure 96), *Gnaphosa microps* (Figure 26), and *Zelotes latreillei* (Figure 97) typically occurring in unburned bogs, were notably absent after the fire (Spuðgis *et al.* 2005). Typical species that colonized and were also present in the unburned bogs included *Trochosa spinipalpis* (Figure 22; **Lycosidae**) and *Oryphantes angulatus* (Figure 98; **Linyphiidae**) from various depths of *Sphagnum*, *Agroeca proxima* (Figure 93; **Liocranidae**), *Alopecosa aculeata* (Figure 94; **Lycosidae**) [also known after fire in Canada (Aitchison-Benell 1994)], and *Euryopis flavomaculata* (Figure 99; **Theridiidae**) (another slow-moving spider that probably survived the fire). Species such as the **Linyphiidae** *Agyneta cauta*, *Micrargus apertus* (Figure 100), and *Oryphantes angulatus*, and *Robertus lividus* (Figure 101; **Theridiidae**), live in deep layers of moss and probably are able to survive fire (Spuðgis *et al.* 2005). *Agyneta cauta* (**Linyphiidae**), *Tenuiphantes cristatus* (Figure 102; **Linyphiidae**), *Phrurolithus festivus* (Figure 103; **Corinnidae**), *Alopecosa pulverulenta* (Figure 104; **Lycosidae**), and *Hygrolycosa rubrofasciata* (Figure 105; **Lycosidae**) are active in the upper layer of *Sphagnum*, but it is possible that they likewise retreated deep into the moss to escape the heat and dryness of the fire. *Gnaphosa bicolor* (Figure 106; **Gnaphosidae**) and *Porrhomma pallidum* (Figure 107; **Linyphiidae**) were probably early invaders – they are species not typical of peatland. *Aulonia albigera* (Figure 108; **Lycosidae**) is likewise a probable invader; its activity is restricted to the surface except for its retreat in *Sphagnum* (Spuðgis *et al.* 2005). The tiny **Linyphiidae** most likely were least able to survive the fire (Hauge & Kvamme 1983); their small size would make them gain heat faster and lose water faster, at the same time preventing them from moving very far. All things considered, the colonizers, whether from outside or from deep in the peat, are still mostly species typical of peat bogs. This is partly because many of the peatland species are actually xerothermic, capable of surviving the dry summer periods.

In the taiga of southeastern Manitoba, Canada, pitfall traps revealed similar trends to those in Latvia for spider communities of burned and unburned bogs. As in Sudas Bog in Latvia, there were more species in the burned bog after the fire (Aitchison-Benell 1994). The numbers of species remained high for about two months after the fire, then decreased, as one might expect for the usual seasonal activity patterns. In this case, 50 spider species were located in the burned plots and only 45 in the control plots, with 26 species common to both. Species present in burned plots but not in the control bogs included **Lycosidae**: four species of *Pardosa*, *Alopecosa aculeata* (Figure 94), and *Trochosa terricola* (Figure 20-Figure 21); **Liocranidae**: *Agroeca ornata* (Figure 109); **Linyphiidae**: *Bathyphantes pallidus* (Figure 110), *Erigone atra* (Figure 111), *Pocadicnemis americana* (Figure 112), and *Tunagyna debilis* (Figure 113). The control bogs also had unique species that apparently were unable to survive the fire: *Hogna frondicola* (Figure 114; **Lycosidae**); *Gnaphosa microps* (Figure 26; **Gnaphosidae**), and *Neoantistea agilis* (Figure 115; **Hahniidae**). *Gnaphosa microps* likewise disappeared after fire in Latvian bogs (Spuõgis *et al.* 2005).

Maintenance, and even increases, of species richness after fire seem to be common trends among spiders of various habitats (e.g. Aitchison-Benell 1994; Neet 1996; Spuògis *et al.* 2005). But Neet points out that early assessment can be misleading, as seen in the Manitoba bogs (Aitchison-Benell 1994). Rare species that survive in the habitat before a fire can disappear as invading species replace them (Neet 1996).

Larrivée *et al.* (2005) clarified some of the disturbance relationships in a Canadian black spruce (*Picea mariana*) forest. Although this was not a bryophyte study, the principles are most likely the same. When comparing clear-cut sites with burned stands, they found that the hunting spiders (Lycosidae) were more abundant in the clear-cut stands. Although the Lycosidae typically increase after fire, spiders in the clear-cut stands would escape the lethal effects of fire and thus may have retained the original species. This suggestion is supported by the high turnover (2X) of these spiders in the burned areas. Web-building spiders had similar catch rates in these two groups of sites and in uncut controls, but surprisingly had the highest turnover rates and gamma diversity. The clearcuts were characterized by spider communities typical of

dry, open, disturbed forest floor, whereas those in burned stands correlated with high cover of shrubs and dried moss-lichen substrate and deep litter, likely refuges during the fire as well as areas of higher moisture after the fire.

Moretti (2000) examined the effects of winter fires in forests of the Alps and found that 30% of the species occurred only in the burned sites, whereas only 7% were exclusive to the unburned controls. The absence of pioneer species in the burned sites suggests that the spiders were able to survive the fire.

Lycosidae are mobile species and thus are able to invade quickly after a fire, as seen by Spuògis *et al.* (2005) for bogs and Koponen (2005) for forests. Linyphiidae, on the other hand, are nearly immobile and may be greatly reduced in numbers after a fire, as seen by Koponen (2005) for a forested site. In bogs, where wet mosses can provide refuge during the fire, Linyphiidae can survive and thus be present after the fire (Spuògis *et al.* 2005). But this family can diminish in numbers in succeeding years, while the Lycosidae can increase (Koponen 2005).

Summary

Bogs and fens house spiders that benefit from the more constant moisture provided, but also from the moderated temperature, shade, food organisms, and refuge from predation. As in many mossy habitats, the Linyphiidae are prominent. But spiders in the Lycosidae – hunting spiders – can be seen running across the water surface or the surface of sunny *Sphagnum*. Nevertheless, many species are xerophiles, living in exposed areas of the bog or fen. The lycosid genera *Arctosa*, *Pirata*, *Pardosa*, and *Trochosa* are widespread in the peatland habitat, but species vary geographically. They are the most conspicuous, but in smaller numbers than the small Linyphiidae. Although there are a few widespread species in the bogs, rare species such as *Heliophanus dampfi* and *Maro lepidus* may be found somewhat frequently here. Few species seem to be tyrophobionts (species that are confined to living in peat bogs and mires), and that status seems to differ by country.

Some spiders use *Sphagnum* for a winter retreat. Others seem to benefit from the low pH. Some have only an indirect association, living among the tracheophytes that live in the peatlands. Even within the *Sphagnum* mat, niche separation can occur in the temperature-moisture-light gradient among the stems.

Trap-door spiders cut a door cover in the surface soil-moss layer, where the mosses seem to hold the soil together and permit the hinge to work. The mosses also provide camouflage.

Spiders can be used to assess the naturalness and degradation of peatlands and serve as a surrogate for other invertebrate taxa. Fires in peatlands cause a serious loss of spider species, especially rare species. The invading community is somewhat different from the original peatland community, partly due to lack of a nearby recolonization source. Other species survive the fire among the damp peat, but these may disappear within a few years due to interactions with invading spider species, especially the mobile Lycosidae.

Acknowledgments

This chapter is largely original research by Jørgen Lissner following Glime's request for permission to use some of his images. Karen Thingsgaard helped with the bryological identifications.

CHAPTER 7-5

ARTHROPODS: SPIDERS OF PEATLANDS IN DENMARK AND TUNDRA

Figure 1. *Sphagnum* in flush at Cwm Idwal National Nature Reserve, Wales. Flushes at high elevations and in tundra habitats are often carpeted with *Sphagnum*. Photo by Janice Glime.

Peatlands

Sphagnum, while not the only kind of peatland, forms a variety of habitats in wet areas. Among these are flushes (Figure 1), bogs, poor fens, and intermediate fens. Bogs and poor fens are poor in nutrients, whereas intermediate fens are somewhat more nutrient rich. Flushes can likewise be somewhat richer as nutrients are carried into them from higher elevations. These are mostly northern habitats, with similar habitats occurring in the southern hemisphere at similar latitudes, but deprived of the land mass available in the northern hemisphere.

Two Acidic *Sphagnum* Fens

Below are some examples of quantitatively important mosses and associated spiders in selected minerotrophic fens of low (acidic) and of moderate alkalinity. Only

spiders that are believed to be strongly or fairly strongly dependent on mosses for habitat are listed. Species restricted to bogs are known as **tyrphobionts** and include quite a few spiders; however, the inhabitants of bogs are not necessarily associated with the moss layer but may inhabit the herb, shrub or tree layer. Species characteristic of bogs but not confined to them are called **tyrphophiles**.

Sphagnum affine (Figure 2) has become increasingly rare in Denmark, but its presence indicates ombrotrophic conditions and low nutrient availability. Two acidic *Sphagnum* fens near Lake Salten Langsø serve as examples as they have been fairly well investigated in respect to the moss flora and spider fauna. This subchapter largely represents the research of co-author Jørgen Lissner and includes original unpublished research on those spiders associated with bryophytes in bogs and fens in Denmark.

Figure 2. *Sphagnum affine*, a moss of ombrotrophic fens. Photo by Jan-Peter Frahm, with permission.

Dalhof Mire (observations by Lissner)

The Dalhof Mire is situated south of Lake Salten Langsø and covers just 1.5 hectare (Figure 3). This acidic *Sphagnum*-dominated fen has evolved from a formerly overgrown lake. The depth of the peat layer is unknown. As is typical of small acidic mires, it is rather species poor concerning mosses, but nevertheless contains a rich spider fauna, including several very rare species. This undoubtedly relates to the fen being very old and the fact that it is situated in a protected landscape far from direct human influences.

Figure 3. At a distance the Dalhof Mire seems to be dominated by sedges and grasses, but at closer inspection *Sphagnum* is found to cover almost the entire surface. Photo by Jørgen Lissner, with permission.

The fen consists of a micro-topographic mosaic of hummocks and hollows (Figure 4). The upper surfaces of hummocks are elevated to 20-30 cm above the surrounding hollows. This level of spatial heterogeneity provides a relatively high number of niches for spiders to occupy, particularly on and within the well-developed hummocks.

There are only a few flowering plants in the hollows, the dominant one being *Eriophorum angustifolium*. A higher number of flowering plant species is found on the hummocks: *Empetrum nigrum*, *Calluna vulgaris*, *Vaccinium oxycoccus*, *Eriophorum vaginatum*, *Molinia caerulea*, and *Pinus sylvestris* are among the commonest.

Figure 4. Hummock in acidic *Sphagnum* fen. It is quite obvious that hummocks provide spider habitats that are very different from those of the surrounding hollows. Photo by Jørgen Lissner, with permission.

The hollows of the Dalhof Mire are dominated by *Sphagnum cuspidatum* (Figure 5) and *S. fallax* (Figure 6). *Sphagnum papillosum* (Figure 15) and *S. rubellum* (Figure 7) are also present in the lawn and/or carpet. Moss-associated spiders found here include *Erigonella ignobilis* (Figure 8; Linyphiidae), *Carorita limnaea* (Figure 9; Linyphiidae), and *Robertus unguilatus* (Figure 10-Figure 11; Theridiidae). At least three other *Robertus* species [*R. lividus* (Figure 13), *R. arundineti* (Figure 54), *R. scoticus* (Figure 14)] are also frequently found among mosses in Northern Europe, all three in bogs elsewhere, but also forests (*R. lividus*), heathland (*R. arundineti*), and mountains (*R. scoticus*).

Figure 5. *Sphagnum cuspidatum* in Europe. Photo by Michael Lüth, with permission.

Figure 6. *Sphagnum fallax*. Photo by Michael Lüth, with permission.

Figure 7. *Sphagnum rubellum*. Photo by Michael Lüth, with permission.

Erigonella ignobilis (Figure 8) is a common line-weaving spider (**Linyphiidae**) that prefers damp habitats and is found among damp or wet moss, including *Sphagnum* spp. in many different types of bogs and fens across much of Europe. Cherrett (1964) found that this family exhibited habitat specificity in eight vegetation types that strongly correlated with the availability of other arthropods.

Figure 8. *Erigonella ignobilis* (**Linyphiidae**) male (1.4 mm) on *Sphagnum*. Photo by Jørgen Lissner, with permission.

Carorita limnaea (Figure 9; **Linyphiidae**) (1.2 mm) is a rare Palaearctic line-weaving spider, apparently only found in acidic *Sphagnum* fens. At the Dalhof Mire it is most common in mosses growing in the transition zone between hummocks and hollows.

Figure 9. *Carorita limnaea* (**Linyphiidae**) male (1.2 mm) on moss. Photo by Jørgen Lissner, with permission.

Robertus unguatus (Figure 10-Figure 11; **Theridiidae**) (~2 mm) is another rare species that lives among very wet moss in hollows of acidic *Sphagnum* bogs, but specimens have also been found among wet *Plagiomnium* (Figure 12) mosses in rich fens with plentiful seeping groundwater.

Figure 10. *Robertus unguatus* (**Theridiidae**) male (2.2 mm) on moss. Photo by Jørgen Lissner, with permission.

Figure 11. *Robertus unguatus* (**Theridiidae**) on *Sphagnum*. Photo by Jørgen Lissner, with permission.

Figure 12. *Plagiomnium undulatum*. Photo by Jan-Peter Frahm, with permission.

Figure 13. *Robertus lividus* (Theridiidae) female on *Sphagnum*. Photo by Jørgen Lissner, with permission.

Figure 14. *Robertus scoticus* (Theridiidae) female, a species listed as vulnerable in Slovakia, on *Sphagnum*. Photo by Walter Pfliegler, with permission.

The hummocks are more species-rich compared to hollows. The following mosses dominate the hummocks in the Dalhof Mire: *Sphagnum papillosum* (Figure 15), *Sphagnum magellanicum* (Figure 16), *Aulacomnium palustre* (Figure 17), and *Polytrichum strictum* (Figure 18), whereas *Sphagnum angustifolium* (Figure 18), *Polytrichum commune* (Figure 20), *Straminergon stramineum* (Figure 21), and *Sphagnum rubellum* (Figure 7) are less abundant. The hummocks also provide habitat for the rare pseudoscorpion, *Microbisium brevifemuratum* (see Chapter 8).

Figure 21. *Straminergon stramineum*. Photo by David Holyoak, with permission.

Moss-associated spiders found in the hummocks include *Minicia marginella* (Figure 22-Figure 24; **Linyphiidae**), *Sintula corniger* (Figure 25; **Linyphiidae**), and *Theonoe minutissima* (Figure 26; **Theridiidae**). *Sintula corniger* attaches egg sacks within clumps of *Polytrichum commune* (Figure 20; Harvey *et al.* 2002).

Figure 22. A male of the linyphiid *Minicia marginella* (1.6 mm; **Linyphiidae**) clinging to a *Polytrichum commune* leaf. In Denmark, this species is found only in acidic *Sphagnum* bogs and fens where it appears to prefer the drier (upper) portions of hummocks or drier bogs such as degraded raised bogs. It can be sifted from mosses such as *Polytrichum strictum* and *P. commune*. Photo by Jørgen Lissner, with permission.

Figure 25. *Sintula corniger* (**Linyphiidae**) male (ca. 1.6 mm). A widespread but very local species found among moss and sedges in wet heathland and *Sphagnum* bogs and fens. Photo by Jørgen Lissner, with permission.

Figure 26. *Theonoe minutissima* (**Theridiidae**) on moss. Photo by Jørgen Lissner, with permission.

Other Dalhof Mire spider species, which only sometimes utilize mosses or moss-covered areas as habitat include the **Hahniidae**: *Antistea elegans* (Figure 96); **Linyphiidae**: *Aphileta misera* (Figure 27), *Ceratinella brevis* (Figure 28), *Hypselistes jacksoni* (Figure 29), *Metopobactrus prominulus* (Figure 30), *Tallusia experta* (Figure 31), *Walckenaeria cucullata* (Figure 32), *Walckenaeria nudipalpis* (Figure 33); **Lycosidae**: *Pirata latitans* (Figure 34), *Trochosa spinipalpis* (Figure 35). The latter species is found in damp habitats ranging from acidic *Sphagnum* fens to mineral rich fens. It is frequently found by sifting mosses, which serve as hiding places during the daytime.

Figure 35. Female wolf spider *Trochosa spinipalpis* (Lycosidae) (10 mm) photographed with the moss *Paludella squarrosa*. Photo by Jørgen Lissner, with permission.

Some spider species may be found in both hummocks and hollows including the Linyphiidae *Centromerus arcanus* (Figure 36), *Walckenaeria nodosa* (Figure 37- Figure 38), *Walckenaeria acuminata* (Figure 39), and the Lycosidae *Pardosa sphagnicola* (Figure 40).

Figure 36. *Centromerus arcanus* (Linyphiidae) female (2 mm), a common species in a variety of damp habitats, primarily coniferous woodland, wet heathland, and acidic bogs and fens. This tyrphophile species is frequently found among moss, but is not strictly associated with mosses and can be found in wet leaf litter as well. Photo by Jørgen Lissner, with permission.

Figure 37. The male head of *Walckenaeria nodosa* (Linyphiidae) is elevated into a characteristic bulbous lobe. The species measures ca. 2 mm and is associated with *Sphagnum* in poor fens and in depressions of wet heathland. Photo by Jørgen Lissner, with permission.

Figure 38. *Walckenaeria nodosa* (Linyphiidae) female on *Sphagnum*. Photo by Jørgen Lissner, with permission.

Figure 39. The male *Walckenaeria acuminata* (Linyphiidae) (ca. 3 mm) with its peculiar head drawn out into a stalk carrying eight eyes, four midway and four at top. This species is found in a wide array of usually damp habitats. Occasionally it has been sifted from *Sphagnum* lawn carpets of bogs and fens. Photo by Jørgen Lissner, with permission.

The male of *Pardosa sphagnicola* (Figure 40; Lycosidae) has a body length of 5 mm. This species is one of many species of wolf spiders found in moss-dominated bogs and fens. Wolf spiders are capable of running rapidly

about during periods with warm and sunny conditions and hunt their prey on the surface of mosses as well as on water surfaces. When disturbed by trampling they can be observed to run on water surfaces, seeking cover. During cold periods they hide within mosses. Sifting mosses often reveals a high number of wolf spiders of all sizes, mostly belonging to the species-rich genera *Pardosa* and *Pirata*. Many species construct vertical silk tubes within moss clumps. These tubes are used as retreats when the spiders are not running about.

Figure 40. *Pardosa sphagnicola* (Lycosidae) male (5 mm) on moss. Photo by Jørgen Lissner, with permission.

Naesgaard Mire (observations by Lissner)

The Naesgaard Mire (Figure 41) is a small (0.75 ha) mire formed in a dead-ice depression near the west end of Lake Salten Langsø. There are hardly any hummocks and the entire mire is very wet, particularly during the winter (Figure 41). The moss vegetation is dominated by *Sphagnum cuspidatum* (Figure 5), much of which is growing submersed, and *Sphagnum fallax* (Figure 6). *Eriophorum vaginatum* dominates among the flowering plants.

Figure 41. The Naesgaard Mire is a very wet *Sphagnum* fen dominated by *Sphagnum cuspidatum* (Figure 42) and *Eriophorum vaginatum*, the latter species forming the tussocks seen on the image. There are only a few, indistinct hummocks. Photo by Jørgen Lissner, with permission.

The spider fauna is not particularly rich, but it does include some rare species, among these *Glyphesis cottonae* (Figure 55; Linyphiidae) found in wet *Sphagnum*. Other

species associated with mosses include *Drepanotylus uncatus* (Figure 56; Linyphiidae), *Maro lepidus* (Figure 57; Linyphiidae), *Pirata piscatorius* (Figure 58; Lycosidae), and *Theonoe minutissima* (Figure 26; Theridiidae).

Figure 42. *Sphagnum cuspidatum*, a species that typically grows submersed, frequently bordering a lake or pool. Photo by Michael Lüth, with permission.

The female of the small comb-footed spider, *Theonoe minutissima* (Figure 26; Theridiidae), measures just 1.2 mm. It may be found in a variety of habitats, but is most commonly found in acidic *Sphagnum* bogs and fens. At the Dalhof Mire this species is found often deep down in hummocks dominated by *Sphagnum magellanicum* (Figure 16). Perhaps it prefers cavities within hummocks just above the water surface.

Other Naesgaard Mire spider species which may not strictly depend on mosses include Hahniidae: *Antistea elegans* (Figure 96); Linyphiidae: *Cnephlocotes obscurus* (Figure 44), *Diplocephalus permixtus* (Figure 43), *Erigonella ignobilis* (Figure 8), *Gnathonarium dentatum* (Figure 45), *Gongyliellum vivum* (Figure 46), *Lophomma punctatum* (Figure 47), *Micrargus herbigradus* (Figure 48), *Oedothorax gibbosus* (Figure 49-Figure 50), *Oryphantes angulatus* (Figure 51), *Palliduphantes ericaeus* (Figure 52-Figure 53), and *Tallusia experta* (Figure 31); Lycosidae: *Pirata latitans* (Figure 34); Theridiidae: *Robertus arundineti* (Figure 54).

Figure 48. *Micrargus herbigradus* (Linyphiidae) female on moss. Photo by Jørgen Lissner, with permission.

Figure 49. *Oedothorax gibbosus* (Linyphiidae) female on *Sphagnum*. Photo by Jørgen Lissner, with permission.

Figure 50. *Oedothorax gibbosus* (Linyphiidae) male on *Sphagnum*. Photo by Jørgen Lissner, with permission.

Figure 51. *Oryphantes angulatus* (Linyphiidae) female on *Sphagnum*. Photo by Jørgen Lissner, with permission.

The rare and very small *Sphagnum* mire inhabitant, *Glyphesis cottonae* (Figure 55; Linyphiidae) (0.9-1.0 mm), has a very scattered occurrence throughout its range, apparently being absent from most *Sphagnum* bogs and mires. At the Naesgaard Mire it is found in *Sphagnum fallax* (Figure 6) and *S. cuspidatum* (Figure 5) in wet parts of the mire. It is unlikely that the species is widely overlooked as it is often abundant where it occurs. Perhaps the dispersal capacity of this species is low since there are

plenty of mires having suitable micro-habitats without the presence of this species. Both *Sphagnum fallax* and *S. cuspidatum* are very common members of the moss flora in northern European acidic fens, so we should expect a more common occurrence of *Glyphesis cottonae*.

Figure 52. *Palliduphantes ericaeus* (Linyphiidae) female on moss. Photo by Jørgen Lissner, with permission.

Figure 53. *Palliduphantes ericaeus* (Linyphiidae) male on moss. Photo by Jørgen Lissner, with permission.

Figure 55. *Glyphesis cottonae* (Linyphiidae) (0.9-1.0 mm) on *Sphagnum* in a mire. Photo by Jørgen Lissner, with permission.

Another widespread Palearctic moss inhabitant, *Drepanotylus uncatus* (Figure 56; Linyphiidae), reaches a body length of 3 mm. The male is easily recognized by the curved palpal tibial apophysis just visible on the image. This species is found among mosses in acidic bogs and fens. More rarely, records relate to mosses of neutral or alkaline mesotrophic fens.

Figure 56. Male *Drepanotylus uncatus* (Linyphiidae) (3 mm) on *Sphagnum*. Note the curved palpal tibial apophysis just visible on the image. Photo by Jørgen Lissner, with permission.

The small male of *Maro lepidus* (Figure 57; Linyphiidae) measures just 1.2 mm in body length and belongs to the line-weaving spider family. This is a rather uncommon species most often found in wet *Sphagnum* of acidic bogs and fens, such as raised bogs and *Sphagnum* depressions of wet heathland. In Denmark, this species has been found among *Sphagnum fallax* (Figure 6) on several occasions.

Figure 57. *Maro lepidus* (Linyphiidae) male (1.2 mm) on moss. Photo by Jørgen Lissner, with permission.

As one of the largest members of *Pirata*, *P. piscatorius* (Lycosidae) (8 mm) bears resemblance to fishing spiders (*Dolomedes* spp.). The species is confined to very wet habitats and constructs a vertical silken tube (retreat) in *Sphagnum* mats which extends down below the water surface. If disturbed the spider will escape down below the water surface (Bristowe 1923 in Harvey *et al.* 2002). It is found in a wide array of wetlands such as carr, mires, bogs and fens, but is more frequent in acidic bogs and fens than in rich fens.

Figure 58. *Pirata piscatorius* (Lycosidae) (8 mm) bears resemblance to fishing spiders (*Dolomedes* spp.). Photo by Jørgen Lissner, with permission.

Raised Bogs

In their treatise on spiders of raised peat bogs in Poland, Kupryjanowicz *et al.* (1998) considered the spiders of raised peat bogs to form three groups: 1) inhabiting sunlit peat bog [*Sphagnetum magellanici* (Figure 16)], 2) occupying moderately illuminated *Ledo-Sphagnetum*, 3) preferring shaded peat bogs (*Vaccinio uliginosi-Pinetum*). These three habitats are separated by the relative contributions of peat bog and forest species. Forest shading decreases the number of peat bog species. They found that there are a number of **hygrophilous** (water-loving) and **heliophilous** (sun-loving) species that were common to all the study areas.

As discussed earlier, Kupryjanowicz *et al.* (1998) found 203 species of spiders in the six raised bogs of their

Polish study areas. Komposch (2000) found no relationship between percentage of endangered arachnids and diversity or evenness of wetland communities or with percentage of endangered plant species. Some species are not known outside raised bogs. These include **Gnaphosidae**: *Gnaphosa microps* (Figure 59); **Lycosidae**: *Arctosa alpigena lamperti* (Figure 60); **Linyphiidae**: *Glyphesis cottonae* (Figure 55), *Meioneta mossica* (see Figure 61); **Liocranidae**: *Scotina palliardi*; **Salticidae**: *Heliophanus dampfi* (Figure 62); and **Theridiidae**: *Theonoe minutissima* (Figure 26). Most of the raised bog species are more general peat bog species, including **Linyphiidae**: *Agyneta cauta*, *Aphileta misera* (Figure 27), **Gnaphosidae**: *Gnaphosa nigerrima* (Figure 63), **Lycosidae**: *Pardosa hyperborea* (Figure 64), *P. maisa*, and *P. sphagnicola* (Figure 65); or hygrophilous species such as **Linyphiidae**: *Drepanotylus uncatus* (Figure 56), and *Notioscopus sarcinatus* (Figure 98); and **Lycosidae**: *Pirata uliginosus* (Figure 66).

Figure 66. *Pirata uliginosus* (Lycosidae), a bog dweller. Photo by Jørgen Lissner, with permission.

Stewart (2001) found *Heliophanus dampfi* (Figure 62; Salticidae) in Britain for the first time on a raised bog at Flanders Moss. In all, he found 118 species of spiders at Flanders Moss. Lycosids comprised 41% of the trapped specimens, with *Pirata uliginosus* (Figure 66; Lycosidae) (177 individuals) overshadowing the usually more common *Pirata piraticus* (Figure 67) (2 individuals). But the most common species in traps was the tetragnathid *Pachygnatha degeeri* (Figure 68) (440 individuals), most of which were trapped in the drier area at the edge of the moss, in heather and tufts of grass, perhaps not really using the moss habitat.

Figure 67. *Pirata piraticus* in bog. Photo by Trevor and Dilys Pendleton at <<http://www.eakingbirds.com/>>, with permission.

Figure 68. *Pachygnatha degeeri* (Tetragnathidae) male on moss. Photo by Jørgen Lissner, with permission.

Other species from mosses in Flanders Moss include *Agroeca proxima* (Figure 69; Liocranidae) (nocturnal hunter), *Neon reticulatus* (Figure 70; Salticidae), *Ozyptila* (Figure 71; slow walkers; Thomisidae), *Pirata piraticus* (Figure 67; Lycosidae), *Scotina gracilipes* (Figure 72; Liocranidae) (nocturnal hunter), *Xysticus* (Figure 73; Thomisidae) (slow walkers), *Zora spinimana* (Figure 74; Zoridae) (daytime hunter) (Stewart 2001).

Figure 74. *Zora spinimana* (Zoridae) female on sand. Photo ©Pierre Oger, with permission.

Robertus lividus (Figure 13; Theridiidae) is a common spider of a number of grassy and mossy habitats. It appeared in only one of the two bogs in this Danish study. *Pholcomma gibbum* (Figure 75; Theridiidae) is a 1.5 mm spider common in grass, moss, and detritus at Flanders Moss, but absent in the Danish studies.

Figure 75. *Pholcomma gibbum* (Theridiidae) female on moss. Photo by Jørgen Lissner, with permission.

Of interest is the presence of *Pachygnatha clercki* (Figure 76-Figure 77; Tetragnathidae) at Flanders Moss. We did not find this spider listed in any of the other studies included in this chapter, but it is a very common species in many habitats where it is found among low vegetation in places such as bogs or marshes and the edges of ponds, rivers, and streams (Harvey *et al.* 2002). This spider makes no web and hunts at ground level among mosses and low plants in damp places (Stewart 2001).

Raised Bogs in Denmark (observations by Lissner)

The spider fauna of raised bogs is relatively rich, at least when compared to the vegetation, which is rather species poor. A significant fraction of the spider species is associated with higher strata of the vegetation or is mainly confined to leaf litter in the lagg-zone. Three raised bogs situated in Denmark serve as examples here.

Lille Vildmose is the largest raised bog found in northwestern Europe, covering more than 20 sq. km. An additional 2.5 sq. km of degraded raised bog is found in the area. The Kongens Mose raised bog and the Storelung raised bog are much smaller, covering 1.6 sq. km and 0.3 sq. km, respectively, both with degraded parts. Projects aimed at restoring degraded parts of these bogs have been initiated.

The **Lille Vildmose** raised bog in Denmark contains relatively large, undisturbed areas dominated by *Sphagnum cuspidatum* (Figure 5) in the hollows and *S. magellanicum* (Figure 16) and *S. rubellum* (Figure 7) on the hummocks. Unique, raised bog structures have evolved, such as well-developed secondary lakes created over time by relatively higher decomposition rates of *S. cuspidatum* dominating the hollows compared to decomposition rates of other *Sphagnum* species growing on the hummocks. Plants occurring with some abundance, but otherwise rare in the region include *Scheuchzeria palustris*, *Rubus chamaemorus*, *Drosera anglica*, and *Sphagnum affine* (Figure 78). The latter has become increasingly rare in Denmark; its presence indicates ombrotrophic conditions and low nutrient availability. *Calluna vulgaris* is one of the commonest flowering plant species on the bog surface. A range of biotopes adjoin the bog area, including various forest types and open areas with acidic and calcareous grassland as well as dry and wet heathland. As a consequence of the variety of habitats the entire area is

very species rich. About 300 spider species have been recorded at the Lille Vildmose, more than half the number of species known from the entire country of Denmark.

Figure 78. *Sphagnum affine*. Photo by Jan-Peter Frahm, with permission.

The **Kongens Mose** raised bog contains remnants of undisturbed raised bog but also areas that have been degraded by peat cutting and drainage. The bog is bordered to the east by Draved Forest, one of the best natural forests of Denmark. The combined spider fauna of these two areas is very rich.

The **Storelung** raised bog consists mostly of forested wetland, but about 10 ha is raised bog with degraded parts or recently restored areas.

Spider species found among mosses in these three raised bogs include *Clubiona norvegica* (Figure 79; **Clubionidae**), *Gnaphosa nigerrima* (Figure 63; **Gnaphosidae**), and *Centromerus levitarsis* (Figure 81; **Linyphiidae**).

The female *Clubiona norvegica* measures 6.5 mm. It belongs to the family **Clubionidae** (sac spiders), so-named because they make silken sacs (Figure 80) as retreats on plants and rocks. In much of its range it is a rare inhabitant of *Sphagnum* bogs, including raised bogs. Here, it can be sifted from moss and *Sphagnum*, but it may also sometimes be swept from higher vegetation, such as *Salix*.

Figure 79. This female *Clubiona norvegica* (**Clubionidae**) measures 6.5 mm. This specimen was found among *Sphagnum* with sparse *Molinia* in an wet area of the bog with much open water. Photo by Jørgen Lissner, with permission.

Figure 80. **Clubionidae** retreat sac. Photo by Aniruddha Dhamorikar through Creative Commons.

Figure 81. Ventral view of the female *Centromerus levitarsis* (**Linyphiidae**) showing the characteristic long, slender scape of the epigyne. This specimen was sifted from *Sphagnum palustre* at the Storelung raised bog and measures ca. 1.8 mm. Photo by Jørgen Lissner, with permission.

Two Spring-Fed Mires

Lake Bredsgård (12 ha) and Lake Rosborg (75 ha, Figure 100) serve as examples of **mesotrophic fens** with a high number of moss species and a diversity of microhabitats. Both fens are the results of failed land reclamation projects which were aimed at draining the lakes for agriculture and pasture. However, the areas remained too wet after drainage due to the presence numerous springs along the former bottoms and lake sides supplying a large and constant amount of cold groundwater. At the fens, seep areas are found with rare, but characteristic, bryophytes, e.g. *Cratoneuron filicinum* (Figure 82), *Paludella squarrosa* (Figure 83), and *Hamatocaulis vernicosus* (Figure 84). The two fens are also microrefugia for the yellow marsh saxifrage (*Saxifraga hirculus*), a threatened and declining plant in most of Europe.

Figure 82. *Cratoneuron filicinum*. Photo by Barry Stewart, with permission.

Figure 83. *Paludella squarrosa* in Europe. Photo by Michael Lüth, with permission.

Figure 84. *Hamatocaulis vernicosus* in Europe. Photo by Michael Lüth, with permission.

The combined moss flora of both fens counts to about 65 species, indicating that these fens are of regional importance. A number of liverworts are known from the fens, but only *Marchantia polymorpha* (Figure 85) occurs with some abundance. At least twelve *Sphagnum* species occur in the fens. *Sphagnum palustre* (Figure 86), *Sphagnum teres* (Figure 87), *Sphagnum fimbriatum* (Figure 88), and *Sphagnum warnstorffii* (Figure 89) are quantitatively important and form mats of some sizes

locally. *Aulacomnium palustre* (Figure 17), *Calliergonella cuspidata* (Figure 90), *Climacium dendroides* (Figure 91), *Dicranum bonjeanii* (Figure 92), and *Polytrichum commune* (Figure 20) dominate among the other bryophyte species. In addition, *Helodium blandowii* (Figure 93) and *Tomentypnum nitens* (Figure 94) may locally dominate seep areas.

Lake Bredsgård (observations by Lissner)

The spider fauna of Lake Bredsgård is not thoroughly investigated. Moss-associated spider species include **Hahniidae**: *Antistea elegans* (Figure 96); **Linyphiidae**: *Ceratinella brevis* (Figure 95), *Erigonella ignobilis* (Figure 8), *Maso sundevalli* (Figure 97), *Notioscopus sarcinatus* (Figure 98), *Oedothorax gibbosus* (Figure 49-Figure 50), *Walckenaeria cuspidata* (Figure 103); **Salticidae**: *Sitticus caricis* (Figure 102); **Theridiidae**: *Robertus arundineti* (Figure 54).

Figure 95. *Ceratinella brevis* (Linyphiidae) on moss. Photo by Jørgen Lissner, with permission.

Antistea elegans (Figure 96; Hahniidae) belongs to the lesser cobweb spiders, characterized by having the spinners arranged in a transverse row. The male has a body length of about 3 mm. The species builds a small sheet over depressions at ground level (Cattin *et al.* 2003). It has been recorded from a variety of damp habitats, including bogs with wet *Sphagnum*.

Figure 96. *Antistea elegans* (Hahniidae) on *Sphagnum*. The male shown here has a body length of 3 mm. Photo by Jørgen Lissner, with permission.

Figure 98. *Notioscopus sarcinatus* (Linyphiidae) male (2 mm) positioned on *Cinclidium stygium* (Figure 99), a rare moss of minerotrophic fens. The spider is found in a variety of mosses, perhaps most numerous in *Sphagnum warnstorffii* (Figure 89), a common species of minerotrophic fens. Note the peculiar conical process on the carapace separated from the head by a narrow slit. Photo by Jørgen Lissner, with permission.

Figure 99. *Cinclidium stygium*. Photo by Kristian Peters through Wikimedia Commons.

Lake Rosborg (observations by Lissner)

Moss-associated spiders of Lake Rosborg (Figure 100) include **Linyphiidae**: *Aphileta misera* (Figure 27), *Gnathonarium dentatum* (Figure 45), *Lophomma punctatum* (Figure 47); **Gnaphosidae**: *Gnaphosa nigerrima* (Figure 63); and **Salticidae**: *Sitticus caricis* (Figure 102).

Figure 100. Lake Rosborg, a spring-fed mire with a rich moss flora. Photo by Jørgen Lissner, with permission.

Aphileta misera (Figure 27; **Linyphiidae**) is a small and indistinct species of the line-weaving spiders. The female shown measures ca. 2 mm. The species is fairly common in various types of acidic bogs. Some records from rich fens could relate to mineral poor areas of heterogeneous rich fens. Egg sacks have been found affixed within clumps of *Polytrichum commune* (Figure 20) (Harvey *et al.* 2002).

Another ground spider, *Gnaphosa nigerrima* (Figure 101) is found in among mosses in both acidic bogs and rich fens. The male measures ca. 7 mm. The species can be found in wet *Sphagnum*-dominated hollows of raised bogs as well as within dense clumps of ribbed bog moss [*Aulacomnium palustre* (Figure 17)] in rich fens, mosses of quite different bryological life forms. This nocturnal spider emerges at night to hunt actively, but hides during the day in a silken retreat within the moss carpet. The spider is rather rare in much of its range, which is peculiar considering it is frequently found among common moss species. One of its favorites, *Aulacomnium palustre*, is very common in a wide array of mire habitats. Nevertheless, this spider species (at least in Denmark) is only found in the very best bogs and mires with high species diversity.

Tundra Peatlands

Tundra peatlands are extensive and the influence of *Sphagnum* on the water regime and nutrient cycling is extensive. The *Sphagnum* acts like a sponge, holding water until its capacity is reached, then releasing it suddenly, causing rushes because the permafrost beneath it is impenetrable. In the summer, this vast peat carpet becomes a safe site for spiders, providing moisture and a refuge from the high UV light of the tundra sunshine.

In the Arctic tundra, the tundra influence may be greater than the influence of bogs and *Sphagnum*. The Arctic bogs of the Yukon have more **Linyphiidae** than do the forests there (Dondale *et al.* 1997). Dondale *et al.* found *Ceratinopsis stativa* in moss and litter (and also in mosses in forests), *Erigone blaesae* in bog litter, *Hybauchenidium gibbosum* (Figure 104) in moss and plant litter, *Kaestneria rufula* (Figure 105) in moss and plant litter, *Oreonetides vaginatus* (Figure 106) in plant litter, *Procerocymbium sibiricum* in moss and litter in spruce bogs, *Scotiotylus sacer* in bog litter, and *Walckenaeria clavicornis* (Figure 107) in moss in bogs and heaths.

Not surprisingly, due to the open nature of the habitat, the Yukon **Lycosidae** are represented by a number of species (Dondale *et al.* 1997). *Arctosa raptor*, *Pardosa sodalis* in moss in larch or spruce bogs, *Pirata piraticus* (Figure 67) in moss and herbs in bogs, and *Pirata zelotes* in bogs and swamps. These are probably only surface relationships, but the mosses undoubtedly play a role in creating a suitable habitat. Likewise, in the **Salticidae** *Cobanus cambridgei* (as *Sitticus finschii*) occurs in litter in spruce bogs. The **Gnaphosidae** are represented by *Micaria pulicaria* and *M. tripunctata* among bog mosses, the latter in spruce bogs.

In the Faroe Islands, many of the species are found in bogs or with *Sphagnum*, but most are also in other habitats. These multi-habitat species associated with *Sphagnum* or bogs included **Hahniidae**: *Hahnia montana* (Figure 108) (Harvey *et al.* 2002; Lissner 2010, 2011), **Linyphiidae**: *Centromerita bicolor* (Figure 109) (Lissner 2011), *Centromerus arcanus* (Figure 36) [bogs (Harvey *et al.* 2002)], *Erigone psychrophila* (Figure 110) [*Sphagnum* at the edge of bog pools (Harvey *et al.* 2002), *Hilaira nubigena* (Figure 111) [*Sphagnum* bog; also in Britain (Holm 1980; Lissner 2011)], *Improphantes complicatus* (Figure 112) [*Sphagnum* bogs (Lissner 2011)], *Saaristoa abnormis* (Figure 113) [among *Sphagnum* (Holm 1980)], *Semljicola faustus* (Figure 114) [among *Sphagnum* in bog of pine forest (Bengtson & Hauge 1979; Holm 1980)], *Walckenaeria clavicornis* (Figure 107) [in bogs of Greenland (Holm 1967) and in *Sphagnum* in Britain (Harvey *et al.* 2002)]. *Walckenaeria nodosa* (Figure 37-Figure 38) [a moss dweller in the Faroes (Lissner 2011), occurs in lowland bogs in Britain (Harvey *et al.* 2002)] and *Walckenaeria nudipalpis* (Figure 33) in bogs (Holm 1980). The **Lycosidae**, as in lower latitude bogs and tundra in general, are relatively common, including *Arctosa alpigena* (Figure 115) [in *Racomitrium* (Figure 116-Figure 117) of the Faroes (Harvey *et al.* 2002) and *Sphagnum* bogs of Sweden (Almqvist 2005)], and *Pardosa palustris* (Figure 118) [*Sphagnum* bogs (Schenkel 1925; Holm 1980; Bengtson & Hauge 1979)].

The US Fish and Wildlife Service (Global Species 2013) constructed a food web for the fauna of *Sphagnum fuscum* (Figure 121) in the Alaskan tundra. Among the organisms featured in this web was the spider *Pirata piraticus* (Figure 67; **Lycosidae**). He indicated that the springtail (**Collembola**) *Bourletiella hortensis* served as a primary food source for this spider in the *S. fuscum* hummocks. On the other hand, birds were the main predators of the spiders, including the Lapland Longspur (*Calcarius lapponicus*), Common Redpoll (*Carduelis flammea*), and Boreal Chickadee (*Poecile hudsonica*). While this food web serves only to provide examples, it does emphasize the importance of tundra *Sphagnum* habitats as a source of food for spiders, in this case emphasizing springtails.

This tundra moss species synonymium was described by Popp in 1962. He found *Limnozetes ciliatus* and *L. rugosus* in association with it.

Summary

Peatlands include flushes, bogs, poor fens, and intermediate fens, as well as moors and mires. They are extensive in the Arctic, where they are important in controlling the hydrology and temperature.

The Danish mires are represented by spider families that are typical in mires elsewhere, including the **Linyphiidae**, **Theridiidae**, **Hahniidae**, and **Lycosidae**. Many of these are small spiders that live among the stems of the *Sphagnum*. Some Lycosidae make tubes that permit them to move quickly from the surface of the moss mat to below the water surface, providing a quick escape route.

Raised bogs represent true bogs where water input is entirely from precipitation. Their communities of spiders depend on the amount of sunlight reaching the moss canopy, with shading causing a decrease in bog species. In addition to the families common in the Danish mires, they also house the **Gnaphosidae** and **Salticidae**, and even the **Tetragnathidae**. Others may be **Liocranidae**, **Thomisidae**, and **Zoridae**. In Denmark, **Clubionidae** join the fauna.

Springfed mires are fens with more nutrients than bogs but still have at least twelve species of *Sphagnum*. The spider families are similar, despite the differences in plant species. *Gnaphosa nigerrima* hides in a silken

retreat in the moss carpet, especially *Aulacomnium palustre*, but is rare despite its widespread preferred moss species.

The tundra peatlands often have unique flora, perhaps due to their geographic isolation. Their species sometimes coincide with those of lowland bogs. Due to the open nature and available sunshine, **Lycosidae** are common. *Racomitrium* hummocks are common and can be inhabited by *Arctosa alpigena*. Other arthropods, especially **Collembola**, are important as food for the spiders.

Of the 112 families of spiders, the number of families typical of peatlands are only a small representation.

Acknowledgments

This chapter is largely original research by Jørgen Lissner following Glime's request for permission to use some of his images. Karen Thingsgaard helped with the bryological identifications. We appreciate all the photographers who put their images on the internet through Creative Commons and those who have given us permission to use their images.

Table 1. Species of spiders known to me that occur in association with bryophytes. Most of these have been collected by methods that targeted bryophytes. None has specifically identified liverworts, although they presumably were included in some cases. The number of citations are an indication of the frequency of the species among locations, but the same is not true for genera. If only the genus was named, it has not been listed separately from a known species, albeit sometimes from a different location. + indicates species for which I have seen photographs of the spiders associated with a moss, but the association may be spurious or staged.

CHAPTER 8

ARTHROPODS: HARVESTMEN AND PSEUDOSCORPIONS

Figure 1. *Phalangium opilio* on the moss *Tortula* sp. Photo by Christophe Quintin through Creative Commons.

Order Opiliones – Harvestmen

These long-legged arachnids are variously known as daddy-long-legs, granddaddy-long-legs, and harvestmen (Figure 1). The name harvestmen most likely derives from their peak abundance around harvest time. They live on every continent but Antarctica. The adults are usually too big to live within the moss mat, but some do, and some have discovered other uses.

Adaptations

The harvestman typically lives among vegetation, including gardens, where it obtains droplets of water resting on the plants. I have not found any discussion of harvestmen adaptations to bryophytes, but we can consider

these based on those seen in other groups of organisms. Camouflage would not seem to be a problem. These arthropods are the shape and size of a medium-sized seed and typically are some shade of brown, often with disruptive patterns, seemingly regardless of habitat. This coloration makes them relatively inconspicuous. Their legs are long and thin, making those appendages all but invisible among the bryophyte branches (Figure 2-Figure 4).

Harvestmen range in body size from less than 1 mm to 7 mm, but their long legs make them appear to be much larger. The long legs and their "push-up" positioning makes maneuvering within moss mats a difficult

proposition. On the other hand, these long legs permit them to move quickly across the surface without attracting undue attention. They are light weight, and their long legs act like a spring board, softening their impact as they run, another feature that is useful for running across loose vertical bryophyte structures.

Figure 2. *Leibunum rotundum* male on mosses, demonstrating the slender black legs of this species. Photo by Morten D. D. Hansen, with permission.

An adaptation for living **within** the bryophyte community might be to have short legs that would enable them to enter the bryophyte domain without getting their legs tangled or caught. In fact, being smaller in all ways could help. For example, *Siro carpathicus* (Sironidae; see Figure 3) is one of the few harvestmen known from within moss clumps and is among the smaller species of harvestmen (Rafalski 1956, 1958). But this species has the disadvantage that it is easy prey for the larger arthropods.

Figure 3. *Siro* sp. on mosses. *Siro carpathicus* is a species that lives among mosses. Note how short the legs are on this harvestman, compared to the more familiar garden species. Photo by M. Hedin, through Creative Commons.

A native of Great Britain and other areas of western Europe, the moss visitor *Leibunum rotundum* (Sclerosomatidae), like many, has scent glands that discourage predators (Wikipedia 2011). For years I

watched my dog chase daddy-long-legs. One day he actually caught one, but he was quick to spit it back out. After that, he still chased them, but he didn't attempt to catch them anymore.

Figure 4. This harvestman, in Inohae Valley, Japan, is relatively inconspicuous among the mosses on the tree trunk, with its thin legs blending with the small bryophyte branches. Bryophytes in this environment could provide a source of water, obtained from droplets, in this rather dry habitat. Photo by Janice Glime.

The harvestmen have gotten the reputation of being venomous, a long-perpetuated myth. They have no venom glands, no fangs, and cannot pierce human skin. This reputation may have been based on the smell that emanates when they are handled (Opiliones Internet Discussion Group 2011). At the sides of the eyes are two pores that secrete a foul-smelling fluid. This is most likely what discouraged my dog. The chemical can burn the eyes and mouth, encouraging the would-be predator to release the captured harvestman. In a cave in southwestern Canada, cohabiting cricket, frog, and salamander guts were examined, but no harvestmen were in evidence (Holmberg *et al.* 1984). Bats, on the other hand, do eat Opiliones (Whitaker *et al.* 1977).

This moss visitor, *Leibunum rotundum*, is one of the harvestmen that can release a leg if it gets caught, but

generally this leg cannot regenerate (Figure 5). If one watches this process, a surprise ensues. The detached leg continues to twitch! This can last from as little as a minute to as long as an hour, depending on the species (Opiliones Internet Discussion Group 2011). There are "pacemakers" in the ends of the femur of the leg that signal the muscles to extend the leg. The leg relaxes between signals, causing a repeated twitching motion. This could draw the attention of the predator away from the harvestman, allowing it to escape.

Figure 5. *Leioibunum rotundum* male on mosses, demonstrating the detachable legs of this species. This fellow seems to have sacrificed one of its eight legs already. Photo by Morten D. D. Hansen, with permission.

Some species of harvestmen are known for their aggregation behavior (Figure 6; Coddington *et al.* 1990). When in these masses, they can sometimes resemble a moss until closer inspection is possible (Bugs in the News 2011). Aggregations of *Leioibunum* in southeastern USA have as many as a thousand individuals (Cockerill 1988). Wagner (1954) reported 70,000 individuals in aggregations of *Leioibunum cactorum* (*nomen nudum*). Mukherjee *et al.* (2010) reported up to 300,000 individuals of *Pseudogagrella* sp. (Sclerosomatidae) in a winter aggregation in a rainforest in China, although the individual patches had only 10-30 individuals.

Figure 6. Aggregation of harvestmen. Photo by Luis Fernández García through Creative Commons.

The function of these aggregations remains unknown, and research has served largely to negate hypotheses (Holmberg *et al.* 1984; Machado & Vasconcelos 1998).

Machado and Vasconcelos (1998) examined aggregation behavior of three species at 1200 m elevation in Brazil. Among these, only *Holoversia nigra* (Gonyleptidae) released repugnatory substances when disturbed. The other two species fled or hid. Yet, among some species elsewhere, disturbance elicits a pulsating behavior among the members of the aggregation (Cockerill 1988), giving the appearance of a larger, more foreboding organism (Opiliones Internet Discussion Group 2011). Other possible advantages may include regulation of temperature, humidity, or light. Cockerill (1988) found several species of *Leioibunum* (Figure 5) that aggregated during the day but not at night, lending support for this microclimate hypothesis.

Holmberg *et al.* (1984) suggested that the aggregation behavior of *Leioibunum paessleri* in southwestern Canada provided a safe microenvironment. When day length exceeded 14 hours, they migrated into caves, where they formed vertical aggregations. Mating occurred after they vacated the caves in spring. In lab experiments, survival below freezing was poor. For organisms that are hibernating or resting, aggregation behavior could offer environmental protection as well as providing an alarm system when predators approach. On tree trunks and other exposed places, the stacking of individuals, as in Figure 6, could not only offer protection from predators, but reduce wind velocity, reducing desiccation.

The Harvestman Presence

Edgar (1990) mentions that harvestmen occur in mosses, as well as in leaf litter, under logs, and in caves. Biström and Pajunen (1989) investigated the arthropods, including harvestmen, in two forested areas near "boggy" sites in southern Finland. They visited the Borgå sites 8 times between early May and early October and the Esbo sites 21 times during approximately the same period. Samples of moss measuring 25x25 cm and 10 cm deep were sieved to find the organisms. The bryophyte samples were primarily *Polytrichum commune* (Figure 19), *Sphagnum girgensohnii* (Figure 20), and *S. squarrosum*. Among the arthropods, the Opiliones were the third most abundant (157 individuals among 1671 arthropods) and were represented by five species. *Nemastoma lugubre* (Nemastomatidae; Figure 7-Figure 8) was a generalist harvestman found at all five of the main sites, ranging in abundance from 0.2 to 3.7 individuals per square meter. When the researchers divided the samples into wet, moist, and dry, three of the harvestmen species [*Mitopus morio* (Phalangiidae; Figure 9-Figure 12), *Oligolophus tridens* (Phalangiidae; Figure 13-Figure 14), *Lacinius ephippiatus* (Phalangiidae; Figure 16-Figure 16)] had a "tendency" to occur in the drier stands. *Rilaena triangularis* (Phalangiidae; formerly *Platybunus triangularis*; Figure 17-Figure 18) also occurred among these mosses, but there were insufficient data to determine any preferences.

Further evidence of the abundant and widespread nature of some of these species is that one can find *Mitopus morio*, *Nemastoma lugubre*, *Rilaena triangularis*, and *Lacinius ephippiatus* in the Faroe Islands (Kauri 1980). The *Oligolophus* species there is a different one named *O. meadii*.

Figure 15. *Lacinius ehippiatus* female. Photo by Morten D. D. Hansen, with permission.

Biström and Pajunen (1989) found a slight indication that the fauna of *Sphagnum girgensohnii* (Figure 20) could be distinguished from that of the other moss stands, but this may be due to habitat differences that suited both the moss and the harvestmen rather than a preference for this *Sphagnum* species. At Borgå, there was a significant

difference in arachnid species richness between *Polytrichum commune* (Figure 19) and *S. girgensohnii* (Figure 20). These differences may relate to moisture differences between the microhabitats since *Sphagnum* species are much better adapted to hold water than are those of *Polytrichum*.

Sampling such as that of Biström and Pajunen (1989) are suitable for finding inhabitants within a moss mat, but one needs to be more clever to achieve representative sampling of those organisms that live on the surface. The harvestmen can move fairly rapidly, so those living in peatlands on the surface are unlikely ever to be sampled by removing cores. Differences in day/night habitat may also hinder sampling efforts, particularly for those that might migrate between shrubs/trees and the moss layer. Some harvestmen hang from the undersides of branches and leaves in the daytime, taking advantage of the shade to avoid overheating and desiccation, but become active at night. I have been constantly amazed at the number of species that are preferentially nocturnal in their activities, a concept that day-active humans like myself often fail to embrace. I am convinced that unless we develop and use a good sampling protocol for dusk and nightfall sampling we will not have a good understanding of those organisms that utilize the bryophyte habitat in their daily activities.

In Poland, the endangered *Siro carpathicus* (Figure 3) lives in mosses, under rocks, and in grass in the deciduous forests (Błaszak 2011). This small species may be one of the few species actually adapted to moving about within the moss clumps. In the Tyne Valley, UK, *Obisium muscorum* lives among mosses in marshes (Jackson 1904-1907).

Mating Sites

It appears that mosses play a role in the mating of at least some harvestmen, such as the striped harvestman *Leiobunum vittatum* (Figure 21). This species is common in the eastern United States. The males position themselves on moss-covered rocks, often remaining there for days at a time (Macías-Ordóñez 2000). One might suppose that being on a moss prevents desiccation during this prolonged visit. Following copulation, the female investigates potential sites for her eggs by injecting her ovipositor into cracks and crevices until she finds a suitable place to deposit the eggs (Machado & Macías-Ordóñez 2007). It would be interesting to investigate whether the state of hydration of the moss determines selection of location and timing.

Figure 21. *Leiobunum vittatum*, a harvestman that uses mossy rocks for mating. Photo by Hugh Yemen, with permission.

As a prelude to mating, the female must actually touch the male before recognizing him as a male harvestman (Macías-Ordóñez 2000). The male then pounces on the female and mates with her. The moss continues to play a role as the female *L. vittatum* completes the reproductive process by laying her eggs on or under the rock, but not on large, vertical rocks. This may just be convenience – presumably rocks with mosses are selected for the moisture of the moss, but that particular rock is most likely used for laying eggs because of its proximity. The male continues to follow her as she searches for crevices and other suitable places to lay her eggs.

For some species of harvestmen, bryophytes are included among egg-laying sites (Juberthie 1964; Bumblebee.org 2011). This appears to be the case for an invading *Leiobunum* species in Europe (Wijnhoven 2011). The female inserted her ovipositor into mosses on the tree trunk at about 30 cm above the ground. This was the only observation of oviposition on a tree, but other individuals did deposit eggs on mosses in crevices.

Species with short ovipositors lay their eggs on mosses or rock walls (Juberthie 1964). The eggs are protected by a mucous layer that prevents desiccation. *Leiobunum rotundum* (Figure 22-Figure 24), *Mitopus morio* (Figure 10), and *Oligolophus tridens* (Figure 14) hide their eggs (Juberthie 1964; Kaestner 1968). *Leiobunum vittatum*

(Figure 21) not only hides its eggs, but deposits a "repugnant" substance on them (Edgar 1971; Clawson 1988; Macías-Ordóñez 1997).

Figure 22. *Leiobunum rotundum*, a species that hides its eggs. Photo by Ed Nieuwenhuys, with permission.

Figure 23. Close views of *Leiobunum rotundum* on bark. Photo by Ed Nieuwenhuys, with permission.

Figure 24. Close view of *Leiobunum rotundum*. Photo by Trevor & Dilys Pendleton <www.eakringbirds.com>, with permission.

Often the harvestmen must walk a tightrope between moisture and dryness (Edgar 1971). Too little moisture causes the eggs to develop incompletely; too much encourages the growth of mold. While it would seem that bryophytes might be able to ameliorate the extremes of this moisture gradient compared to soil, documentation that

such is the case, or even that bryophytes are used, is lacking.

Seasons

Life cycles tend to dictate the presence or absence of many species. Eggs are essentially invisible to most people, or impossible to identify, so only active invertebrates are noted. Seasonal behavior of bryophyte-dwelling harvestmen does not seem to have attracted the attention of arachnologists, but we can derive indications from seasonal studies in other contexts.

The name harvestman refers to the many species that spend the winter as eggs, hence disappearing about the time harvest ends. Swain and Usher (2004) studied seasonal behavior of harvestmen as part of a restoration study at Flanders Moss, United Kingdom. The bog-dwelling *Mitopus morio* (Figure 11) has its peak abundance there in summer to early autumn, followed by *Paroligolophus agrestis* (Phalangidae; Figure 25-Figure 26) in late autumn to early winter. This results from the appearance of *M. morio* several weeks before, and its disappearance likewise several weeks before, *P. agrestis*.

Figure 25. *Paroligolophus agrestis* (formerly *Oligolophus agrestis*) among mosses. Photo by Trevor & Dilys Pendleton <www.eakringbirds.com>, with permission.

Figure 26. *Paroligolophus agrestis* (formerly *Oligolophus agrestis*) among mosses. Photos by Trevor & Dilys Pendleton <www.eakringbirds.com>, with permission.

Other species had much shorter active periods (Swain & Usher 2004). Forest-dwelling species like *Oligolophus hansenii* (Phalangidae; Figure 27-Figure 28) and *Lophopilio palpinalis* (Phalangidae; Figure 29) appeared for only a few weeks each year, with strong abundance peaks in early winter for *O. hansenii* and in late summer for *L. palpinalis*. Bog-dwelling species with year-long presence, like *Rilaena triangularis* (Figure 18), lack a strong abundance peak; in this species there was a very small spring peak. *Nemastoma bimaculatum* (Nemastomatidae; Figure 30-Figure 31), likewise a bog dweller, had a peak in autumn, and likewise exhibited low density throughout the year, as also demonstrated for *Nemastoma lugubre* by Vanhercke (Figure 32; Vanhercke 2004). These various phenologies combined to create the highest diversity in summer and autumn, when abundance likewise was at its highest. Winter diversity was the lowest, as one might expect.

Figure 27. *Oligolophus hansenii* on bark. Photos by Ruth Ahlburg, with permission.

Figure 28. *Oligolophus hansenii* on lichens. Photos by Ruth Ahlburg, with permission.

But these trends may not be indicative of harvestmen living among bryophytes elsewhere. Bryophytes can buffer

the temperature and moisture fluctuations, so it is possible that these harvestmen may have longer activity periods than plant/tree-dwelling species, and possibly even longer than those living in litter or soil.

Figure 31. *Nemastoma bimaculatum* among mosses and litter. Photo by Trevor & Dilys Pendleton <www.eakringbirds.com>, with permission.

Figure 32. Seasonal dynamics of *Nemastoma bimaculatum*, based on abundance in museum collections. Absence of juveniles, except a few in June and August, is most likely due to collector bias. Redrawn from Vanhercke 2004.

The liverwort host *Neosadocus maximus* (Gonyleptidae; Figure 33) has behavioral activities that can be grouped into five categories (Osses *et al.* 2008). Osses and coworkers found in their Brazilian study that 53% of the time was spent at rest and 31% in exploration. Females spent more time resting than did males. Unlike the human species, it was the males who spent more time grooming. This species was most active at night and during summer, and had increased activity at warmer temperatures, but not at higher humidities.

Epizoid Liverworts on Harvestmen

On quite another note, tropical liverworts (and Cyanobacteria) are known to grow epizootically on the backs of harvestmen (Machado & Vital 2001). On Cardoso Island in Southeastern Brazil, *Aphanolejeunea subdiaphana* (see Figure 34) and *Lejeunea* (Figure 35) aff. *confusa* joined the Cyanobacteria on the backs of at least four specimens of *Neosadocus maximus* (Figure 33 & Figure 36), but only two occurred out of 130 specimens in the coastal sand forest. On the other hand, out of only ten individuals in the rainforest, two had liverworts on their backs.

Figure 33. *Neosadocus maximus* from Intervales State Park, São Paulo state, southeastern Brazil, with liverworts on its back. Photo by Bruno A. Buzatto, with permission.

These liverworts seem especially adapted for such habitats. They have adhesive cells on their **propagules** (dispersal units, in this case **gemmae**) that aid attachment and they colonize rapidly (Machado & Vital 2001). The harvestmen seem to accommodate the colonization by having depressions in the dorsal scutes, similar to those of the beetles that are colonized by bryophytes. Setae, pubescent areas, and tubercles may also help by retaining moisture (Gressitt *et al.* 1968; Gradstein *et al.* 1984). And, like the beetles, these harvestmen have a long life span (3-4 years) (Juberthie & Munoz-Cuevas 1971, Cokendolpher & Jones 1991, Gnaspini 1995) that may aid establishment (Gradstein & Equihua 1995). Both are slow-moving and widespread. The female harvestmen lay 26-64 eggs on vegetation and remain to tend the eggs, which mature rapidly (Machado & Vital 2001). Machado and Vital suggest that the reluctance shown by this species to exude its repugnant odor (Cokendolpher 1987, Machado & Vasconcelos 1998) may be an additional adaptation to invite bryophyte establishment.

Figure 34. *Aphanolejeunea truncatifolia* from Uganda, showing the small size of this genus. Photo by Martin Wigginton, with permission.

Figure 35. *Lejeunea* sp., member of a genus that is known to grow on the backs of harvestmen. Photo by Michael Lüth, with permission.

In *Neosadocus variabilis*, the females guard the eggs and young (Machado & Vital 2001). It is possible the same behavior occurs in *N. maximus*. The role of liverworts in nesting of *N. maximus* is unknown.

Figure 36. The harvestman *Neosadocus maximus* from Cardoso Island, São Paulo state, southeastern Brazil, with liverworts on its back. Photo by Ricardo J. Sawaya.

Predators on Bryophyte Inhabitants

Although the connection is speculative, it is likely that some harvestmen are predators on unsuspecting fauna of epiphytic bryophytes. Castanho and da Rocha (2005) found that *Neosadocus maximus* (Figure 36), in the **Gonyleptidae**, eats tree frogs (Hylidae) in the rainforest of southeastern Brazil. However, it is possible that they were being detritivores, feeding on dead treefrogs rather than capturing living ones. But one must wonder, since this same harvestman blends in well with its bryophytic surroundings, making it possible to lie in wait without itself becoming dinner.

One discovery of a food item for harvestmen that was rather unexpected is their ability to eat earthworms (**Lumbricidae**). Halaj and Cady (2000) discovered that among 1032 night-active *Leiobunum* sp., they consumed earthworms as about 47% of their diet. *Leiobunum rotundum* (Figure 2) is a moss dweller and could find earthworms among the mosses. But trials with another species, *Habrobunus maculosus*, indicated that they might not be able to kill the earthworms, but instead eat ones already dead.

Harvestmen are often prey of parasitic mites, as seen in Figure 37 (Cokendolpher 1993).

Figure 37. Harvestman with parasitic mites. Photo © Stuart Dunlop <www.donegal-wildlife.blogspot.com>, with permission.

Peatlands

It is interesting that the harvestmen found in Flanders Moss include so many of the species already discussed as bryophyte inhabitants (Swain & Usher 2004). But, as seen in Table 1, There are some new ones as well.

Table 1. Harvestmen collected in pitfall traps, October 2002 - October 2003, on Flanders Moss, United Kingdom (Swain & Usher 2004).

Paroligolophus agrestis (**Phalangiidae**; Figure 39- Figure 41) is an ubiquitous European endemic and is the only member of its genus. It is listed as one of the species in the bog at Flanders Moss (Table 1). The legs are somewhat short for a harvestman and the body is only 3-5

mm (TrekNatur 2007). The short legs could be an advantage in navigating mosses, particularly if it were to duck into the mat to avoid a predator or escape the sun.

Figure 39. *Paroligolophus agrestis* (formerly *Oligolophus agrestis*). Photo by Trevor & Dilys Pendleton <www.eakringbirds.com>, with permission.

Figure 41. Female *Paroligolophus agrestis* on a moss, possibly *Pleurozium schreberi*. Photo by Morten D. D. Hansen, with permission.

Peatland harvestmen tend to be generalists (Swain & Usher 2004), occurring in a wide range of habitats. Swain and Usher suggest that the high exposure and rapid temperature fluctuations of mires creates a harsh environment that requires adaptations to a wide range of microclimatic conditions, thus explaining the preponderance of generalists.

Order Pseudoscorpionida – Pseudoscorpions

These tiny creatures with claws look a bit like miniature flattened crabs. They were once called book scorpions because they often appeared in books, where they preyed on book lice (Wikipedia 2012). They typically live among leaf litter and mosses above the soil (epedaphic), and one pseudoscorpion website states that they might more accurately be called moss scorpions (Project Noah 2012; Pseudoscorpions 2012). Their diet of Collembola (springtails), mites, and other small, soil-dwelling animals (BugLife 2012) is usually readily available among the soil-dwelling mosses.

Although pseudoscorpions are rare among bryophytes, some make the bryophytes home (Thydsen Meinertz 1962). Nevertheless, one of the most common of British pseudoscorpion species, *Neobisium carcinoides* (Neobisiidae; formerly *N. muscorum*) (Figure 42-Figure 45), can occur among them (Kinchin 1992) and is known as a moss scorpion. This species is particularly interesting because it gets transported to new habitats by hitching a ride on flying insects! (Natural England). It should be happy among mosses because its diet is especially rich in mites and springtails, both fairly common moss inhabitants.

Figure 45. Pseudoscorpion *Neobisium carcinoides* feeding on the springtail *Orchesella cincta*. Photos by Ab H. Baas, with permission.

In Finland forested and boggy sites, Biström and Pajunen (1989) reported *Neobisium carcinoides* among mosses at all five main sites. These sites were dominated by *Sphagnum girgensohnii* (Figure 20), *S. squarrosum* (Figure 46), and *Polytrichum commune* (Figure 19). This pseudoscorpion was a generalist, occurring with a density of 0.7 to 2.0 individuals per square meter. It seemed to have little preference for wet vs dry habitat.

Figure 46. *Sphagnum squarrosum*. Photo by Janice Glime.

Whereas *Neobisium carcinoides* is somewhat of a generalist, the bog chelifer *Microbisium brevifemuratum* (Neobisiidae; Figure 47) seems to be restricted to *Sphagnum* bogs and fens (Jørgen Lissner, pers. comm. 3 February 2011). *Microbisium brevifemuratum* (Figure 47) ranges 1.6-2.4 mm in length. It is a rare pseudoscorpion and a true **tyrphobiont** found only in *Sphagnum* mires (Jørgen Lissner, pers. comm. March 2011). It can be sifted from coarse *Sphagnum* species such as *Sphagnum papillosum* (Figure 48) and *Sphagnum magellanicum* (Figure 49), and seems to prefer microhabitats found on hummocks. *Neobisium carcinoides* is much more widespread and abundant in *Sphagnum* fens as well as in many other European types of bogs and fens. However, this widely distributed species thrives in a wide range of environments (**eurypotic**) and is not dependent on mosses for habitat.

Figure 48. *Sphagnum papillosum* with sundews. Photo by Michael Lüth, with permission.

Graves and Graves (1969) likewise found specificity lacking among pseudoscorpions in their study. They seemed to have a wide niche ranging among fungi, mosses, *Rhododendron* leaf litter, and other microhabitats in a North Carolina, USA, highland forest floor.

Figure 49. *Sphagnum magellanicum*, a species that typically develops red coloration in the sun. Photo by Michael Lüth, with permission.

Apochthonius minimus (Chthoniidae; see Figure 50) is a small pseudoscorpion that inhabits bark, mosses, and leaf litter in the northwestern USA and British Columbia, Canada (Johnson & Wellington 1980). The Collembola that share its bryophyte habitat provide food. The larger *Neobisium carcinoides* appears to account for significant mortality of these springtails, most likely competing with the smaller *Apochthonius minimus*.

Figure 50. *Apochthonius diabolus*. Photo by Steve Taylor and Mike Slay, with permission.

Another species of *Apochthonius*, *A. forbesi*, occurs in lava tube sinks in central Oregon (Benedict 1979). The warm thermal caves house relict species. Cold air is trapped deeper in the cave and permanent ice forms at the end where a mossy-litter layer houses pseudoscorpions such as *A. forbesi* and *Syarinus* sp. (Syarinidae).

Order Scorpiones

Be careful what you grab! Although this order is not usually represented among the bryophyte fauna, Tamás Pócs (Bryonet 1 April 2016) found one crawling from his moss packet after a collecting trip in Batumi (Georgia, Abkhazia). The moss was an epiphyte. It continued to live among wet mosses for weeks afterwards.

Summary

Most harvestmen on or near bryophytes are casual visitors whose long legs make navigation within the bryophyte clump more than a challenge. Their use of bryophytes seems to be that of gaining moisture by moving across them. Some, however are adapted by having short legs and overall smaller size and often resemble a seed or other forest floor element. Some of these harvestmen prefer peatlands, where they associate with such mosses as *Polytrichum commune*, *Sphagnum girgensohnii*, and *Sphagnum squarrosum*. Distinct differences were present among the communities of these three mosses at some sites, suggesting a moisture relationship. This moisture may be why some harvestmen mate on moss-covered rocks. Some species lay their eggs on bryophytes. Bryophytes may also serve as overwintering sites for some species, but evidence is lacking. In peatlands harvestmen tend to be generalists, permitting them to survive the wide range of microhabitats found there.

Some harvestmen (*Nemastoma*, *Neosadocus*) actually can have leafy liverworts (*Lejeuneaceae*) growing on their backs. The liverworts have adhesive cells on their propagules that help in their establishment, and the harvestmen have long lives to accommodate them.

Pseudoscorpions often live among mosses, where they find suitable food in springtails, mites, and other small soil invertebrates. Some species are specific to *Sphagnum*, but most seem to lack specificity in their habitats.

Acknowledgments

My sister Eileen Dumire reviewed this chapter for readability and clarity. Glauco Machado helped me obtain the pictures of harvestmen with liverworts on their backs. Zoologists and photographers have been very generous in giving me permission to use their images.

CHAPTER 9-1

ARTHROPODS: MITES (ACARI)

Figure 1. SEM of *Lorryia formosa* (yellow mite; **Tydeidae**) on leaf. This citrus dweller (<250 μm) also lives on a variety of other plant species. Its habit of eating fungi actually reduces fungal infections on citrus crops (Mendel & Gerson 1982). Its commonness is at least partly due to the ability to produce young through unfertilized embryos. Some mites that infect crops use bryophytes during seasons when crop plants are unavailable. Photo Eric Erb , through public domain.

Order Acari – Mites

Mites are similar to spiders, but differ in having no separation between the thorax and abdomen (and available at <<http://digitalcommons.mtu.edu/bryophyte-ecology2/>>.). Like the spiders, the adults have eight legs, but the larval stage has only six.

I still remember my first experience with a mite among mosses. I was working late at night rehydrating and identifying mosses collected the previous summer for my M.S. research. No one else was around, and I was getting tired. Then I looked through my dissecting microscope and there was an apparition – a tiny, pink, roundish creature with six legs and red eyes! Despite its six legs, I knew by its shape it was no insect. A bit of exploring in my books revealed that this tiny creature was the larval stage of a mite (Figure 2). The extra pair of legs is a nymphal and adult characteristic. Mite life cycles include larval, several nymphal, and the adult stages.

Figure 2. Larval mite (chigger), showing its six legs. Photo by Hansell F. Cross, through Creative Commons.

Habitat Relations

Mites have been associated with bryophytes from their mutual beginnings. Fossil records from 470 million years ago (Ordovician period) provide evidence of fungi in fecal pellets of mites. McNamara and Selden (1993) suggest that these mites fed on the decomposing remains of bryophytes.

Although many mites traverse the cushions and mats of bryophytes at some time during their lives (Figure 3), a smaller number actually live there. And of those, we must ask how many require the bryophytes in any part of their life cycle. Temporary ponds, floodplains, and tidally influenced coastal regions are amphibious habitats that alternate between wet and dry conditions. Changes in these phases often open up new nutrient loads that are favorable to many of their inhabitants (Wiggins *et al.* 1980). In such amphibious habitats, an organism must be adapted for both very wet and quite dry conditions, or move elsewhere when conditions change. But being able to survive these changes in amphibious habitats can also make the organism suited for other habitats within that range of conditions. Wohltmann (2005) asked the question, "No place for generalists?" To answer the question, he compared members of the Parasitengonina, which seems an appropriate group for asking the question. Wohltmann found that the temporary pools of forests and the rocky shores of estuaries had a large percentage of habitat-specific mites, but that floodplains had mostly opportunistic colonizers. Can we use the literature to answer this question for any mossy habitats?

Figure 3. *Eutrombidium* sp., a mite that is parasitic on grasshoppers, sits here on a bed of mosses, most likely just travelling through. Photo by Jenilee, through Creative Commons.

Habitat is tied to food choice, locomotion, and respiration as a driver of evolution in many mites (Wohltmann 1991). For those mites that are able to swim in open water, respiration is greater, as one might expect. And for those in open water, catching swimming prey provides additional food choices, but a short survival period without food (about 2 weeks), and again requires a higher respiratory rate. For those mites that live in amphibious habitats such as temporary pools, being able to survive long periods without food is important, and the respiratory rate is lower. Mites survived up to 400 days with no food (*Thyas barbiger* and *Limnochares aquatica*), but these were species that ate only immobile food and **crawled** on their substrate to eat. Both of these species are

able to use bryophytes as substrates (Smith in Smith *et al.* 2011; Andreas Wohltmann, pers. comm. 17 September 2011). Smith and Cook (2005) noted that the sclerotized plates on the backs of *Limnochares* species provided substrate for muscle attachment, hence facilitating their ability to crawl.

Lawrey (1987) cautioned that what may appear to be a preference of certain species may instead be a preference for the substrate of that species. Andre (1979) determined that what appeared to be an association with certain bark-inhabiting lichens was instead an association with the tree species where these lichens grew – *i.e.*, the mites and lichens preferred the same species of trees. Similar relationships are likely for mites inhabiting bryophytes.

Mite Adaptations to Bryophyte-Dwelling

Many of the mites are brilliant red or orange (Hingley 1993; Figure 4). This coloration is due to carotenoids and is thought to protect the mites from UV light (David E. Walter, pers. comm. 6 June 2011). However, David Walter finds that even in *Sphagnum*, most of the mites are duller colors, with brown to beige predominating (Figure 5). This cryptic coloration makes them less conspicuous against the soil and among the bryophytes. Oribatid (moss mites), usually the most abundant mites in mosses, are almost uniformly dull. These are slow-moving creatures (Kinchin 1990) and some feed on contents of moss leaf cells or on capsules (Figure 6; Gerson 1969). The prostigmatids, on the other hand, are often bright red (Figure 4) and may be very fast-moving (Kinchin 1990). It is likely that the bright red color serves as a warning coloration against some predators.

Figure 4. Velvet mite, probably *Austrothrombium* (Parasitengonina: Trombidiidae), among liverworts and lichens on a tree trunk. This mite has a parasitic larval stage. Photo by Michael Whitehead, through Creative Commons.

Figure 5. *Atropacarus* sp. mite, showing the subdued colors typical of many peatland-dwelling and moss mites. Photo by Scott Justis, with permission.

Figure 6. **Erythraeidae** mite on a moss capsule. Lipid sources in the spores may serve as a rich food source, but these spores are still young and the capsule most likely presents an impenetrable barrier to the mite. Photo by Aniruddha Dhamorikar, through Creative Commons.

Figure 7. *Leptus beroni* larva on the harvestman *Mitopus*. Both are moss dwellers. Photo by Andreas Wohltmann, with permission.

Mites are tiny creatures, mostly less than 1 mm in length (Wikipedia: Acari 2011), sometimes appearing as specks on the legs and other body parts of insects and other arachnids (Figure 8-Figure 9). This small size makes it easy for them to maneuver among the stems and leaves of bryophytes. And their sucking mouth parts permit some of them to use the bryophytes as a food source.

Figure 8. *Mitopus morio* (harvestman) with a red mite larva in the genus *Leptus* (**Parasitengonina**: **Erythraeidae**) attached to its leg. Photo by Ed Nieuwenhuys, with permission.

Figure 9. *Leptus trimaculatus* adult, a known moss dweller. Photo by Andreas Wohltmann, with permission.

Since many of the moss mites are bright colored, camouflage is not going to work for them. This seems to be the case for some of the bright red moss mites such as *Trombidium*. Instead of hiding or running (many mites are not very good at this), they roll onto their backs and play dead (**thanatosis**). Figure 10 shows one of these moss mites doing just that. Aside from being motionless, and thus attracting less attention, I have never figured out how that helps, but opossums seem to think so, and so do some salamanders, snakes, and insects, and so do humans facing grizzly bears!

Miyatake *et al.* (2004) asked that same question about potential advantage. And to our good fortune, they asked it using an arthropod, the beetle *Tribolium castaneum*. First, they showed that there was heritable variability in the duration of the death-feigning behavior. Using ten

generations of this species, they showed that the strain that had the greatest inheritance of the behavior (longest duration of death feigning) had the greatest frequency of thanatosis. Next they showed that there was greater fitness (greater survival) of those with the long-duration thanatosis trait when they were presented with a predator, a female Adanson jumper spider (*Hasarius adansoni*, Salticidae). Finally, they showed that the frequency of predation was lower on those mites in the strain with long-duration death feigning than from those with short-duration feigning. These experiments met the three criteria proposed by Endler (1986) to demonstrate the evolution of an adaptive trait by natural selection: variation of the trait among individuals; differences in fitness as related to the trait; inheritance of the trait.

Figure 10. *Trombidium holosericeum* in a state of **thanatosis** (playing dead). In this case, the mite was touched with a brush. Photo by Andreas Wohltmann, with permission.

The behavior of the spider, when encountering her prey, may help us to understand how this trait is adaptive. The Adanson's jumper spider had rather different behavior when provided with a live fly, *Drosophila hydei*. She never set the fly free and immediately ate it. But when the spider was presented with the *Tribolium castaneum*, she always let go again. The researchers suggested that this was due to the hard cuticle and/or a chemical released as anti-predator defense (Happ 1968). Only if the beetle moved after the attack did the spider once again attack, and in several cases, eat the beetle.

There might be a nutritional reason as well. If the fly has evolved along with its prey organisms, dead organisms, at least arthropods, could mean a waste of energy when attempting to eat them. Enzymes released from the cells of the insect quickly digest the interior of the insect, leaving mostly chitin, which presumably supplies little energy and may take more energy to penetrate than will be obtained. It is likely that some of the same powerful enzymes that help the mites digest their food are also released when they die, potentially digesting the interior of the mite as well.

Having a number of species with the same adaptive defense behavior of playing dead is considered a form of **aggressive mimicry**. According to the World of Darkness Wiki (2010), the appearance of death is supposed to conjure up the sense of rot and decay and all that goes along with death. But I would think that would require the attendant odors as well. Could it be that these beasts elicit the odor of rotting bodies that we humans have not yet detected, but that these animals have? In fact, that may be the case for the beetle *Tribolium costatum* and others (Miyatake *et al.* 2004).

Symbioribates papuensis has an unusual adaptations to mosses. It lives on mosses that grow in the backs of Papuan weevils, hence getting a free ride that provides dispersal (Aoki 1966).

The Inhabitants

Mites are abundant in bryophytic habitats (Sellnick 1908; Willmann 1931, 1932; Rajska 1958; Aoki 1959; Higgins & Woollery 1963; Wood 1966; Popp 1970; Seniczak 1974; Bonnet *et al.* 1975; von der Dunk & von der Dunk 1979; Harada 1980; Seyd 1988; Seyd & Colloff 1991; Smith & Cook 1991; Hoffmann & Riverón 1992; Kinchin 1992; Seniczak *et al.* 1995; Seyd *et al.* 1996; Winchester *et al.* 1999; Fischer 2005; Bettis 2008), so much so that oribatid mites have been termed moss mites. Aoki (2000) reported on oribatid mites in moss cushions on Japanese city constructions. Their abundance is illustrated by a study by Yanoviak *et al.* (2006), who reported that 65% of the arthropod fauna among epiphytes in a Costa Rica cloud forest were mites.

Weiss (1916) reported *Bdella cardinalis* in mosses as well as under leaves and rotten wood in New Jersey, USA. Jacot (1938) later concluded that this species was a synonym of *Bdella oblonga*, which is common on decayed fallen trunks and among their mosses. Members of the family **Bdellidae** (snout mites; Figure 11-Figure 13) occupy mosses in Mexico (Baker & Balock 1944) where they feed on other arthropods, including mites. These include *Biscirus lapidarius* (only a single specimen) and *Bdella oblonga* from mosses at Deseirto de los Leones. The type specimen of *Bdella rio-lermensis* was collected from mosses in Rio Lerma. *Bdella mexicana* is known from mosses in Valle del Bravo. Likewise, the type specimen for both the genus and the species of *Opserythraeus hoffmannae* were collected as larvae from mosses in Rugege Forest, Rwanda (Fain 1996).

Even in habitats where numbers of mites are few, greater numbers are likely to be found among bryophytes (Covarrubias & Mellado 1998). Oribatid mites were recorded from mosses and lichens in the Krkonose Mts. (Czech Republic) along an altitudinal gradient reaching from submontane to the alpine belt (Materna 2000). In 197 stands, 104 oribatid species were present. On the other hand, Materna found rather poor oribatid mite communities

among saxicolous mosses in the Krkonose Mountains, Czech Republic. Among these the predominant taxa were *Oribatula* cf. *pallida* (see Figure 14), *Mycobates tridactylus* (see Figure 15), and *Trichoribates monticola* (see Figure 16). Despite the poor representation in some rock communities, Shure and Ragsdale (1977) found that mites contribute to the fauna during primary succession on granite outcrops.

In wet litter and mosses near bodies of water in the mixed forest plains of Canada, one can find adults of the **Trombellidae** and **Johnstonianidae** (Figure 17; Smith *et al.* 2011). The mite ***Rostrozetes ovulum*** (Figure 22) occurs in bogs. ***Johnstoniana errans*** (Figure 18-Figure 20) lives in forests and at the edge of ponds where its **deutonymph** stage and adult, the two active stages in the life cycle, live primarily in damp mosses on rotting wood (Wohltmann 1996). These mites are nocturnal and use the mosses as hunting grounds for larvae and pupae of the crane fly ***Tipula* spp.** (Diptera; Figure 18). The mite larvae search for the pupae (Figure 19) of the crane flies, where they aggregate and await the transformation from the ***Tipula*** pupa into the emergence of the adult. The larval mites are parasites on ***Tipula*** adults, beginning just after emergence, once the larvae have moved onto the adult body from the surface of the pupa (Figure 18).

Some genera seem to show up on mosses fairly often, as indicated by the number of pictures with a mossy substrate. For example, George (1908) found ***Trombidium bicolor*** (Figure 23) in damp mosses, especially in ditches.

Michael Whitehead shared his picture of a species of *Austrothrombium* (Figure 24) on a leafy liverwort.

minuta in parts of eastern central USA, less than 0.5 mm in length, occurs among mosses, although it occurs mostly on animal substances (Banks 1895).

Figure 22. SEM of *Rostrozetes ovulum*, a bog dweller. Photos by Barb Eamer, with permission.

Figure 23. *Trombidium holosericeum*. Photo by Ruth Ahlburg, with permission.

Some of the moss dwellers seem to be somewhat specialized. The genera *Damaeus* (Figure 25), *Belba*, and *Metabelba* (Figure 28) are fungal eaters and live in habitats that make close contact with the soil, such as mosses (Smrž 2010). They rarely occur among mosses on trees. *Belba*

Armed with names like **Bryobiinae** (Figure 29) and **Bryobia** (Figure 30), I searched with anticipation for information on their habits. My first find was that the common name was **clover mite**, somewhat dashing my hopes for a bryophyte dweller. But when I keyed in moss with its name, I found it did legitimately use *bryo* in its name, using mosses as habitat.

Figure 29. Member of **Bryobiinae**, a family with moss-dwellers. This green one suggests that it is a plant eater, but do they eat bryophytes? Photo by Walter Pfliegler, with permission.

Figure 30. *Bryobia* sp., member of a genus that uses mosses when larger hosts are not available. Photo by Valerie Behan-Pelletier and Barb Eamer, with permission.

Bryobia praetiosa (as *B. humeralis*; Figure 31) was first described by Halbert (1923) from mosses and a wall. Later, Flechtmann and Baker (1970) listed bryophytes among its hosts, and Tuttle and Baker (1976) reported it from mosses in Utah. Nevertheless, it seems to live predominantly on tracheophyte hosts. From there, the records seemed scarce until Hatzinikolis and Panou (1996) discovered *Bryobia emmanoueli* and *B. meteoritica* as new species among mosses in Greece. I suspect that more moss dwellers have been described in the older literature that has not yet found its way to the internet. As you will see, mosses can act as alternate "hosts" when tracheophytes are seasonally absent.

Figure 31. *Bryobia praetiosa*. Photo by Jarmo Holopainen, with permission.

Figure 32. *Erythraeus* (*Parasitengonina*) on bark with a moss branch nearby. Photo by James K. Lindsey, through Creative Commons.

Some mites that live on bark and other substrates traverse mosses and obtain moisture from them. Such is likely the case for some members of the **Erythraeoidea** (Figure 32).

Wood (1967) documented the presence among mosses of the mite *Eustigmaeus* (as *Ledermuelleria*; Figure 33), a genus of red species. In 1972 Wood described new species of *Eustigmaeus*, from mosses in Canada. With publication in the same year, Gerson (1972) sampled 160 mosses in eastern Canada and the USA and found that nearly half of them housed mites. Of these, eleven species were in the genus *Eustigmaeus*. Furthermore, among the 55 species of mosses, 38 housed *Eustigmaeus* species. The species *E. arcticus*, *E. gersoni*, and *E. rhodomela* occurred primarily on mosses that colonize open soil. On the other hand, *E. frigida* preferred mosses in shaded, humid places.

Figure 33. *Eustigmaeus* sp., a genus that is common on mosses and uses some of them for food. Photo by David E. Walter and Anthony O'Toole, with permission.

The Role of Bryophytes

Bryophytes can offer an important physical component that provides a habitat for mites. Dewez and Wauthy (1981) used sponges as artificial substrata and found that mites did colonize the sponges in areas where bryophytes had been removed.

This suggests that the ability to provide a moist environment permits mosses to provide suitable mite habitat even on rocks (Materna 2000). In the Krkonose Mountains of The Czech Republic, mosses in areas approaching the treeline and protected by tracheophytes housed a rich community of ubiquitous mite species with high moisture requirements. Where the rocks lacked tracheophytes, the soil was less developed and few soil mites occurred. The moss mite community had few frequent species. The most common mite was *Oribatula* cf. *pallida* (Figure 14). Two of the species [*Mycobates tridactylus* (see Figure 15) & *Trichoribates monticola* (see Figure 34)] were specialists that lived only on mosses and lichens.

Leafy liverworts such as species of *Frullania* with lobules (Figure 37) provide a protected habitat that maintains moisture when most other places are dry and house such mites as *Birobates hepaticolus* (Figure 37), as both immature and adult individuals (Colloff & Cairns 2011). And for food? It eats liverwort tissue!

Figure 34. SEM of *Trichoribates* sp., member of a genus where some members specialize on moss and lichen habitats. Photo by Birgit Balkenhol and Samantha Kühnel, the Senckenberg Museum of Natural History, Görlitz, with permission.

Experimental work with moss mites can provide us with information to help explain their presence in a given habitat. Smrž (2006) studied the saprophagous mites living among mosses on a roof to determine their biology. Two species of oribatid mites [*Scutovertex minutus* (see Figure 35-Figure 36), *Trichoribates trimaculatus* (see Figure 34)] comprised the moss mite community. They used these mites in laboratory experiments to determine their nutritional needs, moisture relations, mobility, and food selection. Such factors as digestive processes, vertical and horizontal distribution, and ability to disperse defined different niches within the moss community for these two species.

Bryophytes as Food

The oribatid mites eat fungi, algae, and dead organic matter (Bhaduri & Raychaudhuri 1981). With about 10,000 described species (David E. Walter, pers. comm. 15 September 2011), their habitats are varied, including leaf litter, lichens, bryophytes, humus, and compost heaps. Ponge (1991) found all these foods in feces of the phthiracarid mites living among Scots pine litter. Within the bryophyte communities, mites can often find all of their favorite food sources.

Lawrey (1987) contends that "there is only the scantest evidence that mosses are actually eaten" by mites. Nevertheless, Gerson (1969) states that mites are among the few animals known to eat bryophytes regularly. Woodring (1963) reported that he had been able to rear several mites [*Euphthiracarus flavum* (see Figure 38), *Galumna nervosa* (see Figure 39-Figure 41), *Oribotria* spp., *Pseudotritia* spp.] on mosses as food, indicating that at least some mosses are nutritionally adequate for at least some mites.

Gerson (1969) provided us with his personal observation of oribatid mites "gnawing" on various moss capsules and eating the spores. The fact that mites can be sustained on mosses under laboratory conditions suggests

that either the mosses or the microflora and fauna of the mosses provide sustenance (Sengbusch 1954; Woodring 1963; Lawrey 1987). Schuster (1956) found moss remains in the guts of four out of 40 oribatid species. In Brazil, Flechtmann (1984) described the species *Eustigmaeus bryonemus* (see Figure 33) for the first time, noting that it feeds on mosses. When the mite is cleared of its red color, the green moss in the gut becomes visible. But is it the moss that serves the nutritional needs, or micro-organisms and detritus on and among the leaves?

Figure 40. *Galumna* sp. (shield-sided fungus mite) that can subsist on mosses. Photo from Flickr through Creative Commons.

The genus *Eustigmaeus* (Figure 33) is one of the common moss mites to feed on the bryophytes, and evidence suggests that the moss is indeed the intended food item. Gerson (1972) reported, based on laboratory

experiments, that *Eustigmaeus frigida* mites (Figure 42) pierce stem and leaf tissues of mosses with their needlelike chelicerae, enabling them to suck the contents from the cells (David Walter, pers. comm. 6 June 2011), leaving behind skeletons of cell walls (Gerson 1972). Such feeding can cause the young moss shoots to discolor to a silvery grey and shrivel (Gerson (1972). David E. Walter (pers. comm. 15 September 2011) describe this as using "spike-like movable digits to puncture the leaves of the mosses on which they feed." Experiments by Gerson (1972) indicate that they will eat many moss species and survive on the diet. However, they only reproduced following a diet of a restricted few species. In addition to *Eustigmaeus frigida*, *E. rhodomela*, *E. clavata*, and *E. schusteri* also feed on various mosses and have similar life cycles to those of *E. frigida*.

Figure 41. *Galumna* representatives, members of a genus where some species are known to be able to subsist on mosses as food. Photo by Walter Pfliegler, with permission.

Figure 42. *Eustigmaeus frigida*, a common moss inhabitant that has specialized mouth parts for piercing mosses, but not those with thick leaves. Photo by David E. Walter, with permission.

Length of stylet plays a role in species of mosses that can be eaten by mites. Of five species Gerson observed on *Polytrichum* clumps (Figure 43), *E. frigida* has the shortest (23 μ m) and narrowest (1 μ m) stylet, compared to 32-58 μ m long and 2-4 μ m wide stylets among other residents (Gerson 1972). There was no survival of *E. frigida* on relatively large mosses: *Pogonatum urnigerum* (Figure 44),

Polytrichum commune (Figure 43), *Polytrichum piliferum* (Figure 45), *Leucobryum glaucum* (Figure 46), or *Atrichum altecristatum* (Figure 47-Figure 49).

Eustigmaeus (Figure 33) species, in particular, have special stylets that pierce stems and leaves and suck out cell contents (Gerson 1969). Like that of *E. frigida*, part of the specialization to feeding on certain mosses seems to be related to length of stylet (Gerson 1969). *Eustigmaeus clavata* and *E. microsegni* have long (40 & 32 μ m respectively), thick (3-4 μ m) stylets and can survive on *Polytrichum* mats. *Eustigmaeus frigida* in Gerson's experiments has short (23 μ m), thin (1 μ m) stylets and are unable to survive on *Polytrichum* species with their thick dorsal cell walls and covering ventral lamellae.

Gerson (1987) reported mites from 38 species of bryophytes. Among these, all the active stages of *Eustigmaeus* fed on both leaves and stems of mosses, showing no preference for acrocarpous vs pleurocarpous taxa. However, as in earlier experiments, mites with short mouth parts were unable to feed on mosses with thick cell walls.

Woodring (1963) reared four species of mites through their 50- to 70-day life cycle on a diet exclusively of mosses. Josephine Milne (Bryonet 18 March 1996) found ca 18 species of mites, among other invertebrates, to be

abundant on her cultures of the moss *Dicranoloma* (Figure 50) from a cool temperate rainforest in Australia. The mites fed especially on new leaves at the tips of the plants, frequently chewing out the young buds.

Figure 49. *Atrichum altecristatum*. Dehydrated mosses showing the contortion of the leaves. Photo by Eric Schneider, with permission.

Figure 50. *Dicranoloma billardiarei*, potential home for many mite species. Photo by Michael Lüth, with permission.

Penthaleus species (Figure 51) are large, brightly colored mites that feed on plants and are frequent plant pests (Umina 2004). Russell (1979) discovered that at least some of them also eat bryophytes. By keeping one species in the lab, he was able to observe both adults and juveniles feeding on the moss *Orthotrichum* (Figure 91) from Oregon, USA. They subsisted on this food source for up to two weeks.

The Penthaleidae (Earth Mites; Figure 51) have needle-like mouthparts that permit them to puncture leaf cells or fungal hyphae and suck out the contents. These mites spend their early stages in the soil where they feed on fungi, algae, and bryophytes. In contrast, the older stages clamber onto the low-growing vascular plants where they feed on the leaves. The red-legged earth mites look black because of dense concentrations of chlorophyll from their food. The red legs gain their color from carotenoids deposited in the cuticle – a possible adaptation to protect them from UV-light.

Early stages of the Earth mites, Penthaleidae (Figure 51-Figure 52), feed in the soil on fungi, algae, and bryophytes, whereas the older stages move to low-growing tracheophytes where they feed on the leaves (David Walter, pers. comm.). They use their needle-like mouthparts to puncture leaf cells (or hyphae of fungi when they are in the

soil) and drain the cell contents. The red-legged earth mite is a well-known pest that looks nearly black due to dense accumulations of chlorophyll. Their legs are red, presumably protecting them from UV radiation.

Figure 51. *Penthaleus major*. Note the drop of liquid where the anus is. This anal position adapts the mite to its upside-down feeding position. Photo by Scott Justis, with permission.

Figure 52. This mite from an epiphytic leafy liverwort is most likely a member of the **Penthaleidae**. Its green color reveals a recent diet of chlorophyll, possibly the liverwort, or algae/Cyanobacteria growing on it. The brown mite just above it is a nymphal oribatid mite (*Achipteridae*?). Photo by Jessica Nelson and Duncan Hauser, permission status unknown.

When we know so little about organisms that eat bryophytes, it is a rare treat to find a report where the observers were able to watch the bryophyte herbivore closely. But Cronberg and coworkers (2008) did just that – they observed mites feeding on the protonemata of mosses (Figure 53). Whereas it appeared that the springtails lacked the apparatus necessary for protonemal dinners, the mites used their jaws to cut the protonemata into two pieces. They then consistently fed on only the distal (tip) piece. These mites also carried gemmae of *Bryum argenteum*

(Figure 54-Figure 55), but the researchers were not so fortunate as to watch any banquet on these. Too bad for the springtails – they also form part of the diet of the mites! (Figure 56).

Most of the experiments and observations on mites that feed on bryophytes involve mosses, not liverworts. It would be an interesting experiment to give them choices of a range of mosses **and** liverworts to see if both are eaten. Liverworts are known to house a number of secondary compounds that serve as antiherbivore compounds, but then, many (perhaps most) mosses contain phenolic compounds that discourage herbivory as well (Mues 2000).

Other reports of bryophyte-feeding mites include those in laboratory enclosures where mosses were provided for cover and sources of moisture. Wallwork (1958) reported that adult *Achipteria coleoptrata* (Figure 57) ate living young stem tissue of mosses and survived on that diet for more than a month. It appears that bacteria in the gut are necessary to digest at least some cell types in tracheophytes, particularly those with lots of lignin (Haq & Konikkara 1989). It would be interesting to see if a gut flora is equally important in digesting non-lignified bryophytes.

Figure 56. Mite eating a springtail in the mountains of West Virginia, USA. Both can be found among mosses. Photo by Roy A. Norton, permission unknown.

The oribatid mites, known as moss mites, live among bryophytes, but rarely eat them (David walter, pers. comm.). Rather, the bryophytes provide a habitat where the mites can feed on fungi that live among the bryophytes, and at the same time they enjoy the protection of the bryophytes against large predators, UV light, and desiccation.

Figure 57. *Achipteria coleoptrata*, a mite that eats young moss stem tissue. Photo by the CBG Photography Group, Centre for Biodiversity Genomics, through Creative Commons.

Community Food Sources

Bryophytes seem more likely to provide food for the mites indirectly by housing suitable food organisms, as can be seen for a number of moss-dwellers listed in Table 1. Smrž (2010) reported that *Achipteria coleoptrata* (Figure 57) ate fungi and other food types within the moss mats on soil and on trees, as did *Hermannia gibba* (Figure 58). Other mites likewise used the moss habitat on tree trunks as a food source, with *Oribatula tibialis* (Figure 14) feeding on fungi, *Phthiracarus* sp. (Figure 60-Figure 61) feeding on litter, and others [*Achipteria coleoptrata*, *Chamobates cuspidatus* (see Figure 62-Figure 63), *Chamobates subglobus*, *Li acarus coracinus* (Figure 64), *Tectocephus velatus* (Figure 105) finding a variety of suitable foods there. *Melanozetes mollicomus* fed on the epiphytic mosses themselves. Among mosses on tree roots, *Melanozetes mollicomus* again fed on mosses, *Phthiracarus* on plant litter, *Achipteria coleoptrata* and *Damaeus auritus* (Figure 25) on fungi, and the remaining species used a variety of foods [*Hermannia gibba* (see Figure 58), *Hermanniella granulata*, *Hafenrefferia gilvipes* (see Figure 65), *Hypochthonius rufulus* (Figure 66-Figure 69), *Tectocephus velatus* (Figure 105)].

Some bryophytes may even provide a food source underground. The primitive leafy liverwort ***Haplomitrium*** (Figure 70) extends its stem below ground, where it is inhabited by endophytic fungi (Carafa *et al.* 2003). Whether these are available as food for mites remains a question, but many bryophytes have fungal associates that could provide food sources.

Figure 70. *Haplomitrium gibbsiae*, a leafy liverwort that has underground endophytic fungi – an unevaluated potential food source for mites. Photo by Jan-Peter Frahm, with permission.

Wolf and Rockett (1984) experimented with the diet of *Rhysotritia* (Figure 71). They found that those mites taken from their natural habitat contained significantly fewer bacteria in their guts than those maintained in the lab in a soil-moss habitat. This suggests that bryophytes can provide significant bacterial food sources to the mite inhabitants.

Figure 71. *Rhysotritia* sp. from Norfolk, VA, USA; this mite can subsist on bacteria among mosses. Photo by Scott Justis, with permission.

At least some aquatic mites use mosses for food. Gerson (1982) reported that some use the moss *Cratoneuron filicinum* (Figure 72) for food.

Spider mites at Kadoorie Farm & Botanic Garden in Hong Kong also use bryophytes as food. The mites, reported as *Tetranychus* sp. (Figure 74) [but not spider mites, and probably *Halotydeus* (Figure 73-Figure 74) according to David Walter, pers. comm. 6 June 2011], actually eat the gemmae of the epiphytic moss *Octoblepharum albidum* (Figure 75), leaving only the basal cells where the gemmae attach to the leaf margins (Zhang *et al.* 2002, 2003). *Halotydeus signiensis* in the South Orkney Islands and *H. bakerae* in Australia are described from mosses (Walter 2006; David Walter, pers. comm. 7 June 2011). Their food relationships are not described.

Figure 72. *Cratoneuron filicinum*, a moss that serves as food for some mites. Photo by Michael Lüth, with permission.

Determining the diet of such small animal by gut analysis has long been a challenge. However, modern techniques using DNA matching may permit the identification of food eaten by mites collected from the field (see Remén *et al.* 2010), at least to the phylum level, and eventually to much lower levels as our bank of DNA fingerprints increases.

Importance of Bryophytes for Food

David Walter (pers. comm. 6 June 2011) suggests that mosses may be most important as food for earth mites [species of *Halotydeus* (Figure 73-Figure 74, Figure 76, Figure 81), *Penthaleus* (Figure 51)] in early spring before tracheophytes emerge from the ground or produce their leaves. Bryophytes are often the only green plants around, aside from tough conifers, when the snow melts and mites become active. He suggests that bryophytes might also be more important for the early instars – those 6-legged ones like I saw late at night when I was trying to identify the moss. This seems like a fertile topic for experimentation, looking for changes in diet between early and late life cycle stages. It would be interesting to see if older instars or adults might have a wider array of mosses in their diets, or abandon them altogether for tracheophytes.

Figure 74. *Halotydeus* sp. on leaves of the moss *Octoblepharum albidum*. Note its resemblance to *Penthaleus* (Figure 51), but its absence of a dorsal anus. The arrow indicates the location of gemmae. Photo by Li Zhang from Zhang *et al.* 2002, with permission.

Figure 75. Gemmae of *Octoblepharum albidum*. These can be dispersed by bryophytes. Photo by Li Zhang from Zhang *et al.* 2002, with permission.

Ridsdill-Smith and Pavri (2000) demonstrated that the diet of the mite *Halotydeus destructor* (known to feed on mosses; Figure 76) does not depend on a specific plant species. Rather, a diversified diet can provide nutrients for these mites as the seasons and weather change. Its ability to use plants with different nutrient suitability not only permits it to live through the changing seasons, but permits it to take advantage of the differing microclimates from soil to plant leaves. This feeding strategy contributes to its being very abundant, and unfortunately, enables it to be an agricultural pest.

Bryophytes may serve indirectly in providing food in at least some cases. For the mite *Ameronothrus* sp. (Figure 77), algae growing in association with the moss *Schistidium maritimum* (Figure 78) in a coastal splash zone at Yachats, Oregon, USA, provided a food source (Merrifield 1994). These mites emerged from perichaetia, mature capsules, and spent capsules, as well as from samples extracted with a Baermann funnel. A student of Stefan Schneckenburger (Bryonet 7 July 2015) likewise found eggs and adults of small mites in the capsules of *Schistidium* and other **lithophytic** (rock-dwelling) mosses. These capsules had no spores and the opercula were secured.

Lawrey (1987) suggests that mosses are not that different from tracheophytes in their nutritional value. The sugars seem to be the same, although *Sphagnum* has some that are different (Maass & Craigie 1964), and there are lots of mosses that have not been analyzed. Caloric content likewise is similar to that of tracheophytes. Lipids seem to be highest in the spores (Lawrey 1987), perhaps accounting for reports of mites in capsules (Merrifield 1994). The essential elements may be lower in bryophytes – not surprising because of the low nutrient conditions in which many mosses live, with N being quite variable and K and Mg somewhat lower than in tracheophytes (Prins 1981). But mosses seem to have lower concentrations of those soluble carbohydrates and hemicelluloses that are easily digested, exhibiting instead higher concentrations of structural components such as cellulose and polyphenolic lignin-like compounds – compounds that are harder to digest. Tracheophytes, by contrast, have lots of leaf parenchyma cells that lack lignin. While bryophytes all lack lignin, their polyphenolic compounds with lignin-like structure and properties, often serve as chemical deterrents to herbivory. The highly structured *Polytrichum* (= *Polytrichum*) *ohioense* has less "desirable" structural compounds than those found in the lichen *Cladonia cristatella* (Figure 112), *Pinus resinosa* (red pine), or angiosperm tree leaves (Table 2), but I must question if the highly evolved structure of this moss with known cuticle and conducting cells is really a reliable representative of the mosses. This chemical structure could explain why mites in the study by Gerson (1972, 1987) did not survive when provided with only *Polytrichum* as food.

Presence of mites among bryophytes may be more a function of the substrate than of the food source. As Lawrey (1987) concluded, the habitat may be more important than the nutrition. But given a choice among otherwise suitable habitats, it appears that nutrition does play a role (Young & Block (1980). In an experimental study on the Antarctic mite *Alaskozetes antarcticus* (Figure 79), the mites maintained on lichens had the highest respiration rate and metabolism compared to those on the green alga *Prasiola crispa* or on **guano** (bird droppings). The mites also selected the lichens as food among these three choices.

Table 2. Comparison of structural components of a bryophyte (*Polytrichum ohioense*) with two trees and a lichen (*Cladonia cristatella*). Values represent percent of oven-dry weight; n=5. From Lawrey 1977.

<i>Pinus resinosa</i> leaves	35.41	13.44	19.37	23.56
Angiosperm tree leaves	43.89	11.59	20.43	11.04
<i>Polytrichastrum ohioense</i> leafy plant	16.51	14.07	24.37*	12.90
<i>Cladonia cristatella</i> thalli	19.93	66.54 ⁺	2.98 ⁺	0.78 ⁺

*Mosses don't have a true lignin.

⁺Lichens have chitin and lichenin as cell wall components and do not have true hemicellulose, cellulose, or lignin.

Figure 79. *Alaskozetes antarcticus*, a common Antarctic moss-dweller. Photo by Richard E. Lee, Jr., permission pending.

Krantz and Lindquist (1979) consider the **Penthalodidae** and **Eupodidae** to survive in moss substrates, whereas other species are fungivores. Later, McDonald *et al.* (1995) stated that the early life stages of *Penthaleus* (Figure 51) species were "likely to feed on lower plants and microflora found on the soil surface."

The observations of mites feeding on associated algae and fungi were followed by studies on the suitability and use of microflora as food for moss-feeding mites. Maclellan *et al.* (1998) compared the success of development for the plant pest *Halotydeus destructor* (**red-legged earth mite**; Figure 81) when reared on sand, bare soil, microflora from two locations, wheat, vetch, and combinations of microflora with wheat or vetch. This species is a pest in Australia, New Zealand, and southern Africa (Ridsdill-Smith 1997; Umina 2004). Maclellan *et al.* (1998) found that the microflora (including mosses, algae, and detrital matter) was an important supplement to the plant diet (Figure 80). When overgrazing caused the tracheophyte canopy to decline (Grimm *et al.* 1995), the loss of cover caused the microflora to decline. Maclellan *et al.* suggest that the mite densities dropped in response to the declining microflora.

As mentioned by David E. Walter (pers. comm. 6 June 2011), feeding by the immature stages on the microflora avoided competition with the adults. But when tracheophyte food is unavailable, *Halotydeus destructor* (Figure 76) is able to feed for 26 days (duration of the experiment and well into adulthood) on microflora alone in some sites (Bundoora) (Maclellan *et al.* 1998). And even the tracheophyte wheat was not sufficient to sustain them when eaten without microflora as a supplement (Figure 80).

The additional advantage of the mosses and microflora is their ability to provide a suitable microhabitat at times when the tracheophytes are inhospitable. In this study, the microflora crust at Dookie was dominated by the alga *Vaucheria*, but the moss *Bryum dichotomum* (Figure 82) and liverwort *Riccia crystallina* (Figure 83) were also present. At Bundoora, *Tortula truncata* (Figure 84; formerly *Pottia truncata*), *Fissidens vittatus*, *Ceratodon purpureus* (Figure 85-Figure 86), *Barbula unguiculata* (Figure 87), *Zygodon hookeri*, and *Bryum* sp. (see Figure 82) were present, as well as Cyanobacteria.

It appears that the microflora, including mosses, is important for the early life stages. MacLennan *et al.* (1998) found that the larvae and protonymphs spent almost no time on the wheat or vetch, but rather developed in the moss layer (Figure 80). Even adults would retreat there under unfavorable microclimate conditions on their tracheophyte food plants.

In prairie, desert, and other dry habitats where cryptogamic crusts develop, the bryophytes may be particularly important to serve as sources of food for the mites. They are almost a necessity because the bryophytes provide the only locations with sufficient moisture for most species. The co-habitants of fungi, algae, and some Cyanobacteria provide potential food for some mite inhabitants (Lukešová & Frouz 2007). On the other hand, all oribatid mites tested rejected the Cyanobacterium *Nostoc*.

Reproductive Site

Gerson (1969) brought mites, collected from mosses in Quebec, Canada, into the laboratory and allowed them to breed and lay eggs. Among the available mosses, they laid eggs on *Brachythecium* (Figure 88), *Hypnum* (Figure 89), *Didymodon* (Figure 90), and *Ceratodon purpureus* (Figure 85-Figure 86).

One tiny mite even lays its eggs in the tiny capsules of *Orthotrichum pusillum* (Keeley 1913; Figure 91). The eggs are sticky, so the spores adhere, giving the appearance of an oval mass of tiny beads of spores. The eggs are so glutinous that even boiling fails to dislodge the adhering spores. But is this a common occurrence, or just a lucky

one-time find? And what is the fate of the spores when the young mites hatch? Do the mite children eat the spores, or do the mites become unwitting dispersal agents?

Figure 92. *Orthotrichum pusillum*, a moss known to house mite eggs in its capsules. Photo by Robert Klips, with permission.

Eustigmaeus (formerly *Ledermuelleria*; Figure 33) lays eggs on a variety of mosses, but it also seems to avoid some, and there is evidence that eggs or young will not survive on some species (Table 3; Gerson 1987). These mites have a life cycle of 30 days with isolated females producing only male offspring (Gerson 1972). The female lays about 21 eggs, and reproduction seems unrelated to day length.

Johnstoniana exima (formerly *J. tuberculata*) is one of the mites with a parasitic larval stage. This small species lives in moist areas near lakes, where it is completely hidden just below the litter surface (Wohltmann *et al.* 1994). This litter could include mosses, but specific documentation seems to be lacking. The female lays her eggs in autumn and both sexes die shortly afterwards. The eggs overwinter, with larvae emerging in May and June. This emergence synchronizes perfectly with that of the host for the larvae, the crane fly *Limonia* sp. (see Figure 93). This synchronization suggests that the same factors control the development and hatching in both the mite and the adult crane fly. Since *Limonia* often lives among bryophytes [e.g. *L. sexocellata*, *L. capicola* in South Africa (Harrison & Barnard 1972); species in Colorado (Ward & Dufford 1979)], it is likely that the bryophyte habitat may play an important role when the mite attempts to locate a host.

But this overwintering pattern is not true for all *Johnstoniana* species. *Johnstoniana parva* requires a humid habitat, which they are able to find in the litter, and presumably mosses (Wendt *et al.* 1994). It has two egg-laying periods. After insemination in the autumn, overwintering eggs enter diapause in the bedrock. Other females are inseminated in the fall, then these adults hibernate for the winter and lay their eggs in late spring.

At least some of the aquatic mites use pheromones to find their mates (Smith & Hagman 2002). *Arrenurus manubriator* males respond to water in which females of the species have been kept previously. When put into water with these pheromones, the male assumes a readiness posture in readiness for coupling.

But mites are not the only things reproducing. West (1984) found mites and Collembola to be particularly important in *Polytrichum* clumps on South Georgia in the sub Antarctic. He found that different species of *Polytrichum* had different species of mites, using it as food, shelter, or both. Cronberg *et al.* (2006) found that the relationship between mosses and mites (*Scutovertex minutus*; Figure 94) or Collembola (*Isotoma caerulea*) can be even more intimate. In their experiments, these arthropods served as sperm vectors for the moss (Figure 95). This breakthrough discovery helps to explain how sperm may reach females 10 cm, even 1 m, away (Milius 2006). Mosses as close as 2-4 cm failed to reproduce unless cultures were in the company of these arthropods. In fact, it appears that the mites and springtails actually move to the fertile males and females more often than to "sterile" (non-fertile) shoots (Figure 96). The springtails seem to be more effective than the mites.

Figure 94. *Scutovertex sculptus*, member of a genus known to disperse the sperm of the moss *Polytrichum*. Photo by S. E. Thorpe, through Creative Commons.

The mite *Eustigmaeus bryonemus* (see Figure 33) in Brazil not only feeds on mosses, but it lays its eggs there as well (Flechtmann 1984). Its bright red eggs are laid mostly on the middle and lower leaves of fresh moss shoots. These are placed on the surface and not glued.

Figure 95. Comparison of sporophytes produced, indicating fertilizations, with male and female moss patches (*Bryum argenteum*) at 3 distances apart. Bars are mean number of sporophytes produced by 7 replicates. Vertical lines represent standard errors. Redrawn from Cronberg *et al.* 2006.

Figure 96. Preferences of mites (*Scutovertex minutus* & *S. sculptus*) and springtails (*Isotoma caerulea*) for fertile male, fertile female, and sterile plants of *Bryum argenteum*. Percentages are proportion of 30 replicate moss shoots on which animals were present. Bars represent numbers of animals present on fertile or sterile shoots. Probability is based on G test. Redrawn from Cronberg *et al.* 2006

Tydeus tilbrooki, the smallest arthropod in the Antarctic, lays its eggs among mosses, especially *Polytrichum* species that are encrusted with lichens (Gressitt 1967). It eats fungal hyphae and lichens there. *Rhagidia gerlachei* (see Figure 97) and *Rhombognathus gressitti* (an intertidal species) likewise use mosses for egg-laying sites in the Antarctic, as do *Stereotydeus*, *Protereunetes*, *Oppia* (Figure 98), and *Halozetes*.

Parasitic Mites

Many of the mites have larval stages that are parasites on other organisms. This group, known as the **Parasitengonina**, belong to the **Prostigmata** (Krantz & Walter 2009). Compared to the oribatids (moss mites), they are large mites, often display a bright reddish coloration (Figure 99), and are characterized by their particular life cycle, beginning with a parasitic larva. Although most of these larvae parasitize other arthropods (primarily flying insects), humans are familiar with the chiggers that parasitize humans and other vertebrates. The life cycle of this mite group is in an interesting one that makes them both parasites and predators. The parasitic larva matures into a **protonymph**, an immobile stage within the larval skin. This is followed by a predatory stage, the **deutonymph**, that feeds on other arthropods. The third and final nymphal stage is the **tritonymph**, once

more an immobile stage within the deutonymphal skin. This emerges from its "skin" prison as an **adult** that once again preys on other arthropods). Only a few Parasitengonina have a life cycle that varies from this pattern by having free-living larvae or additional moults (Wohltmann 2000).

Figure 99. A water scorpion (**Heteroptera: Nepidae**) infected by parasitic mites, larvae of a species of *Hydrachna*. Photo by Walter Pfliegler, with permission.

Andreas Wohltmann (pers. comm. 17 September 2011) considers that "mosses (and lichens) constitute part of the microhabitat of almost all Parasitengonina except a few species (e.g. desert-dwelling species such as *Dinothrombium* spp. and possibly some subterranean watermites) and thus Parasitengonina mites can be sampled in these substrates during mating, oviposition or searching for prey (or suitable hosts in the case of larvae)." Nevertheless, no evidence exists to suggest that any of the Parasitengonina feed on mosses or that any life cycle is dependent on them for mating or oviposition. Based on his field sampling, Wohltmann has concluded that there seems to be a greater correlation between bryophytes and Parasitengonina among the species in semiaquatic habitats than elsewhere.

Stur *et al.* (2005) examined non-biting midges (Chironomidae) in spring habitats in Luxembourg in search of parasitic water mite larvae. There were several species of midges that were not parasitized, and they suggested that general unavailability of the host or life cycle incompatibility could account for the absence of parasites. But they also suggested that two species of *Chaetocladius* among the mosses, along with their moss-dwelling life style, might also account for the lack of parasites on the sampled *Chaetocladius*. They suggested that the semiterrestrial moss-dwelling life style of these two *Chaetocladius* species made them less available to these aquatic parasitic mite larvae.

Adaptations of Parasitengonina

One of the major subgroups of **Parasitengonina** is the **Hydrachnidae** (formerly Hydracarina; Figure 100). As its

name suggests, this is a group that lives in a broad range of aquatic habitats, many of which have bryophytic substrates (Andreas Wohltmann, pers. comm. 17 September 2011).

Figure 100. *Hydrachna cruenta* amid *Elodea canadensis* leaves. This large mite is 3 mm in diameter. Photo by Andreas Wohltmann, with permission.

The terrestrial subgroups include the **Erythraiae** and the **Trombidae**, both of which include a few terrestrial species. Among the **Trombidae**, the members of the family **Johnstonianidae** are all amphibious. In contrast to the aquatic mites, terrestrial **Parasitengonina** have dense body hairs (**hypertrichy**) that prevent the cuticle from getting wet (Andreas Wohltmann, pers. comm. 17 September 2011). This causes an air bubble to form around the body when it gets wet. Water mites have few hairs and the body makes direct contact with the water. This lowers the **hemolymph osmolality** and reduces osmotic pressure, permitting them to live in fresh water without exploding.

The **Erythraeoidea** have a higher drought resistance than members of the **Trombidoidea** (Wohltmann 1998). This greater resistance results from differences in the body plan much like some of the characteristics that protect bryophytes. These include a reduction of body openings (bryophytes have none in their gametophytes, except in thallose liverworts) and lipids that help to seal others. This combination reduces water loss. But also like most bryophytes, the **Trombidoidea** are able to gain moisture from the atmosphere, although this has not been observed for erythraeid eggs or protonymphs. In the **Trombidoidea**, this vapor uptake can increase fresh body mass by about 50% prior to the protonymph stage. Wohltmann suggests that this increase in body mass may serve to stretch the cuticle and provide more space for the next developing instar. Hence, it might not have any relationship to drought resistance. In fact, one might speculate that stretching the cuticle could even reduce its resistance to losing water.

Bryophytes or Lichens?

Both bryophytes and lichens are small turfs that provide spaces and protection. Hence we should expect many species to live among both. But it appears that we do

not really know very much about why they choose one or the other, or both.

Some species occur predominantly on lichens, and others on bryophytes. *Halozetes crozetensis* is predominately among mosses, but occurs in lichens as well, with the choice apparently depending on the location and its climatic factors (Seyd & Seaward 1984). Some seem to be facultative moss dwellers, using them only when the lichens are unavailable. *Scutovertex minutus* (see Figure 35-Figure 36) and *Zygoribatula frisiae* (see Figure 101) live among mosses when lichens are absent, but are common lichen inhabitants. *Lepidozetes singularis* occurs among mosses in the Black Forest, but lives among lichens elsewhere (Seyd & Seaward 1984).

Figure 101. *Zygoribatula bulanovae*. Some members of this genus prefer lichens but use mosses when no lichens are available. Photo from CBG Photography Group, Centre for Biodiversity Genomics, through Creative Commons.

General

Carabodes labyrinthicus (Figure 102) is widespread on mosses as well as lichens (Seyd & Seaward 1984). *Ommatocephus ocellatus* likewise is known from mosses and liverworts as well as lichens, and is known to feed on saturated lichens. *Tricheremaeus serratus* occurs with both lichens and bryophytes. *Adoribatella punctata* occurs in both, as does *Alaskozetes antarcticus*, a detritivore. *Ameronothrus lineatus* (Figure 77) occurs in both, although it seems to be more common among lichens. *Centroribates uropygium* occurs in both. *Chamobates cuspidatus* (see Figure 62-Figure 63) is primarily a moss dweller, but occurs also on lichens. *Leiosoma palmicincta* occurs on both and survived from egg to adult on lichens alone. *Eremaeus oblongus* (see Figure 103) and *Tectocephus sarekensis* (see Figure 105) occur in a wide range of habitats that include mosses and lichens. In Sierra de Cazorla, *Ghilarovus hispanicus* lives among mosses and lichens on rocks. *Tegoribates bryophilus* in Colorado, USA, and *Metrioppia helvetica* are known from mosses and lichens. *Parachipteria petiti* was taken from the lichen *Parmelia* (Figure 104) as well as from mosses and liverworts. *Micreremus brevipes* seems especially fond of pine forests, where it can be found among litter, but also among corticolous lichens, and mosses.

As food sources, it appears that there are at least preferences between bryophytes and lichens. That is not surprising because the lichen provides primarily fungal food that is relatively easy to eat once the outer covering of the lichen has been penetrated. But in bryophytes, the thick cellulose walls provide a somewhat different challenge for the tiny mites. Some overcome this with a stylet type of apparatus that is able to penetrate the bryophyte cells. Nevertheless, some mites are associated with both mosses and lichens (Travé 1963, 1969), but their food preferences

may still be similar, relying more on the associated organisms than on the bryophyte itself.

Figure 105. *Tectocephus velatus*, a member of a genus that lives on both mosses and lichens. Photo by Monica Young, through Creative Commons.

Cool Sites

In the cold climate of Spitsbergen, numerous mites occupy lichens, but some at least are also found on mosses (Seyd & Seaward 1984). These include *Calyptozetes sarekensis*, but this species is more abundant among lichens. *Camisia invenusta*, a mite of mountain summits and other cool areas, inhabits both, but is more common among lichens and mosses on rocks than in the canopy. *Carabodes willmanni* (see Figure 102), on the other hand, prefers mosses. *Hydrozetes capensis* (see Figure 106) was found in dripping mosses and lichens in a canal.

Figure 106. SEM of *Hydrozetes*, a lichen and moss-dwelling genus common in peatlands. Photos by Valerie Behan-Pelletier and Barb Eamer, with permission.

The Arctic *Diapterobates notatus* (Figure 107-Figure 109) can occur in large numbers in moss and lichen litter. *Halozetes belgicae*, an Antarctic species, lives among both lichens and mosses. *Hermannia reticulata* (Figure 110) occurs on both in areas with cool climates. *Lamellovertex caelatus* occurs among mosses in the Swiss Alps. *Sphaerozetes arcticus* dwells among mosses and lichens in northern Canada and Alaska.

Figure 109. *Diapterobates notatus*, inhabitant of Arctic moss litter. Photo by Steve Coulson using multifocus stacking, with permission.

Sphagnum

Camisia segnis likewise occurs in cooler areas and inhabits both lichens and mosses, including *Sphagnum* (Seyd & Seaward 1984). It is known to eat lichens, but I don't know if it eats mosses. *Carabodes areolatus* and *C. marginatus* live among both lichens and mosses, including *Sphagnum*. *Carabodes minusculus* seems to prefer

lichens, but nonetheless, it does occupy mosses, including *Sphagnum*. Immature *Mycobates parmeliae*, as its name implies, lives most commonly among lichens such as *Parmelia* (Figure 104), but as adults it is most frequently in mosses and liverworts (Travé 1963), including *Sphagnum*. This suggests a change in resource needs, but we don't know which one(s). *Trhypochthonius cladonicola*, named for the lichen genus *Cladonia*, also occurs among mosses, including *Sphagnum*.

Arboreal

Many of the mites that occur in arboreal habitats also occur on rocks and some can be found in association with both bryophytes and lichens. *Phauloppia coineau* occurs among both mosses and lichens on rocks and in trees, but they seem to prefer lichens (Seyd & Seaward 1984). *Pseudachipteria magnus* is predominately a moss dweller, but it also can occur in saxicolous and arboreal lichens. *Liodes theleproctus* lives among lichens, mosses, and liverworts on rocks and in trees in the Pyrénées. *Strenzkea depilata* occurs among lichens, mosses, and liverworts on rocks and trees. Others seem to be predominately arboreal. *Humerobates rostrilamellatus* is arboreal and feeds on fungi and lichens, but it also occurs among mosses. *Lucoppia nemoralis* prefers to live among mosses and lichens on trees, including the trunk. The arboreal *Phauloppia lucorum* can be extremely abundant in lichens, but is known from mosses; it feeds on lichens. *Cymbaeremaeus cymba* lives predominately among arboreal lichens and mosses. *Licneremaeus discoidalis* lives among arboricolous mosses and lichens in Guatemala. *Phereliodes wehncke* occurs among arboreal mosses and lichens in Guatemala. *Poroliodes farinosus* occurs among lichens, especially *Parmelia* (Figure 104), but also among arboreal mosses and liverworts.

Coastal

Hermannia scabra (see Figure 58) lives among mosses and lichens in coastal as well as inland sites (Seyd & Seaward 1984). *Oribatella calcarata* is common among lichens in the intertidal zone, but are also known from mosses, including *Sphagnum*, in coastal areas. *Oribatula*

venusta (see Figure 111) has been taken from mosses as well as lichens on the sea shore as well as inland.

From this somewhat extensive list, it would appear that lichens and bryophytes may offer a number of common features suitable for mites. Lichens can offer cover, except for the crustose forms, and food, possibly from the fungal component (Seyd & Seaward 1984). The difference in food, with lichens providing fungi, may be a major factor dividing the species. For example, although *Oribatula exsudans* (see Figure 111) was collected from mosses, its fecal pellets contained no mosses – only pollen grains, fungal spores, fungal mycelia, and portions of lichen thallus (Seyd & Seaward 1984).

Figure 111. *Oribatula tibialis*, member of a genus that includes mites that live on both lichens and mosses. Photo by CBG Photography Group, Centre for Biodiversity Genomics, through Creative Commons.

Interestingly, for oribatids that occupy both bryophytes and lichens, the lichen is primarily species of *Cladonia* (Figure 112; Seyd & Seaward 1984) and presumably also *Cladina*. This group of lichens has a 3-d structure somewhat like that of a moss, providing a labyrinth of internal spaces that serve as a refuge.

Figure 112. *Cladonia cristatella*, a fruticose lichen that often occurs with mosses and shares many species of mite fauna. Photo by Charles Peirce, USDA Forest Service, through public domain.

Camouflage does not seem to be highly selected. For example, larvae of *Mycobates parmelliae* (see Figure 113) are bright orange and blend with their lichen habitat of *Xanthoria parietina* (Figure 114), but the adults apparently move to bryophytes, where bright orange does not match

the color pattern (Seyd & Seaward 1984). This seeming contradiction may be explained, however, by the better covering ability of the bryophytes.

Figure 113. *Mycobates perates*, member of a genus containing bright orange lichen dwelling larvae (*M. parmelliae*), but that then switch to mosses as adults. Photo by Monica Young, through Creative Commons.

Figure 114. *Xanthoria parietina*, host of the larvae of *Mycobates parmelliae*, a mite that lives among bryophytes as adults. James K. Lindsey, with permission.

Gall Formers?

Galls are unknown on extant thalloid liverworts or hornworts (Aller Hernick *et al.* 2008). But researchers have also reported that some thallose liverworts (*Metzgeriothallus sharoni*) from the Middle Devonian had minute galls that might have been created by mites (Aller Hernick *et al.* 2008; Labandeira 2014). These liverworts are only revealed by projecting polarized light on the shale and siltstone surfaces.

Summary

Mites (Acari = Acarina) are common bryophyte inhabitants, especially the oribatids, resembling tiny spiders (mostly less than 1 mm) with 8 legs but no separation between the thorax and abdomen. Bryophytes provide a moist environment where movement up and down permits the mites to find the microclimate that best fulfills their needs and avoids damaging UV-B radiation. The bryophytes provide protective conditions suitable for many species to use for egg-laying.

Some mites use sucking mouth parts to extract food from bryophyte cells. Stylet size in *Eustigmaeus*, a common genus among bryophytes, determines which bryophytes are edible. Some eat protonemata and others both eat and disperse gemmae. Some available bryophytes are avoided and on some, there is no survival for mites that do survive on other bryophyte taxa when the bryophytes are the sole source of food. Other mites are fungal eaters that take advantage of the soil-bryophyte interface where conditions are good for fungal growth, and others feed on organisms living among the bryophytes. On the other hand, the mites often serve as food for other inhabitants of the bryophytes. The bryophytes may be most important as a food source in early spring when herbaceous tracheophytes have not yet developed. Some mites live in liverwort lobules, taking advantage of the moisture, protection from predators, and liverwort food source.

During their travels among the bryophytes, mites can disperse sperm (and other propagules), and it seems that the reproductive structures of some bryophytes may actually attract them. Hairs protect the terrestrial members by providing trapped air spaces when they get wet. Aquatic members have few hairs.

Members of the Parasitengonina generally occur in habitats where mosses may provide substrate during their life cycle. These mites have a **parasitic larva**, an immobile **protonymph**, a free-living predatory **deutonymph**, another immobile stage – the **tritonymph**, and finally a free-living predatory **adult**.

Lichens provide some of the same advantages as bryophytes, offering small spaces where the mites can escape UV radiation, desiccation, and predation, but lichens offer different food choices, including the lichens themselves, contributing to a degree of specificity in the choice of bryophyte vs lichen.

Acknowledgments

David Walter provided invaluable insights into the mites and provided a critical review of an earlier version of this sub-chapter. Andreas Wohltmann checked identifications on the images I obtained from the internet and provided me with replacements and additional images as well as reference material and his own observations of bryophyte-dwelling mites. Many people have provided images, permission to use images, and free access and permission to use pictures in the public domain.

CHAPTER 9-2

ARTHROPODS: MITE HABITATS AND MINOR ARACHNIDS

Figure 1. Red mite (*Stigmaeidae*) on *Riccia ciliata*. Photo by Michael Lüth, with permission.

Mites occur among bryophytes in a variety of habitats (Figure 1). These can be grouped into forests, aquatic, peatlands, polar/alpine, and tropics to define the major differences in community structure. Within those categories, communities are divided both vertically and seasonally, as well as divisions into niches that differ in light, moisture, and sometimes temperature. This defines those that are generalists and those that are specialists in food or cover type.

Forest Bryophytes

Forests offer a variety of microhabitats for both bryophytes and mites. Monson (1998) found more than

100 species of mites among mosses in Slapton Wood and nearby in the United Kingdom. And the dominant mite species can exhibit considerable variability. For example, *Minunthozetes pseudofusiger* (*Punctoribatidae*) can be very common among mosses in one site and nearly absent in another (Monson 1998). In his study of oribatid mites in mosses at Slapton Wood, UK, Monson found a number of species new for the UK, including *Minunthozetes pseudofusiger* (*Punctoribatidae*), *Cepheus tuberculosus* (*Cepheidae*; see Figure 2), *Microzetes petrocoriensis* (*Microzetidae*), *Liochthonius perfusorius* (*Brachychthoniidae*; see Figure 3), and *Quadroppia pseudocircumita* (*Quadroppiidae*).

Eremaeus stiktos (**Eremaeidae**; see Figure 5-Figure 4) was described from moss-covered logs and other forest habitats in Washington state, USA (Higgins 1962). Other members of this genus and segregates of the genus also occur on mossy logs and among bryophytes on the forest floor (Figure 6-Figure 4). Woolley (1968) reported *Liacarus bidentatus* (**Liacaridae**; see Figure 7) on the forest floor among mosses in Washington state, USA, and in mosses in Wyoming. *Liacarus spiniger* (see Figure 7) also occurs among mosses. In Illinois, USA, *Platynothrurus peltifer* (**Camisiidae**; Figure 9; formerly *Hermannia bistriata*) lives among mosses and under logs (Ewing 1909).

Forest Floor

Mites are a common component on the forest floor, where they may inhabit soil, leaf litter, logs, or moss (Sywestrowicz-Maliszewska *et al.* 1993; Proctor *et al.* 2002). *Epicriopsis rivus* (Ameroseiidae) lives among mosses and litter in pine forests in northern Latvia (Salmane 2011). Members of *Epicrius* (Epicriidae; Figure 10) live among mosses (David E. Walter, pers. comm. 1 September 2011). Some members of the genus

Epidamaeus (Damaeidae; Figure 11) occur among leaf litter and mosses on soil. (Ermilov & Lochyska 2009). **Labidostommatidae** live on and in the soil, as well as in overlying vegetation and litter, including mosses (Krantz & Walter 2009). From this vantage point, they prey on smaller invertebrates (Figure 12). This soil/moss interface provides a moist environment where fungi and other micro-organisms can provide food sources.

Figure 10. *Epicrius* sp., member of a mite genus that can live among forest bryophytes. Photo by David E. Walter, with permission.

Figure 11. *Epidamaeus* sp., a forest floor bryophyte dweller, on leaf litter. Photo by Walter Pfliegler, with permission.

Figure 12. *Labidostomma mamillata* eating a springtail amid dead moss. Photo by Roy A. Norton, in Smith *et al.* 2011, with permission.

Salmane and Brumelis (2008) demonstrated the importance of the moss layer to the diversity of the predatory mites in the **Gamasina** group (an infraorder within the **Mesostigmata**; Figure 13) in the coniferous forest. In coniferous forests, bryophytes are able to establish on the forest floor because the narrow conifer leaves permit them to gain sufficient light to grow through the litter. In these forests, bryophytes are often the predominant forest floor vegetation and provide a moist haven for invertebrates. And, as seen in the previous subchapter, the bryophytes can serve as food.

Feather mosses [*Hylocomium splendens* (Figure 14), *Pleurozium schreberi* (Figure 15), *Ptilium crista-castrensis* (Figure 16)], common boreal forest mosses, harbor a diversity of predatory **Gamasina** mites (Figure 13; Salmane & Brumelis 2008). Salmane and Brumelis removed the feather mosses, then compared species richness, **Shannon diversity**, and equitability. In the spring, these all decreased where the moss layer was removed, but not in the autumn. Moss plots housed 31 mite species, plots with mosses turned over housed 24, and removal plots housed only 16 species. The mosses buffer the temperature (Skre & Oechel 1979; Startsev *et al.* 2007), a possible reason for those mites that lived only among the mosses. It is also likely that the **Collembola**, nematodes, and enchytraeids (annelid worms) among the mosses provided food (Karg 1983; Moore *et al.* 1988; Koehler 1999). The **Collembola** move down into the soil to avoid drought stress (Huhta *et al.* 1986; Pflug & Wolters 2001; Juceviča & Meleciš 2002), and mites can easily follow them.

Figure 13. *Veigaia nemorensis* (Veigaiidae), a **Gamasina** (**Mesostigmata**) mite that depends on mosses for its habitat. Photo by Derek Tan from Diane Srivastava's online Mite Classification Guide at <http://www.zoology.ubc.ca/~srivast/mites/>, with permission.

Although many species of mites occupy both leaf litter and bryophytes on the forest floor, bryophytes can provide unique habitats unlike those of the forest floor leaf litter. Womersley (1961) reported a new species of trachytid mite, *Acroseius tuberculatus* (as *Polyaspinus tuberculatus*; **Ascidae**; see Figure 17; see Bloszyk *et al.* 2005) from Queensland, Australia, noting that it occurred only in the leaf litter and not among the mosses, indicating the uniqueness of the two habitats. David Walter later found

another member of the genus in litter (including mosses) in Queensland (pers. comm. 15 September 2011; Figure 17).

Arboreal Habitats

Canopy communities of mites are distinct from those of the forest floor (Arroya *et al.* 2010). In an old-growth Sitka spruce (*Picea sitchensis*) forest on Vancouver Island, Canada, Behan-Pelletier and Winchester (1998) found 36 oribatid mite species in the canopy and forest floor. In Ireland, 22 species occupied the Sitka spruce forest in the canopy or moss growing on the tree or on the soil.

The canopy community is more homogeneous than that on the soil surface. Five of these species occurred exclusively in the canopy. Three members of *Zerconidae* lived only in the canopy and in moss mats on tree branches. Among these moss-dwelling bryophytes is *Trachytes aegrota* (Figure 18), recorded by Arroya *et al.* (2010) for the first time in Ireland, despite being known since 1841.

Figure 18. *Trachytes* sp., member of an arboreal genus with bryophyte-dwelling members. Photo by David E. Walter, with permission.

Epiphytes

Epiphytic bryophytes serve as habitat for a number of oribatid mites (Travé 1963; Walter & Behan-Pelletier 1999). In arboreal habitats, bryophytes can provide both 3-dimensional structure and a safe haven that protects against desiccation and predation. In these habitats, one can find a variety of arboreal oribatid mites, with differences occurring among habitat types within the forests (Seniczak 1974). Even within the same Sitka spruce (*Picea sitchensis*) forest, those species occurring in canopy moss mats can differ significantly from those located elsewhere in the canopy (Behan-Pelletier & Winchester 1998).

Figure 19. Red mite on moss *Dicranum montanum* on bark near tree base. Photo by Michael Lüth, with permission.

André (1984) found that 34% of the arthropod epiphyte dwellers in the Belgian Lorraine were oribatid mites, represented by 19,000 individuals in 36 species. The typical *Zygoribatula exilis* (Oribatulidae; see Figure 20) association (Pschorn-Walcher & Gunhold 1957; Travé 1963; Lebrun 1971; Gjelstrup 1979) was not present. This mite association is most typical among mosses, liverworts, and foliose lichens in the shade and requires a continuous high humidity (Travé 1963). Thus, it did not find suitable habitat here.

Figure 20. *Zygoribatula bulanovae*. *Zygoribatula exilis* is a typical moss dweller among mosses, liverworts, and lichens in shaded, moist areas. Photo from CBG Photography Group, Centre for Biodiversity Genomics, through Creative Commons.

The activities of mites on the bole of forest trees (which are often covered by bryophytes) raised the question of the role of the tree bore and its bark. As asked by Proctor *et al.* (2002), "Are tree trunks habitats or highways?" In their Australian study of oribatid mites on the hoop pine (*Araucaria cunninghamii*), they found that indeed the bark of the bole harbors a unique community compared to the forest floor. Using insecticides to immobilize the communities, they collected from leaf litter and tree bole. Not only did they find unique communities, but they were nearly 100% distinct! Only *Pseudotocepheus* sp. (Tetracondylidae) occurred in both litter and bark habitats. The richness of litter was greater,

but on the bark the oribatid mites comprised the greater percentage of total mites. The researchers were surprised that, contrary to their expectations, the more consistent physical nature of bark as a substrate did not result in greater similarity of oribatid faunas among trunks compared to litter. Rather, greater similarity occurred among litter faunas. They suggested that tree trunks act as islands and that faunal differences represent dispersal challenges that result from traversing across different habitats to reach a new "island." The conclusion: tree boles are not highways from the ground layer to the canopy, at least in this Australian system.

Trapping experiments by Behan-Pelletier and Winchester (1998) in the Sitka spruce canopy on Vancouver Island, Canada, support the hypothesis that dispersal of mites among canopy habitats is due to random movement. Nevertheless, single unidentified species in the genera *Eporibatula* (Oribatulidae), *Sphaerozetes* (Ceratozetidae), and *Dendrozetes* (Ceratoppiidae; Figure 21) had a frequency greater than 50% in canopy traps, suggesting that random dispersal is a successful means for these taxa. One might conclude that the same random dispersal is likely for the bole, but the boles of the individual trees are not touching, whereas the canopies are. Furthermore, bryophytes often provide the dispersal unit, and they are more likely to become attached on a horizontal surface than on a vertical one.

Figure 21. SEM of *Dendrozetes* sp., member of a genus known from Sitka spruce canopy bryophytes. Photo by Valerie Behan-Pelletier and Barb Eamer, with permission.

Peck and Moldenke (2010) became concerned with the role of moss harvesting on the movement of invertebrate communities, including many mites, to new locations. They used Berlese funnels to assess the fauna of bryophyte mats on two shrub species [vine maple (*Acer circinatum*; Figure 22) and huckleberry (*Vaccinium parvifolium*; Figure 23)] in the Pacific Northwest, USA. This method revealed 205 morphospecies of arthropods, and it is likely that there was a portion of the fauna that did not respond to the Berlese funnel arrangement, hence were not counted. The communities between the tree species did not differ, but

there seemed to be differences in communities that related to the location of the moss mats.

Lobule Mites

Leafy liverworts are common on the boles and canopy branches of forest trees. Among these, *Radula* (Figure 24-Figure 25), *Porella* (Figure 26-Figure 27), *Frullania* (Figure 28-Figure 29), and others have lobes. In *Frullania*, these lobes are modified into **lobules** (Figure 28-Figure 29) that trap and hold water through capillarity.

Figure 29. *Frullania dilatata*, showing the arrangement of leaves, underleaves, and lobules that provide a nearly continuous route of moisture to help mites move about. Photo by Michael Lüth, with permission.

Andi Cairns, Tamás Pócs, Saci Pócs, Chris Cargill, and Elizabeth Brown discovered tiny oribatid mites moving about in the lobules of *Frullania ferdinandi-muelleri* (Figure 30-Figure 31) in the Australian Wet Tropics (Andi Cairns, pers. comm.). Andi later found similar mites in other specimens of *F. ferdinandi-muelleri* they had collected. Matt Colloff determined these to belong to the genus *Birobates* (Figure 31-Figure 33), the first record for the genus in Australia. Because of its association with liverwort lobules, Colloff and Cairns (2011) named this mite *Birobates hepaticolus* (Oripodidae; Figure 31-Figure 33). The lobules of the *Frullania* (Figure 31-Figure 32) buffer the mite against moisture loss. The lobules have an opening, giving mites free access, and generally are close to each other and the underleaves, providing a nearly continuous moist environment. Hence, the liverwort provides a moist habitat that permits these mites to live in otherwise dry habitats. Colloff and Cairns (2011) point out that even if the mites die during periods of liverwort desiccation, the population is likely to survive through its eggs.

Figure 30. *Frullania ferdinandi-muelleri* in Ingham, North Queensland, Australia, a leafy liverwort that serves as home to the newly described *Birobates hepaticolus*. Photo courtesy of Andi Cairns.

Figure 31. *Frullania ferdinandi-muelleri*. Note the many *Birobates hepaticolus* in lobules, but frequently only one per lobule. Photo courtesy of Tamás Pócs.

Figure 32. *Birobates hepaticolus* mite in the lobule of the liverwort *Frullania ferdinandi-muelleri*. Photo courtesy of Tamás Pócs.

Figure 33. *Birobates hepaticolus* taken from a lobule of the leafy liverworts *Frullania ferdinandi-muelleri*. Photo courtesy of Andi Cairns.

Colloff and Cairns (2011) found that lobules that had mites generally had one to four individuals. The frequency of occupied lobules ranged from contiguous occupation to one in thirty. Every one of the many locality samples had mites in this species of liverwort, although abundance varied widely. It is interesting that only two nymphs were found, whereas there were well over 100 adults.

Furthermore, the liverwort apparently serves as a food source (Colloff & Cairns 2011). Presence of fecal pellets indicated that the mites had been in the lobules for an extended period of time. Consumption of liverworts by mites was not known previously. *Frullania* (Figure 28-

Error! Reference source not found.) is known to have volatile compounds that would discourage eating (Asakawa *et al.* 2003). Dense material in the pellets had the same spectral qualities as the liverworts and appeared to be cells of the same (Colloff & Cairns 2011). In addition to being food itself, the lobules house bacteria, protozoa, rotifers and other small invertebrates that can serve as food.

Figure 34. *Frullania ferdinandi-muelleri* grazed, probably by *Birobates hepaticolus*. Photo courtesy of Andi Cairns.

Semiaquatic Habitats

Terrestrial members of **Parasitengonina** (parasitic mites) may be found among mosses in semiaquatic niches. In particular, members of **Johnstonianidae** all can occur in mosses (Wohltmann 2004). Among these, Wohltmann and co-workers have specifically found *Centrotrombidium* (Figure 35; Wohltmann & Wendt 1996), *Diplothrombium* spp. (Wohltmann 2004), and *Johnstoniana* spp. (Figure 36). Sevsay and Özkan (2005) reported the new species *Johnstoniana hakani* from mosses in Turkey.

Figure 35. *Centrotrombidium schneideri*, a mite whose larva is a parasite on the biting midge *Culicoides*. Photo by Andreas Wohltmann, with permission.

Centrotrombidium schneideri (**Johnstonianidae**; Figure 35) larvae recognize the pupae of the biting midge *Culicoides* sp. (Figure 37) and attach to it to await the emergence of the adult (Wohltmann & Wendt 1996). By attaching to this immobile stage, the larva is guaranteed

that its host won't move to an unfavorable location. As an adult, the *Culicoides* remains in a moist environment that provides the humidity needs of the mite. As the host emerges, the larvae become parasitic on the adult stage.

Figure 36. *Johnstoniana* sp. Photo by Walter Pfliegler, with permission.

Figure 37. *Culicoides* (biting midges) adults, host (as a larva) of the mite *Centrotrombidium schneideri*. Photo by A. J. Cann through Creative Commons.

All developmental stages of these **Johnstonianidae** genera desiccate easily when the air is less than saturated. Mosses, as well as litter, provide the necessary humidity for mating, oviposition, and resting. Other members of **Trombidiae** (**Trombiculidae**, **Trombidiidae**, **Microtrombidiidae**) can burrow into the soil as **deutonymphs** and adults – the mobile stages, but the **Johnstonianidae** are unable to do that. Active stages of all of these **Trombidiae** search among the mosses as well as other locations for prey and for hosts for the next life stage.

Unlike the **Johnstonianidae**, which are confined to amphibious habitats, other mites can occur in such habitats as well as other locations (Andreas Wohltmann, pers. comm. 17 September 2011). These mites that sometimes occur in semiaquatic habitats can be frequent in mosses:

Erythraiae: *Calyptostoma* (Figure 38) in the **Calyptostomatidae**, *Abrolophus* (Figure 39), *Leptus* (Figure 40-Figure 41), *Erythraeus* (Figure 42), and *Charletonia* (Figure 43) in the **Erythraeidae**; **Trombidiae:** *Trombidium* (Figure 44) and *Allothrombium* (Figure 45) in the **Trombidiidae**, *Podothrombium* (Figure 46-Figure 47) in the **Podothrombiidae**, *Microtrombidium* (Figure 48), *Atractothrombium*, *Camerotrombidium* (Figure 49), *Enemotrombium* (Figure 50), *Valgothrombium*, *Echinothrombium rhodinum*, and *Platytrombidium* (Figure 51) in the **Microtrombidiidae**.

Figure 53. *Tvetenia calvescens* pupa, host for parasitic mites. Photo by P. Kranzfelder, NTNU University Museum, through Creative Commons.

Hosts of parasitic stages of these mites are typically arthropods, and new ones are still being discovered. Stur *et al.* (2005) suggested that the moss-dwelling habit of the midge *Chaetocladius perennis* (Figure 52) may be the reason for absence of mites in their collections. Aquatic mite larvae typically find hosts in the water, not among mosses. This same absence of mites held true for other moss-dwelling midges in these Luxembourg springs. On the other hand, moss dwellers like *Tvetenia calvescens* (Chironomidae; Figure 53) and *T. bavarica* (Figure 54- Figure 55) were parasitized in the two springs. Their mossy habitat meant they rarely encountered mites. But Stur and coworkers offered three additional explanations: 1) no water mites parasitize these potential hosts; 2) those water mites that could use these hosts are absent in these springs; 3) the midges are efficient in avoiding colonization by mites.

Calyptostoma velutinus (Calyptostomatidae; Figure 38) is a mite that lives on the crane fly *Tipula* (Andreas Wohltmann, pers. comm. 17 September 2011) and probably others. The larvae live on the pupae of *Tipula* (Figure 56), a genus in which the pupal stage often occurs among mosses. This species of mite can also be found on the thorax of the crane fly *Limonia* (Figure 57). Similarly, *Johnstoniana eximia* (Figure 57) lives on the abdomen of *Limonia*. Both of these mites take advantage of the aquatic stages of crane flies for their early development, then emerge when the adult crane flies emerge (Figure 58).

Figure 56. *Tipula* sp. pupa, the stage in the crane fly life cycle that is sought by larvae of the mite *Calyptostoma velutinus*. Several members of *Tipula* pupate among mosses. Photo by Ted Kropiewnicki, through Creative Commons.

Figure 57. Mites *Calyptostoma velutinus* on the thorax and *Johnstoniana eximia* on the abdomen of *Limonia* (crane fly). This genus of crane fly is known to pupate among mosses, permitting the mites to develop there and emerge with the adult crane flies. Photo by Andreas Wohltmann, with permission.

Figure 58. Larva of mite *Calyptostoma velutinus* on thorax of the crane fly *Tipula*. *Tipula* is a common inhabitant of mosses in both its larval and pupal stages. Hence, it is available to moss-dwelling mites as it emerges into the terrestrial habitat. Photo by Andreas Wohltmann, with permission.

Even in the juvenile stage, mites can be subjected to decreased water availability. Although eggs and protonymphs of members of the **Trombidioidea** can take in water vapor from the atmosphere, Wohltmann (1998) demonstrated that this does not occur in **Erythroidea**, including *Calyptostoma velutinus* (Calyptostomatidae; Figure 38). Rather, the **Parasitengona** (including *Calyptostoma velutinus*) may have had this character early in their evolution, but have subsequently lost it. Nevertheless, *Calyptostoma velutinus* and others in the **Erythraeoidea** have a higher drought resistance in both instars than do the **Trombidioidea**. Although water uptake seems to be absent in eggs and protonymphs, water uptake prior to the protonymph stage has been observed in post-parasitic larvae of **Trombidioidea** as well as in *C. velutinus*.

Wohltmann (1998) suggests that instead of preventing desiccation by this mechanism of water uptake, drought protection is achieved by a greater sealing of body openings with lipids, as well as reduction in body openings. Together, these result in reduced water loss. This apparently facilitates the consequent increase in body fresh mass by 50% before the protonymph stage begins by increasing the size of the cuticle. For *Calyptostoma velutinus* (Calyptostomatidae; Figure 38), this results in "a considerable increase in fresh mass at the end of the post-parasitic larval phase." This may be important in explaining the longer (several days long) post-parasitic stage in this species.

Larval mortality is a high selection pressure among the **Parasitengona**. Two evolutionary traits – larger eggs or more eggs – can help to give the species an advantage against this selection pressure. In the case of **Parasitengona**, evolutionary constraints apparently have kept the egg numbers low (100-300) (Wohltmann 1999). These constraints include difficulty of finding a suitable host in time and restriction to only three growth periods during development that limits adult size. However, some

of the terrestrial and aquatic subgroups have indeed adapted by producing 1000 or more eggs per female.

But reproductive problems do not stop there. Finding a mate can be problematic due to the small numbers of individuals in a single bryophyte clump. Witte (1991) examines the indirect sperm transfer in prostigmatic mites. Important considerations include adaptation of **spermatophores** (protein capsule containing mass of **spermatozoa** (motile sperm, transferred during mating in several invertebrate groups) to low or changing humidities. Like the eggs of some mites, the spermatophores may also exhibit passive uptake of atmospheric water vapor. A second consideration is osmotic protection of sperm cells. Other important factors include spermatophore viability, types of signals used to guide individuals to spermatophores or to a partner, and deposition of spermatophores in absence of a female.

Aquatic Habitats

Figure 59. Pearling (air bubbles) on the brook moss *Fontinalis* sp. Photo by Loh Kwek Leong, with permission.

Aquatic mosses have their own mite fauna, the most common being **Hydrachnidia** (Vlčková 2001/2002) [= **Hydracarina** (Clifford 2012)]. These don't look like aquatic organisms with their chubby morphology, suggesting they often need plants for clinging to avoid being swept away. Furthermore, special adaptations may be needed to permit life in this low-oxygen environment. Smith *et al.* (2011) described the mite *Tegeocranellus muscorum* (**Tegeocranellidae**; Figure 60) in eastern North America as having special structures above the middle two pairs of legs for holding an air bubble when submerging (Figure 61). These bubbles, formed in a condition known as **pearling** (Figure 59) when they come from underwater plants (Benito Tan, pers. comm. 6 June 2011), work like a diving bell into which the mite can exchange CO₂ for O₂ gases. When the bubble gets too small, the mite must return to the surface or the plant for another bubble. Oxygen bubbles produced during plant photosynthesis can provide this source of oxygen, and submersed mosses are often so covered with bubbles that their own structure cannot be discerned (Figure 62).

Suren (1991) found that **Hydracarina** were poor indicators of bryophytes compared to gravel in two New Zealand alpine streams, but that they were moderate indicators of shaded conditions. They represented 3.3% of the fauna among gravels in unshaded streams, but only 1.1% among bryophytes there. In the shaded stream, they represented 11.4% of the gravel fauna, but only 5.9% among the bryophytes.

Hynes (1961) found somewhat higher percentages of **Hydracarina** (Figure 63) on bryophytes than on artificial silk mosses in a Welsh mountain stream. This might be the result of better places for these clumsy balls with legs to escape the current among the moss branches, but it could also be related to food availability.

Compared to other arthropods, the **Hydracarina** (Figure 63) on bryophytes are not very abundant. Stern and Stern (1969) found only 1-2 per 0.1 m² of moss/algae in a springbrook in Tennessee, USA. Similarly, Frost (1942) found only ca 1% of the fauna to be **Hydracarina** in her study of moss inhabitants in the River Liffey, Ireland. Nevertheless, these averaged 147 individuals per 200 g wet weight of bryophyte sample in the acid stream and 114 in the alkaline stream and comprised 29 species.

In a "rip-rapped" channel, Linhart *et al.* (2002) found a strong correlation between the size fractions and quantity of organic matter and mineral matter and the number of hydrachnid mites living within the sediments collected by the moss *Fontinalis* sp. (Figure 64). They contended that *Fontinalis* increased the biodiversity because of the number of organisms supported by that habitat. Needham and Christenson had already noted this phenomenon in 1927.

Cowie and Winterbourn (1979) compared the fauna of three mosses [*Achrophyllum quadrifarium* (= *Pterygophyllum quadrifarium*; Figure 67), *Fissidens rigidulus* (Figure 65), *Cratoneuropsis relaxa*] in the Southern Alps in New Zealand. They found the mites *Notopanisus* sp. (**Hydryphantidae**) on all three mosses and *Platymamersopsis* sp. (**Anisitsiellidae**) on *Achrophyllum quadrifarium* (= *Pterygophyllum quadrifarium*; Figure 67) and *Cratoneuropsis relaxa*. Nevertheless, knowledge of the bryophyte fauna is poor (Suren 1992). Suren found four new species of mites in his study of bryophyte communities in alpine streams of New Zealand.

Andreas Wohltmann (pers. comm. 17 September 2011) has found that in temporary pools, *Sphagnum* (Figure 66), and probably other mosses, can house species of **Hydryphantoidea** [*Euthyas* (Figure 68), *Parathyas* (syn. *Thyas*; Figure 69), *Hydryphantes* (Figure 70)]. During their terrestrial phase, these mites sit in the water film around the mosses. Unlike other water mites, **deutonymphs** and **adults** of this group can crawl in these terrestrial conditions and thus can move to more humid areas as the moisture conditions change. On the other hand, the superfamilies **Stygothrombioidea**, **Hydrovolzioidea**, **Hydryphantoidea**, and **Eylaoidea** all have terrestrial larvae, whereas only the **Hydryphantoidea** are able to crawl as deutonymphs and adults in that terrestrial environment. The eggs of all four of these superfamilies are deposited in the water, but larvae climb/crawl to the water surface and seek a host at the surface or in the surrounding terrestrial area. In at least some locations, the terrestrial surroundings as they emerge from the water are likely to be covered with bryophytes that help to conserve water.

On the other hand, the larvae of **Hydrachnoidea**, **Sperchontoidea**, **Arrenuroidea**, **Lebertioidea**, and **Hygrobatoidae** lack the musculature needed for crawling and must seek their larval hosts in the water column. Likewise, the adults of other water mite genera [e.g. *Arrenurus* (*Arrenuridae*; Figure 83-Figure 86), *Limnochares* (*Limnocharidae*; Figure 71), *Piona* (*Pionidae*; Figure 72), *Tiphys* (*Pionidae*; Figure 73)] lack this ability to crawl under terrestrial conditions. Most of them find hosts among the **Diptera**, especially the **Chironomidae** (midges; Figure 54), which are often abundant among aquatic mosses. The mite larvae locate larvae or pupae of these potential hosts and aggregate there, awaiting the emergence of the adult, which they will

parasitize. This method of finding a host (**preparasitic attendance**) is absent among those mites having terrestrial larvae and even among most of the terrestrial **Parasitengonina**.

Larvae of *Panisellus thienemanni* (**Hydryphantoidea**; Figure 74) parasitize the springtail *Arthropleona* (**Collembola**; Figure 74) in the spring. Andreas Wohltmann (pers. comm. 17 September 2011) has found these mites exclusively in wet mosses of amphibious biotopes. Larvae are also known to parasitize both young and adults of the springtails *Pogonognathellus flavescens* (Figure 75) and *Tomocerus minor* (Figure 76) (Boehle 1996).

Some species of *Eylaoidea* [e.g. *Eylais* (*Eylaidae*; Figure 77), *Piersigia* (*Piersigiidae*; Figure 78), but not *Limnochares* (*Limnocharidae*; Figure 81-Figure 82)], and of the so-called 'higher water mites' such as *Tiphys* (*Pionidae*; Figure 73) and some *Arrenurus* (*Arrenuridae*; Figure 83-Figure 86) and *Piona* (*Pionidae*; Figure 72) species inhabit temporary waters where they are likely to interact with bryophytes (Andreas Wohltmann, pers. comm. 17 September 2011). The larvae of the genus *Eylais* commonly parasitize *Coleoptera* (beetles), but Smith (1986) found six species that parasitize water boatmen (*Heteroptera*: *Corixidae*). This is a genus of large species, typically 5-6 mm (Halbert 1903). *Eylais hamata* (see also Figure 77) is heavily endowed with carotenoid pigments that can protect it from UV light and make it less conspicuous in its habitat (Czeczuga & Czerpak 1968). For most of these, data are needed to support just how the bryophytes are used.

Figure 77. *Eylais discreta*, an inhabitant of temporary ponds and pools where bryophytes most likely help them to maintain moisture as water levels decrease. Note the deep golden color due to carotenoid pigments. Photo by Andreas Wohltmann, with permission.

In the genus *Eylais* (*Eylaidae*; Figure 79), as many as twenty species may occur in the same area in central New York, USA, *i.e.*, they are **sympatric** (Lanciani 1970). Their larvae are parasitic on *Heteroptera* (true bugs) and *Coleoptera* (beetles) in shallow ponds. They venture to the surface of the water as larvae and await the host when it goes to the surface to renew its oxygen supply. At that time they are able to hitch a ride and attach to the host. According to the Gaussian principle, such species overlap of closely related mites should not occur unless they use their common resources differently. In this case, they partition the resources. Some separation occurs by having different host species, but for those that occupy the same host, separation can occur by season, location on the host, or **biotope** within the habitat. Once attached to the host, they begin feeding and become immobile (Lanciani 1971). Those that have the largest space available grow the most, and larger species tend to occupy larger hosts.

Figure 79. *Eylais* sp., member of a genus with moss-dwelling species. This decolorized preserved specimen reveals the red spots that are most likely internal eggs. Photo courtesy of BOLD Systems, Biodiversity Institute of Ontario.

In eastern Canada, there are at least ten species of the genus *Tiphys* (*Pionidae*; Figure 73) (Smith 1976, 1987). *Tiphys diversus* (*Pionidae*) lives in stream pools and lakes in the southeastern part of the country (Wiggins *et al.* 1980). Eight of the species live in vernal pools. These ten species of mites survive the drying of the temporary pools as

deutonymphs (non-feeding stage that moults into adult), embedding their mouthparts in the leaf axils of mosses. Here they remain at rest until the following spring when the pool again has water.

Moss crawling seems to be common for moss-inhabiting mites, perhaps as a means to maintain moisture. *Chelomideopsis besselingi* (Athienemanniidae; Figure 80) is one northeastern North American mite that is common crawling in moss mats and in detritus in springs in the mixed wood plains (Smith 1991, 1992). In *Sphagnum* mats of bog pools (Figure 66), one can find the crawling species *Limnochares aquatica* (Limnocharidae; Figure 81; Smith in Smith *et al.* 2011), whose larvae may be attached to the bodies of other arthropods (Figure 82).

The mite *Trichothyas muscicola* (Hydryphantidae) in the eastern USA lives in mats of mosses and algae kept moist by seepage areas and splash (Smith 1991). Its northern limit is the Niagara Gorge of the Lake Erie Lowland Ecoregion.

Another Canadian species is *Arrenurus dinotoformis* (Arrenuridae; see Figure 83-Figure 86), a taxon known exclusively from moss mats at margins of boggy pools where the mites are in and out of the water (Smith in Smith *et al.* 2011). *Arrenurus siegasianus*, a predaceous species (Smith *et al.* 2004) with a boreal distribution, is common in sluggish streams from Newfoundland to Alberta, thus occupying a different niche.

Some mites, such as *Malaconothrus* (*Malaconothridae*; Figure 87), can appear in large numbers among the aquatic mosses (Krantz & Lindquist 1979). Behan-Pelletier (1993) reports that deutonymphs and adults of aquatic mites are often specialized for their habit of crawling among mosses and detritus. Most of them are also cold-adapted. Others, such as *Laversia berulophila* (*Laversiidae*), are more generalized and are able to live in the **profundal** zone (deep zone of inland body of free-standing water, located below range of effective light penetration) of **oligotrophic lakes** (lake relatively low in plant nutrients, containing abundant oxygen in deeper parts) as well (Smith in Smith *et al.* 2011). In bog/fen pools there are nearly 50 species in Canada in the mixed forest plains. These are adapted for clinging to *Sphagnum* (Figure 95) and other mosses (Figure 88), but also for swimming. They are adapted for cool water in the northeastern and boreal peatland pools, mostly in relict habitats.

Figure 87. *Malaconothrus* sp., member of a genus that can be found among aquatic mosses. Photo courtesy of BOLD Systems, Biodiversity Institute of Ontario.

Figure 88. These water mites (probably *Hydryphantoidea*) are inhabiting the moss *Palustriella falcata*, a species common in moderate to highly mineral-rich pools and ponds. Photo by Dan Spitale, with permission.

In **streams**, Badcock (1949) found that mites were most abundant where moss or other substrate provided shelter. In my own collections of stream mosses, I did occasionally find tiny red mites. However, these were never abundant and were infrequent. Stream edge and streamside habitats, on the other hand, provide a moist habitat where these non-streamlined mites are out of the danger of current. Red seems to be a common color for water mites, possibly serving as warning coloration – or not (Figure 1, Figure 88).

In an attempt to determine the role of bryophytes that had been lost from a stream suffering from sewage effluents, Dewez and Wauthy (1981) used sponges to simulate the bryophyte habitat and capture water mites. These sponge colonizations suggested that loss of bryophytes had impacted both numbers and diversity of mites negatively. They also found that the mite *Hygrobatas fluviatilis* (*Hygrobatidae*; Figure 89) played a major role in determining the numbers and organization of the communities. Since sponges served as a suitable habitat, one might conclude that the bryophyte served primarily as a substrate and safe site, not as a direct source of food.

Angelier *et al.* (1985) found that both the presence and type of moss, compared to gravel, were important in determining the mite community. One factor that seemed to play a role in this relationship was stability of the rock substrate. Mosses only developed colonies on rocks that stayed put.

The species *Hydrovolzia mitchelli* (*Hydrovolziidae*; Figure 90), a species from the mixed wood plains, prefers cold **springs** and seepage areas (below 10°C) (Smith in Smith *et al.* 2011). The deutonymphs and adults spend

time crawling through detritus and moss mats, a slow feat for them. The larvae are parasites on adult **Empididae** (Figure 91), a small dipteran whose larvae sometimes live among mosses. Members of the **Unionicolidae** (Figure 92) can be found in streams, where they inhabit mosses like *Hygroamblystegium* (Figure 93) (Paul Davison, pers. comm. 27 September 2011). *Fissidens fontanus* (Figure 94) also serves as a suitable habitat for water mites. These mites avoid open water and seem to need to be in contact with a substrate.

Sphagnum Peatlands

Peatlands present unique challenges to their inhabitants (Behan-Pelletier & Bissett 1994). Not only do they experience highly fluctuating temperatures at the surface, seasonal water-logging, and low nutrients, but they also have a low pH resulting from the activities of the *Sphagnum* (Figure 95) itself (see below). Furthermore, the low conductivity of the moss results in a shorter frost-free season than that of the surrounding habitats. Relative humidity among the moss stalks generally remains at 100%, but at the surface it may drop to 40% during the day. For those mites able to migrate up and down (see below), finding a suitable temperature and humidity combination should not be difficult.

Figure 95. *Sphagnum capillifolium* lawn. Photo by Bernd Haynold, through Creative Commons.

Among the microarthropods, the mites are the most abundant and diverse group of organisms on the peatland bryophytes (Behan-Pelletier & Bissett 1994), but not in the open water. These peatland mites include water mites, oribatids, and **Mesostigmata** (Hingley 1993). The **Oribatida** (moss mites) are predominant among these (Behan-Pelletier & Bissett 1994). Behan-Pelletier and Bissett (1994) reported 71 species of oribatids in the peatlands of Canada. These are species of widespread distributions, either Holarctic or worldwide. The aquatic

species, on the other hand, seem to be restricted to the Nearctic.

Peatland mosses typically offer a compact cover that is generally moist, hence providing both protection from predators and from desiccation. For mites, this habitat is therefore often an inviting one (Seyd 1988). This habitat is, nevertheless, quite variable in water availability. Silvan *et al.* (2000) demonstrated that "soil" mites increased in numbers with drainage and draw-down of peat soils, suggesting that in many areas the peatlands are simply too wet for many species. In fact, older drained sites typically had mite populations ten times as large as those on undrained sites. Re-wetting caused an abrupt drop in numbers. Among those invertebrates found, the oribatid mites were the most frequent, comprising nearly 60% of the fauna on undrained sites.

Many mite families found elsewhere in the general area, including those on mosses (e.g. some **Eremaeidae**, **Opipiidae**, **Galumnidae**), are absent or poorly represented in peatlands. Both wet and dry extremes in peatlands have few mite species but a high number of individuals. Thus, it is the intermediate levels of moisture that provide the best locations for most of the oribatid mite species (Tarras-Wahlberg 1961; Belanger 1976; Borcard 1988, 1991c, e; Behan-Pelletier & Bissett 1994).

Within the peatlands, one can find multiple niches with considerable differences in microclimate. Belanger (1976) found 44 species of oribatids in a North American poor fen peatland, 26 of which were also known from European peatlands. Among the microarthropods there, oribatids comprised 84% of the species within the peat, 70% of that on *Sphagnum* (Figure 95) stalks, and 39% of that on *Sphagnum* tops. But from the perspective of the mites, the *Sphagnum* stalks seemed to be the "optimum microhabitat" in the *Sphagnum* because of its species richness and density. This was the habitat where the oribatid assemblage was the most stable.

In Europe, the mite fauna of *Sphagnum* (Figure 95) peatlands is well known (e.g. Scandinavia: Tarras-Wahlberg 1954, 1961; Dalenius 1960, 1962; Solhøy 1979; Markkula 1986a, 1986b; Russia: Laskova 1980; Druk 1982; Lithuania: Eitminavichyute *et al.* 1972; Germany: Beier 1928; Willmann 1928, 1931a, b, 1933; Peus 1932; Sellnick 1929; Popp 1962; Switzerland: Borcard 1988, 1991a, b, c, d, e). These studies indicate that the peatland oribatid species are seldom restricted to peatlands. North American studies seem to have lagged behind, with notable ones scattered broadly in time (Banks 1895; Jacot 1930; Belanger 1976; Behan-Pelletier 1989; Larson & House 1990; Palmer 1990; Hingley 1993; Behan-Pelletier & Bissett 1994).

The Fauna

Peatlands generally have low numbers of mite species. Smith (in Smith *et al.* 2011) reported that **Hydrozetes** (**Hydrozetidae**; Figure 96) are the most numerous of the oribatids in peatland pools, where they move about by clinging to the surface film of the water. In eastern Canada, the most species-rich genus within the moss mat is **Limnozetes** (**Limnozetidae**; Figure 97), often being the only genus in the dripping *Sphagnum* (Figure 95) and layers of peat (Behan-Pelletier & Bissett 1994; Smith in

Smith *et al.* 2011). Borcard (1991c) reported up to 100,000 specimens of oribatid mites from just one cubic meter of wet *Sphagnum* in Canada. Popp (1962) reported *Limnozetes ciliata* and *L. rugosus* (see Figure 107-Figure 112) in the *Sphagnum fuscum* (Figure 98) association in Germany; in the same bog, *Pilogalumna tenuiclavus* (*Galumnidae*) occurred in the *Sphagnum magellanicum* association (Figure 99).

Donaldson (1996) demonstrated the richness of oribatid mites in a moat bog in New Hampshire, USA. Among the 220 adult oribatids collected, 44 species were represented from three *Sphagnum* species. These three species formed a moisture gradient with increasing height above the water surface, from *S. cuspidatum* (Figure 100) in the water, to *S. recurvum* (Figure 101), to *S. magellanicum* (Figure 99) on top. This same gradient also represented increasing light levels. The oribatid mite species diversity increased from water level to hummock top. The genus *Limnozetes* (*Limnozetidae*; Figure 107-Figure 112) was well represented by four species associated with *Sphagnum* in this bog.

This study was surpassed in breadth by that of Mumladze *et al.* (2013). They reviewed studies on the oribatid mites throughout the Holarctic region by examining data from 46 peat bog localities and found reports of 410 species. They found a non-random metacommunity structure for all the ecological guilds studied. Although they found no latitudinal gradients in species composition, they did find a non-linear decay with distance between communities. They found that at the community level, structure of the species is determined primarily by interspecific interactions and common biogeographical history. At the metacommunity level, on the other hand, the postglacial colonization processes are the most important factors in determining patterns.

Among the oribatids, the community composition varies among peatlands, with many of the species also found in other types of wetlands. Nevertheless, two genera have a high fidelity to Canadian peatlands: *Malaconothrus* (*Malaconothridae*; Figure 87) and *Limnozetes* (*Limnozetidae*; Figure 107-Figure 112) (Behan-Pelletier & Bissett 1994). But even these may be absent in some dry, oligotrophic bogs (Solhøy 1979). *Limnozetes*, a fungal grazer on the surface of the *Sphagnum* (Figure 95) plants, is so important in describing the community that Behan-Pelletier and Bissett (1994) suggested that the species composition could be useful to characterize peatlands. The adults of *Limnozetes* species graze all surfaces of the moss, whereas the immatures graze only the inner, cupped surfaces. *Ceratozetes parvulus* (*Ceratozetidae*; see Figure 102), a "constant component" of the peatland fauna, seems to have some subtle restrictions; in one virgin bog in Finland it was restricted to the hollows (Markkula 1986a).

Figure 102. *Ceratozetes* sp. *Ceratozetes parvulus* is a predictable bog dweller. Photo from CBG Photography Group, Centre for Biodiversity Genomics, through Creative Commons.

In some areas of Europe, the bog mite fauna seems to lack study. The family *Cunaxidae* (Figure 103) lives in saturated mosses such as those at the edge of bog pools (Hughes 1959). Krogerus (1960) found records of three species of *Erythraeoidea* from Finnish bogs, but there were no preserved specimens available for species verification (Gabryś *et al.* 2009).

In Great Britain, over 60 species have been recorded in peatlands (Hingley 1993). Many species of oribatids (seed mites) occur. In addition, there are several species of *Hydracarina* (water mites) and *Mesostigmata*. The characteristic genera include *Malaconothrus*

(*Trimalaconothrus*; *Malaconothridae*; Figure 87), *Hydrozetes* (*Hydrozetidae*; Figure 104-Figure 106), and *Limnozetes* (*Limnozetidae*; Figure 107-Figure 112). *Hydrozetes lacustris*, and probably also *Limnozetes ciliatus* (see Figure 107-Figure 112), live among the stems and leaves. *Trimalaconothrus maior* (*Malaconothridae*) lives in the leaf axils. Seeming to defy the Gaussian principle, up to five species of *Limnozetes* (see Figure 107-Figure 112) can occur on a single *Sphagnum* (Figure 98-Figure 99) sample, but perhaps no resource, especially space, is limiting. None of these species is limited to *Sphagnum*. Fewer species but more individuals occur in the drier parts of the peatlands.

In Canada, the genera are somewhat different from those in Europe, with mites such as *Parhypochthonius* (*Parhypochthoniidae*; Figure 113) and *Nanhermannia* (*Nanhermanniidae*; Figure 114) occurring in peatlands (Smith *et al.* 2011). The latter is one of the most common and most abundant of the oribatid mites in northeastern North American peatlands (Behan-Pelletier & Bissett 1994). By contrast, the poorly represented families *Oppiidae* and *Suctobelbidae* in Canada are dominant in some bogs in Europe (Sweden: Tarras-Wahlberg 1961; Finland: Markkula 1986a; Switzerland: Borcard 1992), with

Oppiella nova (Oppiidae; Figure 115) being among the most abundant (Behan-Pelletier & Bissett 1994).

Trampling

I know of no other study on the effects of trampling in bogs and poor fens, but the study by Borcard and Matthey (1995) is quite interesting. Not only does it demonstrate differences between species of *Sphagnum* (Figure 95, Figure 98-Figure 99) in their response to this abuse, but its primary objective was to determine the effects on the oribatid mite community.

During cranberry season, and in some bogs and poor fens, during blueberry season, the mosses can be subjected to considerable trampling by berry pickers. I have been to these habitats just after picking season and could see the destruction. I have also seen it following a class field trip, causing me to keep the students off the mat in later trips. But I had given little thought to the effects on the organisms within the mat.

In experiments involving 1 m² plots, Borcard and Matthey (1995) compared mite communities associated with hollow (wet) species *Sphagnum recurvum* (Figure 101) with that of hummock (drier) species *Sphagnum fuscum* (Figure 98) in a raised bog in Switzerland. Two plots of each species were trampled for ten minutes each, three times per year for four years, and compared with control plots. The plot with *S. recurvum* became a "muddy depression." The oribatid mites fared no better, dropping from 20 species to 4. *Limnozetes ciliatus* (Limnozetidae; see Figure 97), a common peatland mite, had a 96% relative frequency and was the overwhelming dominant following trampling.

The *Sphagnum fuscum* (Figure 98) hummock had a quite different response. The moss died, but the hummock retained its shape. The mite community, as in *S. recurvum* (Figure 101), had a reduction in species, but in this case was only reduced to 10 compared to its former 23. The surprise was that one species, *Ceratozetes parvulus* (Ceratozetidae; see Figure 102), that had been nearly absent before the trampling actually benefitted from the trampling.

Several factors account for the decrease in mite diversity and abundance. In both cases, the mosses were strongly compacted. The density of the top 3.5 cm increased more than 2-fold in both species. The entire vertical expanse became very homogeneous, lacking the vertical stratification of space and moisture available in the controls. Water content increased on a per volume basis. This compaction and increased water content made a habitat unsuitable for the original moss mite inhabitants.

The sampling itself made changes to both control and experimental plots. Removal of three cores (5 cm diameter, 13 cm deep) created a less dense habitat that permitted greater drying. This resulted in species shifts, even in control plots. In *Sphagnum recurvum* (Figure 101) control plots, *Oppiella nova* (Oppiidae; Figure 115) increased in numbers, possibly benefitting from drying around sampler holes. More hygrophilous species [*Limnozetes ciliatus* (Limnozetidae; see Figure 97), *Hoplophthiracarus pavidus* (Phthiracaridae)] tended to decrease for the same reasons. On the other hand, fungi invaded sample holes, providing a potential food source for fungivorous mites.

Loss of abundance followed different patterns in the two moss species (Figure 116). Those in *Sphagnum recurvum* (Figure 101) exhibited a "saw-tooth" pattern that indicates partial recovery between autumn and spring or summer sampling/trampling dates. Furthermore, the evenness dropped precipitously, with the semi-aquatic *Limnozetes ciliatus* (Limnozetidae) see Figure 97) having extreme dominance. By contrast, the decrease in number of species in *S. fuscum* (Figure 98) was less dramatic, and evenness did not change significantly. The latter greater constancy is attributable to a greater retention of non-inundated spaces within the hummock.

Figure 116. Changes in number of oribatid mite species and abundance in sample *Sphagnum* cores (5 cm diameter, 13 cm deep) through four successive years of trampling. Redrawn from Borcard & Matthey 1995.

Figure 117. Vertical distribution of oribatid mites in two *Sphagnum* species in trampled and non-trampled control plots in a bog in Switzerland. Redrawn from Borcard & Matthey 1995.

As one might expect, the vertical distribution of the mites changed as the structure of the moss strata changed (Figure 117). In *Sphagnum recurvum* (Figure 101), there was a severe loss of mites from lower strata, with remaining individuals located predominately in the upper 3.5 cm. Such dramatic change was not evident in *Sphagnum fuscum* (Figure 98), where original structure changed little following trampling, despite death of the moss.

One interesting result is a dramatic increase of the tiny *Ceratozetes parvulus* (see Figure 102) in the *Sphagnum fuscum* (Figure 98) hummock. This species is rare throughout the bog, so its increase to 13-30% under disturbance is a surprise. Could this flattened species have benefitted from compaction that permitted it to maneuver out of reach of larger predators?

Predation

Hiding oneself deep in the *Sphagnum* (Figure 98) peat may prevent at least some predation on the mite fauna. This would seem to be likely for those known to be prey of the newt *Notophthalmus viridescens* (Figure 118), also a peatland dweller. At least 45 species of oribatids are known food items for this species (Norton & MacNamara 1976). The compact peat is often impenetrable for this newt. But known oribatid predators such as the smaller beetles and ants (Riha 1951; Schuster 1966; Schmid 1988; Norton & Behan-Pelletier 1991) that co-inhabit the mosses should be able to penetrate many of the same small spaces as the mites. For those living in the pools and channels of the peatlands, the naiads of dragon- and damselflies (*Odonata*) can be major predators. Behan-Pelletier and Bissett (1994) found that 63% of the 60 *Aeshna sitchensis* guts they examined had oribatid mites in them, with a mean of 7 per gut. Presence in the other four species examined ranged from 10% frequency upward. Adult mites were more common than immatures, a phenomenon that Behan-Pelletier and Bissett suggested might relate to the habit of the immatures to graze only on the inner surfaces of the leaves where they were much more protected. The *Odonata* were apparently better collectors than the researchers – several species in the gut had not been located previously in the bog pools! The *Odonata* guts also contained predators of the mites, suggesting that these insect naiads were both friend and foe.

Acidity Problems

One problem that organisms always face in *Sphagnum* peatlands (Figure 66) is the low pH. Although *Sphagnum* is usually too acid for most mites, *Hydrovolzia placophora* (*Hydrovolziidae*; see Figure 90) seems to be tolerant of the low pH and occurs in the axils of leaves that protect it from open water (Gledhill 1960). This mite is not able to swim.

For mites, the acidity could present itself as difficulty in hardening of the cuticle due to the need for calcium. Although a common form of calcium is calcium carbonate, it appears that calcium oxalate (whewellite) can also serve this purpose, at least for the mites *Eniochthonius minutissimus* (*Eniochthoniidae*; Figure 119), *Archoplophora rostralis* (*Mesoplophoridae*), and *Prototritia major* (*Protoplophoridae*), and is deposited even in *Sphagnum* peatlands (Figure 66) (Norton & Behan-Pelletier 1991). Norton and Behan-Pelletier (1991) suggested that the calcium oxalate is probably obtained from crystals precipitated by fungi and used as food by the mites. This discovery was the first to demonstrate the role of minerals in hardening of the cuticle of arachnids.

Jarmo Holopainen (pers. comm. 16 September 2011) considers the biochemistry of peatlands to have a negative impact on mites. Volatile organic compounds are released from the *Sphagnum* (Figure 95) and many of the compounds produced by this genus have antibiotic effects against microbes – important food organisms for many mites. The peat has a high content of *Actinobacteria* (= *Actinomycetes* – formerly thought to be fungi; Figure 120), a group that produces antibiotics that might also have an effect on mite abundance. On the other hand, oribatid mites are known to have *Actinobacteria* in their digestive systems (Cromack *et al.* 1977), suggesting that at least some might benefit from the fungi.

Figure 120. *Actinomyces israelii* with false color, a member of **Actinobacteria**. Photo by Graham Colm through Creative Commons.

Mites have a role in this scenario in another way. Spores of the Actinomycetes, and other **propagules** (dispersal units), are transported by the mites (Ruddick & Williams 1972) and in some cases undoubtedly introduce them to peatlands and other bryophytic habitats.

Historical Indicators

Like the testate amoebae, mites have been used to reconstruct the long-term history of peatlands and lakes (Erickson 1988; Markkula 1986a; Behan-Pelletier & Bissett 1994; Luoto 2009). Birks *et al.* (2000) used community structure of subfossil vegetation including mosses and invertebrates including mites to reconstruct past history (late-glacial and early-Holocene) of Kraekenes Lake, western Norway. *Hydrozetes oryktosis* (**Hydrozetidae**; see Figure 104-Figure 106) and *Limnozetes cf. rugosis* (**Limnozetidae**; see Figure 107-Figure 112) can be used to infer lake levels (Erickson 1988; Solhøy 2001). In the Antarctic, Hodgson and Convey (2007) found *Alaskozetes antarcticus* (**Ameronothridae**; Figure 130) and *Halozetes belgicae* (**Ameronothridae**), both known moss dwellers, in a sediment core. The expansion of their numbers indicated a temperate period. In Finland, Markkula (1986a) found that *Limnozetes ciliatis* (see Figure 97) indicated presence of hollows, being absent in the hummocks. For the genus *Limnozetes*, acidity is important in defining which species occur (Behan-Pelletier & Bissett 1994).

Antarctic and Arctic

The Antarctic usually provides a good source of information on moss-dwelling invertebrates, and mites are no exception (Goddard 1979; West 1984; Schenker & Block 1986; Mitra 1999). In the Antarctic, bryophytes are an especially important habitat for mites (Booth & Usher 1986). Barendse *et al.* (2002) suggest that bryophytes and lichens may have served as glacial refugia during the Neogene (23.03 ± 0.05 million years ago), had their own fauna, and still provide a source from which tracheophytes can be colonized.

Ino (1992) found that moss colonies at Langhovde, East Antarctica, housed mites, among other invertebrates. Barman (2000) examined the mites inhabiting mosses on the Schirmacher Oasis in East Antarctica. He found the family **Haplochthoniidae** (Figure 121), the first report

from the Antarctic, and reported three new species [*Haplochthonius antarcticus* (**Haplochthoniidae**), *H. maitri*, and *H. longisetosus*]. *Tyrophagus antarcticus* (**Acaridae**; see) was likewise recorded for the first time in the Antarctic. He considered the prostigmatid mites to be some of the toughest terrestrial animals in the world, occupying nunataks on the Antarctic continent. The Antarctic *Nanorchestes antarcticus* (see Figure 123) is only 0.3 mm long.

Figure 121. **Hypochthoniidae** mite, probably *Eohypochthonius*. Photo by David E. Walter, with permission.

Figure 123. *Nanorchestes* sp., member of an Antarctic bryophyte-dwelling genus. Photo by David E Walter, with permission.

One might expect bryophytes to be a safe site in the Antarctic, with edible moss tissue and cover to protect from larger predators. But not all bryophytes are equally protective. Usher and Booth (1986) found that the predatory *Cyrtolaelaps* (*Gamasellus*; **Ologamasidae**) lacked any pattern of distribution related to scale of sampling, exhibiting random distribution, whereas the prostigmatic *Ereynetes* (**Ereynetidae**), *Eupodes* (**Eupodidae**; Figure 124), and *Nanorchestes* (**Nanorchestidae**; Figure 123) had distinct patterns at a scale less than 30-40 cm. A small scale pattern was present at 10-20 cm in *Polytrichum* (Figure 125), with slightly larger scales (up to 30 cm) in *Chorisodontium* (Figure 126) as well as in lichens. For other species, large scale (40-50 cm or more) differences were related to environmental variables. By contrast, relationships between species were more important at smaller scales (5-10 cm). Perhaps the *Cyrtolaelaps* (*Gamasellus*) lacks a pattern of scale because it goes where the food is, crossing "zones."

Figure 124. *Eupodes longisetatus*. The genus *Eupodes* is a moss dweller in the Antarctic. Photo from Museum of New Zealand, Te Papa Tongarewa, with online permission.

Among these same mosses, Davis (1981) found the turf communities [*Polytrichum strictum* (formerly *P. alpestre*; Figure 125) and *Chorisodontium aciphyllum* (Figure 126)] and the carpet communities [*Calliergidium austrostramineum* (Figure 126), *Warnstorfia sarmentosa* (Figure 127), and *Sanionia uncinata* (Figure 128)] had similar levels of productivity, trophic structure, and organic matter transfer efficiency, but the standing crops of Collembola and mites differed. Concurrent with these standing crop differences were differences in moss turnover and accumulation of dead organic matter. There was no bryophyte consumption in these two communities.

But in the Stillwell Hills region of Kemp Land, East Antarctica, Kennedy (1999) found that microalgae supported more of the microarthropods than did the sites with a mix of mosses, lichens, and macroalgae. Kennedy suggested that the mites were able to avoid the extremes of temperature, but that they were limited by heat stress and desiccation. Furthermore, they found only three taxa, all under rocks.

Schwarz *et al.* (1993) found the greatest abundance of mites and other invertebrate groups in the top 5 cm of mosses in post-melt conditions. Usher and Booth (1984; Booth & Usher 1986) found a distinct vertical distribution among the mites and **Collembola** living among mosses in an Antarctic turf. The distribution of a species varied with its developmental stage. The populations were aggregated, but again, that aggregation within the mite species depended on the developmental stage. A major factor in the vertical distribution was the state of the moss tissue. The green moss community (living; 0-1.5 cm layer at surface) differed from the dead moss community (below 3 cm). The same six species of mites and **Collembola** occurred in both communities, but the relative proportions differed considerably. An interesting aside to this story is the fact that Booth and Usher (1984) found that the chemical characteristics (sodium, potassium, calcium, phosphorus) of the environment most influenced the distribution of the arthropods in the green moss communities, with physical characteristics being of less importance. The percentage of the various mite species in the green moss zone ranged from 24% (**Ereynetidae**: *Ereynetes macquariensis*) to 63% (**Ologamasidae**: *Gamasellus racovitzai*). In the *Polytrichum* (Figure 125) cover, only a weak relationship existed between moss cover and arthropods, including mites, in the green moss zone, whereas none existed in the dead moss zone.

At the Canada Glacier, mites were less abundant than protozoa, rotifers, nematodes, and tardigrades (Schwarz *et al.* 1993). On the other hand, Strong (1967) found mites to have the greatest species richness at Palmer Station, with at least 11 species representing the suborders **Prostigmata**, **Mesostigmata**, and **Cryptostigmata**. The **Collembola** comprised 4 species and **Diptera** 1. The two predatory mites feed mostly on the **Collembola**. Three of the oribatid species form aggregations to survive the winter. The others spend the winter in the same locations as their summer homes.

Antarctic Lakes likewise have an important mite fauna. In Priyadarshani, an oligotrophic lake, mosses and algae cover the bottom sediments. There one can find a microfauna that includes mites (Ingole & Parulekar 1990).

Temperature and Humidity Protection

Bryophytes may afford a protection from the Antarctic temperature that is not present elsewhere. Gressitt (1967) measured temperatures among mosses and found that some could create thermal conditions quite different from those in the atmosphere. *Polytrichum* (Figure 125) could reach January temperatures up to 13°C above atmospheric temperature, but *Drepanocladus* (*sensu lato*; Figure 127-Figure 128) maintained temperatures that differed little from ambient. (Note that the actual bryophyte species of these two genera may now be in different genera.)

As suggested for the two lycosid spiders earlier in this volume, other arthropods may also benefit from the ameliorating effects that bryophytes have on temperature. For example, the mites and **Collembola** have no known tolerance to freezing and survive winter by supercooling (Sømme 1981). This seems to involve both use of such cryoprotective compounds as glycerol and the elimination of nucleating proteins from the gut.

Block *et al.* (1978) noted that the mite *Alaskozetes antarcticus* (**Ameronothridae**; Figure 130) in the Antarctic has the ability to supercool to -30°C, but to realize this ability it depends on starvation, and possibly desiccation. They reported that about 1% of its fresh weight is glycerol. Cannon (1986b) found that for this species, those cold-hardy mites provided with distilled water and glucose lost about 20-25°C in supercooling ability. When no liquid was provided, they lost only about 4°C. In both cases, the glycerol concentrations in the mites decreased. In the Antarctic, even the summer temperatures can be quite cool. Block (1985) found that these could reach -8.4°C within the moss mats.

Figure 129. *Ameronothrus lineatus*, a moss-dweller from the high Arctic of Svalbard. Photo by Steve J. Coulson, with permission.

Figure 130. *Alaskozetes antarcticus*, an Antarctic moss-dweller that is capable of supercooling. Photo by Richard E. Lee, Jr., permission unknown.

Cannon (1986a) experimented with the humidity relations of *Alaskozetes antarcticus* (**Ameronothridae**; Figure 130) at 0, 26, 42, 55, 86, and 100% relative humidity at 4°C. He found that under saturated conditions the winter mites gradually lost cold hardiness while losing glycerol and increasing the temperature to which they could supercool. When they were maintained in dry conditions (r.h. <55%), their glycerol levels were relatively high (accumulation of glycerol was directly related to rate of water loss) and their supercooling temperature remained relatively constant. Even in summer conditions, the loss of water stimulated the accumulation of glycerol and the depression of the supercooling temperature.

Ice nucleation is always a danger at sub-freezing temperatures. Most invertebrates evacuate the gut in preparation for low temperatures (Sømme 1982), and this may relate to the problems seen when glucose was made available.

On the other hand, **tritonymphs** (third developmental stage) and adults of the mite *Alaskozetes antarcticus* (**Ameronothridae**; Figure 130) collected from mosses (or soil) in the Antarctic summer exhibited poor supercooling ability (-3 to -4°C) compared to those collected from beneath rocks (-20 to -30.8°C for tritonymphs, -2 to -29°C for adults) (Shimada *et al.* 1993). They were able to survive at temperatures below 0°C until they were frozen. This supports the notion that desiccation may be important to their cryoprotection mechanisms. Active mites survived lower temperatures than did the resting mites, and Shimada and coworkers suggested that items in their diet might contribute ice nucleating proteins that permit them to survive. It also appears that these mites are able to make antifreeze proteins that protect them from freezing in the fluctuating temperatures of summer (Block & Duman 1989). They are aided in their survival of low temperatures by having a very dark color that makes them into a "black body" that absorbs heat from the sun. Their slow development (5-7 years) is most likely a result of the low temperatures, but it could also mean they require less resources to continue their development.

Like most things, not all cryoprotection depends on the same conditions. Block (1979) found that the cryptostigmatid mites of the Alaskan taiga had supercooling ability that increased with the cold of autumn and early winter. But for these mites, there was no correlation with water content. Freezing was generally lethal, but supercooling prevented death until a frozen condition was reached.

One can only speculate on the role of the bryophytes in maintaining survival of *Alaskozetes antarcticus* (**Ameronothridae**; Figure 130). Since the bryophytes are likely to be frozen during a large portion of the year in the Antarctic, it is possible that ice crystals on their surfaces could contribute to desiccation of the mites by drawing the nearby water to the ice crystals of the bryophytes. Removal of water in this way from the mites would reduce the danger of crystal formation within the mites. Evacuation of the gut would further support the inability to form internal ice crystals. This could potentially protect the mites within the mats from episodes of fog and other moisture sources during cold weather, wherein small objects tend to collect the moisture and hold it, be they

mites or mosses. Certainly research is needed to support my hypothesis on the role of the bryophytes.

A major problem for such small organisms in the Antarctic climate is the great variability in climatic conditions. Not only does the mite experience extremes through time, but it has great variability among its niches at the same time. Hence, having plasticity in one's response to this environmental heterogeneity is an asset for organisms such as mites. *Halozetes belgicae* (**Ameronothridae**) has **superplasticity** in its acclimation potential, as shown by the cold acclimation of an Antarctic population (Hawes *et al.* 2007). This species can cold harden very rapidly in the range of 0 to -10°C. In just two hours at 0°C, mites that had been acclimated at 10°C adjusted their supercooling points by 15°C. This is the most efficient ability to lower the lethal temperature known for any terrestrial arthropod. They seem to achieve this supercooling ability by evacuation of the gut, thus ridding themselves of potential nucleation sites in the gut. This could be a difference in physiological races or microspecies because the ability varies latitudinally, but it also varies with seasons.

Nielsen and Wall (2013) predicted that climate change responses will differ between Arctic and Antarctic invertebrate communities. They consider the changes in the Arctic to be driven by changes in the vegetation, whereas the Antarctic will respond to changes in the microbial community as well as changes in the plant communities. Both areas will most likely have a greater arrival of non-native species. In the species-rich Arctic, this may have a locally negative impact, with invaders reducing the diversity of native species by competition. These changes could cause the Arctic to become a carbon source, whereas the Antarctic could become a carbon sink.

The moss-dwelling *Ameronothrus lineatus* (**Ameronothridae**; Figure 129) lives in the high Arctic heath of the Svalbard, West Spitsbergen (Coulson & Birkemoe 2000). Collections of soil demonstrated that at least some individuals can survive temperatures of -22°C. But how tolerant will these high Arctic species be to greater maximum temperatures? Deep *Sphagnum* may be a refuge, but dark colors in the sun, including red *Sphagnum* species, will actually become warmer than the atmosphere on sunny days.

On the other hand, warming alone might not harm the mites. In the Arctic, Coulson *et al.* (1996) found no change in mite populations and species composition between controls and soil heated by having small polythene tents covering them. At the same time, numbers of **Collembola** declined significantly. The number of juveniles of mites increased significantly in the polar semi-desert regions of the Arctic, suggesting that this life stage might survive better at warmer temperatures, ultimately increasing the population size overall.

Tropics

In the cloud forest of Costa Rica, Yanoviak *et al.* (2006) found abundant arthropods among the epiphytes (including but not limited to bryophytes). There seemed to be little difference in faunal frequency and abundance between the **secondary forest** (forests regenerating largely through natural processes after significant human and/or natural disturbance) and **primary forest** (forest with native

species and no indication of human intervention) except for the significantly greater abundance of ants (11.4% with more than 10 per sample) in the secondary forest compared to 1.7% in the primary forest. Wet versus dry season seemed to make little difference in abundance. There was a slight tendency toward more morphospecies (10%) of arthropods in the wet season compared to the dry season. Yanoviak and coworkers warned that arthropods might be undercollected during the dry season because they become dormant and therefore do not fall into the Tullgren funnel due to lack of movement.

Nadkarni and Longino (1990) found in montane forests of Costa Rica that relative abundances of the major arthropod taxa were "the same" in the canopy and on the forest floor. They interpreted this to mean that the organic matter was similar in these two habitats, resulting in similar invertebrate communities. On the other hand, densities were 2.6 times as high on the ground as in the canopy. The highly mobile ants seemed to have equal densities in both places. Mites were among the dominant taxa in both canopy and ground detritus, but were less abundant in the canopy. They considered more wind, more frequent mist, higher maximum air temperatures, and more frequent wetting/drying cycles as contributing to a high biomass (4730 kg ha⁻¹) of organic matter in the canopy. These same factors seemed to contribute to reduced densities of arthropods. Tree species seem to make little difference in contributions by the thick epiphytic mats (Lawton & Dryer 1980).

These invertebrates are major fragmenters of the organic matter in tropical montane forests, although in most sites oligochaetes (worms such as earthworms) are also major contributors (Collins 1980, Pearson & Derr 1986, Leakey & Proctor 1987). Reported differences in abundance of oligochaetes in other studies, accompanied by lower relative abundances of arthropods, may reflect the different sampling techniques, where this study used sifting methods and others used hand sorting (Nadkarni & Longino 1990).

Epizootic

Even in the miniature community of bryophytes, there are animals that get a free ride on other animals. Among these is the oribatid mite, *Symbioribates papuensis* (*Symbioribatidae*; Figure 133), that is epizootic on backs of Papuan weevils (Aoki 1966). The beetle genus *Gymnopholus* (subfamily *Leptopiinae*; Figure 131) is inhabited by both lichens and liverworts, and liverworts in turn house the oribatid mite (Gressitt & Sedlacek 1967). Gressitt and Sedlacek (1967) reported a new species of weevil from New Guinea (*Gymnopholus carolynae*) that had abundant algae, fungi, and mosses growing on its back.

Vertical Distribution

Various types of gradients exist in habitats, and the responses of mites is to have different communities in

different areas of these gradients (Popp 1970; Behan-Pelletier & Winchester 1998; Proctor *et al.* 2002; Smrž 2006). Bryophytes can provide amelioration of some of the critical differences among habitats due to their ability to absorb water rapidly, reduce substrate evaporation, and reduce extremes of both moisture and temperature (Gerson 1982; Smrž 1992). Oribatid mites commonly are abundant where there is decaying plant material and high moisture, both of which are present in bryophyte communities (Bonnet *et al.* 1975; Seyd & Seward 1984).

Figure 131. *Gymnopholus reticulatus* with the moss *Daltonia angustifolia* living epizootically on the weevil. Mites are known to live in this association. Photo courtesy of Rob Gradstein.

Lindo *et al.* (2008) found that within one year, 90 artificial canopy habitats of soil and mosses attached to planks were colonized by 59 oribatid mite species. These artificial habitats were distributed at three heights on 10 western red cedar (*Thuja plicata*; Figure 132) trees and represented three patch sizes. The established communities exhibited a typical species-area relationship. Richness increased with moisture content and size of habitat patch. Hence, species richness and abundance decreased with increased height in the canopy. The community composition and species richness patterns exhibited a non-random distribution and were significantly nested. Non-randomness could be explained in part by individual species tolerances and dispersal abilities. Previously known canopy-specific species [*Eupterotegeus rhamphosus* (*Cepheidae*), *Epidamaeus* nr *floccosus* (*Damaeidae*; see Figure 11), *Schelorbitates* (*Schelorbitatidae*; Figure 133)] from the area were all present on the artificial substrata. These species were even found in the small, desiccated patches located highest in the canopy and exhibited drought tolerance and adaptations to living in a patchy environment. The earliest colonists were generally strongly desiccation tolerant. These canopy specialists seemed to lack dispersal limitation.

Forest Habitat Strata

Vertical differences exist within the forest. In the canopy, bryophytes are often a primary habitat (Winchester

et al. 1999). Proctor *et al.* (2002) found distinct communities among the base, trunk, and canopy habitats in Australia. Bonnet *et al.* (1975) examined the vertical gradient of mites at Tarn, France, from soil to arboreal mosses. There were 63 species of mites, although only 58 could be identified. The importance of temperature and humidity were clear, with invertebrate communities following the same transitions as the habitat. These communities can differ in both abundance and species composition. In the tropical montane forest of Costa Rica, where mites represented one of the numerically dominant groups, Nadkarni and Longino (1990) found that the forest floor fauna had a mean density 2.6 X that of the canopy.

In attempts to determine the impact of moss harvesting on invertebrate faunas, Peck and Moldenke (1999) compared the fauna at the stem base and at the tips of shrubs in the Eugene District, Oregon, USA. They found that presence of hardwood trees and greater abundance of mosses increased the mite fauna. At the bases of the shrubs, typical moss fauna were *Ceratoppia* sp. (**Ceratoppiidae**; Figure 134), *Hermannia* spp. (**Hermannidae**; Figure 135), and *Phthiracarus* sp. (**Hermannidae**; Figure 136) (all turtle mites). Samples at the tips were characterized by **microspiders** and **springtails**. Based on these community structures, they recommended that moss harvesting be prohibited in mixed or hardwood-dominated stands and from the lower 0.5 m of any shrubs.

Figure 135. *Hermannia reticulata*. Photo by Bold Systems Biodiversity Institute of Ontario, with permission.

Figure 136. *Phthiracarus* sp. Photo by Walter Pfliegler, with permission.

Wagner *et al.* (2007) examined the distribution of epiphytes and invertebrates on the bole of red maple trees (*Acer rubrum*; Figure 137) in Maine, USA. They found that mites were among the predominant fauna at the base and **Diptera** (flies) above 2 m. Gap harvesting reduced the cover of epiphytes and the arthropod fauna, suggesting that the epiphytic bryophytes could play a role in the distribution of these invertebrates.

Within Bryophyte Clumps

Because of moisture differences, and possible UV damage, vertical differences exist among mite communities within bryophyte clones (Dalenius 1962; Harada 1980). The importance of humidity differences (Smrž 1994) is reflected in the vertical positioning of the mites within the moss clone.

In Canada, nearly 50% of the 100 moss samples collected by Richardson (1981) had mites living among them. The distribution of mite species can differ within the vertical strata of the mosses, indicating differences in conditions at these depths (Harada & Aoki 1984; Usher & Booth 1984). Borcard (1993) found that the 38 species of

oribatid mites in *Sphagnum* (Figure 95) differed between two vertical layers of moss. Evidence for these differences is further supported by the daily migrations of mites that have been observed in some mosses (Rajski 1958).

In a cloud forest in Costa Rica, Yanoviak *et al.* (2004) found a vertical distribution of mites within epiphytic mats of bryophytes, with a greater mass of oribatid mites occurring in the brown portions than in the upper green portions. The brown tissue was more dense and its grain was finer than that of the green portion. On the other hand, the green portions had a greater density and richness of arthropods than did the brown parts. Mites were the most abundant arthropod group in this habitat. As expected, Booth and Usher (1984) found an increase in arthropod abundance with an increase in moss dry mass.

Vertical Migration

Vertical migration permits some species to escape the heat and desiccating events of the day by escaping to deeper layers of the mosses. Among the moss habitats, this may be most prevalent in *Sphagnum* (Figure 95) habitats, where the surface is exposed to full sun and can become quite hot and dry while lower depths remain cool and moist. Popp (1962) observed such vertical migration behavior for *Limnozetes ciliatus* (see Figure 107-Figure 112) and *Hypochthonius rufulus* (Figure 138) in response to hummock temperature changes.

Figure 138. *Hypochthonius rufulus* on *Sphagnum*. Photo by Walter Pfliegler, with permission.

Ceratozetes (Ceratozetidae; Figure 102) and *Eremaeus* (Eremaeidae; Figure 5-Figure 4) species migrate in the soil to optimize moisture and temperature conditions (Mitchell 1978). They also segregate by ages, with younger members occupying lower depths that have a more ameliorated climate. These migrate upward as adults. These two genera are also known among bryophytes, so it is likely that at least some of these bryophyte dwellers also exhibit vertical migrations.

Magalhães *et al.* (2002) showed that some mites respond to species-specific predator odors that stimulate their migration upward or downward in response. In tracheophytes, this behavior combination can actually benefit the plants. Mite predators sit in the rapidly growing

tender tips, causing the herbivorous mites to migrate downward, thus protecting these sensitive plant areas (Magalhães *et al.* 2002; Onzo *et al.* 2003) from mite herbivory. I can find no study to indicate whether bryophyte-dwelling mites respond to similar chemical stimuli of predators among the bryophytes. If they do, would this likewise protect growing tips from mite damage, or is their often fungivorous diet sufficient protection for the bryophytes? Might the chemical odors of the bryophytes override predator odors, or nullify them, or in some other manner ameliorate their effectiveness?

Elevational Differences

Elevational differences exist as well. Andrew *et al.* (2003) examined the elevational relationships of mites among bryophytes in New Zealand (Table 1-Table 2). Taxa on Mt. Field and Mt. Rufus represented the **Mixonomatides** and the families **Oribatellidae**, **Galumnidae**, **Oppiidae**, **Microzetidae**, **Cepheidae**, **Adelphacaridae**, **Mycobatidae**, **Phthiracaridae**, **Carabodidae** (Figure 139-Figure 140), and **Cymbaeremaeidae**. All but **Adelphacaridae** and **Cymbaeremaeidae** were collected in more than one location. On Mt. Otira, New Zealand, the researchers found **Oribatulidae**, **Eutieidae**, **Epilohmanniidae** (only at higher elevations of 1000-1500 m), **Oribotritiidae**, **Nanhermanniidae** (Figure 114), **Pedrocortesellidae** (the latter three only from lower elevations of 250 m), **Microzetidae** (1 location at 750 m), and **Tectocephidae** (in 10 out of 12 locations at 1500 m only).

Elevational patterns for mite species richness were not in evidence in this study (Andrew *et al.* 2003), and those that did exist differed widely between mountains. Nevertheless, for some families, as mentioned above, distinct elevational ranges are suggested. Evidence is needed to tie these elevational differences to differences in bryophyte species. Nigel Andrew (Bryonet) suggested that moss species and growth form were important factors in determining arthropod abundance and diversity in the New Zealand mountains; these are likely to differ with elevation.

Table 1. Elevational distribution of mite families living among bryophytes on Kaikoura, New Zealand. Each location is represented by six samples. Elevations are in meters. Data are presence out of six locations at that elevation. From Andrew *et al.* 2003.

Seasons

Sampling season will influence the abundance of mites in the soil (Popp (1970), and presumably among the bryophytes. Merrifield and Ingham (1998) found that the abundance of aquatic mites (and tardigrades) among mosses varied significantly between sampling dates in the Oregon Coastal Range, USA. Gerson (1969) reported oribatids that live on mosses under the snow. Block (1966) found that mites were most abundant in May and December, and least abundant in August in Westmorland, UK, but this can be modified by the weather.

Just as vertical differences exist within the moss mat on any given day, they likewise exist seasonally. Moss depths provide a safe overwintering habitat for mites, protecting them from extreme temperatures and desiccation. Popp (1962) found that the peatland oribatids *Limnozetes ciliatus* (**Limnozetidae**; see Figure 107-Figure 112), *Ceratozetes parvulus* (**Ceratozetidae**; see Figure 102), and *Trimalaconothrus novus* (**Malaconothridae**; see Figure 87) migrate to the deeper layers of the peat hummocks to spend the winter.

Gerson (1969) dug the mosses *Ceratodon purpureus* (Figure 141) and *Bryum* (Figure 142) out from 1.6 m of snow on Montreal Island, Quebec, Canada, and found

many live *Eustigmaeus* (**Stigmaeidae**; Figure 143) present. These began to oviposit when warmed on a suitable substrate in the lab. It is likely that bryophytes are important overwintering sites for a number of mites. The ability of at least some members of this genus to eat mosses (Walter & Latonas 2011) may help them to survive there.

Salmane (2000) investigated the seasonal activity of **Gamasina** (an infraorder of the **Mesostigmata**) mites (Figure 13) in soil under mosses in a pine forest in Latvia. She determined that the abundance and diversity of this predatory mite group was seasonally dynamic. These

changes in abundance and diversity related first to relative humidity and secondarily to temperature. The greatest diversity was in August (17 species), but some species (*Rhodacaridae: Rhodacarus reconditus*) did not appear until October. In her April to October study, the greatest numbers of **oribatid** and **Gamasina** mites were in April and August.

Disturbance Effects

Starzomski and Srivastava (2007) conducted one of the few experimental studies on terrestrial arthropod communities, where mites (**Acari**) and springtails (**Collembola**) comprised part of the fauna. These were tiny animals, mostly less than 1 mm in length, that inhabited patches of the mosses *Polytrichum* (Figure 125) and *Bryum* spp. (Figure 142) on granitic outcrops in Vancouver, British Columbia, Canada. In their experiments, they simulated drought frequencies as a form of disturbance. Effects of humidity on *Scutovertex minutus* (**Oribatida**; see Figure 144) were already known from studies by Smrž (1994). The oribatid microarthropods may reach 200 or more morphospecies in an area of less than 20 m² (Starzomski & Srivastava 2007). In their BC study, 163 species were found, comprising 26,274 individuals.

Figure 144. SEM of *Scutovertex sculptus*, members of a genus that lives on *Polytrichum* and *Bryum*. Photo by Jürgen Schulz, with permission.

Connectedness between patches is important in determining number of species, although microarthropods may migrate across bare rock to other moss patches (Starzomski & Srivastava 2007). Increases in drought disturbances decreased the number of species, but not the number of individuals. On the other hand, fragmentation caused an increase in species abundance. In unconnected plots with no disturbance, the mean number of individuals was 620, whereas in the undisturbed connected patches, mean abundance was only 372. However, disturbance in the fragmented sites caused a drop in abundance below that of the other treatments. The smallest regions experienced the greatest rate of drop in both species richness and abundance (2.5X faster for species richness, 4X faster for number of individuals). In connected regions, oribatid

mites exhibited a dampened response to disturbance compared to other species, perhaps due to protection from desiccation by their hard exoskeleton. For all the other taxa, abundance, body size, and trophic position had no effect on their responses to disturbance.

Although corridors are undoubtedly important in providing safe sites for migration between patches of bryophytes, they do not always provide the same benefits. Starzomski and Srivastava (2007) found that the microarthropods offer increased community resilience to disturbance and enhanced species richness in small patches. Corridors facilitate movement (Schmiegelow *et al.* 1997), maintain ecosystem processes (Gonzalez & Chaneton 2002; Levey *et al.* 2005), and prevent local extinctions (Gonzalez *et al.* 1998). However, Hoyle and Gilbert (2004) found that different connectivity treatments did not contribute to species richness, a finding supported by Starzomski and Srivastava (2007). Both of these studies did suggest that corridors are important under disturbance (in this case drought) conditions, supporting the contention of Honnay *et al.* (2002) that they may be very important in the presence of climate change.

Cryptogamic crusts are subject to disturbance by grazing animals. Within these crusts of lichens, mosses, and algae/Cyanobacteria, many invertebrate types dwell, including mites (Brantley & Shepherd 2004). In a piñon-juniper woodland in central New Mexico, 29 of 38 taxa of invertebrates occurred on mossy patches and 27 on mixed lichen and moss patches. Mosses had the highest abundance, suggesting that their ability to hold moisture might benefit these organisms. Furthermore, abundance was greater in winter than in summer.

Pollution Indicators

Watermites (**Prostigmata**) can serve as bioindicators of pollution in streams, in part because they are affected by the changes in moss growth caused by the pollution (Bolle *et al.* 1977). Most moss mites (Oribatida) decline in numbers when exposed to industrial pollution. On the other hand, the pollution-tolerant mite *Hygrobat* *fluvialis* (**Hygrobatidae**; Figure 145) increases with industrial effluent additions (Bolle *et al.* 1977).

Figure 145. *Hygrobat fluvialis*, a pollution-tolerant moss mite. Photo by Nigrice through Creative Commons

Terrestrial mites can be used as well; in a Scots pine forest in Poland, bryophyte mite fauna responded to nitrogen fertilizer pollution (Seniczak *et al.* 1995).

Recent evidence of increasing levels of UV-B suggest that bryophytes could provide refugia for invertebrates such as mites, blocking the dangerous radiation from reaching their inhabitants (Robson *et al.* 2001). To my surprise, Robson and coworkers found that biodiversity of **microfauna** among *Sphagnum* (Figure 95) species increased in plots exposed to higher UV-B levels. Nevertheless, mites responded negatively to the increase in near UV-B by having reduced numbers (Robson *et al.* 2005). Robson and coworkers suggested that under UV-B radiation at near-ambient levels, leaching of nutrients from the mosses may result and possibly changes occur in the morphology of the *Sphagnum* capitulum.

Steiner (1995a) found that air pollution can alter the species composition and abundance of the mites among mosses. Richness decreases and the mite communities become more uniform. The species *Zygoribatula exilis* (Oribatulidae; see Figure 20) proved to be the most useful as an air quality indicator. Not only does air pollution have direct effects on the mites, but it also can alter relative humidity, substrate availability, and pH of the mosses, which in turn influence the mite species able to live there. Even so, the mites are less sensitive to pollution than nematodes and tardigrades (Steiner 1995b). Exceeding tolerance demonstrated by tardigrades is quite a feat.

Dispersal of Mites and Bryophytes

It is likely that dispersal works both ways in the moss-mite relationship. Several studies have indicated the role of mites in bryophyte dispersal. Both mites and bryophytes can be dispersed aerially (Mandrioli & Ariatti 2001).

Risse (1987) pointed to studies that indicate the bryophyte gemmae do not develop below the ground surface, and this includes rhizoidal gemmae and tubers. But the attachment of gemmae of *Schistostega pennata* (Figure 146-Figure 149) to the legs of mites indicates that these bryophytes have a means of dispersal that is likely to drop off at least some of the propagules at the surface (Ignatov & Ignatova 2001). Such a form of dispersal is likely to remove them from the territory of the parent, where the gemmae may be inhibited, presumably by chemicals from the parent.

Figure 146. *Schistostega pennata* mature leafy gametophyte plants. This species has gemmae that are dispersed by attaching to the legs of mites. Photo courtesy of Martine Lapointe.

Figure 147. *Schistostega pennata*. Reflective protonemata with a few leafy plants. The protonemata produce gemmae that can be dispersed by mites. Photo courtesy of Martine Lapointe.

Figure 149. *Schistostega pennata*. Microscopic view of the protonemata, showing the loosely connected cells that can develop into new leafy plants. The long, fusiform branch is a protonemal gemma that can be carried to the surface by mites. Photo courtesy of Misha Ignatov.

Zhang and coworkers (2002) provide further evidence of possible transport of gemmae in the moss *Octoblepharum albidum* (Figure 150-Figure 151). In this species, mites consume the gemmae, and in the process could manage to transport some of those gemmae to new locations. At the very least, they are likely to dislodge some gemmae that drop before they get eaten. One must wonder if gemmae cells survive the digestive system, providing yet another mechanism for transport. More experiments waiting to be done!

Figure 150. *Octoblepharum albidum*, a moss whose gemmae are dispersed by mites. Photo by Janice Glime.

But mites themselves can have some difficulties getting dispersed. Sudzuki (1972) did wind tunnel experiments with mosses, using various wind speeds. During the two months of experiments, mites were apparently never dispersed, and the Crustacea and Arachnomorpha were rarely dispersed at wind velocities under 2 m s^{-1} . They concluded that mites are not transported by wind. On the other hand, this does not preclude the passive dispersal of mites along with mosses that are moved by the wind, especially in such vulnerable locations as the canopy or among the terrestrial moss balls.

Lindo (2011) suggested mosses might serve as "magic carpets" for the mites. She reported 57 species of oribatid mites among litterfall, including mosses, in her study of canopy and ground level litter. She found a high species richness in litterfall in canopy habitats and suggested that the mosses not only served as transportation vessels, but that they also increased survivorship during the journey.

Figure 151. Gemmae of *Octoblepharum albidum*, potentially distributed by mites that also eat some of them. Photo by Li Zhang, with permission.

No Place for Generalists?

At the beginning of the first subchapter on mites, I introduced the question "Can we use the literature to answer this question for [mites in] any mossy habitats?" My first response to this is that I would have to change my professional path from bryology to acarology to attempt to answer it. My second response is almost as wishy-washy.

Certainly many examples in this chapter have included mites that go to bryophytes to replenish moisture, and probably to hide. These might be called generalists because they use a variety of habitats. But we know that many mites that are plant pests seem to be specialists. The mosses, on the other hand, often seem to be only a refuge habitat when the primary habitat becomes unavailable or unsuitable. But the bryophytes where they seek refuge may in some cases be the only suitably moist habitat. It's a good thing that some of these plant specialists can go for a long time without eating.

I am inclined to think that those mites that live on bacteria and fungi are generalists, able to live wherever there is sufficient moisture and a fungal or bacterial food source. For many, this means soil, leaf litter, and mosses.

At the other end of the spectrum are those mites that eat mosses and lay their eggs there, but how many of these can survive as well in other locations? To answer that question we must await more research, experimentation, and publication of older literature on the web. And before that can provide us with definitive answers, DNA-based identification of species will be necessary to separate the cryptic species that may indeed represent specialists.

Limitations of Methods

The high abundance of mites among bryophytes often requires special extraction techniques (Borcard 1986; see discussion in Chapter 6-1 of this volume). When general surveys are done, they typically have a bias against some groups of organisms and favor others. Furthermore, most require that the organisms are mobile, so dormant organisms are missed. Yanoviak *et al.* (2003) reminded us of the limitations of fogging, a common canopy method, for invertebrates such as mites because they would typically remain within the moss mat.

Likewise, information on bryophyte-dwelling mites requires special and extensive searching techniques. Most of the information is hiding in species descriptions, or not mentioned at all. As I am finishing this chapter, I have the feeling I have only scratched the surface on the available information of bryophyte-dwelling mites.

Nelson and Hauser (2012), students at Lewis and Clark College working on an undergraduate report, tested two methods of surveying invertebrate communities of epiphytic bryophytes in the Tryon Creek State Natural Area, Oregon, USA. They compared arthropod extraction using a Berlese funnel to a simple water technique. In the latter, they examined ten drops of water from each wet bryophyte sample. Acari were the most abundant and most frequent. They could find no differences in communities between mosses and liverworts. But a comparison of the two extraction techniques demonstrated almost no overlap in taxa! Rather, the two techniques complemented each other. The Berlese funnel sampling provided the greatest numbers of different species of Acari.

Order Acari – Ticks

Ticks are not organisms we normally think of as moss fauna, but Slowik and Lane (2001) showed that the western black-legged tick *Ixodes pacificus* (Ixodidae; Figure 152) was more common on moss-covered oak trees than on trees without mosses. They found that the moss reduced the

surface temperature by $\sim 1.9^{\circ}\text{C}$ and increased the relative humidity 2.5%, perhaps contributing to the greater abundance of these ticks as bryophyte associates. Slowik and Lane suggested that the bark provided refugia and that the western fence lizard could be responsible for presence of these ticks on the bark. Mites, on the other hand, are quite common as bryophyte fauna (Kinchin 1990; Seyd & Colloff 1991; Seyd *et al.* 1996).

In the Antarctic, the tick *Ixodes uriae* (Ixodidae; Figure 153) likewise makes use of mosses. It lays its eggs under mosses or grasses (Gressitt 1967).

SUBPHYLUM MYRIAPODA

The myriapods represent a much smaller subphylum ($\sim 13,000$) than that of the **Arachnida** (Wikipedia: Myriapoda 2010). The name myriad literally refers to 10,000 (legs). Although this is not literally true, these arthropods can have from fewer than 10 up to 750 legs. Three classes are represented among bryophytes: **Chilopoda** (centipedes), **Diplopoda** (millipedes), and **Symphyla** (garden centipedes). The eggs hatch into miniature myriapods with fewer segments and legs. Secretions from many of the members can cause one's skin to blister.

Class Chilopoda (Centipedes)

Centipedes are mostly carnivorous and are distinguished by one pair of legs per segment (Wikipedia: Chilopoda 2010). They lack a waxy covering and lose water easily, hence preferring high humidity and low light (Mitić & Tomić 2002). It is likely this dependence on water that makes mosses such as *Sphagnum* suitable habitat for some species. *Lithobius curtipes* (Lithobiidae; Figure 154) lives among the mosses [*Polytrichum commune* (Figure 156), *Sphagnum girgensohnii* (Figure 157), *S. squarrosum* (Figure 155)] on the forest floor in Finland (Biström & Pajunen 1989). In Great Britain, Eason (2009) found it in great numbers in moss, under stones, and on bark. In the Ural Mountains, this is the only centipede species that extends into the tundra (Farzaliyeva & Eshyunin 2008). *Geophilus proximus* (Geophilidae; see Figure 158) also occurs on *Polytrichum commune* (Biström & Pajunen 1989).

Figure 158. *Geophilus carpophagus*, a centipede member of a genus that is present among bryophytes, shown here on leaf litter. Photo by Walter Pfliegler, with permission.

In their study of invertebrate communities among bryophytes [predominantly *Atrichum undulatum* (Figure 159), *Brachythecium rutabulum* (Figure 160), and *Hypnum cupressiforme* (Figure 161-Figure 162)] in the Czech Republic, Božanić *et al.* (2013) found that the **Chilopoda** chose habitats on the ground or close to it. They, like the **Diplopoda** and **Isopoda**, were numerous in small cushions, whereas the **Enchytraeidae** (Annelida) were abundant in larger moss carpets. The larger centipedes, including adults of somewhat smaller species,

feed on smaller chilopods such as *Lithobius* (**Lithobiidae**; Figure 154) species that inhabit the soil surface (Rawcliffe 1988). This causes some of the *Lithobius* species to escape into the mosses at the lower parts of living trees (Biström & Pajunen 1989). Others such as *Lithobius mutabilis* (Figure 163) and juveniles of other species of *Lithobius* occur among mosses on larger trees (Božanić *et al.* 2013).

Class Diplopoda (Millipedes)

The millipedes are unusual in having each pair of segments fused, hence having two pairs of legs per fused segment (Wikipedia: Diplopoda 2010; Figure 164). They are not common among mosses, or at least there are few reports. Biström and Pajunen (1989) found *Polyzonium germanicum* (Polyzoniidae; Figure 165), *Proteroiulus fuscus* (Figure 166), *Polydesmus complanatus* (Polydesmidae; Figure 167), and *Leptoiulus proximus* (Julidae; Figure 170), on the *Polytrichum commune* (Figure 156) in Finnish forests. *Polydesmus complanatus* occurred not only on *Polytrichum commune*, but also on *Sphagnum girgensohnii* (Figure 157) and *S. squarrosum* (Figure 155).

Božanić *et al.* (2013) found that type of substrate and height above ground are often the most important factors in determining the invertebrate fauna of the bryophytes in the Litovelské luhy National Nature Reserve, Czech Republic. The mosses here are mostly *Atrichum undulatum* (Figure 159), *Brachythecium oedipodium* (Figure 168), *B.*

rutabulum (Figure 160, and *Hypnum cupressiforme* (Figure 161-Figure 162). As a whole, these house the highest numbers of invertebrate species. In contrast to the **Chilopoda**, the **Diplopoda** live among mosses high in the trees, sometimes as high as 160 cm above the ground. They prefer small cushions to larger carpets.

Figure 168. *Brachythecium oedipodium*, a moss that houses **Chilopoda**. Photo by Michael Lüth, with permission.

Polydesmus angustus (Polydesmidae; Figure 169) commonly make nests on moss cushions in London, UK, especially during April to July (Banerjee 1973). The nests are constructed from "worked-up" soil from the gut of the female. As the millipedes develop, different instars construct their own molting chambers using bits of soil and humus.

Figure 169. *Polydesmus angustus* at Crowle Moors, UK. Photo by Brian Eversham, with permission.

Figure 170. *Leptoiulus proximus*, a millipede known from *Polytrichum commune*. Photo by Stefan Schmidt through Creative Commons.

In the UK, Stenhouse (2007) reported *Ommatoiulus sabulosus* (striped millipede; **Julidae**; Figure 171) in moss and the daddy-long-legs *Nemastoma bimaculatum* (**Nemastomatidae**; Figure 172) under moss.

Figure 171. *Ommatoiulus sabulosus* on mosses. Photo by Roger S. Key, with permission.

Figure 172. *Nemastoma bimaculatum*, a daddy-long-legs that lives under mosses. Photo by Tom Murray, through Creative Commons.

Tachypodoiulus niger (black snake millipede; **Julidae**; Figure 173), a millipede of chalky and limestone soils, is very common in the UK and occurs among mosses and similar habitats (Stenhouse 2007). Haacker (1968) considers it to be a dry-resistant or xerophilous species that prefers cool temperatures, but has only limited freezing tolerance (David & Vannier 1997). *Tachypodoiulus niger* is active mostly from one hour after sunset to one hour before sunrise, but can become active in the afternoon during summer (Banerjee 1967). When disturbed, it will coil itself into a spiral with its legs on the inside and its head in the center (Figure 174; Wikipedia 2012), but it also has the option to flee with side-winding movements like some snakes. These millipedes feed on algae, detritus, and some fruits such as raspberries (Wikipedia 2012).

Figure 174. *Tachypodoiulus niger* curled in its defensive position. Note legs on inner side of spiral and head in the middle. Photo from Wikimedia Commons.

Josh Jones (pers. comm.) found *Cylindroiulus punctatus* (Julidae; Figure 175) on a species of the moss *Thuidium* (Figure 175). It has a diurnal cycle with a major activity period from one hour before sunrise to one hour after in April, May, and July, but also one hour before sunset to one hour after throughout March-August except July (Banerjee 1967).

Figure 175. The moss *Thuidium* sp. with the millipede *Cylindroiulus punctatus*. Photo courtesy of Josh Jones.

In January 2012, Erin Shortlidge queried Bryonet about an unusual invertebrate she found among the bryophytes. This, Bryonettors identified as the millipede *Polyxenus* (Polyxenidae; Figure 176-Figure 177), differing somewhat from the European *P. lagurus* (Figure 178) (Edi Urmi, Bryonet 8 January 2012). The bristles serve as defense against ants (Paul G. Davison, Bryonet 8 January 2012). Jean Faubert offered the identification of *P. fasciculatus* (Figure 176-Figure 177).

Figure 178. *Polyxenus lagurus*. Photo by Mick E. Talbot, through Creative Commons.

Božanić (2008) found that the most abundant taxa of invertebrates among mosses were **Isopoda** (439 individuals among 66 moss samples) and **Diplopoda** (240 individuals). The most important factors in determining taxa were type of substrate, height above ground, and size of moss sample. For epiphytic bryophyte dwellers, the tree diameter was important. One should exercise some caution in interpreting these results because researchers used a Tullgren funnel with heat extraction, a method that works against less-mobile organisms that are unable to escape the moss clump before dying from heat or desiccation.

Epizootic Bryophytes

Rob Gradstein (14 November 2011) sent me a note that I might be interested in a Colombian millipede with ten bryophyte species (Figure 179) growing on it! Of course I was interested. These ten species represented five families (**Fissidentaceae**, **Lejeuneaceae**, **Metzgeriaceae**, **Leucomiaceae**, **Pilotrichaceae**) that comprised both mosses and liverworts (Martínez-Torres *et al.* 2011), a record Gradstein suggested might be suitable for the Guinness Book of World Records. The millipede of interest is *Psammodesmus*, ultimately named *Psammodesmus bryophorus* (**Platyrrhacidae**; Figure 180), from a transitional Andean-Pacific montane rainforest in Colombia (Hoffmann *et al.* 2011).

Figure 179. Percentage of bryophyte species on the exoskeletons of *Psammodesmus bryophorus*. Redrawn from Martínez-Torres *et al.* 2011.

Figure 181. The moss *Fissidens* sp. on *Psammodesmus bryophorus*. Photo by Shirley Daniella Martínez-Torres, with permission.

Out of 18 individuals of *Psammodesmus bryophorus* (**Platyrhacidae**; Figure 180), 11 had more than 400 individuals of bryophytes, mostly on the dorsal side. In all, 22 individuals were inspected, and 15 of these had a species mosaic, primarily of *Lepidopilum scabrisetum* (Figure 182), *Lejeunea* sp. 1 (Figure 183-Figure 184), and *Fissidens weirii* (Figure 181) (Martínez-Torres *et al.* 2011). All species were epiphylls except for the two **Fissidentaceae** species, which are typical of soil. The bryophytes were especially located on the keels (Figure 181-Figure 185).

Class Pauropoda

Pauropods (Figure 186) are small, light-colored arthropods that resemble centipedes but are more closely related to millipedes. They live mostly in the soil and leaf litter, but some find mosses to be a suitable habitat (Greenslade 2008). In the temperate rainforests of Tasmania the mosses typically have a higher moisture content than their usual habitats elsewhere, and here one can find numerous **Pauropoda**. Greenslade found fifteen species among mosses in 79 collection records. These species were not common in other habitats of the collections areas, attesting to the importance of the mosses as a habitat.

Figure 186. Typical member of Pauropoda. Photo by David R. Maddison through Tree of Life Creative Commons.

Class Symphyla

This small class includes the common house-hold centipede with the long legs. Symphylans lack eyes, so their long antennae serve as sensory organs. The female

lays her eggs and attaches them in crevices or to moss or lichen with her mouth (Barnes 1982). In the Finnish forests, Biström and Pajunen (1989) found an unidentified member of the **Scutigereidae** (Figure 187) in two samples of *Polytrichum* (Figure 125).

Figure 187. *Scutigereella* sp., member of a family of symphylans known to inhabit bryophytes. Photo by Walter Pfliegler, with permission.

Summary

Bryophytes on the forest floor can provide unique habitats that have moss mite faunas different from that of the leaf litter. However, it is often the interface between the bryophytes and the soil where mites find food and suitable moisture environments.

Epiphytic leafy liverworts with lobules seem to be especially good at providing both a safe site and moisture, and fecal pellet volatile compounds suggest they are also a food source. This lobule niche is especially important in the tropical canopy.

Aquatic bryophytes provide safe sites not only against some predators, but against the rapid current in streams. In peatlands, the need for calcium carbonate, unavailable in the low pH, can be avoided by using calcium oxalate in the hardening of the cuticle.

Peatland genera differ between Europe and North America, with *Limnozetes* and *Malaconothrus* dominating in Canadian peatlands. *Limnozetes* is also the most species-rich and its communities may be useful in characterizing peatlands. Oribatids are the predominant mite group in both European and North American peatlands.

Peatland pools may have *Hydrozetes*. Predation by **Odonata** causes some mites to hide in the concavity of the upper surfaces of *Sphagnum* leaves.

In the Antarctic, bryophytes can have temperatures up to 13°C above the ambient air temperature; some mites are able to supercool. Tropical bryophytes, especially epiphytes, are often rich habitats for invertebrates, including mites. The mites can contribute to the breakdown of canopy litter and thus have a role in nutrient cycling.

Vertical zonations exist among both the bryophytes and the mites, with the canopy increasing stresses due to UV-B light and desiccation. Within a bryophyte mat, zonation can separate communities of the older, brown portions and the young growing tips. The lower brown

portion of these two habitats differs in providing more decaying material, greater moisture, and less exposure to UV-B radiation. The temperature at that depth may be greater or lower than near the surface and is usually buffered compared to apical portions. The apical green portions (growing tips) provide greater ease of movement and fresh moss material for those able to use it as food.

Vertical migrations permit mites to seek suitable combinations of moisture and temperature within the moss mat. Some may migrate in response to predators, and some may migrate as a response to entering a new life cycle stage.

Communities of bryophyte-dwelling mites differ as elevation increases, with both numbers and kinds of species changing. Seasons affect numbers, with most mites becoming dormant during cold seasons. Some mites will migrate lower into the ground or lower portions of the moss to escape cold of winter or heat of summer.

When bryophyte patches are disturbed, corridors help mites to reach other patches, although some will traverse bare rocks and soil to reach a new patch. Dispersal is passive in most cases and does not seem to be facilitated by wind, but mites can be dispersed with their mossy shelter. On the other hand, mobile mites can carry sperm and gemmae to new locations.

Mites can serve as pollution indicators and monitors. Most will decline in numbers under stress of industrial pollution. However, *Hygrobatas fluviatilis* will actually increase in numbers. Most species are sensitive to UV-B light and will respond negatively.

It is likely that moss mites provide a significant role in recycling nutrients from moss communities back to the ecosystem. This miniature ecosystem and the role of its fauna is poorly known and may yield fascinating relationships as we explore the interrelationships.

Ticks, centipedes, and millipedes occur among bryophytes, but both diversity and numbers are low.

Acknowledgments

David Walter provided invaluable insights into the mites and provided a critical review of that portion of this sub-chapter. Andreas Wohltmann checked identifications on the images I obtained from the internet and provided me with replacements and additional images as well as reference material and his own observations of bryophyte-dwelling mites. Benito Tan helped me to obtain the picture of pearling, provided by Loh Kwek Leong. Andi Cairns provided invaluable help in telling the story of the lobule mites and providing images. Thank you to Rob Gradstein and Pina Milne for alerting me to the publications on *Psammodesmus bryophorus*. Many people have contributed to the images; I especially thank all those generous people who have placed their wonderful images in the public domain.

CHAPTER 10-1

ARTHROPODS: CRUSTACEA – COPEPODA AND CLADOCERA

Figure 1. *Simoecephalus* sp. with eggs in the carapace. Note the white *Vorticella* on the lower left edge of the carapace and near the base of the antennae. Photo by Jasper Nance through Creative Commons.

SUBPHYLUM CRUSTACEA

Crustaceans (Figure 1) are those tiny arthropods that most of us have never noticed on the bryophytes. But in some habitats, and some parts of the world, the bryophytes – invaders of land – are home for such terrestrialized arthropods.

This large subphylum is mostly marine or aquatic, including such familiar animals as barnacles, crabs, crayfish, krill, lobsters, and shrimp (Wikipedia: Crustacean 2011). But it is mostly the smaller animals, the microcrustacea, that inhabit the bryophytes. The Crustacea are distinguished from other arthropods by their two-parted limbs (**biramous**; e.g. the pincers on the end of a crab claw or divided antenna of *Daphnia* or *Simoecephalus* – Figure 13) and a life cycle that includes a **nauplius** larva stage (first larval stage of many crustaceans, having an unsegmented body and usually a single eye, Figure 2), although most have additional larval stages after that. Almost all of them have a chitinous exoskeleton.

Figure 2. Nauplius of copepod. Photo from Wikipedia Creative Commons.

Reproduction

Most crustaceans have separate sexes, but some change sex and many are **parthenogenetic**, with females producing viable eggs that develop into new organisms in the absence of fertilization (Wikipedia: Crustacean 2011). Eggs are generally released into the water column, but some **isopods** form a brood pouch and carry their eggs and young around with them. Many **copepods** form egg sacs that hang from the body until the young hatch. **Decapods** typically carry their eggs attached to their swimmerets. The **meiofauna** [small metazoans that pass through 500µm or greater sieves, but are retained on 40 or 62 or 40 µm sieves (Dražina *et al.* 2011)] of springs typically have shorter life cycles, permitting such groups as cyclopoid copepods to have a rapid recruitment ability (Robertson 2002) and other copepods and ostracods to develop rapidly compared to insects, completing their development in only a few months (Dole-Olivier *et al.* 2000).

Dispersal

As with mites and other bryophyte dwellers, microcrustacea might be dispersed on a "magic carpet" – bryophyte fragments on which they are living. Sudzuki (1972) tested this hypothesis by exposing moss-soil samples to wind velocities of 2.9 m s⁻¹. Sampling at distances of 100-400 cm from the "wind" source, they determined that even after 2 months, wind velocities up to 2 m s⁻¹ failed to disperse the Crustacea. Those animals dispersed were primarily protozoa. Nevertheless, encysted animals could get dispersed with bryophyte fragments or even with moss clumps that get carried by small mammals or wind.

Habitat Fragmentation

Microarthropods must move from one leaf patch to another, or from hiding places to food sources. During this time, especially if disturbed during the daytime, they are vulnerable to desiccation. Gonzalez *et al.* (1998) experimented with such fragmented microcosms to determine parameters that led to success of the inhabitants. They found that when microecosystems were fragmented, species declines occurred. But when the patches were connected by habitat corridors, much as has been shown for large mammals, both abundance and distribution of the fauna experienced a rescue effect through immigration. Bryophytes can often serve as such corridors, providing places to replenish lost moisture and to hide from predators.

Gonzalez and Chaneton (2002) used bryophyte habitats for experimentation. They fragmented the bryophyte communities and found that this system likewise experienced loss of both faunal species richness and community biomass. Rare species were more likely to become extinct. Moss habitat corridors that connected fragments to a larger "mainland" of bryophytes permitted immigration and maintained microarthropod richness, abundance, and biomass in the fragments.

While we tend to view corridors as continuous suitable habitats, such continuity is probably not necessary for the larger arthropods like isopods. They can use the bryophyte clumps as islands of safety between larger suitable habitats such as leaf litter.

Habitat Importance

Krebs (2001) reminded us that habitat heterogeneity is related to the creation of more ecological niches. Bryophytes can create many niches, providing protected space for the small microcrustaceans. Srivastava *et al.* (2004) contend that moss-arthropod ecosystems form natural microcosms that are useful for testing such concepts as fragmentation, metacommunity theory, and connections between biodiversity and ecosystem processes. Their small size, short generation times, hierarchical spatial structure, and contained, definable systems provide advantages in conducting field experiments that are subject to natural conditions and interactions with neighboring communities. The authors argue that "natural microcosms are as versatile as artificial microcosms, but as complex and biologically realistic as other [larger] natural systems."

Terrestrial

Acosta-Mercado *et al.* (2012) found strong support for the hypothesis that abiotic factors (especially water chemistry of the bryophytes and pH) are important determinants of terrestrial microcrustacean diversity. They added that water-holding capacity is correlated with the morphology and canopy structure of the bryophytes. Roughness of the bryophyte canopy in the Bahoruco Cloud Forest, Cachote, Dominican Republic, was important in determining differences in species composition. For amoebae, the lowest species richness was on *Acroporium pungens* (Figure 3), a species with low roughness and faunal density, whereas *Thuidium urceolatum* had the highest roughness index, highest faunal richness, and highest species density. But for the 26 microcrustacean morphospecies among 11 bryophyte species, there was no detectable canopy effect on faunal richness or density. The lowest density of 1 individual per 50 cm² was on the cushions of *Leucobryum* (Figure 4) with a maximum of 6±3.37 on the same area of the thallose liverwort *Monoclea* (Figure 5), suggesting that openness of the community might play a role in diversity.

Figure 3. *Acroporium pungens* in the Neotropics, a species with low roughness and low faunal density. Photo by Michael Lüth, with permission.

Figure 4. *Leucobryum glaucum* cushion, a species with low faunal density. Photo by Janice Glime.

Figure 5. *Monoclea forsteri*, a liverwort that harbors a relatively high microcrustacean diversity. Photo by Jan-Peter Frahm, with permission.

Peatlands

Peatlands, for our purposes those habitats dominated by *Sphagnum* and not including other types of peatlands (Figure 6), provide a mix of moist and dry mosses and pools influenced by those mosses. The "terrestrial plankton" are often sensitive to high CO₂ concentrations and low O₂ tensions such as those found among rotting leaves and other areas with high rates of decomposition (Stout 1963). For these organisms with good tolerance for low pH (sometimes below 4.0), *Sphagnum* provides a suitable habitat. Krebs (2001) found that the center of the *Sphagnum* moss mat had a higher species diversity than the edges, perhaps due to additional niches (habitat heterogeneity) resulting from the plant-associated species dwelling there.

On the other hand, the low pH created through cation exchange and organic acids produced by mosses in the genus *Sphagnum* (Figure 6) is detrimental to many organisms. Hillbricht-Ilkowska *et al.* (1998) examined the role of pH on Crustacea and other organisms by providing powdered lime to the system. Measurements after 1-4 years and 20-23 years indicated that both the water Ca and that of the sediment were permanently raised. This change coincided with a significantly increased rate of decomposition and an increase in species richness and diversity of crustaceans, among others. Overall diversity was doubled. The treatment eliminated peatmosses from encroaching on the lake but had no effect on those of the surrounding area.

Figure 6. Bohemia bog with *Sphagnum cuspidatum*, *S. denticulatum*, and others, showing the varied habitats of hummocks, hollows, and small pools available to bog fauna. Photo by Jonathan Sleath, with permission.

To add to this image of *Sphagnum* (Figure 6) as an unfriendly substrate, Smirnov (1961) stated that few animals were specialized to gain their nutrition by consuming emerged *Sphagnum*. He cited only one species of flies whose larvae are known to feed directly on *Sphagnum*. On the other hand, in such *Sphagnum* lakes the bladderwort, an insectivorous plant, traps and digests Crustacea such as *Daphnia* (Cladocera) – a not so friendly place for many.

But *Sphagnum* (Figure 6) may play a more positive role in the lives of these fauna. *Sphagnum* has long been known for its antibiotic properties; it was used as a wound dressing in WWI. Could it protect the crustaceans from fungal or bacterial attacks? Furthermore, for these invertebrates it may serve as a refugium – a place to escape predators (Kuczyńska-Kippen 2008), possibly due to its antifeedant properties as well as small hiding places.

Springs

Among the favored habitats of limnoterrestrial (living in wet films on land) Crustacea are mosses of springs, *i.e.* these Crustacea are crenophilous, where temperature and pH were important determinants of community composition in four Northern Apennine springs (Bottazzi *et al.* 2011). Mosses in these springs usually had harpacticoid copepods and ostracods representing the Crustacea. The moss inhabitants had a seasonality, whereas drift assemblages did not. Bottazzi *et al.* suggest that the mosses were important in increasing the species diversity in these springs.

Springs are often a transitional habitat between aquatic and terrestrial systems. Even within the spring habitat, such a transition is typical, and moisture zones within the habitat can change as the seasons and weather change. Thus, the bryophytes of this habitat provide not only a refuge, but an avenue (more like a labyrinth) where macroinvertebrates can travel to escape the receding preferred moisture level.

Crustacea are not usually seen among bryophytes, but in some areas they can be quite abundant. For example, Michaelis (1977) reported that at Pupu Springs in New Zealand, there were ten species of bryophytes. The fauna included Crustacea among the most abundant groups. Suren (1993) suggests that the abundance of crustaceans in the New Zealand bryofauna may be due to the absence of some of the bryophyte dwellers found elsewhere, *i.e.* some families of Trichoptera (caddisflies), Plecoptera (stoneflies), and Ephemeroptera (mayflies).

Bottazzi *et al.* (2011) reported the **ostracods** and **Harpacticoida** (an order of copepods) among the three most abundant taxon groups among mosses in northern Apennine **rheocrene springs** (springs that become streams immediately upon emerging from the ground). Like Michaelis (1977) and Suren (1993), they suggested that favorable habitats, including mosses, accounted for the high diversity and the large numbers of these two crustacean groups.

Bottazzi *et al.* (2011) concluded that emergent mosses were important in increasing species diversity of these springs (see also Barquín & Death 2009; Ilmonen & Paasivirta 2005). Bryophytes act as an ecotone between the aquatic and terrestrial habitat by creating a range of microhabitats that vary both horizontally and vertically (Lindgaard *et al.* 1975; Thorup & Lindgaard 1977), including the **madicolous** zone (having thin sheets of water flowing over rock surfaces). These provide a range of moisture conditions that permit the meiofauna to migrate to a more suitable location as moisture conditions change. While providing a refuge from rapid flow (Madaliński 1961; Elliot 1967; Gurtz & Wallace 1984; Suren 1992; Glime 1994), bryophytes provide a variety of food sizes in trapped particulate matter (Habdija *et al.* 2004). Linhart *et al.* (2002c) demonstrated a direct association between harpacticoid copepods, including nauplii, and trapped organic and mineral matter among the mosses.

Lindgaard *et al.* (1975) found that in the Danish spring at Ravnkilde these vertical and horizontal differences among the bryophytes provided a source of diversity among the macroinvertebrates. They found that whereas the horizontal zonation sported different assemblages of species, the fauna of the neighboring stones had little influence on the moss fauna. More importantly, the flow rate and available detritus as a food source could account for the horizontal differences.

Lindgaard *et al.* (1975) found that the numbers of individuals fluctuated throughout the year, corresponding with changes in the life cycle stages of the dominate species. Bryophyte habitation is also seasonal in Northern Apennine springs, with a maximum in the spring and minimum in winter, whereas seasonal habitation is nearly constant in non-bryophyte areas sampled by the traps Bottazzi *et al.* (2011). On the other hand, permanent meiofauna had its minimum in autumn; temporary meiofauna of the mosses peaked in spring, then decreased thereafter.

Streams

Bryophytes in streams create a rich source of invertebrate fauna, so much so that the aquatic moss *Fontinalis antipyretica* (Figure 7) was transplanted to streams in South Africa to increase the food source for

trout (Richards 1947). The bryophytes are able to provide a refuge from fast-flowing water and to increase stream heterogeneity (Tada & Satake 1994; Wulforst 1994; Dražina *et al.* 2011).

Figure 7. *Fontinalis antipyretica*. Photo by Jan-Peter Frahm, with permission.

Despite their seeming rarity among bryophytes, Amos (1999) included ostracods, cladocerans, copepods, and amphipods as "life in the torrent" in the UK – a description of the inhabitants of *Fontinalis* (Figure 7). His point was that "all was quiet" at the bottom of the moss clump despite the torrent occurring at the surface.

Linhart *et al.* (2002a), in Europe, found that regulated channels had a much greater meiofauna, including **Cladocera** and **Harpacticoida** (copepods), when the channel was overgrown by aquatic bryophytes, in this case *Fontinalis antipyretica* (Figure 7). In a different stream, the meiofauna of mosses was an order of magnitude higher than that in the surrounding mineral substrate (Linhart *et al.* 2000), but the crustaceans were not a significant part of this fauna. Rather, the density of the **Harpacticoida** was the second most abundant group in the gravel, where the fine particulate matter was also highest compared to that among the mosses. They further determined that high flow rates approaching the mosses had a negative impact on the crustaceans [**Cladocera**, **Ostracoda**, and **Cyclopoida** (an order of copepods)], although the velocity seemed to have no effect on the **Harpacticoida** (Linhart *et al.* 2002b, c). They suggested that fine detritus trapped by the *F. antipyretica* provided food for the **harpacticoid copepods**. It is interesting that in their 2000 study Linhart *et al.* suggested that it is "questionable whether *F. antipyretica* can serve as a refuge from the current for stream meiobenthos," a seeming contradiction to their conclusions in a different stream. It appears that food is the primary factor in distribution of the microcrustacea, but that does not rule out the role of the mosses as a refuge when sufficient food is present.

Collection Methods

Methods of collection can have a biasing effect on the relative numbers of taxa collected. Copepods and other **Crustacea** in aquatic habitats can be collected by squeezing mosses into a collection bottle or squeezing the mosses in place and collecting the crustaceans downstream from the mosses with a plankton net (Gerecke *et al.* 1998; Reid 2001; Stoch 2007). Copepods, ostracods, and

amphipods may all be extracted from forest litter by the Berlese funnel, but as the litter dries out many will perish before they can escape (Stout 1963). Heat extraction can present the same problem. Chapman (1960) was successful in extracting terrestrial ostracods alive by slowly drying out the leaf litter (but it would work for bryophytes as well) in a Berlese funnel, using a water-jacket at 40° C to avoid overheating, in which case the ostracods close their valves and stop moving. The end of the funnel led to water rather than alcohol.

CLASS BRANCHIOPODA, ORDER CLADOCERA

The class name of **Branchiopoda** literally means gill feet and refers to the **pereiopods** by which the aquatic species can swim. The order name **Cladocera** derives from the Ancient Greek κλάδος (kládos, "branch") and κέρας (kéras, "horn").

Adaptations

Structural

Cladocera are a predominately aquatic group of small individuals known as water fleas (no relationship to the insect group of fleas). They swim using their antennae, using a series of jerks similar to the hops of a flea. Some have adapted to terrestrial habitats with free water, such as bromeliad basins. Others are able to use the film of water from the capillary spaces and leaf surfaces of bryophytes. Not only are the antennae important for swimming, but they are also powerful chemical sensory organs (Ecomare 2014). They can use these not only to find food, but also to detect the presence of enemies. The body of a cladoceran is a valve-like carapace that covers an unsegmented thorax and abdomen. Adults have a single compound eye.

Life Cycle Strategies

Cladocerans spend most of their lives as a female population that reproduces multiple times asexually by **cyclical parthenogenesis**. When conditions become unfavorable, they produce male offspring and subsequently reproduce sexually, producing resting eggs that remain within the carapace (*Daphnia*; Figure 8). In this state, they can dry out and travel long distances on wind currents or as hitch hikers on other travelling animals or even moss fragments. In fact, some of these dormant eggs are known to remain viable for 70-80 years in Lake Superior sediments (Kerfoot & Weider 2004) and can even survive the digestive tracts of birds (Figuerola & Green 2002).

Habitats

Cladocera are primarily aquatic and marine, but a few are adapted to terrestrial living, taking advantage of films of water, pools in bromeliads, and other surfaces where they have easy access to water when they are active.

Terrestrial

Since Cladocera live primarily in fresh or marine water, living on land requires special adaptations for both water conservation and locomotion. It seems that few cladoceran species have accomplished this, or we simply

haven't found them yet. There are indications that appendage reduction is a terrestrial adaptation in this group. After all, why waste energy to make appendages that are not useful. Frey (1980) describes the non-swimming chydorid *Bryospilus* (Figure 9) from wet cloud forests as lacking a compound eye, a change that still requires explanation. The genus resembles the limnoterrestrial genus *Monospilus*, possibly through convergence. They exhibit reduced setation on their antennae and trunk limb, perhaps facilitating their slow crawl among wet bryophytes as high as 3-5 m above the forest floor.

Figure 8. *Daphnia pulex* with three eggs shown here to the right of the digestive tract. Photo by Paul Hebert, through Wikimedia Commons.

Figure 9. *Bryospilus repens*, a chydorid cladoceran that lives mostly in wet moss.. Photo by Francisco D. R. Sousa <Cladocera.wordpress.com>, with permission.

Existing 3-5 meters above the rainforest floor are Cladocera that crawl from place to place, unable to swim. Frey (1980) reported the cladoceran *Bryospilus repens* (Figure 9), a semiterrestrial species known from wet mosses in Puerto Rico, Venezuela, and New Zealand, and

Bryospilus bifidus from New Zealand, both in the same subfamily of Chydoridae as *Alona* (Figure 10-Figure 11), a common cladoceran from springs. Resting eggs are often buried in deep masses of vegetation (Powers & Bliss 1983) where they are protected from water loss. Dispersal of fragments of mosses they inhabit can aid in dispersal of both eggs and adults to new sites. Frey suggested that the mossy habitat in the rainforest exhibited the same continuity through time as ancient lakes, thus being a likely site for even more endemic species. Van Damme *et al.* (2011) consider *B. repens* (Figure 9) to be a "well known" species that lives in wet moss. They consider its occasional presence in river samples to be the result of individuals that got washed into the river from these mossy homes.

There may be more species of these tiny cladocerans hiding among bryophytes in terrestrial habitats. These organisms are typically studied by aquatic biologists who spend their time looking at plankton. Terrestrial bryophyte habitats are rarely studied with the aim of locating **Cladocera**. I have to wonder if somewhere there might be some Cladoceran species living in liverwort lobules.

Peat Bogs

Living among *Sphagnum* (Figure 6) or in the bog pools requires a tolerance of low pH. Nevertheless, *Sphagnum* can increase the abundance of **Cladocera** by as much as tenfold in Swedish peatlands (Henrickson 1993). The heterogeneity of the *Sphagnum* habitat illustrated in Figure 6 provides shelter and refuge against predation while being a suitable foraging site. The bryophytes further contribute to this habitat through their production of antibiotics, organic acids, and cation exchange.

Bog lakes can support a number of species of Cladocera. Minelli (2004) listed *Alona quadrangularis* (Figure 10), *Alona affinis* (Figure 11), *Simocephalus exspinosus* (Figure 12), *S. vetulus* (Figure 13), and *Ceriodaphnia pulchella* as being among the common species in bog lakes in Italy. Hingley (1993) reported *Streblocerus serricaudatus* (Figure 14) and *Acantholeberis curvirostris* (Figure 15) swimming in UK peat pools. Macan (1974) likewise reported the latter species in *Sphagnum* (Figure 6). *Chydorus piger* (Figure 16) is typical of bare substrates such as rock or sand, but including *Sphagnum*, and is known from acidic pools in peatlands in Europe (Duigan & Birks 2000).

Kairesalo *et al.* (1992) considers the peatland habitat to be unsuitable for *Daphnia* (Figure 17) because the available food is "recalcitrant." In a lake in southern Finland that was bordered by the mosses *Warnstorfia* (Figure 18) and *Sphagnum* (Figure 6), the organic carbon excreted by *Warnstorfia* suppressed the growth of planktonic algae and provided little contribution to bacterial productivity. This meant that bacterial productivity was necessarily dependent on humic acids for their carbon source, resulting in decreased availability of this food source for the *Daphnia*. The predominantly particulate matter in the water was largely useless for the *Daphnia* as a food source.

Cladocera have played a role in reconstructing the history of some peatlands. Duigan and Birks (2000) report on *Sphagnum* (Figure 6) and other bryophytes from 9200 BP microfossils in western Norway with *Alonella nana* (Figure 19), *Alonella excisa* (Figure 20), and *Alona rustica* (Figure 21). *Alona rustica* is also known in peat bogs among mosses in Italy (Minelli 2004).

Aquatic

Lakes

Typically, cladocerans are rare among aquatic mosses, being adapted for planktonic life. However, in the subAntarctic lakes of South Georgia, the most common invertebrate was the cladoceran genus *Alona* (Figure 22), with 2544 individuals in a liter of water (Hansson *et al.* 1996). Several species in this genus were present, with the greatest numbers among mosses that extended into shallow lakes. In fact, the littoral mosses had the highest number of invertebrate species (20) and abundance (1539 individuals) of invertebrates in those lakes. With increasing UV levels reaching the shallow Antarctic lakes, mosses may provide refugia that protect these invertebrates from UV damage.

Figure 22. *Alona* sp., a genus with a number of terrestrial bryophyte-dwelling species. Photo by Yuuji Tsukii, with permission.

Van Damme *et al.* (2011) explain the absence of *Alona karelica* in littoral samples of European lakes by suggesting that it may actually be a terrestrial cladoceran that is normally associated with moss. This species has been reported twice from *Sphagnum* (Figure 6) in Europe (Flößner 2000; Kuczyńska-Kippen 2008) and its European distribution coincides with that of regions of high *Sphagnum* diversity (see Séneca & Söderström 2008; Van Damme *et al.* 2011). Another species of *Alona*, *A. bromelicola*, is from Nicaragua and lives in the basins of bromeliads (Van Damme *et al.* 2011). Yet another species, *Alona rustica* (Figure 21), is present in collections of bryophytes from stream banks in Italy (Margaritora *et al.* 2002), another transitional habitat. Such transitional habitats often have both higher diversity and density of organisms, a phenomenon known as the **edge effect** (Leopold 1933; Lay 1938; Good & Dambach 1943; Bider 1968; Wiens 1976).

Kuczyńska-Kippen (2008) examined the role of *Sphagnum* (Figure 6) compared to open water for zooplankton in a lake in Poland. The highest species diversity values occurred in the peat mat (mean = 0.67 for crustaceans compared to 1.76 for rotifers), whereas the

lowest values occurred in open water (0.36 and 0.99 respectively). The cladocerans present in the transition zone between the peat mat and the open water seem to relate to the presence of both invertebrate and vertebrate predators, and competition between the large cladocerans and smaller rotifers. For the cladocerans, *Sphagnum* (Figure 23) can serve as a refugium to protect them from other invertebrate predators.

Figure 23. *Sphagnum cuspidatum* mat (foreground) and nearby hummock (upper left), habitats where one can find more Cladocera than in the open water (upper left). Photo by Michael Lüth, with permission.

Cammaerts and Mertens (1999) discovered *Bryospilus repens* (Figure 9) in the **Palaeotropics** (tropical areas of Africa, Asia, and Oceania, excluding Australia) of western Africa, where it occurred in vernal pools of forests. This dispels the notion that this genus is strictly a moss dweller.

One problem in sorting out the Cladocera-bryophyte relationship is that species descriptions frequently fail to include the substrate, reporting only the general habitat, if even that.

Streams

Stream drift, a popular topic in the 60's and 70's, is generally a phenomenon we relate to the insects and other macroinvertebrates. But microcrustacea can be part of this as well. For moss-dwelling Cladocera, this is a means to get from one moss clump to another in an unfriendly moving environment. Peric *et al.* (2014) found that of 60 invertebrate taxa in a moss-rich karst system in Croatia, six were annelids and arthropods from the meiofauna, representing 35% of the total drift, but among the most abundant drift organisms were several species of *Alona* (26.7%) (Figure 22), a cladoceran known for being a moss-dweller (Hansson *et al.* 1996; Van Damme *et al.* 2011). The drift was lowest in winter and highest in autumn and late spring to early summer.

CLASS MAXILLOPODA, SUBCLASS COPEPODA

The name **Copepoda** comes from the Greek word *κοῦπιπποδ*, which literally means oar-feet (Wikipedia: Copepod 2014). Copepods are microcrustacea, mostly 0.5-2 mm (Encyclopaedia Britannica 2012), usually occurring as planktonic or benthic organisms and not ones we would

expect to be frequent in moss communities. The entire group comprises about 13,000 species with three of its ten orders being the most common (**Harpacticoida**, **Cyclopoida**, **Calanoida**) and containing the ones known from bryophytes (Wikipedia: Copepod 2014). Copepods have two pairs of antennae and a single red compound eye (in most). They are perhaps the fastest organisms alive, swimming in irregular spurts (Kiørboe *et al.* 2010). Some of the meiofauna taxa have switched to **direct development** (lacking the larval stage) and care of their young (Dahms & Qian 2004), traits that are absent in most copepods but that are beneficial in a terrestrial environment.

The **Harpacticoida** (Figure 24) have a short pair of first antennae (Figure 25), often a somewhat wormlike body, and are mostly benthic (living on the bottom) (Wikipedia: Harpacticoida 2013). Nevertheless, Dumont and Maas (1988) consider the harpacticoid copepods to be widespread in wet habitats such as wet mosses. The harpacticoid copepods include crawlers, walkers, and burrowers (Dole-Olivier *et al.* 2000), pre-adapting the crawlers and walkers to mobility in the water film of bryophytes.

Figure 25. *Canthocamptus*, a harpacticoid copepod showing antennae. Photo by Yuuji Tsukii, with permission.

The **Cyclopoida** (Figure 26) are mostly **planktonic** (live in water column and float or drift – can't swim against a current) (Wikipedia: Cyclopoida 2013). Their antennae are longer than those of Harpacticoida but shorter than those of Calanoida, reaching no farther than the thorax. They are capable of rapid movement.

Figure 26. *Cyclops vicinus*, a cyclopoid copepod carrying egg sacs. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

The **Calanoida** (Figure 27) are also mostly planktonic species (Wikipedia: Calanoida 2013). Unlike the short antennae of the Harpacticoida, the first antennae of the Calanoida extend about half the length of the body or more.

Figure 27. *Neocalanus cristatus*, a calanoid copepod showing the long antennae. Photo by Seward Line <www.sfos.uaf.edu>, with online permission for educational use.

Copepods are known for their egg longevity, with some surviving as much as 322 years (Hairston *et al.* 1995).

Adaptations

Copepods, like several other crustacean groups, have evolved to a terrestrial life style, but still live where water is generally available (Stout 1963). Bryophytes provide such a habitat. Stout suggests that through evolutionary time both copepods and ostracods moved from streams to adjoining moss carpets and currently are able to live among *Sphagnum* (Figure 23) as well as forest litter (Harding 1953, 1955).

Bryophyte-dwelling copepods are not very numerous, which probably explains, in part, the absence of descriptions of adaptations to the bryophytic habitat. Nevertheless, one might consider the adaptations to a terrestrial life style as exemplary of bryophytic adaptations. One such adaptation is the absence of hemoglobin (Green 1959). This is a stretch, because it appears that this pigment has evolved primarily in those species with a parasitic life style and a limited number of mud-dwelling taxa. Nevertheless, it suggests that oxygen is in adequate supply in the bryophytic habitat, so energy-requiring pigment development is not necessary.

Structure

The moss-dwelling **nauplius** (larval stage; Figure 28) of the copepod uses its antennae for swimming and possesses a single eye that can disappear in some species in later developmental stages. The copepod eye, in at least some species, senses the direction of light and permits the copepod, by moving its tail, to keep its back oriented toward the light (Land 1988). This behavior furthermore permits the copepod to distinguish its own species from other species by the movement patterns. Directed movement in response to light seems to be useful in minimizing exposure to UV light in tidal areas (Martin *et al.* 2000). These light avoidance behaviors are probably less useful among bryophytes.

Figure 28. Copepoda nauplius, the immature state. Photo by Graham Matthews <http://www.micromagus.net/microscopes/pondlife_copepoda.html>, with permission.

Life Cycle Strategies

Whether living in water that freezes, pools that dry up, or among mosses and other terrestrial habitats, life cycle strategies are important in enduring unfavorable seasons

(Santer 1998). Terrestrial habitats are all unstable. Evolution favors traits that help the copepods sense and prepare for these potentially deadly periods. These strategies include dormancy and migration as escape mechanisms, but also include synchronizing growth and reproduction with favorable periods.

Dormancy is a common trait among copepods, particularly in higher and temperate latitudes (Dahms 1995; Williams-Howze 1997). It permits them to survive periods of desiccation and other unfavorable conditions. The timing of dormancy varies with the species and can occur in different forms in multiple life cycle stages, including desiccation-resistant resting eggs, arrested larval development, **encystment** of juveniles and adults (Deevey 1941; Dahms 1995), and arrested development of adults (Dahms 1995; Williams-Howze 1997). Dormancy saves energy during a time when living conditions are unfavorable. In addition to facilitating copepod survival during desiccation, dormancy helps copepods escape unfavorable temperatures, insufficient oxygen availability, limited food availability, and predation.

Among these dormancy strategies, one potential adaptation is encystment. *Canthocamptus staphylinoides* (Figure 29) is a harpacticoid copepod that encysts (Deevey 1941). Some members of this genus are known from mosses in the aquatic environment and peat bogs, where encystment can permit them to survive not only desiccation but also unfavorable temperatures.

Figure 29. *Canthocamptus staphylinoides*. Photo from US Geological Survey, through public domain.

Diapause can be defined as a delay in development in response to regular and recurring periods of adverse environmental conditions. In its narrow sense, it is initiated and terminated by triggers such as photoperiod, temperature, chemical cues, population density, and physiological factors (Dahms 1995).

Feeding

Fryer (1957a, b) considered chance encounter to be a primary mechanism in finding food for the mostly planktonic copepods. Nevertheless, chemoreceptors help them to distinguish edible from inedible food particles and thus may help somewhat in locating food. The carnivorous diet appears to be the primitive condition, with the change to an algal diet facilitating adaptive radiation.

Habitats

Reid (1986, 1987, 1999, 2011) has contributed considerably to our knowledge of bryophyte-dwelling

copepods. She reported them from such overlooked habitats as mosses (including *Sphagnum* – Figure 23) and liverworts, as well as from tree holes (Reid 1986). She described the new species *Muscocyclops thersasiae* from Brazil, primarily from soils, but also from mosses. Reid (2001) considered the publications on the harpacticoids and small cyclopoids from mosses in humid climates to be so numerous that they were almost impossible to review. She found that such "aquatic" mosses as *Sphagnum* (Figure 23) and *Hypnum* (Figure 30) as well as those bryophytes from more humid habitats provide homes for their own unique communities of copepods. Stoch (2007) attributes the copepod abundance to the complex spatial structure and high availability of food resources among bryophytes. In their study on *Fontinalis antipyretica* (Figure 7) meiofauna in Central Europe, Vlčková *et al.* (2002) found that harpacticoid copepods were able to feed on organic matter in the size range of 30-100 µm trapped within the moss clumps.

Figure 30. *Calliergonella lindbergii* (= *Hypnum lindbergii*), a moss genus where copepods are known to live. Photo by Jan-Peter Frahm, with permission.

Terrestrial

One would not expect a plankton organism like the copepods to occur on mosses on land, but a few have managed to venture into that habitat. Paul Davison (pers. comm. 9 November 2011) reported to me that harpacticoid copepods are well known from terrestrial mosses, but finding documentation of that has been challenging. Menzel (1921, 1925) reported both cyclopoid and harpacticoid copepods as moss dwellers. Bryophytes do not harbor a rich fauna, so they have not attracted much attention from the copepodologists. Nevertheless, those copepods that live among mosses can, at times, be important to ecosystem functioning. For example, the harpacticoid copepods are a first food source for the young salamanders living near and among the mosses (Paul Davison, pers. comm. 9 November 2011) (See Epiphytes below).

Scattered reports of terrestrial bryophyte-dwelling copepods, especially harpacticoids, occur in the literature (e.g. Olofsson 1918; Lang 1931), including mosses

(including *Sphagnum* – Figure 23) and liverworts as habitat.

The genus *Bryocamptus* seems to be among the more common taxa in the Eastern Hemisphere. *Bryocamptus pygmaeus* and *B. zschokkei* (Figure 31) occur primarily among mosses in Central Europe (Illies 1952). Harding (1958) reported *Bryocamptus stouti* from mosses in New Zealand.

Figure 31. *Bryocamptus zschokkei* female, a moss dweller. Photo from US Geological Survey, through public domain.

Lewis (1984) reported twelve species of harpacticoid copepods from terrestrial mosses in forests and open areas in New Zealand. Lewis (1972a) found copepods in New Zealand among forest mosses that remained moist most of the year. These included *Elaphoidella silvestris* (see Figure 32), a copepod among damp mosses on the forest floor or nearby, but this species is limited to the damp conditions of higher altitude bush areas of North Island and dripping wet forests of the West Coast of South Island.

Figure 32. *Elaphoidella bidens*. Members of this genus live among damp mosses on the forest floor of New Zealand. Photo through Creative Commons.

Mrázek (1893) found the harpacticoid copepod *Maraenobiotus vej dovski* among mosses in Bohemia, and Harding (1953) reported them from woodland mosses in Scotland. These copepods are small and slender, permitting them to live an aquatic life in the water film among mosses (Harding 1953).

Scourfield (1939) reported *Bryocyclops* and *Muscocyclops* as living among mosses in Wales. With a name like *Bryocyclops muscicola*, one expects to find a moss-dweller. Reid (1999) reported this species, originally described from Indonesia, from a plant nursery in Florida, USA, apparently introduced with some of the plants, perhaps mosses. This is the only species of *Bryocyclops* known from continental US, although *Bryocyclops caroli* is known from Puerto Rico. In the Eastern Hemisphere the genus seems to be more common than in the Western Hemisphere, or perhaps just better known.

Menzel (1926) described the new species *Bryocyclops anninae* from moist mosses in Java and reported

Bryocyclops bogoriensis from the Fiji Islands among mosses and in tree holes. More recently, Watiroyram *et al.* (2012) listed ten additional wet moss dwellers in the genus *Bryocyclops* in Thailand, mostly near springs and waterfalls.

Harding (1953) reported that *Epactophanes* (Figure 54) and *Maraenobiotus* live in damp mosses in Europe. *Epactophanes muscicola* (in UK) avoids mosses that are very wet. Michailova-Neikova (1973) found that of the nine harpacticoid copepods living among wet mosses near water bodies on a mountain in Bulgaria, eight also lived among leaf litter.

In an apparently rare Western Hemisphere record of bryophyte dwellers, Rocha (1994) described *Metacyclops oraemaris* as a new species from moist moss in São Paulo, Brazil. In neighboring Suriname, Menzel (1916) found *Parastenocaris staheli* (see Figure 33) among mosses in the old leaf axils of the palm *Livingstonia*.

Figure 33. *Parastenocaris lacustris* female, member of a genus with species that live among epiphytic mosses. Photo from US Geological Survey, through public domain.

North American records seem to be almost non-existent. Nevertheless, Margaret (Maggie) Ray (pers. comm. 9 November 2011) told me that she found copepods in many of her bryophyte samples across North Carolina, USA. Paul Davison (pers. comm. 9 November 2011) likewise has often found them among bryophytic epiphytes in Alabama. Others have reported on them as a group (Camann 2011; Camann *et al.* 2011).

Seepage Areas – Seepage areas, typically with bryophytes, seem like a logical place to look for limnoterrestrial copepods. Scourfield (1932) found *Bryocyclops pygmaeus*, a common species, and *Speocyclops dimentiensis* among mosses of seeps on rock outcrops at Tenby in Wales. In New Caledonia, Hamond (1987) found *Fibulacamptus* among wet mosses as well as other wet terrestrial substrata.

Fiers and Ghenne (2000) suggested an interesting role for mosses in forests. They provide epigeal highways, especially for the tiny (~0.5 mm long) species, that help to connect the various patches of leaf litter and moist soils while also serving as a temporary or permanent habitat.

Epiphytes – It is interesting that one can see canopy food webs similar to those in the water, with bryophytes forming the habitat structure. In a (regrettably) rare North American study, Camann and coworkers (Camann 2011; Camann *et al.* 2011) report communities at 84 m above the forest floor in the redwood forest of California, USA. In these humus moss patches harpacticoid copepods dwell, encysting when conditions get dry. And further up the food web are Wandering Salamanders (*Aneides vagrans*; Figure 34), likewise bryophyte dwellers, that use the copepods as food. Most likely there are birds or other vertebrates that prey on the salamanders.

Figure 34. *Aneides vagrans*, a salamander whose larvae feed on terrestrial copepods. Photo by John P. Clare, through Creative Commons..

Antarctic

Pesta (1928) described the harpacticoid copepod *Attheyella koenigi* (Harpacticoida: Canthocamptidae; see Figure 35) from mosses in a stream on the island of South Georgia in the Antarctic. Also on the island of South Georgia, it is likewise the family Canthocamptidae that has the only known copepod species living among mosses at the edges of shallow lakes (Hansson *et al.* 1996). Although only three larval forms were found, the mosses were the only location where these copepods appeared in that study of Antarctic lakes. Also among these Antarctic dwellers is the harpacticoid copepod *Marionobiotus jeanneli* (family Thalestridae) living among wet mosses (Pugh *et al.* 2002).

Peat Bogs and Sphagnum

Bog lakes and pools in peat bogs are often rich in copepod species (Minelli 2004). In the Italian bog pools and lakes (and likely throughout most of Europe as well), the copepods are represented by the orders Cyclopoida and Harpacticoida. The most abundant species are typically widespread predators, including *Megacyclops viridis* (Figure 36), *Macrocyclus albidus* (Figure 37-Figure 38), and *Diacyclops bicuspidatus* (Figure 39), and algal or detritus feeders including *Paracyclops fimbriatus* (see Figure 48), *Eucyclops serrulatus* (Figure 55), *Thermocyclops dybowskii* (see Figure 40), and *Tropocyclops prasinus* (Figure 41). *Megacyclops viridis* seems to have been introduced to the Great Lakes of North

America; in Austria it is commonly associated with salt pools (Kipp *et al.* 2012). The most common species in high-altitude peat bogs of Europe is *Acanthocyclops vernalis* (Figure 42), reaching an altitude of 2800 m in the Alps.

Peat bogs, with a ground cover of *Sphagnum* species (Figure 43), provide the film of water needed by limnoterrestrial copepods. *Diacyclops languidus* and *D. hypnicola* (see Figure 44) are small species adapted to living in the water film on the mosses and characteristic of peat bogs in the Alps, Apennines, and central and northern Europe (Minelli 2004). Among European alpine *Sphagnum* and other moss cushions one can find *Bryocamptus pygmaeus*, *Epactophanes richardi* (Figure 54), and *Phyllognathopus viguieri*. Barclay (1969) found the latter species in New Zealand among mosses at the base of gravel piles in the winter when the mosses become quite soggy. A species of *Bryocyclops* is common in this same habitat.

Figure 43. *Sphagnum* blanket bog. Photo through Creative Commons.

Figure 44. *Diacyclops* sp., a genus of small copepods with some species adapted for living in the water film of bog mosses. Photo from USGS, through public domain.

Stoch (1998b) originally described the new species *Moraria alpina* and re-described *M. radovnae* (see Figure 45) from the Alps of Italy and Slovenia, where they occurred among mosses, in bogs, and in interstitial spaces in brooks. Additional European alpine species, for example *Bryocamptus veidovskji*, *Elaphoidella gracilis*, *Moraria mrazeki*, *M. alpina*, *Maraenobiotus veidovskji*, and *Hypocamptus brehmi*, live only in peat bogs and interstitial mountain habitats (Minelli 2004). In Britain, one can find *Moraria arboricola* among *Sphagnum* (Figure 43), as well as in leaf litter and tree hole pools (Fryer 1993). It seems none of these are strict **tyrphobionts** (living only in peat bogs and mires).

Figure 45. *Moraria laurentica* female, member of a genus including moss dwellers in the Antarctic South Georgia Island and known from mossy swamps and wet mosses on stream banks in the Great Lakes area, USA. Photo from US Geological Survey, through public domain.

Herbst (1959) reported *Metacyclops paludicola* and *Ectocyclops herbsti* (see Figure 46) from a *Sphagnum* bog in São Paulo, Brazil. Hingley (1993) reported *Moraria sphagnicola* (see Figure 45) and *Canthocamptus weberi* (see Figure 47) as associated with *Sphagnum* (Figure 43) in Europe. In addition to living in mossy tarns, *Attheyella* (*Delachauxiella*) *brehmi* and *Attheyella* (*Chappuisiella*) *maorica* (see Figure 35) occur among *Sphagnum* in New Zealand (Lewis 1972a).

In peatlands, the mosses can have an indirect influence on the fauna due to the tracheophytes they support. The rare North American copepod *Paracyclops canadensis* (Figure 48) is common in the pool of water in the leaves of the pitcher plant (*Sarracenia purpurea*, Figure 49) (Hamilton *et al.* 2000). In *Sphagnum* (Figure 43) peatlands, the mosses are a necessary habitat element to support the growth of pitcher plants.

Aquatic

Reid (2001) reported that squeezing aquatic mosses would reveal small copepods such as members of *Acanthocyclops* (Figure 50-Figure 51), *Diacyclops* (Figure 52), and other small cyclopoid genera (Gurney 1932; Scourfield 1932, 1939). Aquatic bryophytes can provide cyclopoid genera with safe sites from strong flow, hide them from predators, and trap particulate matter that serves as food.

Mossy Tarns

Tarns (Figure 53) are small mountain lakes. For the crustaceans, the mossy tarn habitat is similar in many ways to peatland pools, but it may differ in its pH and does not necessarily have *Sphagnum* (Figure 43) or may have different *Sphagnum* species. Several copepod species seem to prefer mossy tarns in New Zealand (Lewis 1972a). Among these are *Attheyella* (*Delachauxiella*) *brehmi* and *Attheyella* (*Chappuisiella*) *maorica* (species known to occur among *Sphagnum*; see Figure 35) and *Attheyella* (*Delachauxiella*) *bennetti*, genera known also from peatlands.

Figure 53. Tarn in Siskiyou Wilderness, CA, USA. Photo by Miguel Vieira, through Creative Commons.

Springs

Stoch (2007) found that mosses in springs in Italy were particularly good habitats for copepods, supporting large numbers. This may be due to their complex structure and highly available food sources. At the same time, the spring-dwelling species are often not true **crenobionts** (occurring only in springs and spring brooks) (Stoch 1998a), also occurring in other damp or aquatic habitats such as the littoral zone of lakes, moist mosses elsewhere, in groundwater, and in the epirithral region (upstream stream region suitable for trout) (Gerecke *et al.* 1998; Jersabek *et al.* 2001; Galassi *et al.* 2002; Stoch 1998a, 2003, 2006, 2007). Within the springs, species often segregate into microhabitats that supply their needs, including hygropetric rivulets, mosses, and patches of sediments with different characteristics (Stoch 2003; Fiasca *et al.* 2005). Bottazzi *et al.* (2011) reported **crenophilous** ("loving" springs and spring brooks) crustaceans from mosses in the Northern Apennine **rheocrene** springs (springs that flow to surface from underground), with pH and temperature best explaining their distribution and diversity pattern. In fact, the harpacticoid copepods and ostracods dominated the moss fauna, along with stoneflies and Chironomidae. The mosses were important contributors to the biodiversity.

We know that the copepod genera *Moraria* (Figure 45) and *Bryocamptus* are associated with wet or submerged mosses in Europe, including springs (Harding 1953). In their Italian study, Bottazzi *et al.* (2008) used traps, tubes, and moss samples to determine the copepod fauna of **rheocrene springs** (those that exhibit flow immediately after emerging from the substrate). They found 63% of the copepod taxa in these springs were represented among the

mooses, including a species of *Moraria*, in this case, *M. poppei*. Some of the copepod taxa occurred only in the moss habitat (i.e., were not collected in traps). These were the harpacticoid copepods *Bryocamptus tatrensis*, *B. alpestris* (see Figure 31), *Moraria vej dovski*, *M. vej dovski truncatus*, *M. poppei*, *Epactophanes richardi* (Figure 54), *Attheyella crassa* (see Figure 35), and the cyclopoid *Eucyclops serrulatus* (Figure 55). *Bryocamptus* species were evenly recorded from both moss and trap samples.

Figure 54. *Epactophanes richardi* female, a harpacticoid copepod of rheocene springs that seems to prefer mosses. Photo from US Geological Survey, through public domain.

Figure 55. *Eucyclops serrulatus*, a harpacticoid copepod that lives among mosses of rheocene springs. Photo by Fausto at <microscopio.it.gg>, with permission.

Bottazzi *et al.* (2011) also reported that the taxa most represented in the Northern Apennine rheocene springs were the harpacticoid copepods: *Bryocamptus zschokkei* (Figure 31) (mean number of individuals per sample = 2 for traps, 14 for mosses) and *B. pygmaeus* (1 individual/sample for traps, 5 for mosses). Out of their total of 3,284 invertebrates collected, **Ostracoda**, **harpacticoid Copepoda**, and **Diptera** were the most abundant among the 54 taxa. Bottazzi and coworkers considered the mosses to be a favorable habitat that contributed to the high species diversity.

Rivulets

Rivulets, often as outflow from springs, often have mosses that serve as copepod habitats. Stoch (2003, 2007) reported copepods from mosses in **hygropetric** rivulets (having water forming a surface film on rocks). Genera such as *Moraria* (Figure 45), *Epactophanes* (Figure 54), *Arcticocamptus*, *Nitocrella*, *Parastenocaris* (see Figure 33), *Speocyclops*, and *Diacyclops* (Figure 52) occur among hygropetric rivulet mosses (Fiasca *et al.* 2005).

Streams

It appears that copepods are important bryophyte inhabitants in mountain streams of New Zealand. In unshaded areas of the streams, Suren (1992) found *Canthocamptus howardorum*, *C. maoricus* (see Figure 56), *Attheyella stillicidarum*, *A. cf. brehmi* (see Figure 35), *Antarctobiotus elongatus*, and *A. cf. diversus*, all in the **Harpacticoida** (Figure 57). In 1992, Suren suggested that the large numbers of Copepoda found in association with bryophytes there may relate to the high food value of abundant periphyton that grow on the surfaces and the ability of the bryophytes to serve as safe sites against fast water currents. But in 1993, he refined his assessment to suggest that the copepods are especially important on bryophytes that are covered with detritus rather than periphyton (Suren 1993).

Figure 56. *Canthocamptus* from moss; note nauplius in insert. Photo by Graham Matthews <http://www.micromagus.net/microscopes/pondlife_copepoda.html>, with permission.

Figure 57. Harpacticoid copepod on leaf of *Fontinalis antipyretica*, demonstrating how tiny it is. Photo by Dan Spitale, with permission.

Leaf axils of bryophytes can be particularly protective against the current, but they also serve as collection sites for detritus. The differences in periphyton vs organic detritus may relate to location in sun vs shade. Cox (1988) found that bryophytes from an unshaded location had predominantly periphyton associated with them, whereas

those from the shaded site had predominately fine amorphous detritus associated with them. This is reasonable, as more light would promote greater algal growth. But flow rates will play into this as well, and oxygen content will differ with both flow rate and periphyton vs detrital matter.

Chironomidae (midges) are typically the dominant group on stream bryophytes [see, for example Williams (1989) in southern Ontario, Canada, and Nolte (1991) in Germany, who found that chironomids dominated on the submerged moss *Hygroamblystegium tenax* (Figure 58)]. In New Zealand alpine streams, Suren (1992) found that harpacticoid copepods and ostracods were among the most abundant groups of non-chironomids. Suren found that there was a "strong positive relationship" between copepod density and high water velocity, with densities among the bryophytes there reaching twice that of macroinvertebrates. At first, this seems like a contradiction because meiofauna are intolerant of high water velocity (Winner 1975) and avoid it by burrowing into the hyporheic zone (sediment). Suren (1992) pointed out that the copepods *Bryocamptus vej dovskyi* and *B. zschokkei* (Figure 31) in Minnesota, USA, can only be found in the hyporheos in fast-flowing streams. He suggests that the bryophytes provide a "biotic hyporheic zone." The studies by Suren (1992) in New Zealand are in sharp contrast to those of Cox (1988) who found that in streams in Tennessee, USA, it was rotifers that dominated the bryophytic "hyporheic zone" in the mosses *Fontinalis novae-angliae* (Figure 59) and *Platyhypnidium riparioides* (Figure 60).

Figure 60. *Platyhypnidium riparioides*, a moss that supports a dominant rotifer fauna rather than a copepod fauna in the hyporheic zone in Tennessee, USA. Photo by Michael Lüth, with permission.

Splash Zones

Stream edges and waterfall splash zones provide a suitable habitat for some limnoterrestrial copepods (Lewis 1972a). In New Zealand one can find such taxa as *Attheyella stillicidarum* (see Figure 35) among the mosses and liverworts, preferring either permanently dripping mossy banks or areas in the splash zones of streams, apparently requiring moving (fresh, not stagnant) water. *Attheyella humidarum* and *Attheyella fluviatilis* likewise prefer dripping mossy banks and damp "bush" moss. In addition to these *Attheyella* species, Lewis (1972b) also described six new species in the genus *Antarctobiotus* (*A. ignobilis*, *A. diversus*, *A. elongatus*, *A. australis*, *A. exiguus*, *A. triplex*) from damp mosses in New Zealand.

Cave Pool

Galas *et al.* (1996) examined the decomposition of litter in a cave pool in Poland. These pools included copepods, among other fauna. Respiration released more energy by activity of microorganisms on mosses (*Polytrichum*, Figure 61) than on the litter of *Sorbus* and *Alnus* in the pool. This higher rate among the bryophytes suggests that they may have provided a better food source of fine particulates and microorganisms for small organisms such as copepods than that associated with the submersed leaf litter.

Figure 61. *Polytrichum commune* in a geothermal spring, Yellowstone, WY, USA. Photo by Janice Glime.

Summary

Microcrustacea are primarily aquatic and marine, but some, including Copepoda and Cladocera, have developed characteristics that permit them to live on land in such habitats as wet bryophytes. Moisture, water chemistry, pH, and roughness of the moss habitat can be important determinants of microcrustacean diversity.

Adaptations to land may include separate sexes, ability to change sex, and parthenogenesis. Cyclopoid copepods have short life cycles that permits them to increase recruitment. They can sometimes disperse with their bryophyte substrate.

Truly terrestrial Cladocera are few, with *Bryospilus* being best represented among this group. Springs seem to be a transitional habitat between aquatic and terrestrial systems, with bryophytes serving as a refuge vertically and horizontally as moisture levels change. In streams, bryophytes can serve as a safety net to catch drifting organisms. The bottom of the moss clump provides a safe haven from the torrential waters above while being a collection site for food. Food is often fine detritus trapped by the bryophytes. In these aquatic and wet habitats, the bryophytes can contribute significantly to increasing the faunal diversity. Peatlands/*Sphagnum* bogs increase diversity by offering multiple niches both in the mosses and among the tracheophyte vegetation. *Alona* and *Alonella* are among the most common there; *Alona* is also the most common drift cladoceran in streams.

Cladoceran adaptations can include appendage reduction, shorter life cycle, eggs placed in dense masses of vegetation, and ability to swim in a thin film of water.

Copepods on land use their antennae to swim in the larval stage. Dormancy permits them to survive dry periods, including resting eggs, arrested development, and encystment of both juveniles and adults.

The ability of land-dwelling copepods to live among bryophytes is reflected in such names as *Muscocyclops*, *Bryocyclops*, and *Epactophanes muscicola*. Bryophytes can provide moist islands when copepods move from one location to another. Other species live among canopy epiphytes. Some even live among bryophytes in the Antarctic. *Attheyella* and *Moraria* are among the genera known from peat bogs, with genera such as *Paracyclops* found in pitcher plants there. Small copepods hide among the aquatic bryophytes. Harpacticoid copepods can dominate the moss fauna in springs, where temperature and pH are important factors in diversity. *Canthocamptus* and *Attheyella* are well represented in streams in New Zealand. Like the Cladocera, copepods often feed on periphyton or detritus among the bryophytes.

Acknowledgments

I especially appreciate Dan Spitale for his contribution of the image of a copepod on *Fontinalis* and to Paul Davison for his anecdotal information, images, and

continued encouragement. Thank you to Larry Williams for numerous comments and suggestions that have improved the clarity of the manuscript. Thank you to all the photographers who have placed their images in Creative Commons on the internet.

CHAPTER 10-2

ARTHROPODS: CRUSTACEA – OSTRACODA AND AMPHIPODA

Figure 1. Terrestrial amphipod on leafy liverworts from New Zealand. Photo by Paddy Ryan, with permission.

The amphipods (Figure 1) and ostracods (Figure 2) might be considered as mimics that live in the bryophyte world. The amphipods look like miniature shrimp and the ostracods look like miniature mussel shells with a shrimp inside instead of a mussel.

CLASS OSTRACODA

Mark Papp (pers. comm. 19 November 2011) reported to me that he had a very sore neck and shoulders, but no ostracods to report. He had been looking at roof mosses where he had originally taken many ostracods at Chalfont St. Peter, UK. Their identity as ostracods was confirmed by a marine ecologist. He did find the remains of a copepod. The ostracods are evasive, making it that much more delightful when you find them. Those on the roof had apparently moved on.

The name **Ostracoda** comes from the Greek *óstrakon*, meaning shell. Ostracods (sometimes known as seed shrimp) look like miniature clams (or seeds) with a tiny shrimp-like animal living inside the shell. They typically are marine and freshwater organisms, but some have

become terrestrialized. They are not common among bryophytes, but they do sometimes occur there.

Figure 2. Ostracod, showing internal digestive system through the shell. Photo by Anna Syme through Wikipedia Commons.

Adaptations

Harding (1953) claimed the first find of a terrestrial ostracod (*Mesocypris terrestris*) as a new species occurring among mosses at the source of a small stream on Mt. Elgon in Kenya. Another occurred among mosses in a waterfall. But this ostracod is too large and globular for close alliance to the aquatic environment, so Harding (1953) reasoned that it must be more truly terrestrial. This ostracod is blind, presumably surviving loss of eyes because eyes are of little use among the mosses, and their swimming setae are very reduced as well. Instead, the second pair of antennae is especially powerful and Harding suggested that it might aid in movement in the water film among the mosses, a movement typically accomplished on mosses and liverworts by crawling (Powers & Bliss 1983). Excretion seems to be poorly understood, but some form of nitrogenous waste is excreted through glands on the maxillae, antennae, or both (Barnes 1982). Their food includes diatoms, bacteria, and detritus (Miracle 2014), items found not only in aquatic habitats, but also among terrestrial bryophytes.

Swimming to Crawling

A loss of ability to swim seems to be the result of an evolutionary loss of setae on antennae and reduction of setae on antennules (Harding 1953; De Deckker 1983; Martens *et al.* 2004). Instead, the terrestrial ostracods use their antennae to move along solid surfaces, much as benthic ostracods move along the bottom surface (Harding 1953; De Deckker 1983). On a moss, the ostracod is surrounded by a film of water at the bottom of the carapace (shell). This water is trapped by numerous hairs, especially ventrally and laterally, to about mid-height. This mechanism seems to work only on moist substrates. When *Austromesocypris australiensis* (= *Mesocypris australiensis*) was placed on a dry Petri plate, it was unable to retain all of the water when it moved (De Deckker 1983). Whereas most ostracods lie on their sides when at rest, this moss-dweller remains upright. As members of this species dry, they migrate to wetter conditions, but when it is too dry they close their shells (compare Figure 3 to Figure 9) to curtail water loss.

Figure 3. Dead **ostracod** with its shell open, revealing the exoskeleton. When taken out of water, this shell immediately closes. Photo by Paul Davison, with permission.

Reproduction

About half the non-marine ostracod species belong to the family **Cyprididae** (Wikipedia 2014). Many of these occur in temporary water bodies, requiring a degree of terrestrialization, and have drought-resistant eggs, mixed sexual and parthenogenetic reproduction, preadapting them to terrestrialization, and to living among bryophytes (Powers & Bliss 1983). There seems to be a prevalence of asexual reproduction among terrestrial ostracods compared to their aquatic counterparts (Pinto *et al.* 2005a). Nevertheless, terrestrialization of some may include retention of the fertilized eggs, protecting them from desiccation. Observations by Chapman (1961) suggest that the developing embryos of the moss-dweller *Scottia audax* (= *Mesocypris audax*) may be retained within the shell of the mother until they become free-living juveniles.

Habitats

Terrestrial

Although most ostracods are marine or aquatic, some, such as *Mesocypris* spp., live in wet terrestrial habitats, including mosses (Introduction to the Ostracoda 2002). This genus seems to be widespread among bryophytes in the Eastern Hemisphere from the Russian Far East (I'm unable to confirm this record) to Australia (Martens *et al.* 2004). Terrestrial species also occur in South America (Pinto *et al.* 2005a, b).

Although Harding (1953) claimed the first record of terrestrial ostracods in Africa with his finding of *Mesocypris terrestris*, this one was still in the wet habitats of a waterfall and source waters of a stream among mosses. De Deckker (1983) collected *Austromesocypris australiensis* from Cammoo Caves in Queensland, Australia, from wet moss. De Deckker points out that although most ostracods are aquatic or marine, several species are able to live among leaf litter and mosses that are able to provide a moist environment. Among these, the type specimen of *Austromesocypris australiensis* was found among mosses, and others were living among *Sphagnum* (Figure 4) on the side of a road near a small creek in New South Wales, Australia. In fact, these individuals were unable to swim freely even in free water.

Figure 4. *Sphagnum cristatum* from a soil bank in New Zealand. Photo by Janice Glime.

In Queensland, the terrestrial ostracod *Scottia audax* (also known from mosses in New Zealand; Chapman 1961) occurred along with *Austromesocypris australiensis* in mosses (De Deckker 1983). *Scottia birigida* (Figure 5)

occurs among mosses in Japan (Robin James Smith, pers. comm. 31 March 2014). In Tasmania, *Mesocypris tasmaniensis* likewise occurs among mosses as well as litter (De Deckker 1983). Røen (1956) named *Bryocypris grandipes* from Africa (GBIF 2013), but I have only its name to suggest it dwells among bryophytes. De Deckker stated that terrestrial ostracods are known only from Gondwanaland: Africa, Madagascar, Australia, and New Zealand, but they have since been found in Europe (Pieri *et al.* 2009; Mark Papp, pers. comm. 19 November 2011) and South America, where *Caaporacandona iguassuensis* occurs among moist Brazilian forest mosses (Pinto *et al.* 2005a). Although members of the Cyprididae occur in North America, thus far terrestrial representatives seem to be undocumented. Nevertheless, Paul Davison (pers. comm. 31 May 2014) reports them from dripping cliffs (Figure 6) among algae and suspects they could inhabit bryophytes under similar conditions. Bryologists should watch for them!

Figure 5. *Scottia birigida*, a moss dweller in Japan. Photo by Robin James Smith, with permission.

Figure 6. Ostracod from wet wall, a potential bryophyte dweller. Photo by Paul Davison, with permission.

Pieri *et al.* (2009), reporting on ostracods from Friuli Venezia Giulia, Italy, found three species distributed on mosses: *Cypria ophthalmica* (Figure 7), *Cyclocypris laevis* (Figure 8), *Cyclocypris ovum* (Figure 9). It is not clear what the habitat was for these mosses. *Cypria*

ophthalmica is known as a widespread species from the karst region of Italy (Wagenleitner 1990). All three species occur at the margins of lakes in the reed belt among the vegetation and on the sediment surface (Kiss 2007). The mosses were only examined from one site. One should note that these three species are also among the three most common taxa in the study (Figure 10), which included all the likely habitats for ostracods in the study area.

Peat Bogs

Peat bogs seem to be a rich site for ostracod species. Harding (1953, 1955) states that ostracods tend to occur in *Sphagnum* (Figure 11) as well as in forest litter. Bryophytes influence the species composition by creating a diversity of niches, from pools to dry hummock tops, and many microniches among the stems and leaves. Likewise, a gradation of pH can sometimes be found vertically and horizontally, providing more niche choices. Temperature differs between the surface and deeper portions of peat. Figure 10 shows the relationships of four environmental parameters with the five most common ostracod species in 200 sites in the sampling of surface, interstitial, and ground waters of Friuli Venezia Giulia, Italy (Pieri *et al.* 2009).

Figure 10. Comparison of environmental parameters for the five most common species in Friuli Venezia Giulia, Italy that also occur in peat bogs. The boxes show 25-75% quartiles. The horizontal line is the median, and vertical bars (whiskers) show the maximum and minimum values. The numbers of analyzed samples appear in parentheses below the species names. Redrawn from Pieri *et al.* 2009.

At Friuli Venezia Giulia, Italy, the five most widespread and common species of ostracods also occurred in peatlands (Pieri *et al.* 2009). Pieri and coworkers reported 24 species in 16 genera from peat bogs (Table 1).

It is interesting that some of these Italian bog-dwelling species are so widespread. For example, *Penthesilenula brasiliensis* is known on all the continents except Antarctica and North America (Pieri *et al.* 2009). Its wide range of habitats (rivers, streams, interstitial water, bromeliad basins, rain forest leaf litter, and bog mosses) may permit this widespread geographic distribution. Furthermore, three of the most common species in this part of Italy have a wide altitudinal distribution (Figure 26). Surely they occur among bryophytes in other European countries as well.

Some species seem to be restricted to bogs, making them **tyrphobionts**. In their study of Friuli Venezia Giulia, Italy, *Cavernocypris subterranea* and *Cryptocandona vavrai* were apparently restricted to peat bogs at high altitudes (Pieri *et al.* 2009). Barclay (1968) reported the new species *Penthesilenula sphagna* (= *Darwinula sphagna*) from New Zealand, living above the water among *Sphagnum* (Figure 4). Similar relationships of ostracods to *Sphagnum* are known from eastern Africa (Menzel 1916).

The importance of mosses in bogs can be indirect. In *Sphagnum* (Figure 11) peatlands, mosses are a necessary habitat element to support the growth of pitcher plants (*Sarracenia purpurea*; Figure 27). The leaves of these plants form pitchers of water that provide a suitable habitat

for some ostracods in North America (Hamilton *et al.* 2000), including those in Florida, USA (Harvey & Miller 1996).

Aquatic

Streams

Potamocypris pallida (Figure 28) in Macedonia occurs in moss cushions on the sandy and rocky bottoms of mountain springs and brooks (Petrovski & Meisch 1995). In my own stream bryophyte collections in Appalachian Mountain, USA, streams, I rarely encountered ostracods and considered them to be accidental or temporary residents since they more commonly occur in quiet water.

Springs

Spring habitats have a number of features in common with peat bogs. They typically have a dominant bryophyte flora, and they can be dry during part of the year. But their

pH range can reach into basic values, creating conditions that favor different communities.

Bottazzi *et al.* (2011) compared ostracods collected in traps with those collected from mosses in **rheocrene** springs (where aquifer water reaches the surface) of the Northern Apennines. Ostracods were among the most abundant taxa, particularly among the permanent meiofauna. Such common inhabitants of springs can be called **crenophiles** (literally, spring-lovers). Only *Psychrodromus bertharrami* was collected in both traps and mosses, with similar numbers (20 individuals per sample in traps, 17 for mosses). *Ilyocypris bradyi* (Figure 29) was only recovered from mosses. All other taxa (except one of questionable identity) were collected in traps. Fryer (1955) described *Potamocypris thienemanni* (see Figure 28) as new to Britain, inhabiting bryophytes, including *Sphagnum* (Figure 11), in a spring. This species was also known from three springs in Germany.

CLASS MALACOSTRACA, ORDER AMPHIPODA

I have occasionally found amphipods in my collections of stream mosses, but they are more typically in quiet water

of larger streams. Nevertheless, it appears that in some cases they can be an important part of the aquatic moss faunal community (Minckley 1963; Minckley & Cole 1963; Matonickin & Pavletic 1964; Willoughby & Sutcliffe 1976). Badcock (1949) found *Gammarus* (Figure 30) to be most numerous in mosses and other protected niches, reporting an estimated fifty in a single tuft of moss (Cheney 1895). They are even known from terrestrial mosses (Merrifield & Ingham 1998).

Figure 30. *Gammarus pulex* showing the massive numbers in shallow pools. Photo through Creative Commons.

In some systems, amphipods can be quite abundant among the bryophytes. Wulffhorst (1994) found this to be true in two acid streams in the Harz Mountains, Germany, where they far exceeded those in the interstitial spaces (Figure 31).

Figure 31. Abundance (number of individuals per liter) of the amphipods *Gammarus pulex* and *Niphargus aquilex* (Figure 32) among mosses and the interstitial spaces at 10 and 30 cm depth at six stations in two Harz Mountain streams. Bars indicate 95% confidence interval; n = 14 for mosses and 28-36 for interstitial spaces. Redrawn from Wulffhorst 1994.

Adaptations to Land – and Bryophytes

Stout (1963) summarized three evolutionary pathways for terrestrial plankton. Among these, Hurley (1959) proposed that amphipods moved from the **supralittoral** (splash zone) fauna directly to the forest floor. Another suggestion is that fauna such as amphipods may have originated in freshwater streams, extended to the wet mossy banks and *Sphagnum* (Figure 11) bogs to the forest floor and ultimately to mineral soil. Stout considers the latter route to be the most convincing.

Hurley (1959, 1968) reported that all the terrestrial species of amphipods are in the family **Talitridae**, occurring in damp habitats. To survive in these terrestrial habitats required several morphological and behavioral changes, not to mention the physiological changes needed. They needed to become air breathers, jump instead of swim (accomplished by reduced **pleopods**, *i.e.* swimmerets, – to stumps in some species), adapt their life cycle to the changes in the seasons (Hurley 1959), and excrete uric acid instead of ammonia (Dresel & Moyle 1950). But they can have more than 50% ammonia excretion (Hurley 1959), perhaps releasing their ammonia as a gas like the isopods (O'Donnell & Wright 1995). It appears that they may have evolved different solutions to some of these problems from those of some of the other crustacean groups.

We can understand the small number of terrestrial amphipod species by comparing them to the isopods, where both aquatic and terrestrial species likewise exist. Terrestrial amphipods are less adapted to their terrestrial life than the isopods, being restricted to more narrow niches (Hurley 1968). The amphipods lack the isopod advantages of evaporative cooling at high temperatures and have exoskeletons with greater permeability, leading to greater risk of desiccation (Hurley 1959). Terrestrial isopods have lost their antennae, whereas in amphipods they are merely simplified. Both groups have modified their behavior to stay where it is cool and moist.

In wet leaf litter, the amphipods may move upward, a behavior we should look for among mosses (Hurley 1968). It is interesting that in the Fiordland of New Zealand the high level of rainfall and saturated ground has driven the amphipods to living among mosses or under bark of trees rather than their usual habitat of leaf litter. Avoidance of leaf litter there seems to be especially true for *Arcitalitrus sylvaticus* (= *Talitrus sylvaticus*; Figure 33). Its relative

Arcitalitrus dorrieni (Figure 34) also occurs with mosses on bark in Australia.

Figure 34. *Arcitalitrus dorrieni* on bark among mosses. Photo by Dluogs through Creative Commons.

Obtaining water, no problem for aquatic species, requires special behavioral techniques for the land dwellers. It is interesting that the water-obtaining behavior is similar to that of the terrestrial oniscid isopods. The terrestrial amphipods both gain and eliminate water by dabbing the uropod tips (tails) onto wet or dry substrata, respectively (Moore & Richardson 1992). The water is exchanged rapidly in or out of the central channel through the capillary spaces between the body parts. Beating **pleopods** (abdominal appendages also known as swimmerets) transfer water from the abdomen to the thorax in most terrestrial taxa. Water that pools beneath the tail is taken in by anal drinking.

Reproduction and Early Development

Among amphipods, the male is typically larger than the female and mounts her dorsally when she is ready to molt (Sutcliffe 1992). This behavior of having the male carry the female beneath him, known as **mate guarding**, helps to protect her during the crucial mating molt while

she is more vulnerable to predation, and on land to desiccation. The eggs are deposited in the external brood pouch when she molts, followed by deposition of the sperm by the male. Following fertilization, embryos are carried by the female, but hatchlings, resembling miniature adults, are on their own. The terrestrial *Talitrus saltator* (a sandhopper; Figure 35) lays its eggs four days after molting, compared to laying them immediately after copulation (Figure 36) in the aquatic *Gammarus* (Hurley 1959). The latter species can hold the spermatozoa in a brood pouch for up to four days. The aquatic male *Gammarus* carries the female under him for several days (Figure 36), whereas the terrestrial male of *Talitrus saltator* does not carry the female, a behavior difference that seems backwards until you realize he is jumping around on the sand and the female would get in the way. The 1-10 terrestrial eggs are much larger than the small and numerous aquatic eggs. The eggs of the terrestrial species furthermore remain in the brood pouch longer, affording them greater protection from desiccation.

Figure 36. *Gammarus pulex* copulating, with the larger male on top. Photo by J. C. Schou, with permission.

A further means to conserve both energy and water is **neoteny**. *Orchestia* (Figure 37) reaches sexual maturity at an earlier growth stage and smaller size (Powers & Bliss 1983). This results in fewer offspring. They have a female bias, somewhat compensating for the smaller number of offspring, and females are larger than males, which is atypical for amphipods. Stephensen (1935) reported *Orchestia floresiana* from moss in Java, where it grows in waterfalls, rivulets, and fountains.

Food among the Bryophytes

Felten *et al.* (2008) found that some aquatic amphipods, or at least *Gammarus fossarum* (Figure 38), eat mosses, and that the relative proportion in the diet increases as they grow from 2 mm to 4 mm, increasing only slightly after that (Figure 39). Conversely, the proportion of fine amorphous detritus steadily decreases as the amphipods grow. Felten *et al.* suggest that the younger (smaller) amphipods do not have mouth parts that are developed well enough to eat the larger food items like bryophytes. The proportion of bryophytes in the diet also depends on where they are living, with those living among bryophytes eating a greater proportion of bryophytes (Figure 40). It is interesting that those in the detrital pools have a greater proportion of minerals, suggesting that they are unable to sort out the nutritious items from the non-nutritious items that surround them. It was unclear if the detrital pool populations were actually nibbling on the bryophytes or just eating fragments that had collected where they were.

Figure 40. Comparison of mean proportion (\pm SD) of bryophytes vs other food items eaten by *Gammarus fossarum* in three habitat types. Modified from Felten *et al.* 2008.

Gladyshev *et al.* (2000) examined the gut contents of *Gammarus lacustris* (Figure 41) and found that they ingested mostly seston, obtaining omega 3 fatty acids from bottom sediment particles. They also consumed cells of the green alga *Botryococcus*. This alga not only survived the digestive tract, but its photosynthetic activity increased. They considered this activity to contribute to the dispersal of the alga, causing blooms in the littoral zone. Could this also be true of bryophytes they consume?

Figure 41. *Gammarus lacustris*, an amphipod that consumes mostly seston. Photo by Bold Systems Creative Commons.

Food particle size can determine which species are able to survive in a habitat. Graca *et al.* (1994) found that *Gammarus pulex* (Figure 30-Figure 36) occupies different zones in rivers from those of the isopod *Asellus aquaticus* (Figure 42). The researchers found that the selection of substrate by *G. pulex* was based on size, with larger individuals choosing larger-sized substratum particles; juveniles were mostly associated with plants, including mosses. The substrate choices were most likely food choices. For the aquatic amphipods, it is likely that the detritus collected by the mosses serves as a food source. It would be interesting to determine the role of food sources in the choices of terrestrial amphipods for particular bryophytes.

Figure 42. *Asellus aquaticus*, an aquatic isopod shown here on leaf litter. Photo by Malcolm Storey through Discover Life.

Acosta and Prat (2011) partially supported the idea of mosses as food collectors for the amphipod *Hyaella* sp. (Figure 43) in the headwaters of a High Andes river. Those living among layers of travertine had 69.5% fine particulate organic matter (FPOM), but even the bryophyte-dwellers had 56.8% FPOM. Those from leaf litter, on the other hand, had 68% of their gut contents from coarse particulate organic matter, suggesting a high level of flexibility in the diet.

Figure 43. *Hyaella azteca*, a common bryophyte dweller in streams and rivers. Photo by Barbara Albrecht at <<http://www.ipm.ucdavis.edu/WATER/U/hyaella.html>>, with permission.

One hypothesis is that increased density of bryophytes would increase available organic detritus and thereby increase invertebrate abundance. However, Suren and Winterbourn (1992) found that reducing stem density of mosses had little effect on periphyton biomass, but that the detrital biomass was reduced on low-density artificial mosses. In any case, stem density had little effect on invertebrate abundance. Nevertheless, detrital and periphyton availability seemed to be the determining factor for invertebrate density.

Gladyshev *et al.* (2012) examined the gut contents of gammarids as part of a food chain study including *Fontinalis antipyretica* (Figure 44). Following Kalachova *et al.* (2011), they used acetylenic acids, considered as biomarkers for *Fontinalis antipyretica*, to trace the food through the mosses, periphyton, Trichoptera, gammarids, and Siberian grayling (Gladyshev *et al.* 2012). Gladyshev *et al.* (2012) found small amounts of consumption of the mosses among both the Trichoptera (caddisflies) and the gammarid *Eulimnogammarus* (*Philolimnogammarus*) *viridis*. The latter species had the highest concentrations of acetylenic acids in the winter and the lowest in summer (Kalachova *et al.* 2011), suggesting a shift to mosses in winter. It is likely that both the caddisflies and gammarids ate the moss to gain the periphyton and detritus accumulated there. The moss and associated periphyton and detritus are especially important in winter when other food sources are scarce (Gladyshev *et al.* 2012).

Figure 44. *Fontinalis antipyretica* var *gracilis*, home for the amphipod *Eulimnogammarus* (*Philolimnogammarus*) *viridis*. Photo by Des Callaghan, with permission.

But Parker *et al.* (2007) found that even when the moss *Fontinalis novae-angliae* (Figure 52) was cleaned of particulate matter, the amphipods still ate significant quantities of it. Earlier studies by Minckley and Cole (1963) likewise indicated that amphipods ate mosses. On the other hand, Mulholland *et al.* (2000) found that the amphipod *Gammarus minus* (Figure 45) depended on fine benthic (bottom) organic matter, despite the presence of bryophytes.

One feeding possibility in nature that might not be evident in laboratory studies is the role of fungi. Barlocher and Porter (1986) demonstrated that *Gammarus tigrinus* (Figure 46) was able to digest plant polysaccharides and release sugars from maple leaves. They also had the right enzymes to break down glycosidic linkages in small molecules, much as that done in microbial decomposition.

Furthermore, fungal carbohydrases ingested with the food of the *Gammarus* remained active in the gut. The implication seems to be that *Gammarus* could benefit from fungi associated with bryophytes in the field. Similarly, Sarah Lloyd (pers. comm.) has documented that terrestrial amphipods eat slime molds that live on mosses (Figure 47).

It appears that at least some bryophytes are not suitable food for *Gammarus* (Figure 30-Figure 36). Willoughby and Sutcliffe (1976) conducted feeding experiments on *Gammarus pulex* (Figure 30) from the River Dutton. They found that those provided with only the liverwort *Nardia* sp. (Figure 48) were unable to grow or survive.

Habitats

Terrestrial

Terrestrial amphipods are rare, but bryophytes can provide the kind of moist habitat needed for them to survive. Merrifield and Ingham (1998) found amphipods in their Oregon Coast Range, USA, study of the fauna of *Eurhynchium oregonum* (Figure 49). In most months they were not evident, but in the December collection their numbers rose to 1 per gram of moss in 10 5-cm samples. The second "peak" was in April, with 0.6 per gram. Sarah Lloyd (pers. comm.) found what appears to be *Keratroides*, possibly *K. vulgaris*, among mosses in a wet eucalypt forest in northern Tasmania.

Figure 50. Terrestrial amphipod, probably *Keratroides*, possibly *K. vulgaris*, on mosses in wet sclerophyll (eucalypt) forest at Birrallee in Northern Tasmania, Australia. Photo courtesy of Sarah Lloyd.

Friend (1987) described the new species *Orchestiella neambulans* from litter that accumulated between mosses in Tasmania.

The Antarctic seems to be the most likely place to find limnoterrestrial Crustacea among mosses, but the amphipods are poorly represented. Pugh *et al.* (2002) found only one (*Makawe insularis*) in their study, a species with a broad niche of wood, leaf litter, lichens, tussock grass, under stones, penguin nests, and...among mosses.

Aquatic

Rocky streams are often dominated by mosses and liverworts in extensive mats over the rocks. These provide a foothold that protects their inhabitants from being swept away. Macan and Worthington (1951) found that amphipods such as *Gammarus* (Figure 30-Figure 36) were more likely on mosses that were not so thick, whereas thicker mosses were dominated by Chironomidae. They found that fish food organisms increased in number when the streams had rooted plants or mosses. One problem faced by the inhabitants of tracheophytes is that the plants begin die-off in late summer and the amphipods must find a new substrate with sufficient periphyton and detritus to provide food. *Gammarus* is among the slow colonizers (Fontaine & Nigh 1983), so it might benefit from the stable year-round habitat of bryophytes as a source of shelter and detrital and periphytic food.

Elliott (2005) found that *Gammarus pulex* had significant day-night differences in its habitat distribution. These were explained by dry weights of bryophytes, leaf material, organic detritus, distance from bank, water depth, water velocity, and particle size class. The bryophyte weight correlated positively with larger particle sizes and negatively with smaller particle sizes, perhaps explaining some of the choices by *G. pulex* for bryophytes. But this correlation may have been due to the preference of

bryophytes for larger stones. Juvenile densities in the daytime correlated positively with smaller particles and negatively to larger particles, also correlating with the weight of bryophytes. However, at night the densities were unrelated to particle sizes or bryophyte weight.

Parker *et al.* (2007) found that the amphipod *Crangonyx gracilis* (see Figure 51) was a common inhabitant of the brook moss *Fontinalis novae-angliae* (Figure 52), where it used the moss shelter as a food source. Badcock (1949) found that *Gammarus* (Figure 30-Figure 36) species were more numerous in sheltered sites such as mosses. Minckley (1963) found *Gammarus* among the moss *Fissidens* sp. (Figure 53) in a Kentucky, USA, stream. It not only lived there, but ate the moss that served as its home (Minckley & Cole 1963).

In an unlikely place, the depths of Yellowstone Lake, associated with active geothermal vents, *Fontinalis* abounds (Lovalvo *et al.* 2010). Associated with this unusual inhabitant are, among other invertebrates, the amphipods *Hyalella* (Figure 43) and *Gammarus* (Figure 30-Figure 36, Figure 41, Figure 45).

Summary

Both Ostracoda and Amphipoda are primarily marine, with fewer species in freshwater and much fewer in terrestrial habitats. Nevertheless, ostracods are known from roof mosses, and the genus *Mesocypris* is a common terrestrial moss dweller, especially in the Southern Hemisphere.

Their adaptations to living among bryophytes (and other terrestrial locations) include swimming instead of crawling, small size, loss of eyes in some, reduced setae (used for swimming), excretion of nitrogenous waste from maxillae, antennae, or possibly through the carapace (perhaps as gaseous ammonia), drought-resistant eggs, and parthenogenesis. Food often consists of detritus, algae, and bacteria, but some amphipods eat bryophytes as well.

Bogs offer habitats where ostracods can migrate vertically or horizontally to find suitable conditions as the temperature and moisture change. Some are even true **tyrphobionts**. But there appear to be few, if any, records for amphipods. Some ostracods live among the pitcher plants in the bogs.

Few ostracods are known from among mosses in streams, but several amphipods can be found there. However springs seem to be suitable habitats for several species in both groups.

The microcrustacea may have advanced onto land through wet mosses of springs and stream banks. They are represented by few families, the **Cypridae** among the ostracods and the **Talitridae** among the amphipods.

Terrestrial amphipods are not well known, and thus far their presence among *Sphagnum* does not seem to be documented.

interesting images and identifying the organisms. Robin James Smith not only gave me permission to use his images, but provided me with another moss record of an ostracod in Japan. Paul Davison has provided constant support with his interest, his images, and in this subchapter providing a critical review.

CHAPTER 10-3

ARTHROPODS: CRUSTACEA – ISOPODA, MYSIDA, AND DECAPODA

Figure 1. *Porcellio scaber* eating *Pleurozium schreberi* at midnight in Houghton, Michigan, USA. Photo by John Hribljan, with permission.

CLASS MALACOSTRACA, ORDER ISOPODA

Then there are the Isopoda (Figure 1), the well-known pillbugs, woodlice, roly polies, potato bugs, or sowbugs (but they aren't bugs!). These aren't insects at all, but are arthropods with legs on each segment, sometimes included among the **multipedes**, which is an unofficial classification referring to arthropods with many legs. And at least some of them seem to love mosses.

As a teacher, these were my favorite creatures. They have wonderful behavior responses to all sorts of things, especially light, moisture, and contact. Hence, they were excellent experimental organisms for behavior experiments for beginning students. They were easy to collect (just put out potatoes, with holes drilled through them, in a deciduous forest and give them 2-3 days to colonize). And they responded quickly and predictably.

But for research on herbivory on bryophytes, these organisms are unparalleled. Both aquatic and terrestrial species eat mosses, are abundant, and can be used to test

for preferences. Nevertheless, they should not be considered as models for the feeding preferences of other invertebrates, as you will see when we discuss digestion.

I have a small moss garden, and it is occasionally the site of my experiments, planned or otherwise! I had inherited a mat of mosses that had made themselves unwelcome on an asphalt parking lot. Some of these I had draped over a large rock in hopes that they would find it similar to their past home. In an attempt to keep them in place, I had used a mix of raw egg to act as glue. All seemed well for 2-3 weeks. Then one day when I went to look at them the mat looked like Swiss cheese! This carpet of a half-meter diameter had numerous relatively large holes in it! I found the carpet was loose, so I lifted it from the rock. As I did that, woodlice (mostly *Porcellio scaber*, Figure 2) fell to the ground and scrambled for cover. There were at least 20 of them! And many still remained on or within the mat.

Figure 2. *Porcellio scaber*, a common moss inhabitant. Photo from <www.aphotofauna.com>, with permission.

Compared to other arthropods, the isopods, at least on land, probably have the most interaction with the bryophyte community. Božanić (2008) sampled 66 mosses and extracted their inhabitants using heat with a Tullgren apparatus. She recorded multiple factors to determine the niche requirements of the faunal species. The mosses represented 15 species. The **Isopoda** were the most abundant taxa (439 individuals); others included **Chilopoda** (centipedes), **Diplopoda** (millipedes), **Araneae** (spiders), **Pseudoscorpionida** (pseudoscorpions), **Opilionida** (daddy-long-legs), **Lumbricidae** (earthworms), and **Formicidae** (ants). The diplopods (another multipede) were second in abundance (240 individuals). The most important environmental factors in determining the faunal higher taxa were type of substrate, height above ground, and moss/sample area. The species factors, like those of the higher taxa, were substrate type and height above the ground, but in addition to these the tree diameter was important, possibly indicating colonization time. Farkas (2007) likewise found tree diameter to be important for the isopods *Porcellium collicola* (Figure 3), *P. conspersum*, and *Trachelipus rathkii* (Figure 4), all rather common among epiphytic mosses in Hungary.

Figure 4. *Trachelipus rathkii*, an isopod that lives among epiphytic mosses in Hungary. Photo by Dragiša Savić, with permission.

External Anatomy

Isopods have two compound eyes (Figure 5) that permit them to detect motion easily. They have a very small head, long thorax, and short abdomen (Figure 6). There are two pairs of antennae, but the first is short and not always visible (Figure 5). That pair may have a chemosensory function to detect odors and tastes (Massey University 2014). The second pair of antennae is large and easily seen; the function is **tactile** (touch sensation).

Figure 6. *Ligia*, a genus that sometimes inhabits bryophytes, showing typical isopod external anatomy. Redrawn from Richard Fox.

Adaptations to Terrestrial Life and to Bryophytes

Isopods are predominately aquatic and marine. Life on land requires special adaptations. Even so, some isopod taxa have rather broad niches. *Porcellio laevis* (Figure 7), a cosmopolitan species and largest member of the genus, at least in the UK (Harding & Sutton 1985), is known for its plasticity in response to the environment (Lardies & Bozinovic 2008), and this plasticity may be the most important adaptation of all. There seem to be few morphological adaptations specific to land dwelling, although one could argue there are no really large species like some of the marine species.

Figure 7. *Porcellio laevis*, an isopod from which we have learned many terrestrial adaptations. Photo by Roger S. Key, with permission.

Bryophytes make good homes for isopods. These organisms hide from light and require a moist environment, conditions which can be provided by bryophytes. There are probably many species still to be discovered on land, especially among bryophytes, because of the sheltering behavior of isopods in daylight.

Water Relations

For any organisms evolving from water to land, maintenance of hydration is a critical adaptation. Dias *et al.* (2013) experimented with 22 species of terrestrial northwestern European isopods to determine the importance of three traits related to desiccation resistance. They found that 90% of the interspecific variation could be explained by water loss rate and fatal water loss. Body surface area affects desiccation resistance through modification of water loss rate. Soil moisture affects species distributions, and by extension, it is likely that bryophyte moisture does as well.

Edney (1951a) examined the evaporation of water from woodland isopods and found that in *Armadillidium* (Figure 8-Figure 9) and *Porcellio* (Figure 7) it was the **pleopods** (abdominal appendages also known as swimmerets, Figure 6, Figure 10) that lost water most rapidly, ranging 10-20 times as fast per unit area as the dorsal or ventral surfaces. However, the most water was actually lost from the dorsal and ventral surfaces because of the much greater area. Water loss rates differed among the terrestrial genera tested, in the order from greatest loss to least as *Ligia* (Figure 11), *Philoscia* (Figure 12), [*Oniscus*

(Figure 13), *Porcellio* (Figure 7), *Cylisticus*], and *Armadillidium nasatum* (Figure 9) to *A. vulgare* (Figure 8). This order also reflects the progression from most moist to least moist habitat preferences. *Armadillidium* species further conserve water by curling (Figure 9), a behavioral adaptation that earned it the name of roly poly.

Figure 8. *Armadillidium vulgare*, the common roly poly that rolls into a ball. Photo from <www.aphotofauna.com>, with permission.

Figure 9. *Armadillidium nasatum* curled into a ball, permitting it to reduce water loss. Photo by Lynette Schimming, through Creative Commons.

Figure 10. *Oniscus asellus* lying on its back and exposing its **pleopods** (see Figure 6). The **pleopods** are on the white abdomen behind these 7 pairs of legs and cannot be discerned in this picture. Note that the head is to the right where you can see two of the antennae. Figure 13. *Oniscus asellus*, a frequent moss-dweller in western and northern Europe. Photo by Brian Eversham, with permission.

When terrestrial isopods become desiccated, they can restore their original weight by absorption of moisture through the mouth and anus by contact with free water surfaces, and by mouth from moist surfaces (Edney 1954). This suggests a possible role for the bryophytes as pillbugs traverse such dry habitats as tree bark, rocks, or even soil. They could run from clump to clump of moss, rehydrating when they visit the mosses (or liverworts). Edney (1954) suggests that they are most susceptible to mortality during their wandering rather than while in their selected permanent shelter habitat. Interestingly, living isopods

could rehydrate by absorption of water vapor or liquid water, but dead ones could not (Edney 1951a).

Waste Elimination

Even the elimination of waste products must be modified to conserve water on land. Digestive and bodily processes accumulate nitrogenous wastes, and these are toxic, requiring a means of efficient elimination. In aquatic animals, these are usually eliminated as toxic ammonia that is diluted in water (Dresel & Moyle 1950). But terrestrial animals cannot afford the large quantity of water needed to dilute ammonia to safe levels. Nevertheless, like aquatic isopods, most terrestrial isopods still excrete ammonia, but with a twist. They lack any organ homologous to the kidney or liver to detoxify or facilitate excretion of ammonia (Hartenstein 1968). Hartenstein studied this ammonia elimination mystery in *Oniscus asellus* (Figure 13) and concluded that rather than excreting liquid ammonia like most aquatic animals, the terrestrial isopods eliminate their ammonia as a gas. In addition, some of the nitrogen waste is stored in the body wall as uric acid and is eliminated during molting. Wieser and Schweizer (1970) likewise found that the terrestrial isopods *Oniscus asellus* and *Porcellio scaber* (Figure 1-Figure 2) eliminate their ammonia as gas. Their data refute earlier ideas that nitrogen metabolism is suppressed; instead, they accounted for loss of all the excess nitrogen intake through body wall storage and mostly through the body wall as ammonia gas, thus eliminating the need for large water losses – or kidneys.

Osmotic Balance

The osmotic pressure of the blood of terrestrial species is somewhat lower than that of sea water and adaptation to land seems to be achieved by osmotic tolerance rather than regulation (Edney 1954). Nevertheless, *Porcellio scaber* does not change its body fluid concentration as rapidly as it loses weight during desiccation (Horowitz 1970), implying it could have a limited balancing mechanism. Lindqvist and Fitzgerald (1976) explored this further and determined that initially the blood osmotic concentration remains essentially unchanged until about a 10% loss of body weight. Meanwhile, the oral fluid increases its osmotic concentration rapidly during about 90 minutes of drying. When severe desiccation occurs, these two compartments progress to an osmotic equilibrium, presumably due mostly to withdrawal of water from the gut lumen into the blood.

Molting has the potential to affect the osmotic balance. Calcium is an important element in the exoskeleton. Before the animal molts, the calcium is resorbed and stored in the body of terrestrial isopods and little is lost, whereas in aquatic taxa, little is resorbed and most of the exoskeleton calcium is lost (Greenaway 1985). When needed, additional calcium is gained from food and **exuviae** (shed exoskeleton). Despite this resorption of high amounts of calcium in terrestrial species, most of it is not stored in ionic form and thus has little effect on the osmotic balance.

Respiration

Terrestrial isopods have **pseudotracheae**, assisting them with respiration in dry air (Edney 1954), whereas the importance of integumental oxygen absorption decreases in terrestrial species compared to aquatic species. The inner

branch of each **pleopod** (Figure 6, Figure 10) is modified into a gill-like structure (Figure 14) with a thin, permeable cuticle where gas exchange occurs (Schotte *et al.* 2008-2014). These even somewhat resemble lungs in the terrestrial isopods.

Figure 14. *Porcellio siculoccidentalis* pleopods modified to function in gas exchange and resembling lungs. Photo by Giuseppe Montesanto, with permission.

Temperature Tolerance

The temperature tolerance follows the same sequence of genera as for water loss rates above [least in *Ligia* - Figure 11 < *Philoscia* - Figure 12 < (*Oniscus* - Figure 13, *Porcellio* - Figure 7, *Cylisticus*) < *Armadillidium* (Figure 8)], with *Armadillidium* having the highest temperature tolerance (Edney 1951b). There was no difference in body temperature between living and dead woodlice, and once the animals reached equilibrium their temperatures differed from that of the air by no more than 0.1°C in moist air. However, in dry air the isopod temperatures were depressed relative to air temperature, apparently due to evaporative cooling.

Moisture and Temperature Interaction

Temperature and moisture rarely act alone in ecosystems, and responses by isopods to one of these typically depends on the other. In experiments with the isopods discussed above, Edney (1951b) found that after 30 minutes in dry air at 20° and 37°C, mean temperature depressions were for *Ligia* (Figure 11), 2.6°C and 6.8°C; *Oniscus* (Figure 13), 1.5 and 2.7°C; *Porcellio* (Figure 7), 0.4 and 1.3°C; *Armadillidium* (Figure 8), 0.5 and 1.8°C, respectively. *Ligia* differed from the others, with its body temperature rising for at least 2 hours, whereas the others reached equilibrium at a temperature lower than ambient air temperature after 25 minutes. It is the ability to evaporate water rapidly that permits these isopods to maintain a safe temperature for short intervals,

and this at least partly explains their need for moist environments. On the other hand, if the air is saturated, they are unable to use evaporative cooling, and higher temperatures become lethal. Both temperature and moisture needs explain the migration of the isopods to deeper moss layers or even into the soil in the daytime, returning to the surface for feeding at night.

Behavior

The best adaptations of this group seem to be behavioral (Edney 1954), and these behaviors are what make them so interesting to watch. Pick up a rock and pillbugs scramble in all directions, soon disappearing under leaves or into the soil. They run from light, which might be an indicator of drying conditions. They seem to lack a well-developed cuticle, although both endocuticular and epicuticular layers are known from some species (Edney 1968), and thus they are able to use evaporative cooling, but this only works for a short time, hence making a behavioral solution essential.

Edney (1968) suggests that the nightly activity of *Porcellio scaber* (Figure 1-Figure 2) on trees may permit them to transpire excess water. *Armadillidium vulgare* (Figure 8) also has greater activity at night when the air is more moist. It appears that males of *Porcellio scaber* and *Armadillidium vulgare* use surface shelters, including bryophytes, between foraging events (Dangerfield & Hassall 1994), sometimes providing them with a location to gain or reduce water content.

Congregating Behavior

Aggregating or congregating (Figure 15) in large numbers in a suitable habitat, as is easily observed under a log, board, or small rock, is generally accepted as a means to reduce their water loss to the atmosphere (Broly *et al.* 2013). This behavior is mostly **thigmotactic** (a contact response), and possibly **olfactic** (an odor response) (Edney 1968). Olfaction seems to play a role in seeking shelter. But the role of aggregation in preventing water loss may be misleading. Broly and coworkers suggest other potential benefits, including reduction of oxygen consumption, increase in body growth, stimuli for reproduction, better access to mates, shared predator defense, promotion of coprophagy, sheltering, and acquisition of internal symbionts. They suggest that congregating behavior provides terrestrial isopods with a non-physiological alternative to coping with climate constraints.

Figure 15. Isopod congregation. Photo by William Leonard, with permission.

But crowding does not seem to have the same benefit for all terrestrial isopods. *Armadillidium nasatum* (Figure 16) and *A. vulgare* (Figure 8), members of the most xeric genus, had reduced growth rate, survivorship, and size at first reproduction as density increased in laboratory experiments (Ganter 1984). Since limited food reduced both growth rate and mortality in these experiments, these same detrimental factors might not exist in nature where foraging might be unlimited.

Figure 16. *Armadillidium nasatum* showing two color variants. Photo by Stan Gilliam, through Creative Commons.

To put this in perspective, Hassall *et al.* (2010) experimented with aggregation behavior in *Philoscia muscorum* (Figure 17), *Oniscus asellus* (Figure 13), *Porcellio scaber* (Figure 1-Figure 2), and *Armadillidium vulgare* (Figure 8) from Norwich, UK. The first three are isopods known from terrestrial bryophytes, whereas *Armadillidium vulgare* tends to occur in drier habitats. The first three species clump more at lower levels of relative humidity and at higher temperature, whereas changing the humidity has little effect on clumping in *A. vulgare*.

Figure 17. *Philoscia muscorum* on moss. Photo by Dick Jones, with permission.

Sheltering

Sheltering (staying in one place that is protected) is common among some isopods, but not others (Hassall & Tuck 2007). *Porcellio scaber* (Figure 1-Figure 2), a common moss dweller, sheltered significantly more than either *Platyarthrus hoffmannseggii* (Figure 18) or *Armadillidium vulgare* (Figure 8), and *Philoscia muscorum* (Figure 17) sheltered the least, despite some individuals spending at least winter under mosses. Sheltering declined in all four species after the breeding season, continuing through winter. *Porcellio scaber* sheltered more where the soil was more **calcareous** (occurring on chalk or limestone), *Philoscia muscorum* more under the shade of trees, and both *P. muscorum* and *Armadillidium vulgare* more in grazed than in ungrazed areas. For *A. vulgare* sheltering was positively correlated with both rainfall and temperature of the day before sampling, whereas for *Philoscia muscorum* it was negatively correlated with rainfall.

Figure 18. *Platyarthrus hoffmannseggii*, an isopod that shelters under mosses. Photo by Jan van Duinen <<http://www.janvanduinen.nl/>>, with permission.

Dias *et al.* (2012) examined the influence of microclimate on sheltering in three terrestrial isopods: *Porcellio scaber* (Figure 1-Figure 2), *Oniscus asellus* (Figure 13), and *Armadillidium vulgare* (Figure 8, Figure 23). The first two are common among mosses, whereas *A. vulgare* typically lives in drier habitats. All three species spent more time sheltering and less in activities when the environment was drier (50% relative humidity) compared to more moist conditions (90% relative humidity). *Oniscus asellus* is the least terrestrialized of these three and thus the most susceptible to desiccation. Sheltering can also reduce the quality of food consumed because less time is spent on foraging.

Reproduction

Reproduction among terrestrial invertebrates usually requires modifications from that of aquatic taxa. Terrestrial isopods carry their young in a **marsupium** (brood pouch, Figure 19). The marsupium is filled with fluid and the eggs and embryos are surrounded by mucous. Warburg (1987) considers this to be one of the most important innovations for successful living on land. The mucous may contribute to nourishment of the young, possibly explaining their ability to survive when the mother doesn't eat.

Figure 19. *Armadillidium vulgare* lying on its back, showing young (cream-colored) isopods in a brood pouch on the ventral side. Photo by Malcolm Storey, through Creative Commons.

In the isopods, gonadal development is stimulated by a long photoperiod and high temperatures (Edney 1968). Temperature seems to play a role in controlling reproductive output and consequent water loss.

Females are dominant throughout most of the year in *Porcellio scaber* (Figure 1-Figure 2) (Nair 1998), and this is likely true in other species as well, sometimes indicating **parthenogenesis** (reproduction from an egg without fertilization). Some species that exhibit parthenogenesis do not necessarily do so in their populations everywhere (Christensen 1979; Fussey & Sutton 1981; Fussey 1984). For example, in the British Isles some populations of an isopod that often lives among bryophytes, *Trichoniscus pusillus* (Figure 25), are parthenogenetic and others are not. Christensen (1979) demonstrated that the parthenogenetic populations represented different genotypes in this species. Fussey (1984) was unable to find a relationship between this parthenogenetic expression and latitude, longitude, altitude, or seven climatic variables, but it did correspond with calcareous habitats.

But genes are not the only causes of alteration in the reproductive type. The bacterium *Wolbachia pipientis* is able to infect the isopods *Hyloniscus riparius* (Figure 20), *Trachelipus rathkii* (Figure 26), and *Trachelipus ratzeburgii* (Figure 21) (Nyirő *et al.* 2002), all species known to inhabit mosses (Božanić 2011). The bacterium lives in the ovaries and can cause such changes as loss of maleness and shift to parthenogenesis in these isopods. The bacterium also infects the eggs and thus is transferred from mother to offspring. Could the antibiotic properties of bryophytes protect the isopods from this population-altering bacterium?

Figure 21. *Trachelipus ratzeburgii*, an isopod whose gender is altered by the bacterium *Wolbachia pipientis*. Photo by Dragiša Savić, with permission.

Food quality can have a strong effect on the success of both reproduction and survival of the offspring. For example, Kautz *et al.* (2000) were only able to maintain a stable population of *Trichoniscus pusillus* (Figure 25) on a diet of *Alnus* litter with high microbial activity. Such needs may explain changes in the diet of isopods throughout the year. It would be interesting to test the effect of a bryophyte diet on reproductive success.

On the other hand, Lavy *et al.* (2001) found that in *Porcellio scaber* (Figure 1-Figure 2) and *Oniscus asellus* (Figure 13) diet had no effect on the number of juveniles or their weight. Rather, the weight of the offspring was correlated with the weight of the female. Nair (1998) found that for *Porcellio scaber* in Benghazi, Libya, the total number of eggs correlated with body length of the female.

High temperatures can be lethal or detrimental to developing isopods. In the terrestrial *Porcellio ficulneus*, at 25°C, oocytes matured sooner, and many were resorbed (Hornung & Warburg 1993). The Mediterranean population compensated for these losses by breeding earlier. Females must balance the advantages of faster brood development in higher temperatures with the risk of excessive water loss (Dangerfield & Hassall 1994).

Incubation periods for *Porcellio scaber* (Figure 1-Figure 2) in Benghazi were 18 days in summer and autumn but extended to 32 in late winter and spring (Nair 1998). Spring embryo production was higher in spring compared to summer and autumn. In *Armadillidium vulgare* (Figure 8), if females are dehydrated, they reproduce instead of growing (Warburg 1987).

Terrestrial isopods care for their young, an uncommon feature in the aquatic habitat (Lardies *et al.* 2004). Such care can be costly energetically, but it increases the survival of the young in the terrestrial environment, and it might even reduce water loss of the adult, much like the congregating behavior. But there is a downside. Lardies and coworkers found that in *Porcellio laevis* (Figure 7) not only was the carrying of developing eggs energetically costly, the females carrying them had a lower ingestion rate and lower ability to digest food than non-carrying females. The net result was that egg-carrying females stored only about 20% as much energy as females with no eggs.

Carrying eggs and young creates other problems for these woodlice. Females carrying broods were slower and moved shorter distances to avoid light than non-brooding females of *Porcellio laevis* (Figure 7) (Kight & Nevo 2004). Physical stress causes a reduction in both distance travelled and velocity in brooding females. Many eggs and embryos die before reaching their swimming stage. These are typically eaten by their siblings in the marsupium and larger larvae often eat the smaller ones (Warburg 1987). Once the young leave the marsupium they begin a life free of their mother.

Predators

Bryophytes can serve as a refuge for hiding from large predators like birds, but they may not be so safe from insect predators. Ants such as *Tetramorium caespitum* (Figure 22) influence the behavior of the isopods *Armadillidium vulgare* (Figure 8) and *Porcellio laevis* (Figure 7) (Castillo & Kight 2005). *Armadillidium vulgare* females were hidden better than those of *P. laevis* whether ants were present or not. But some of their behavior was rather strange. Isopods that had no experience with ants remained further from them than those with previous exposure, with *P. laevis* keeping a significantly greater distance than that of *A. vulgare*. This difference in behavior of the two species may be explained by the ability of *A. vulgare* to roll into a ball (Figure 23), whereas *P. laevis* is endowed with the ability of rapid locomotion.

Figure 22. Ant *Tetramorium caespitum* eating larva, most likely of an insect. This ant causes soil isopods to stay hidden. Photo from Antwiki, through Creative Commons.

Figure 23. *Armadillidium vulgare* in a ball, a protection against predators. Photo from <www.aphotofauna.com>, with permission.

The brooding period of *Armadillidium vulgare* (Figure 8) was shortened when it was exposed to ants, whereas

such exposure had no effect on brood time for *Porcellio laevis* (Figure 7) (Castillo & Kight 2005). This is a greater advantage for *A. vulgare* because it is unable to roll into a sealed ball when it is carrying its brood. Nevertheless, *P. laevis* is slowed down when carrying a brood (Kight & Ozga 2001; Kight & Nevo 2004).

Overwintering

It is difficult to find information on the use of bryophytes for overwintering of crustaceans. Samouelle (1819) reported that one could find *Philoscia muscorum* (Figure 17) under mosses in January in Great Britain. Le Gay Brereton (1957) reported that the isopod *Porcellio scaber* (Figure 1-Figure 2, Figure 24) overwintered "in large numbers" in the moss layers at the bases of oaks (*Quercus*) and ash (*Fraxinus*). These same aggregations did not occur at eye level, suggesting that the larger moss clumps at the tree bases were more suitable than the small clumps or shallow mats of the bole. One would presume that the tree base had both warmer and less desiccating conditions than any position on the bole.

Figure 24. *Porcellio scaber*, a common moss dweller and consumer that eats its own feces to assimilate more nutrients. Photo by Eric Schneider, with permission.

Terrestrial isopods are not well adapted to cold temperatures and must seek locations where they are insulated from the cold. *Porcellio scaber* (Figure 1-Figure 2, Figure 24), a common species that is known from bryophytes and under many other objects, is able to adjust somewhat by acclimation, but is nevertheless susceptible to both freezing and chilling (Tanaka & Udagawa 1993). The temperature causing 50% mortality was -1.37°C in August but dropped to -4.58°C in December. At -7°C , the animal was unable to avoid freezing of its tissues, a temperature limit that was the same throughout the year.

The winterization in *Porcellio scaber* (Figure 1-Figure 2, Figure 24) corresponded to the presence of low molecular weight carbohydrates that may have protected it against chilling injury (Tanaka & Udagawa 1993). The supercooling temperature of -7°C seemed to be associated with the year-round gut content. We know that at least in the autumn this species can live among mosses and deciduous and conifer leaf litter where it prefers mosses as food (Hribljan 2009; Hribljan & Glime in prep). Could the mosses help to prepare it for winter by contributing arachidonic acids that have lower freezing points (see Prins 1982)? Hansen and Rossi (1991) showed that *Rhytidadelphus triquetrus* (Figure 49), a food of *Porcellio scaber* in autumn (Figure 53; Hribljan 2009; Hribljan &

Glime in prep), contains 30% arachidonic acid at 20°C, which slightly decreases at lower temperatures. Tanaka and Udagawa (1993) also suggest that food derivatives could serve as ice nucleation centers that could reduce freezing of tissues.

Bryophytes as Food

In the other crustaceans, we have seen that bryophytes serve mostly as trapping devices, collecting detritus and growing periphyton that can serve as food for the crustaceans. The crustaceans have carried their aquatic habit of eating detritus into the terrestrial environment. Isopods are also litter-dwelling organisms that eat litter, but they eat bryophytes too.

Digestion

Generally bryologists might not care much about the digestive process of a bryophyte dweller, but understanding isopod digestion helps us explain bryophyte herbivory and why isopods can be such good bryovores whereas other invertebrates generally are not. As organisms derived from aquatic ancestry, isopods required adaptations to digest terrestrial food. They are among the few organisms known to readily eat bryophytes. Food sources on land can differ somewhat for isopods, although leaf litter, a common food for them, is available in streams and lakes as well as on land.

Hames and Hopkin (1989) observed the digestive tracts of two terrestrial isopods known from mosses, *Oniscus asellus* (Figure 13) and *Porcellio scaber* (Figure 1-Figure 2, Figure 24), and determined that their digestive tracts are divided into five regions: foregut, anterior chamber, papillate region, rectum, and hepatopancreas. The latter opens into the foregut. There is a powerful muscular sphincter between the papillate region and the rectum.

As food passes from the foregut to the hindgut it is mixed with secretions from the hepatopancreas (Hames & Hopkin 1989). When the hindgut is full, muscles contract to force the liquids and fine food particles back to the foregut through special channels. This re-entry can occur several times, each time being subject to further degradation by the microbial gut flora. Material left in the hindgut passes to the rectum where the fecal pellets are compacted for expulsion. And like a rabbit, *Armadillidium vulgare* (Figure 8) and *Porcellio scaber* (Figure 1-Figure 2, Figure 24) eat their own fecal pellets, preferring fresh ones to decaying ones (Hassall & Rushton 1982). Hames and Hopkin (1989) suggest that the ability to recycle the food, each time extracting more liquid, may be one of the major changes making their life on land successful.

Isopods are good at digesting their food but poor at assimilating it. This may also help explain their ingestion of feces, to gain more nutrients from it (Warburg 1987). Food quality is important for growth (Merriam 1971), and fresh leaves are better for growth than decayed leaves (Beck & Bretowsky 1980).

But we are left with the question of circumventing the high **phenolic** content of bryophytes and some types of leaf litter. **Phenolic** compounds are known for their production as a stress response in bryophytes (Graham *et al.* 2004). There is ample evidence that they deter herbivory in both

terrestrial and aquatic bryophytes, as discussed below. But it appears that not all isopods are created equal in their tolerance of phenolic compounds. And not all bryophytes are equal in making them.

Zimmer (1997) showed that the common moss dweller *Porcellio scaber* (Figure 1-Figure 2, Figure 24) has significant ability to reduce gut surface tension. Phenolic compounds, well known to prevent digestion in other invertebrates due to the ability of the phenolics to increase the surface tension, seem to have a less negative effect on this species. These surfactants may be the key to the ability of *Porcellio scaber* to eat mosses without suffering from the typical binding of proteins suffered by many other kinds of organisms that eat phenolics. In insects, the phenolics precipitate proteins in the diet, preventing the insects from assimilating these essential nutrients, but in the isopods the surfactants bind the phenolics, leaving the proteins free for assimilation by the isopods. The concentration of surfactants in *Porcellio scaber* was 80 times as high as the "critical micelle concentration" needed to permit binding of the phenolics.

Further research on *Porcellio scaber* (Figure 1-Figure 2, Figure 24) indicated that endosymbiotic bacteria residing in the hepatopancreas were able to oxidize the phenolics, disabling their adverse properties (Zimmer 1999). When the gut flora of *Porcellio scaber* was reduced, Zimmer demonstrated that bacteria in the gut apparently had an important role in hydrolyzing gallotannins. When galloylglucose esters were ingested, they greatly reduced the microbial component of the hindgut. Ingestion of gallic acid reduced both palatable fungi and bacteria, but not as strongly, and increased the gut microflora. Zimmer's study suggests that the ingestion of hydrolyzable tannins, as found in some mosses, can inhibit the digestion of other foods in the diet of this species. The gut differences among the isopod species can account for their preferences among bryophytes, and possibly account for those taxa that don't eat bryophytes at all. Similarly, differences in hydrolyzable tannin concentrations among bryophyte species can account for preferences for some bryophytes over others.

Zimmer and Brune (2005) examined the physiological properties of the gut of four species of terrestrial isopods [*Oniscus asellus* (Figure 13), *Porcellio scaber* (Figure 1-Figure 2, Figure 24), *Trichoniscus pusillus* (Figure 25), and *Trachelipus rathkii* (Figure 26)]. These adaptations were manifest as a steep gradient of oxygen, high at the periphery and low at the center of the gut transection. This gradient provides suitable habitat for both aerobic and anaerobic symbionts that can contribute to digestion. The pH gradient ran from acidic in the anterior hindgut to neutral in the posterior hindgut of *O. asellus*, *P. scaber*, and *T. rathkii*. In *Trichoniscus pusillus*, the pH in the hindgut lumen was nearly constant. Zimmer and Brune (2005) suggested that the pH gradient differences may be adaptive in providing differences in the digestion of lignocellulose from their food sources. Bryophytes lack true lignin, so the expenditure of resources to create the conditions suitable for digesting lignin could be spared in those isopods that eat mosses. These differences in gut physiology could also account for some of the differences in food preferences and survival of isopods on bryophytes vs other foods.

Terrestrial Consumers

Terrestrial isopods seem to prefer a varied diet and exhibit food preferences (Dudgeon *et al.* 1990). Dudgeon and coworkers found that four species of isopods from a Hong Kong forest ate more food when given a mixture of leaves than when only one type was available. Their preferences did not seem to relate to ash, calcium, copper, soluble tannin, or energy content. Dudgeon and coworkers suggested that the isopods satisfied their nutrient requirements by consuming certain foods, then switching to others to avoid excessive tannins or other allelochemicals.

Rushton and Hassall (1983a, b) examined the feeding preferences and rates of *Armadillidium vulgare* (Figure 8) among dicotyledonous and monocotyledonous plants and bryophytes (*Calliergonella cuspidata*, Figure 27). This pillbug, known as a roly poly due to its ability to roll into a ball, can live in drier habitats than *Porcellio* and is much less likely to be associated with mosses. These isopods initially preferred the dicotyledonous plants to the other two choices. But after the monocotyledonous plants began to decay, these were preferred. Nevertheless, eating monocots increased mortality and drastically reduced growth rates and reproductive output, even when it was in a later decay state. Defenses in the food become more concentrated as the food decays and carbon sources are removed. Chemical defenses in mosses may play a role in the isopod choice of leaf litter over mosses in *Armadillidium vulgare*.

Figure 27. *Calliergonella cuspidata*, a moss that seems to deter feeding by *Armadillidium vulgare*. Photo by J. C. Schou, through Creative Commons.

Rushton and Hassall (1983a) suggested that *Armadillidium vulgare* (Figure 8) compensates for low quality food by eating more, but that plant defenses can interfere with this compensation. Even though the moss is likely to provide a suitable moist habitat, and *Armadillidium vulgare* may be able to absorb at a high rate on low quality food by increasing its rate of consumption, it appears that plant defenses of *Calliergonella cuspidata* (Figure 27) might outweigh its habitat desirability (Rushton & Hassall 1983a).

Dead mosses may be less desirable than dead tree leaves or even monocot leaves, particularly after the tracheophyte leaves begin to decay. It is likely that very little nutritional material is available relative to cell wall material in dead mosses (see Pakarinen & Vitt 1974 for lower N content), especially if nutrients are moved from dead portions to living portions, but that relationship requires further testing.

Figure 28. *Hypopterygium didictyon* from Chile, a moss in the same genus as one grazed in Costa Rica. Photo by Juan Larrain, with permission.

Nevertheless, at times isopods can be voracious consumers of bryophytes. Angela Newton (Bryonet, 20 November 2006) reported seeing extensive grazing on *Hypopterygium* sp. (Figure 28) in the montane rainforest of Costa Rica. The isopods sheared off the green lamina and left the branches and costa, much like the feeding behavior

of insects on tracheophyte leaves. However, grazing of isopods and silverfish on damp herbarium labels and plants in packets made her question whether they were simply feeding on the associated fungi and consumed the mosses in the process.

Isopods can be downright pests on garden mosses. Henk Greven, in a communication to Bryonet (23 October 2003) writes: "Apart from mammals, birds and slugs, sow-bugs (*Oniscus asellus* L.; Figure 13) are fervent bryophyte eaters. In my garden, I keep several *Grimmia* species on pieces of rock. When I put these on the ground, sow-bugs are hiding during the day under these rocks. In the evening they climb above and start eating my *Grimmias*. They have a special preference for *Grimmias* growing on limestone, basic sandstone, and basic basalt. In no time, they have eaten all my *Grimmia plagiopoda* (Figure 29), *G. crinita* (Figure 30), and *G. orbicularis* (Figure 31). Species on acidic rock, however, are not safe either. The only species they don't like is *Ptychomitrium polyphyllum* (Figure 32). I had this species nearly ten years on a piece of rock on my garden floor. I learnt my lesson and now I keep pieces of rock on a table where they are safe from sow-bugs."

Figure 32. *Ptychomitrium polyphyllum*, a moss that is not eaten by *Oniscus asellus*. Photo by David T. Holyoak, with permission.

Likewise, I have already reported above on my own sad experience with *Porcellio scaber* (Figure 24) eating my carpet of mosses so that it looked like Swiss cheese. And Daniel Marsh (Bryonet, 18 November 2006) reported that wood lice (isopods) have usually consumed any liverwort he tried to cultivate in his garden or greenhouse. "The attraction seems to be immediate." In contrast, he reports that he has not noticed such consumption of liverworts by isopods in wild communities.

We (Weston 1995; Liao & Glime unpubl) attempted to find out what sorts of things might deter pillbugs (*Porcellio scaber* (Figure 24). Using *Polytrichum juniperinum* (Figure 33) and *P. commune* (Figure 34) from Houghton, MI, USA, we compared consumption of stems and leaves. *Polytrichum juniperinum* leaves were consumed 3:1 over stems; *P. commune* leaves were consumed 5.5:1 over stems (Figure 35). It made no difference whether the leaves were still connected to the stems or not.

Figure 33. *Polytrichum juniperinum*, a species in which *Porcellio scaber* prefers eating leaves over stems. Photo by Li Zhang, with permission.

Figure 34. *Polytrichum commune*, a species in which *Porcellio scaber* prefers eating leaves over stems. Photo by David T. Holyoak, with permission.

Figure 35. Comparison of mean isopod (*Porcellio*) consumption \pm 95% CI of excised leaves and stems vs intact leaves and stems in two species of moss. Data based on unpublished laboratory data of Weston 1995; Liao & Glime unpublished data; n = 3.

In both *Polytrichum juniperinum* (Figure 33) and *P. commune* (Figure 34), the leaves had roughly double the protein content per dry weight compared to the stems (Figure 36) (Weston 1995; Liao & Glime unpubl), suggesting that the isopod *Porcellio scaber* (Figure 24) could gain more protein nutrition from eating leaves. And structurally leaves would seem to be easier to chew than the tough stems endowed with thickened walls and coloration suggesting phenolic compounds. But it is surprising to find that the leaves of at least *P. commune* seem to have a higher concentration of phenolic compounds than do their stems (Figure 37), yet that species had the higher consumption ratio of leaves to stems. Perhaps the presence of folded-over leaf edges in *Polytrichum juniperinum* (Figure 38), absent in *P. commune* (Figure 39), makes it easier to obtain the nutritious photosynthetic lamellae in *P. commune* (Figure 39).

Figure 36. Comparison of mean protein \pm 95% CI in stems and leaves of two *Polytrichum* species. Based on Weston 1995; Liao & Glime unpublished data; Bradford's (1976) test, n = 3.

Figure 37. Comparison of mean phenolic content \pm 95% CI in stems and leaves of two *Polytrichum* species. Based on Weston 1995; Liao & Glime unpublished data; Folin-Denis test (Swain & Hillis 1959) and Prussian Blue test for tannin; n = 3.

Isopods can be a major inhabitant of bryophytes, becoming especially obvious at night when they migrate to the surface to feed (Hribljan & Glime in prep.). But even the isopods are fussy about which bryophytes they eat. Phenolic content seems to deter isopod consumption of various leaves (Warburg 1987). But deterrents may not be the only answer to these food preferences. *Porcellio scaber* (Figure 24) will eat *Thuidium delicatulum* (Figure 40-Figure 41) ravenously, but ignore *Dicranum polysetum* (Figure 42) and sometimes ignore *Pleurozium schreberi* (Figure 43) (Liao 1993; Glime 2006). When faced with *Polytrichum* (Figure 33), they eat the leaves, but little of the stems (Liao 1993, unpublished data; Hribljan 2009). This suggests that chemistry might be more important than structure, as *Thuidium delicatulum* is a crunchy moss with papillae (but small leaves, Figure 41) whereas *P. schreberi* and *D. polysetum* are softer and more flexible, lacking papillae (but with large leaves). But it appears that we may not have examined enough potential deterrents in *Thuidium*. And we need to beware of differences between populations and seasons. Fatoba *et al.* (2003) found that whereas *Thuidium gratum* from the Nigerian tropics lacked detectable phenolics, it had tannins, alkaloids, and cardiac glycosides. In a different location in tropical Nigeria (and a different date), Adebisi *et al.* (2012) found that this same species had a high content of saponins (absent in the Fatoba *et al.* 2003 study) and flavonoids, but also had a very low content of phenolics. Perhaps isopods, like many humans, just prefer a crunchy snack.

Figure 43. *Pleurozium schreberi*, a moss that is sometimes eaten and sometimes ignored by the wood louse *Porcellio scaber*. Photo by Janice Glime.

Hribljan and Glime (in prep) explored the food preferences of populations of *Porcellio scaber* (Figure 24) in the Keweenaw Peninsula of Michigan, USA. In food preference experiments, these isopods preferred the moss *Pleurozium schreberi* (Figure 44) over leaf litter from *Acer saccharum* (Figure 45) and *Pinus strobus* (Figure 46) in each of three study months of September – November (Figure 47). They compared the carbohydrates, proteins, and phenolics in these three species for the three months of the feeding trials and found that *Pleurozium schreberi* had the lowest levels of phenolics and highest levels of carbohydrates of the three choices of food (Figure 48). This is interesting because some studies (e.g. Pakarinen & Vitt 1974) have suggested that mosses were unable to provide enough energy for herbivores, but it appears that compared to leaf litter the mosses may, at least at times, have more carbohydrates than litter and be preferred food for isopods. Furthermore, all five mosses tested [*Pleurozium schreberi*, *Thuidium delicatulum* (Figure 40-Figure 41), *Polytrichum juniperinum* (Figure 33), *Rhytidiadelphus triquetrus* (Figure 49), and *Dicranum polysetum* (Figure 42)] had higher carbohydrate contents than the leaf litter of the trees tested (Figure 50-Figure 51). However, protein was higher in both types of tree leaf litter tested compared to that of *Pleurozium schreberi* (Figure 48).

Figure 44. *Pleurozium schreberi* showing damage from *Porcellio scaber* that feeds on it at night. Note the less green plants on left that have suffered considerable damage. On the right you can see naked red stem tips where leaves and buds have been eaten. Photo by John Hribljan, with permission.

Figure 45. Freshly fallen *Acer saccharum* (sugar maple) leaves, a food source less preferred by *Porcellio scaber* than the moss *Pleurozium schreberi* in September to November. Photo by Janice Glime.

Figure 46. A common sight of needles of *Pinus strobus* (white pine) mixed with the moss *Pleurozium schreberi*. The needles are a food less preferred in September to November by *Porcellio scaber* than the moss *Pleurozium schreberi*. Photo by Janice Glime.

Figure 47. Comparison of mean air-dried mass ($\pm 95\%$ CI) consumed by isopods in 24 hours when given the choice of the moss *Pleurozium schreberi* and the tree leaves of *Acer saccharum* and *Pinus strobus*. The same letters signify means that are not significantly different from each other ($\alpha = 0.05$ post two-way ANOVA & Tukey test, $n = 10$). Hribljan 2009; Hribljan & Glime in prep.

Based on these experiments, Hribljan and Glime (in prep) compared the preferences among five species of mosses that occurred within the foraging distance of the isopods. *Porcellio scaber* (Figure 24) significantly preferred the moss *Pleurozium schreberi* (Figure 44) to the mosses *Rhytidiadelphus triquetrus* (Figure 49), *Thuidium delicatulum* (Figure 40), *Dicranum polysetum* (Figure 42), and *Polytrichum juniperinum* (Figure 50), with *Pleurozium schreberi* and *Rhytidiadelphus triquetrus* having lower phenolic concentrations than *Dicranum polysetum* and *Polytrichum juniperinum* (Figure 51). The

Thuidium delicatulum, preferred in earlier experiments over *Pleurozium schreberi* (Liao 1993; Glime 2006), was not among the top preferences, perhaps due to its lower carbohydrate content at a time of year when the isopods were preparing for winter.

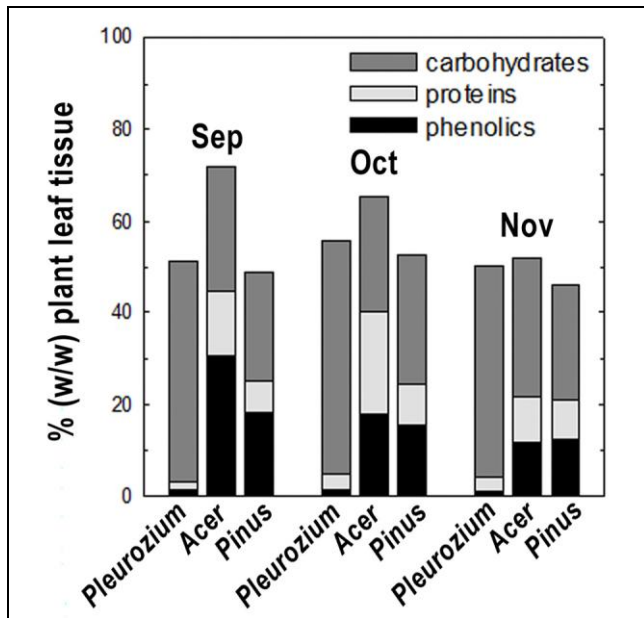

Figure 48. Comparison of percent of carbohydrates, proteins, and phenolics in freeze-dried leaves of the moss *Pleurozium schreberi*, sugar maple tree *Acer saccharum*, and white pine *Pinus strobus*. Samples were taken once each month during to compare stages of decay in the tree leaves. Values are means of 10 samples. Redrawn from Hribljan & Glime (in prep).

Chemical analysis revealed that *P. schreberi* contains a high protein:phenolic ratio (Figure 55) (Hribljan & Glime in prep). Despite the high phenolic content and low protein content of *Rhytidiadelphus triquetrus* (Figure 49), these isopods would still consume it (Figure 52-Figure 53), perhaps for its high carbohydrate content, but it was not a preferred food (Figure 50-Figure 51). On the other hand, the feces indicated that this moss had not been well digested (Figure 54). As a terrestrial moss, it collects only minimal detritus, suggesting that it could have limited food value. *Dicranum polysetum* was least preferred despite a relatively high carbohydrate content (Figure 50-Figure 51).

Hribljan (2009) suggested that the protein:phenolic ratio might be more important in determining isopod herbivory than concentration of phenolic compounds alone. In this case, *Pleurozium schreberi* (Figure 44) had the highest ratio of proteins:phenolics (Figure 55), but it was not significantly different from that of *Dicranum polysetum* (Figure 42), which had the lowest mass eaten, suggesting that this ratio alone did not account for the preference (Hribljan & Glime in prep). With their unusual digestive tracts (see Digestion above), the terrestrial isopods may be able to gain sufficient nutrition from

mosses despite phenolics, whereas other arthropods like the crane fly *Tipula montana*, a moss-food-avoider, cannot (Smith *et al.* 2001).

Figure 55. The mean protein:phenolic ratio of leaves (\pm 95% CI), arranged in order from most to least consumption, of freeze-dried mosses *Pleurozium schreberi* (PLE), *Thuidium delicatulum* (THU), *Polytrichum juniperinum* (POL), *Rhytidiadelphus triquetrus* (RHY), and *Dicranum polysetum* (DIC). $n = 10$; bars with the same letter are not significantly different, post ANOVA Tukey test, $\alpha = 0.05$.

We cannot rule out the possible importance of carbohydrates, and Forman (1968) provides evidence that caloric content is highest in two of the mosses that seem to be preferred in our experiments (Hribljan & Glime in prep). Forman showed that *Thuidium delicatulum* (Figure 40) had the highest caloric value (4305 cal/gdw) among the ten mosses he tested; *Pleurozium schreberi* (Figure 43) had the second highest caloric content (4240 cal/gdw), fitting with our data on carbohydrates. On the other hand, the lowest content was that of *Dicranella heteromalla* (Figure 56) (3749 cal/gdw), a moss in the same family as *Dicranum polysetum* (Figure 42), the latter being least preferred in our experiments. Furthermore, Sveinbjörnsson and Oechel (1991) found that the carbohydrate concentration varied with season in *Polytrichum commune* (Figure 34), but not in *Polytrichastrum alpinum* (Figure 57). Could it be that some bryophytes become more desirable in autumn due to higher carbohydrate concentrations?

Figure 56. *Dicranella heteromalla* in its typical soil bank habitat. This moss has a relatively low caloric content. Photo by Janice Glime.

Figure 57. *Polytrichastrum alpinum* with capsules. Photo by Michael Lüth, with permission.

Several other factors could account for the preferences. First, we know that other deterrents such as saponins, alkaloids, and steroids are present in some mosses and were not tested here (Adebiyi *et al.* 2012). Leaf structure could make it difficult to obtain energy from the leaves or they might be harder to chew and break off (**toughness**). We have no measures of such toughness differences for these species, so we must keep an open mind about that possibility. The structure of the cell wall might make it difficult to obtain the cell contents easily (Figure 58-Figure 59). As seen in Figure 58, *Pleurozium schreberi* has much thinner cell walls than the much less preferred *Dicranum polysetum* (Figure 42, Figure 59). But does this really translate to toughness? Or edibility? And the leaves might differ from the stems in their phenolic content, making measurements of whole plants meaningless if only leaves are eaten. However, Hribljan and Glime (in prep) used only leaves for their analyses of proteins, carbohydrates, and phenolics. They did compare the chemistry of stems and leaves in *Pleurozium schreberi*; for all three chemical groups (phenolics, protein, carbohydrates), leaves had the higher content (Figure 60).

Figure 58. Leaf cell structure of *Pleurozium schreberi* showing thin cell wall and high ratio of cell contents to cell wall. This species was most consumed among the five moss species in the study by Hribljan and Glime (in prep.). Photo from Wikimedia Commons.

Figure 59. Leaf cell structure of *Dicranum polysetum* showing thick cell wall and low ratio of cell contents to cell wall. This species was least consumed among the five moss species in the study by Hribljan and Glime (in prep.). Photo by Walter Obermayer, with permission.

Figure 60. Comparison of mean phenolic, protein, and carbohydrate content (\pm 95% CI) of *Pleurozium schreberi* between freeze-dried leaves and stems (paired t-test, an asterisk indicates a significant difference between the two bars, $\alpha = 0.05$, $n = 3$).

These studies leave many questions unanswered, especially regarding season. Do the concentrations in the bryophytes change with season? Do the isopod needs change with season? Does the tree litter change in such a way that bryophytes are preferable at some times and not others without requiring any change in the bryophytes? And are the relationships the same if liverworts are presented instead of mosses? Finally, what evolutionary patterns can we observe and how do they relate to habitat and dominant herbivores?

Defenses and Apparency Theory

Plant defenses can be grouped into **physical** and **chemical defenses**. **Physical defenses** include structural modifications into such deterrents as thorns and spines or tissue modifications that include hard cell walls (Cooper & Owen-Smith 1986). The small bryophyte structure does not permit the large thorns found in some tracheophytes, but hard cell walls and hard papillae as extensions of the cell wall do fall into this category.

Chemical defenses can be divided into **quantitative** and **qualitative defenses** (Feeney 1975, 1976; Rhoades & Cates 1976; Yamamura & Tsuji 1995). **Qualitative defenses** include toxic substances like the milky juices of milkweed plants. Few bryophytes have been tested for such substances as those found in the milkweed, but as mentioned above, similar compounds do exist in the few that were tested (Fatoba *et al.* 2003; Adebisi *et al.* 2012). **Quantitative defenses**, on the other hand, are quite common in bryophytes and typically interfere with digestion (Yamamura & Tsuji 1995), creating malnutrition in the herbivore. Phenolics typically fall in this category.

The **apparency theory** (Feeney 1976) was developed to explain the production of secondary compounds such as **phenolics** among some plants and not others (Coley *et al.* 1985). Coley and coworkers contended that resource availability in the environment was a primary determinant of both the amount and type of plant defense. Under resource limitation, slow-growing plants are favored by the environment over fast-growing plants because the former use lower levels of resources. At the same time, slow growth rates favor larger investments in **antiherbivore** defenses because growth is not fast enough to replace effects of herbivory. Since bryophytes are slow-growing, they are often able to inhabit locations with low levels of resources, including sunlight, where few other plants grow robustly, making the bryophytes one of the obvious, or **apparent**, plants in the area. Hence, bryophytes could benefit in these situations by the production of antiherbivore compounds. In fact, development of such compounds may have been essential to their success on land as the arthropods likewise became terrestrialized (Graham *et al.* 2004). Phenolic compounds, occurring in varying concentrations from the bryophytes tested, are useful as antiherbivore compounds. And it appears that bryophytes are not eaten by many kinds of organisms. Isopods are a notable exception to that avoidance. But even they have preferences.

We have seen above that for the isopod *Porcellio scaber* (Figure 1-Figure 2), *Dicranum polysetum* (Figure 42, Figure 59) is a less-preferred moss compared to *Thuidium delicatulum* (Figure 50) (Hribljan & Glime in prep). The former is an **apparent** moss (one with high visibility in its habitat) with high concentrations of secondary compounds (phenolic compounds), whereas *Thuidium delicatulum* is **unapparent** (grows with other potential food plants) and is low in secondary compounds (Liao 1993). Furthermore, *Thuidium delicatulum* tends to grow where there is more sun and often more nutrients, thus supporting the concept that production of phenolic compounds may be related to resource limitation (see Coley *et al.* 1985).

But it is not so simple. *Pleurozium schreberi* (Figure 43) is a very apparent moss, sometimes covering hectares with 100% cover, yet had the highest consumption. The study by Liao (unpublished) and the discussion here related to the study by Hribljan and Glime (in prep) seem to be the only studies that have tested the apparency theory in bryophytes. This should be an interesting topic for study.

Aquatic Consumers

Among the aquatic isopods, some consume bryophytes, but others apparently do not. Torres-Ruiz *et*

al. (2007) traced food and fatty acids in macroinvertebrates and determined that the isopods in a stream food web fed on terrestrial food sources and on algae. *Asellus* species consume a variety of aquatic vegetation. Marcus *et al.* (1978) experimented with a sometimes moss dweller, *Asellus aquaticus* (Figure 61), and demonstrated that it ate both *Elodea canadensis* and **periphyton** (adhering algae), being able to survive on either. They found fragments of *Elodea* leaves and pieces of oak (*Quercus*), as well as the alga *Oedogonium* in the guts of some individuals of this species from Lake Windermere, England.

Figure 61. *Asellus aquaticus*, an aquatic isopod that dines on *Fontinalis novae-angliae*. Photo from Wikimedia Commons.

Parker *et al.* (2007) found that *Asellus aquaticus* (Figure 61) consumed large quantities of the brook moss *Fontinalis novae-angliae* (Figure 62) but rejected the riverweed *Podostemum ceratophyllum* (Figure 63), despite having similar protein content in both. The isopods continued to eat the *F. novae-angliae* even when the organic matter was removed from the plants, demonstrating that the moss itself was most likely a food source. They suggested that the mosses served as a refuge against larger predators that could eat the *A. aquaticus*, largely because such predators as crayfish (*Procambarus spiculifer*, Figure 64; Figure 95) and Canada geese (*Branta canadensis*; Figure 65) avoided the mosses despite its comprising 89% of the plant cover in the stream. It seems that the chemical deterrents to the geese and crayfish served to protect the many macroinvertebrates living there. And to the advantage of the *A. aquaticus*, these isopods rejected the riverweed. On the other hand, this species was not deterred by the chemical defenses of the mosses.

Asellus cf. militaris (Figure 66) eats *Fontinalis antipyretica* (Figure 66) in lab experiments and in the field (LaCroix 1996a). Likewise, *A. cf. militaris* feeds on *Fontinalis novae-angliae* (Figure 62) in its native aquatic habitat (LaCroix 1996a; Parker *et al.* 2007). Fragments of

F. antipyretica were found in the feces of freshly collected *A. cf. militaris* (Figure 67), and when *A. cf. militaris* was cultured in the lab with the moss as a substrate it produced fecal pellets containing the moss. Gut analysis revealed diatoms and detrital matter along with small fragments of *Fontinalis* (Figure 68). LaCroix found that even terrestrial isopods would eat *F. antipyretica*.

Figure 68. *Fontinalis antipyretica* and diatoms in gut of *Asellus cf. militaris*. Photo by Jacob LaCroix, with permission.

Stern and Stern (1969) determined the greatest abundance in February and the lowest in July in a cold springbrook in Putnam County, Tennessee, USA. *Asellus*

militaris occurs on *Fontinalis antipyretica* for the first few instars, then moves to the leaf litter.

Observations by LaCroix and Glime (unpublished) suggest that this species can live among the mosses for a much greater part of the life cycle in northern Michigan, USA. Like terrestrial isopods, *Asellus cf. militaris* (Figure 66) avoids the light. Hence, more of these isopods were on the mosses in the shade in the stream than in the sun (LaCroix 1996a; Glime 2006). When both sun and shade mosses were brought to the lab and placed under the same light conditions, the isopods preferred those that had grown in the sun. Furthermore, the isopods chose to go to the mosses collected from the sunny location under both light and dark conditions (LaCroix 1996a). Surprisingly, the shade populations had higher concentrations of phenolic compounds (LaCroix 1996a), a phenomenon contrary to the use of phenolic compounds as light protectants in tracheophytes (Swain & Hillis 1959; Martin & Martin 1982; Mole *et al.* 1988; Vergeer *et al.* 1995), but consistent with the preference for those grown in the sun when light was no longer a factor. Bryophytes often take advantage of phenolic compounds as protection against UV radiation (Jorgensen 1994; Clarke & Robinson 2008; Wolf *et al.* 2010), suggesting that herbivory was a stronger factor in this case than light. This combination of circumstances raises several questions.

First, how can we explain isopod preference for high phenolic shade bryophytes in the field but preference for lower phenolic sun bryophytes in the lab (Figure 69)? Parker *et al.* (2007) showed *Asellus aquaticus* (Figure 61) was not deterred by extracts from *Fontinalis novae-angliae* (Figure 62). Parker *et al.* suggested these isopods have some means to render the deterrent compounds ineffective, as suggested above in the discussion of the digestive system. LaCroix (1996a, b) concluded that food quality of the moss determined what isopods ate, but that shade was a more important determining factor controlling their location (and hence available food) in the field. This combination can structure communities in which small invertebrates live among unpalatable hosts that provide enemy-free space, and isopods have the benefit of avoiding their own predators while being able to eat the substrate.

Figure 69. Comparison of moss *Fontinalis antipyretica* mean phenolic content (\pm 95% CI) and number of moss-dwelling isopods *Asellus cf. militaris* (\pm 95% CI) choosing to inhabit it. Most of the isopods in the lab chose to go to the sun-grown *Fontinalis antipyretica* that had a lower phenolic content than that in the shade plants. Based on LaCroix 1996b.

Apparency or UV Protection?

Having suggested an explanation for the behavior of the isopods, we are left with the question of the higher production of phenolic compounds by the bryophytes in the shade compared to those in the sun. As suggested above for terrestrial bryophytes, it is possible that the production of phenolic compounds by mosses in the shade is an evolutionary response to **apparency**. In shady locations of streams, mosses are likely to be the dominant macrophyte vegetation, with aquatic tracheophytes preferring sun (LaCroix 1996a). As the dominant (most apparent) organism, probability would make the bryophytes the most likely to be eaten. Furthermore, the *Fontinalis* had phenolic compounds in both locations, so it is likely that they had sufficient levels in the sun to provide the needed protection against UV radiation.

Could it be that the *Fontinalis* produces phenolic compounds in response to herbivory? If so, are they able to signal (chemically) to the nearby mosses to do likewise? Or might this moss have evolved to produce more phenolic compounds in the shade under the selective pressure of one of its primary herbivores, aquatic isopods, that spends most of its time in the shade?

Habitat

You know where isopods hang out. Look under anything with a tiny bit of space to give access and you will find them. They go scurrying away in seek of shelter when you lift their cover. But look out at night. They come out in force to eat your vegetables – and your mosses.

Bryophytes seem to play multiple roles in the niches of isopods. For terrestrial species, bryophytes provide refuge against some predators, but even for litter-dwelling species they may represent islands for rehydration amid a dry food area. But the bryophytes can also serve as food, especially at night when desiccation is less of a problem. Aquatic bryophytes likewise serve as a refuge against predators and can also serve as food or a food substrate for periphyton and detritus. Zimmer and Topp (1997) found that *Porcellio scaber* (Figure 1-Figure 2) populations decreased in response to acidification, and that microorganisms, often reduced by acid conditions, were important in the maintenance of juveniles.

It seems logical that the first consideration for a habitat for isopods is a moist place with good aeration that provides shelter and darkness, but that also has a food source. In the water, detritus and periphyton can serve as the food source, but on land periphyton is too minor and detritus is more likely to be in the soil. Hence, bryophytes that provide these physical characteristics and are also palatable and chewable become a food source and provide a suitable habitat.

Terrestrial

Terrestrial habitats require special adaptations for these groups, as discussed above. Edney (1954) found that terrestrialization increased in the order of **Ligiidae**, **Trichoniscidae**, **Oniscidae**, **Porcellionidae**, to **Armadillidiidae**. This order can be interpreted as their order for tolerating drought. And each of these families has members known from bryophytes.

Božanić (2011) sampled the moss invertebrate fauna in a forest in the Vrapač National Nature Reserve, Czech Republic. The most abundant groups were **Acarina** (mites – 2946 individuals), **Collembola** (springtails – 1341 individuals), and **Isopoda** (320 individuals). Within moss colonies on the forest floor and tree trunks they found the isopods *Androniscus roseus*, *Hyloniscus riparius* (Figure 86), *Hyloniscus* spp., *Lepidoniscus minutus*, *Ligidium hypnorum*, *Porcellium collicola* (Figure 3), *Porcellium conspersum*, *Trachelipus rathkii* (Figure 26), *Trachelipus ratzeburgii* (Figure 85), *Trachelipus* spp., and *Trichoniscus pusillus* (Figure 25). In the adjoining forest floor, the isopods were not among the most numerous groups sampled. Sample size was important in determining abundance, with more isopods occurring in larger sample sizes of ~400 sq cm. *Trichoniscus pusillus* and *Hyloniscus riparius* in particular preferred thicker mosses, especially in *Plagiomnium undulatum* (Figure 70) with a 50-mm thickness. These two species are known to be **hygrophilous** (water-loving) (Tajovský 2000), perhaps explaining their preference for thicker mats that could retain moisture longer. This preference could create danger as this thicker moss was also in the range of preference of a predator ant, *Myrmica ruginodis* (Figure 71), that occurred primarily in mosses having 40-50 mm thickness (Božanić 2011). In poplar forests of Hungary, *Hyloniscus riparius* (Figure 86) occurs primarily in wet, decaying trees that are covered with mosses (Farkas 1998).

Figure 70. *Plagiomnium undulatum*, a moss that forms 50 mm deep mats where the isopods *Trichoniscus pusillus* (Figure 25) and *Hyloniscus riparius* (Figure 86) take shelter. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Philoscia muscorum (Figure 17), an isopod with a mossy name, is common and widespread in the UK among mosses and other substrata (Stenhouse 2007). *Porcellio* is perhaps the most common genus in the Northern Hemisphere, occurring with mosses in Europe and North America. *Porcellio scaber* (Figure 1-Figure 2) is often found among mosses and is one of the commonest of the

woodlice in the UK (Stenhouse 2007). Its ability to feed on bryophytes is discussed above.

Diver (1938) examined the common woodlouse (*Porcellio scaber*, Figure 24) in five coastal animal successional zones in the British Isles where the plant carpet played a major role in characterizing the habitat. In the *Calluna-Psamma* zone, there was a well-developed lichen-moss carpet that replaced the grass turf. Nevertheless, only one species of isopod occurred there, whereas two more were added in the *Calluna* zone where the ground cover was nearly 100% *Calluna*. In a separate study that compiled many records, Harding and Sutton (1985) reported *Trichoniscus pusillus* (Figure 25) from all five dune zones, but primarily in dune slacks, where it was associated with mossy areas as well as damp hollows, large pieces of concrete, or decaying wood.

Figure 71. *Myrmica ruginodis*, an ant that lives among the same mosses as the isopods *Trichoniscus pusillus* and *Hyloniscus riparius*, and is a known arthropod predator. Photo by Boris Ginestet and Nicolas Calmejane, through Creative Commons.

Božanić and coworkers (Božanić 2008; Božanić *et al.* 2013) used heat to extract invertebrates from 61 terrestrial bryophyte samples from forests of the Czech Republic. They found 45 invertebrate species (13 higher taxonomic groups) from among 15 bryophyte species. The moss *Brachythecium oedipodium* (Figure 72) seems to be a preferred habitat, exhibiting the highest invertebrate diversity on decaying wood, where **Isopoda** were the most abundant (439 specimens), but diversity was also high in *B. salebrosum* (Figure 73) (mean 4 spp. per sample) and *B. rutabulum* (Figure 74) (mean 5.5 spp. per sample).

Atrichum undulatum (Figure 75), *B. rutabulum*, and *Hypnum cupressiforme* (Figure 76) were the most frequent mosses and presented a high number of invertebrate taxa. This abundance is despite the content of hydroxycinnamic and phenolic acids present in *B. rutabulum* (Davidson *et al.* 1989).

Figure 72. *Brachythecium oedipodium*, a preferred habitat for invertebrates, including **Isopoda**. Photo by Michael Lüth, with permission.

Figure 74. *Brachythecium rutabulum* capsules, a moss with high invertebrate diversity, including isopods. Photo by Martin Cooper, through Creative Commons.

Figure 75. *Atrichum undulatum*, mosses where clump size is important in determining isopods (smaller clumps) vs annelids (larger clumps). Photo by Michael Lüth, with permission.

Figure 76. *Hypnum cupressiforme*, a bryophyte with a high diversity of invertebrates. Isopods were most abundant in small cushions. Photo by Michael Lüth, with permission.

Type of substrate, size of cushion, and height above the ground were important determinants of the invertebrate species in these Czech forests (Božanić 2008; Božanić *et al.* 2013). **Isopoda** were numerous in small cushions, in contrast to the **Enchytraeidae** (Annelida) that were abundant in larger moss carpets. The woodlice (isopods) were most abundant among the moss *Plagiomnium* (Figure 77) on the ground. Tree size also played a role, with isopods *Trichoniscus pusillus* (Figure 78) and *Porcellium collicola* (Figure 3) living among mosses on smaller trees, whereas the isopod *Trachelipus rathkii* (Figure 26) occurred among mosses growing on larger trees. It is possible that correlation with tree diameter resulted from colonization rates and succession of the community. Nevertheless, *T. pusillus* also occurred among mosses on volcanic rock in the Azores (Vandel 1968). Because the bryophyte habitat was one of the earliest ones available to invasion of land, Božanić and coworkers (2013) suggest that the bryophytes may serve as refugia in expected future climate change.

Figure 78. *Trichoniscus pusillus*, an isopod that lives among mosses on small trees and among mosses on exposed lava rocks. Photo by Graham Montgomery, with permission.

While pillbugs require moisture, a boggy habitat can be too moist. Although *Armadillidium* is among the best adapted of isopods to terrestrial life, surviving in relatively dry habitats, some species do use mosses as a habitat. Dale and Dale (1986) report *Armadillidium pulchellum* (Figure 79) in moss mats of the coastal cliff slopes in the UK. They were surprised to find this species also inland in abundance under mosses on a wall. Harding and Sutton (1985) likewise report them under mats of mosses as well as under stones and mats of the flowering plants *Thymus* spp. and *Sedum anglicum* in the UK. In the daytime, one can also find *Armadillidium pictum* (Figure 80) under stones and among mosses in the UK (Harding & Sutton 1985).

Figure 80. *Armadillidium pictum*, an isopod that lives under stones and among mosses in the UK. Photo by Jan van Duinen <<http://www.janvanduinen.nl/>>, with permission.

The genus *Ligia* (Figure 81) is one of the less terrestrialized isopods, requiring more moisture than other terrestrial genera that have been studied, often living in tidal zone cliffs and rocky beaches. But on the Hawaiian Island of Kauai, *L. perkinsi* commonly occurs among wet mosses of indigenous trees in the montane rainforests above 600 m, whereas on Oahu it is known instead from a windward wet rocky cliff at only 300 m (Taiti *et al.* 2003).

Figure 81. *Ligia* sp., related to the moss dweller *Ligia perkinsi* that occurs among wet mosses on trees in Hawaiian rainforests. Photo by Steve Nanz, through Creative Commons.

Isopods even live in the exposed higher parts of trees. In the neotropical montane forests of Costa Rica, isopods dwell in both the ground litter and canopy litter, which includes bryophytes (Nadkarni & Longino 1990). But in the montane forests, the isopods had higher densities on the ground.

In the Polynesian islands, *Philoscia truncata* occurs both under stones and among mosses at 500 m on the Society Islands (Jackson 1938). On the Mangareva Islands *Spherillo marquesarum* occurs under mosses and rocks. In the Tasmanian temperate rainforests, isopods and other invertebrates often occur among mosses in places where they are not common on other substrates (Greenslade 2008). The higher moisture content of the mosses most likely accounts for the higher species richness, with 28 species of isopods among the mosses there. *Styloniscus nicholli* is common in Tasmania and can occur among *Sphagnum* (Figure 83) at 1600 m at Point Lookout (Green

1974). In the Antarctic, several species of *Styloniscus* occur among mosses: *S. otakensis* (Figure 88), *S. pallidus*, *S. thompsoni*, *S. verrucosus* (Pugh *et al.* 2002).

Working in the Azores and Madeira, Vandel (1968) found a number of bryophyte-dwelling species not mentioned in other locations cited here, including *Trichoniscus pygmaeus* among mosses, *Miktoniscus chavesi* among mosses in a lava field and the bottom of a crater, but also among liverworts in *Erica* bush, *Chaetophiloscia guernei* among mosses in the *Erica* forest and other indigenous vegetation, and *Eluma purpurascens* among mosses at snowline, under mosses at the roadside of an old lava field, and among mosses in the *Erica* forest and heath. *Androniscus dentiger* (Figure 82) occurred on exposed lava rocks covered with mosses and lichens

Peatlands

Sphagnum (Figure 83) in peatlands often has its own unique fauna, in part due to the unique assemblage of plants. The pH can influence some species. The surface can get quite hot, thus being inhospitable to isopods. But within the peat mats, the gradient of temperature and moisture often provides suitable habitat with the possibility for vertical migration as conditions fluctuate.

Figure 83. *Sphagnum cristatum*, a moss from boggy habitats where the isopod *Trachelipus rathkii* (Figure 26) lives in New Zealand. Photo by Jan-Peter Frahm, with permission.

Antonović *et al.* (2012) used pitfall traps to study the isopods living in the Dubravica peat bog and surrounding forest in Croatia. They found eight species of isopods, comprising 389 individuals, during their two-year study, with little difference in species richness between the bog and forest. They considered the small size of the bog peatland, progressive succession of plant life, and interactions among species to account for the high species richness there. Where the grass *Molinia* spread into the bog, the *Sphagnum* (Figure 83) was less humid and provided habitats for forest isopod species. The edge (**ecotone**) had the highest diversity, probably due to multiple factors: greater variety of niches, seasonal immigration, and less predator abundance relative to the open bog. Within the bog, cohabiting lycosid spiders (see Chapter 7-4 on Peatland Spiders) and *Myrmica* ants (Figure 84) were a threat to the isopods. In the bog *Trachelipus rathkii* (Figure 26), a known bryophyte dweller, was the most common isopod, whereas in the forest it was *Protracheoniscus politus* (Figure 85). Bog-specific species were absent. Instead the isopod fauna was dominated by widespread species with wide niche requirements, which Antonović *et al.* attributed to the degradation process on the bog. Antonović and coworkers considered one bog inhabitant here, *Hyloniscus adonis* (see Figure 86), to be **tyrphoxenous**, *i.e.*, a vagrant not reproducing in the bog.

Springs

I expected to find a number of records of isopods among mosses in springs and was surprised to find relatively few. In some of these, although mosses were abundant, the isopods were in the open water and bottom sediments, but not among the mosses (Gooch & Glazier 1991; Erman 2002). Erman (2002) could find no relationship between moss mats and invertebrate diversity, including that of isopods. The only relationship he found was that the mosses indicated that the spring had constancy and persistence.

In his study of isopods in habitats of the Azores and Madeira, Vandel (1968) found *Trichoniscus pusillus* (Figure 25) among mosses in a spring on the mountain slope and among *Sphagnum* at another spring. But the other spring species were less familiar among moss dwellers, including *Miktoniscus chavesi*, *Chaetophiloscia guernei*, and *Eluma purpurascens* among mosses. *Oniscus asellus* occurred among mosses in sheltered ravines and under wet moss in the ravine.

Waterfalls

Waterfalls provide a variety of niches from very aquatic to damp terrestrial. These microhabitat niches change as water levels recede and may be quite dry in summer when the waterfall recedes or disappears altogether. Stephensen (1935) found terrestrial Talitridae in such habitats in Java in the Marquesas where *Orchestia floresiana* occurred among mosses of rivulets, fountains, and waterfalls.

Aquatic

Aquatic isopods can also be moss inhabitants. Fontaine and Nigh (1983) suggest that aquatic isopods like *Asellus* (Figure 61) may be limited by their slow colonization rate. When such host plants as *Nitellopsis* (Figure 87) die off, the isopods need an alternative substrate with sufficient food available (Hargeby 1990). In habitats where bryophytes occur, these bryophytes could provide the permanence needed by the slow isopod colonizers.

Figure 87. *Nitellopsis obtusa*, an alga that provides habitat for isopods like *Asellus* but that can disappear in some habitats for part of the year, causing the isopods to seek other shelter. Photo through Public Domain.

Although *Asellus aquaticus* (Figure 61) is well known from bryophytes, it is the juveniles that are most abundant in algal and bryophyte mats, whereas the larger adults are typically associated with large-sized substratum particles (Graca *et al.* 1994). As already noted in discussing bryophytes as food, *Asellus* cf. *militaris* (Figure 66) occurs in mats of *Fontinalis* spp. in streams where it feeds on both the mosses and associated detritus and periphyton.

On Macquarie Island in the sub-Antarctic, *Styloniscus otakensis* (Figure 88) lives among mosses on margins of streams, among other places (Greenslade 2008). Cowie and Winterbourn (1979) found that the isopod *Styloniscus otakensis* was the only common invertebrate on the moss *Cratoneuropsis relaxa* (Figure 89) in the outer spray zone of a spring brook in the Southern Alps of New Zealand. They attributed differences in fauna among the moss species to differences in flow rates, availability of detritus, and differences in water saturation.

Figure 88. *Styloniscus otakensis*, an aquatic species in a genus with a number of terrestrial moss-dwelling members in forests and bogs of Tasmania, New Zealand, and nearby islands. Photo by Mark Stevens. PERMISSION PENDING.

South Africa may have species unfamiliar to most of us in the Northern Hemisphere. Enckell (1970) found *Protojanira prenticei* among mosses in the upper part of a streamlet there.

Pollution

Pollution in the form of heavy metals can quickly move up the food chain in streams. Detrital feeders like *Asellus* species can concentrate the metals from the detritus on the streambed or among mosses, then get eaten by larger invertebrates or fish, further concentrating the pollutants (Eimers *et al.* 2001). However, Eimers and coworkers found that when the sediment organic content was increased (20% peatmoss), the cadmium concentration in *Asellus racovitzai* decreased compared to that of mineral sediment treatments, indicating that bryophytes, especially *Sphagnum* (Figure 83), might be able to protect the isopods and organisms higher up the food chain by sequestering the heavy metals and keeping them out of the water column. Other mosses, for example *Fontinalis antipyretica* (Figure 66), occurring in the same waters with *Asellus aquaticus* (Figure 61), also accumulate heavy metals. Lithner *et al.* (1995) found that when the pH decreased, the bioconcentration factors decreased in the bryophytes while several of the metals simultaneously increased in fish. Hence, using aquatic bryophytes as bioaccumulators to protect the organisms is complicated, but they could be a useful tool to predict imminent fish die-off.

CLASS MALACOSTRACA, ORDER MYSIDA

The **Mysida** are known as opossum shrimps because of the brood pouch where females carry their larvae. Mysids are not common on bryophytes, but they can use them as a restaurant in aquatic habitats. *Mysis relicta* (Figure 90) in Char Lake, Northwest Territories, Canada, feeds primarily on diatoms and inorganic particles on moss substrata (Lasenby & Langford 1973). It is known as an opportunistic feeder, permitting it to survive on a variety of resources (Grossnickle 1982).

Figure 90. *Mysis relicta*, a species that feeds on diatoms and detritus among mosses in some habitats. Photo by Perhols, through Creative Commons.

CLASS MALACOSTRACA, ORDER DECAPODA

Decapods include such animals as crayfish, lobsters, crabs, and hermit crabs. For such large invertebrates to succeed on land they have developed morphological, physiological, biochemical, and behavioral adaptations (Bliss & Mantel 1968). Adult land crabs maintain water balance through the coordinated action of gills, pericardial sacs, and the gut, taking up, storing, and redistributing both salts and water to maintain an osmotic and water balance. In larvae, on the other hand, this suite of responses is not practiced. As is known for the isopods, there is evidence that at least some decapods excrete some of their ammonia as a gas (Weihrauch *et al.* 2004). Adult land crabs use both gills and the highly vascularized lining of the branchial chambers for gas exchange (Bliss & Mantel 1968). They generally cannot survive low temperatures, but their cytochrome C seems to help in their survival of high temperatures. Finding a mate is typically accomplished by both visual and acoustic signals, coupled with ritualistic behavior.

Decapods generally are too large to live among most bryophytes, but they are not without interesting bryological interactions. The decapod *Thalassina anomala* (Figure 91-Figure 93), a mud lobster, forms soil mounds (Figure 92-Figure 93) when it builds its nest (Yamaguchi *et al.* 1987). It is on these soil mounds in the mangrove forests of Japan that *Fissidens microcladus* dwells. By living on the soil mounds, the moss is never submerged at high tide and most likely benefits from the moist air.

Coffey and Clayton (1988) have suggested that deep water bryophytes in New Zealand lakes do not occur in the presence of freshwater crayfish. It appears that in the presence of the crayfish *Paranephrops* spp. (Figure 94), the bryophytes suffer both mechanical damage and browsing. In Lake Wanaka, there is a deep water (down to 50 m) community of bryophytes (Coffey & Clayton 1988). But in other New Zealand lakes the mosses were absent. This absence correlated with the presence of large crayfish (*Paranephrops* spp.) populations. Coffey and Clayton suggest that the mosses are absent not due to different habitat needs from the crayfish, but from the browsing and mechanical damage caused by the crayfish.

Figure 94. *Paranephrops planifrons*, member of a genus of crayfish that inflicts mechanical damage on bryophytes. Photo by David Wilson, through Creative Commons.

The relationship of the *Paranephrops* species with stream mosses contrasts with the avoidance of mosses by the crayfish *Procambarus spiculifer* (Figure 64, Figure 95; see also discussion under Isopoda – Aquatic Consumers) reported by Parker *et al.* (2007). The latter crayfish is selective in its plant habitat, choosing the flowering plant *Podostemum ceratophyllum* (riverweed; Figure 96) over *Fontinalis novae-angliae* (Figure 62; Figure 96), despite the greater abundance of the moss (89% of total biomass) (Parker *et al.* 2007). Furthermore, the mosses supported twice as many macroinvertebrates as did the riverweed. This revelation suggests that the mosses might provide a safe refuge for macroinvertebrates, allowing them to escape from larger predators, perhaps due to their chemical defenses. This hypothesis is supported by the presence in the moss of C₁₈ acetylenic acid, octadeca-9,12-dien-6-ynoic acid, a defense compound that inhibits crayfish feeding. A similar avoidance was absent in the amphipods and isopods in the stream, permitting them to find safe refuge there. This discriminatory behavior of the antifeedant against crayfish but not microcrustacea permits these small arthropods to live where they can avoid the predation of larger arthropods.

Figure 95. *Procambarus spiculifer* eating *Egeria densa*. This crayfish avoids eating the moss *Fontinalis novae-angliae*, thus protecting its invertebrates as well. Photo by John Parker, with permission.

Summary

Isopods include a number of terrestrial genera, many of which include bryophyte dwellers, including the families **Ligiidae**, **Trichoniscidae**, **Oniscidae**, **Porcellionidae**, and **Armadillidiidae**. *Asellus* seems to be the most common genus in streams. Springs seem to have few isopods inhabiting mosses. Other taxa benefit from the moisture of bogs, migrating vertically to achieve optimum moisture and temperature.

As descendants of aquatic and marine organisms, isopods benefit from the moisture and protection of bryophytes, finding food among them as detritus, periphyton, and the bryophytes themselves. Their digestive system is modified by reducing gut surface tension and culturing gut flora to render the phenolic compounds safe in their diet. They are known to eat a wide range of bryophytes, but they do have preferences, and some taxa are ignored.

In addition to sheltering, the isopods use the bryophytes as a place to remove excess water or gain needed water. They conserve water by releasing their nitrogenous waste as ammonia gas. Isopods are sensitive to temperature, and bryophytes can provide shade and evaporative cooling.

Isopods often go into the soil in the daytime, emerging and climbing to the tips of the bryophytes to dine at night. They congregate under bryophytes, as well as rocks, logs, and boards, reducing water loss and oxygen consumption, stimulating reproduction, increasing predator defense, promoting coprophagy, and acquiring internal symbionts. Reproduction is typically sexual, but parthenogenesis is possible in some taxa. The eggs and young are carried by the mother.

Some isopods overwinter under bryophytes or in the soil under bryophytes. They generally cannot survive temperatures below -7°C.

At least some bryophytes exemplify the **apparency theory**. The bryophytes are small and slow-growing. They contain a wide range of antiherbivore compounds that deter most herbivores. Isopods, on the other hand, circumvent the antiherbivore compounds through their digestive system, permitting them to gain a food source (bryophytes) where they are protected from a number of would-be predators. However, ants are a predatory threat even among the bryophytes.

Members of the order **Mysida** are rarely reported from bryophytes, but in Char Lake they feed on diatoms and inorganic particles among mosses.

The Decapoda (crayfish) generally do not live among mosses, in some cases actually avoiding them, apparently due to the presence of C₁₈ acetylenic acid, octadeca-9,12-dien-6-ynoic acid in the mosses (and possibly other compounds). Others damage the bryophytes by moving their heavy bodies across them. Invertebrates are able to avoid predation by crayfish by living among the mosses.

of the content of this chapter presents results from undergraduate and graduate research by my students, who were a constant source of inspiration to me. Eileen Dumire reviewed the chapter from the perspective of a novice and Gipo Montesanto provided a scientific review. John Parker provided the images to complete the story of predatory Canada Geese and crayfish that avoid the mosses. John Hribljan provided many discussions, did much of the research on *Porcellio scaber*, and commented on the chapter.

CHAPTER 11-1

AQUATIC INSECTS: BIOLOGY

Figure 1. *Rhyacophila carolina* larva, a free-living caddisfly that occurs commonly on bryophytes. Photo by Bob Henricks, with permission.

Aquatic Insects

Cascading waterfalls, silt-laden torrents, lurking predators, limited oxygen, unpredictable water levels, icy winters – all these dangers face the insects (Figure 1) that call lakes, and especially streams, their homes. So why do the insects choose to live there, and how do bryophytes help to make life in such unfriendly conditions possible?

The relationship between aquatic insects and bryophytes is a topic dear to my heart. When I was working on my M.S. project on the bryophytes, my roommate was working on aquatic insects. Never passing up an opportunity for a field trip, I accompanied her on all her collecting trips. We both soon realized that in her rocky mountain streams of northern West Virginia, USA, there were typically more insects among the bryophytes than in any other microhabitat in these streams. It was this discovery that led me to my Ph. D. research topic on the insects associated with Appalachian stream bryophytes and the many studies I have done on ecology of aquatic mosses since then.

These wonderful bryophyte-insect communities are not a new discovery. Stream ecologists in particular have observed the importance of mosses as cover for aquatic insects and other aquatic invertebrates and even fish (Thienemann 1912; Carpenter 1927; Percival & Whitehead 1929, 1930; Humphries & Frost 1937; Jones 1941, 1948, 1951; Frost 1942; Badcock 1949; Illies 1952; Hynes 1961; Minckley 1963; Egglisshaw 1969; Arnold & Macan 1969; Lindgaard *et al.* 1975; Hawkins 1984; McKenzie-Smith 1987; Suren & Winterbourn 1992a, b; Gislason *et al.* 2001; Linhart *et al.* 2002; Paavola 2003).

In Idaho, USA, Maurer and Brusven (1983) found that *Fontinalis neomexicana* (Figure 2) housed 5-30x the densities of insects found associated with the mineral substrates; biomass, however, was only 2x as great. The moss did not alter insect densities in the underlying **hyporheic** zone (saturated zone beneath the bed of a river or stream that can support invertebrate fauna). The diversity of functional groups was greater among mosses, but the species richness was similar to that of the mineral substrate.

Figure 2. *Fontinalis neomexicana*, a moss that greatly increases the density of stream insects. Photo by Belinda Lo, through Creative Commons.

The numbers of insects among bryophytes can be extensive (Figure 3). Minckley (1963) found that mosses had the highest densities of insects compared to sand, stones, and tracheophytes in a Kentucky, USA, stream. Lillehammer (1966) found that moss-covered stones had 606 individuals m⁻² compared to 471 m⁻² on stones with no mosses.

Figure 3. This branch of *Palustriella commutata* demonstrates the variety and density of aquatic insects that can occur on aquatic mosses. Photo by Dan Spitale.

When more sophisticated statistical methods became available, bryophyte biomass emerged as one of the factors accounting for the variation in insect fauna among streams, and as we might expect, it has a positive influence on the insect fauna (Gislason *et al.* 2001). Furthermore, bryophytes can occupy deeper waters, forming a zone that is lower than that of tracheophytes, and this zone is able to support fauna that could not otherwise live at those depths (Blackstock *et al.* 1993).

Minshall (1984) considered bryophytes to be a major factor in increasing insect numbers because of the increased surface area offered by them. Egglishaw (1969) found that most species of invertebrates, including insects, were less aggregated in clumps among the mosses than they were under stones. One might interpret that this is due to the complex nature of the mosses and the large space in which they can be distributed. On the other hand, it would seem that the stone habitat would be more homogeneous and thus one might expect less clumping. Another mystery.

Life Cycle Stages

Life cycle stages play a major role in the occupancy of water habitats by insects. Most of these orders of insects have poor ability to survive freezing, so escape into water can maintain their temperatures above freezing. The flowing part of water generally remains at ~1°C throughout the winter, and lakes and ponds that don't freeze to the bottom have water just above 0 up to 4°C.

Because of the importance of water in the life cycle of the major groups of aquatic insects, we must understand the types of life cycles among them before we can begin a discussion of the biology and ecology of these groups. There are two major groups of classification among the insects, based on life cycles and their developmental stages.

Collembola

The **Collembola** (Figure 4), or springtails, long considered to be insects, have been kicked out of the **Insecta** by cladistics, due to linkages shown by their DNA and supported by their morphology. Because they have much of their ecology in common with insects, and their earlier inclusion among Insecta, they will be discussed among these aquatic insect subchapters.

The **Collembola** have the simplest life cycle, one in which the hatchling is a miniature of the adult. The immature stage is known as a **nymph**. Their life cycle consists of **egg/embryo**, **nymph**, and **adult**. The **Collembola** hatch from their egg casing and look like the adults, perhaps in somewhat different proportions; they

continue to increase in size without changing their basic form as they become adults.

Figure 4. *Collembola Arthropleona oruarangi*, a group of "pre-insects" that are born looking like little adults. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Hemimetabolous Insects (Hemimetabola)

Nymphs

Among the aquatic insects, this group includes the true bugs (order **Hemiptera**), a group that lacks gills in all stages. The **Hemiptera** are **hemimetabolous** insects and thus lack the pupal stage (familiar to most people as the chrysalis of butterflies). Instead, they have only the **egg/embryo** (Figure 8), **nymph** (including **naiads** in the other hemimetabolous orders), and **adult**. [The **holometabolous** insects, on the other hand, have an **egg/embryo**, **larva**, **pupa**, and **adult (imago)**.]

Naiads

Those orders with obligate aquatic immature stages that do not resemble the adults, but that do not pass through a second stage as a pupa before becoming an adult, have an aquatic stage known as a **naiad**. The **naiad** is a specialized nymph stage known only among aquatic insects and occurs in the orders **Plecoptera** (Figure 5, Figure 73, Figure 74, Figure 77), **Ephemeroptera** (Figure 6), and **Odonata** (Figure 7). The naiad usually differs from the adult in having some form of gills to aid in gaining oxygen in the aquatic environment. When it is time for the adult to emerge, these insects climb to the surface or out of the water, often on an emergent plant, and often hang vertically while they climb out of their naiad **exoskeleton** (Figure 5). The shed exoskeleton is the **exuvia** (pl. **exuviae**; Figure 5). In the **Ephemeroptera**, the emergent stage is a subadult known as a **subimago** (Figure 6). This subimago goes through one additional moult to become the adult (**imago**).

Holometabolous Insects (Holometabola)

The remaining orders of aquatic insects are **holometabolous** and have what is known as **complete metamorphosis**. These insects have four life cycle stages: **egg/embryo** (Figure 8), **larva** (Figure 1), **pupa** (Figure 9), **adult (imago)** (Figure 10). The larva stage looks nothing like the adult. It is familiar to most people in the moths and butterflies as the caterpillar. The larva is a worm-like

creature, with or without legs, or in some cases with prolegs that are of soft tissues. The aquatic larvae have gills in many taxa, but not in others. Some have fleshy legs with hooks at the posterior end.

Figure 5. **Plecoptera** exuvia. Photo by Jason Neuswanger at <Troutnut.com>, with permission.

Figure 6. *Baetis* male subimago emerging to adult. Photo by Jason Neuswanger at <Troutnut.com>, with permission.

Figure 7. *Enallagma* damselfly naiad. Photo by Tom Murray, through Creative Commons.

The **pupa** is usually a stationary phase (known as a chrysalis in butterflies). As the pupa develops, the larva develops a chitinous outer covering that has the imprint of parts like wings and antennae. The insect is likely to be dormant or in **diapause** (in insects, period of suspended development, especially during unfavorable environmental

conditions) during its pupal stage, providing it reprieve from winter's cold or tropical drought. But during this time the insect goes through a number of changes in both form and physiology. When the insect has matured into an adult and conditions are right for its emergence, it breaks out of the pupa. In most cases, those that spend their larval lives in the water emerge into the atmosphere, spending their adult lives as terrestrial organisms (except in most of the beetles).

Figure 9. **Chironomidae** (midge) pupa. Photo by Bob Henricks, with permission.

Figure 10. **Chironomidae** adult male. Photo by Roger S. Key, with permission.

The holometabolous insect orders that live among bryophytes include **Coleoptera**, **Trichoptera**, **Megaloptera**, **Neuroptera**, and **Diptera**.

Adaptations to Aquatic Bryophyte Life

Bryophyte dwellers might benefit from several behavioral and structural adaptations to make life among the bryophytes easier. They need to be able to gain sufficient oxygen (Hynes 1970), to move about freely, to avoid being pulled out if a predator catches a tail or leg, to avoid being swept away by the current, and to eat the available food. In streams where the water level varies a lot or dries up, they need to have a means to avoid desiccation.

Life Cycle Strategies

Although I would normally discuss structural adaptations first, the life cycle adaptations appear to be the most important ones among the insects. Differing requirements among life cycle stages permit insects to survive from year to year in changing environmental conditions.

Blackstock *et al.* (1993) found the insects in a clear sequence of bryophyte to herbaceous swamp to woody plant community occupying different depth zones in the basin of Pant-y-llyn, Wales. These changes, on a large scale, require a degree of mobility on the part of the insect inhabitants as the habitat changes from aquatic to terrestrial seasonally. But even more permanent aquatic habitats have their down times. Success for an aquatic insect means having a strategy to survive during stages when the habitat is dry (Blackstock *et al.* 1993), too cold, or too hot.

To understand the role of bryophytes in the life of their insect inhabitants, one must understand these life cycles. Only twelve orders of insects plus the **Collembola** (Figure 4) are generally considered to have aquatic members, but even these aquatic members typically live out of the water during part of their lives (Thorp & Covich 1991; Ward 1992). Since most of the aquatic insects live in the water in immature stages, an understanding of these stages is necessary to understand fully how bryophytes are so important for them.

Danks (1991) points out that we can understand insect life cycle adaptations best by understanding the options. These include the choices (evolutionarily) to develop or to enter **diapause** (period of suspended development) and to grow rapidly or grow slowly. These developmental options respond to photoperiod and temperature, among other things (Danks 1991; Zwick 1996). Because of dependency on these cues, eggs of some stoneflies are able to remain in the sediments for years, providing a "seed bank" (Zwick 1996). The choices that have been programmed into the life cycle impact the life span of the insect.

Eggs (Figure 8) are an important stage for insects with a terrestrial adult stage and aquatic immature stage(s). The term egg is used somewhat loosely, referring to both the unfertilized egg and the embryonic stage that remains within the egg "shell," indicated herein as **egg/embryo**. Most of these insects lay their eggs in the water, so a substrate that anchors and protects them from both flowing water and predation is important. Even such free-swimming insects as the dragonfly *Sympetrum* (Figure 11) in the **Odonata** sometimes lay their eggs in plates on moss

growths, securing the eggs and hatchlings (Figure 12) (Wesenberg-Lund 1943).

Figure 11. *Sympetrum sanguineum* mating. Photo by Qartl through Creative Commons.

Figure 12. *Sympetrum striolatum* egg-laying among grasses and mosses. Photo by Hugh Venables through Creative Commons.

Some of the aquatic insects live in immature stages in the water for more than one year (Danks 1992; Ulfstrand 1968b). These extended lives may result from slow

development, long or repeated dormancy, or adults that live a long time (Danks 1991, 1992). Others, in particular the mayflies (**Ephemeroptera**), may live for only one day as adults (Figure 13), just long enough to mate and lay eggs, but can spend about one year in the naiad stage in the water. The long life cycles are usually coupled with several factors, including cold, unpredictable temperatures, unreliable or low quality food supplies, natural enemies, and large adult size. Life cycle traits relate strongly to the predictability of the environment where the insect lives and the environmental signals that are provided (Danks 2006). But Danks cautions that much more detail is needed to understand these life cycle patterns in insects.

Figure 13. *Callibaetis ferrugineus* subimago. Photo by Jason Neuswanger, with permission.

Radford and Hartland-Rowe (1971) examined the life cycles of stream insects from Alberta, Canada. Several of these represent genera [*Nemoura*/*Zapada*/*Prostoia* (Figure 14), *Ephemerella*/*Drunella* (Figure 15)] that are common among bryophytes. Of these, *Prostoia* (= *Nemoura*) *besametsa* (see Figure 16) and *Drunella* (= *Ephemerella*) *coloradensis* (Figure 17) are characterized as fast seasonal types. But in the same family, *Zapada* (= *Nemoura*) *cinctipes* (Figure 18), *Z. columbiana* (Figure 19), *Z. oregonensis* (Figure 20-Figure 21), and *Drunella doddsii* (Figure 22) are slow seasonal types. None of these species has more than one brood per year except *Zapada cinctipes*, which has two. Temperature is important in determining growth rate in these species.

Since insects have little tolerance for low temperatures (Dunman *et al.* 1991; Moore & Lee 1991), they must spend winter in a way that avoids the dangers of freezing (Ramløv 2000), as will be discussed in more detail below. It is this need to avoid freezing that forces some insects to spend part of their lives in the water. Bryophytes provide a habitat that helps them to cope with this watery habitat.

As Danks (1991) points out, the life cycle strategies provide options that facilitate survival: develop or enter diapause; grow rapidly or grow slowly. These are typically under the control of such environmental parameters as temperature and photoperiod.

Life Cycle Cues

As already stressed, changes in life cycle phases are often necessary to survive changing weather conditions as the seasons change. Danks (1999) pointed out that life cycles are influenced by climate severity, seasonality, unpredictability, and variability. Some insects solve the unpredictability and variability problems by having flexible life cycles. These modifications can be determined by factors such as food availability and temperature. Danks (1991) points out that various stages in the life cycle are used in combination to adapt the insects to the changes of the seasons in nature.

In cold environments, some of the **Chironomidae** (*Diamesa incallida*; Figure 23) may produce 8-10 generations in a single year, with egg-laying occurring throughout the year (Nolte & Hoffmann 1992). *Diamesa incallida* is a hot-spring-dwelling midge that lives in water at 76-80°C, a community where we are not likely to find bryophytes, but it demonstrates the role of temperature and the wide range of capabilities in a family that is common among bryophytes. Some Arctic **Chironomidae** solve the problem of finding a sexually mature mate by negating the need for mating and being **parthenogenetic** (producing offspring without fertilization) (Langton 1998).

Figure 23. *Diamesa* (Diptera) pupal exuvium, a genus that may produce 8-10 generations in a single year. Photo by Will Bouchard, with permission.

Shama and Robinson (2009) demonstrated that an alpine caddisfly (*Allogamus uncatus*, a bryophyte dweller) in Switzerland responded to late season photoperiod cues by accelerating development, but the species showed adaptive plasticity in response to season length, making responses different among populations with only small geographic differences. Furthermore, the responses of the two sexes can differ (Shama & Robinson 2006).

On the other hand, the bryophyte-dwelling caddisfly *Limnephilus externus* (Figure 24-Figure 26) did not make developmental adjustments in response to diet supplementation, although it did grow to a larger size (Jannot *et al.* 2008). Furthermore, this caddisfly was unable to adjust to pond drying, responding by reduced growth rates and delayed development. This indicates the danger of an unpredictable environment for the aquatic insects.

Figure 24. *Limnephilus externus* larva in case. Photo by Wendy Brown <Gunnison Insects>, with permission.

Figure 26. *Limnephilus externus* larva showing abdominal gills. Photo by Wendy Brown <Gunnison Insects>, with permission.

In unpredictable or unstable environments, flexibility in the life cycle is important (Brittain & Saltveit 1989). Knispel *et al.* (2006) found that the bryophyte-dwelling mayfly *Baetis alpinus* (Figure 27) in the Swiss floodplains has synchronous egg development with high hatching success. By developing faster in warmer habitats it is able to hatch when conditions are favorable in the autumn. Long development time and delayed hatching permit success in unpredictable habitats in the cold glacial conditions. The mayfly *Rhithrogena nivata* (see Figure 28) has a long incubation period; the timing of hatching and glacial discharge conditions determine the success of development. This plasticity permits it to live in the very unstable, cold habitats that are limiting to other species.

Figure 27. *Baetis alpinus* naiad, a mayfly with synchronous egg development that promotes high hatching success. Photo by Andrea Mogliotti, with permission.

Many insects have developmental cues similar to those of plants. These include degree-days (calculated by taking the average of the daily maximum and minimum temperatures compared to a base temperature necessary for growth by the species). As in many plants, degree days may be important in determining the rate of development. For example, the mayfly *Leptophlebia cupida* (Figure 29) in the Bigoray River, Alberta, Canada, has only one reproductive period each year (Clifford *et al.* 1979). Clifford *et al.* (1979) found that degree days of water

temperature was more important than number of days for development, with 34 instars being produced in the laboratory at 20°C. That number is most likely plastic in response to environmental conditions.

Figure 28. *Rhithrogena impersonata* naiad, a genus in which some species have life cycle plasticity that depends on local weather. Photo by Donald S. Chandler, with permission.

Figure 29. *Leptophlebia cupida* naiad, a species with only one reproductive cycle per year. Photo by Jason Neuswanger, with permission.

For aquatic insects, the temperatures are much more tempered than in the terrestrial environment. In a study of 95 aquatic species, Pritchard *et al.* (1996) found that only 4 of 92 possible comparisons among **congenerics** (members of same genus) demonstrated significant differences in degree of cold adaptation. All **Odonata** (damselflies and dragonflies), 71% of **Diptera** (true flies), and 81% of **Ephemeroptera** (mayflies) had significant slopes indicating that they were warm adapted. They suggested that the **Plecoptera** are cold-adapted species that may use the egg stage to survive when the temperatures are too high.

In the stonefly family **Leuctridae**, commonly represented among bryophytes, the length of the naiad stage depends on the temperature. In *Leuctra ferruginea* (Figure 30) those individuals living in the coolest streams required two years for their life cycle, whereas those in the warmest waters were able to complete the life cycle in one

year (Harper 1973). The **Leuctridae** (Figure 30) and **Nemouridae** (Figure 14) are both common at the cooler upstream stations in Southern Ontario. Six species of the stonefly **Isogenoides** (Figure 31) from Colorado, USA, a genus also known from mosses, varied in hatching time both among the species and within some species (Sandberg & Stewart 2004). In one species the eggs hatched over an extended period of time, stopped hatching for the winter, then resumed hatching in May-June the following year. Some eggs even survived and hatched two years later. In one species, a summer diapause was needed before the eggs would hatch. Members of the genus required three months to four years before hatching.

Temperature Relations

As already noted, temperature plays an important role in determining when life cycle stages occur. Freezing, desiccation, and anoxia are all lethal among aquatic insects, from egg to adult (Lencioni 2004). When in the aquatic habitat, these three factors are related, with ice preventing the renewal of oxygen, and ice crystals drawing water from the cells, causing desiccation. Some of the aquatic insects enter **diapause** during winter. This usually requires storage of food as glycogen and lipids, hormonal control, and depression or suppression of oxidative metabolism with mitochondrial degradation.

But the mosses themselves seem to present a relatively constant temperature. Thorup (1963) considered the

temperature among mosses in springs to be so constant that it would not provide the developmental temperature point needed to trigger changes in stages. Correlated with the moss habitats in springs was an insect life cycle with only one generation per year.

Overwintering

Duman *et al.* (1991) defined two physiological mechanisms by which insects survive winter: freeze tolerance and freeze avoidance or freeze resistance (see also Ramløv 2000). Aquatic insects have only limited ability to survive at temperatures below freezing (Moore & Lee 1991). They can supercool to only -3 to -7°C and only some members in the order **Diptera** are known to be freeze tolerant. The adults seem to be somewhat more cold tolerant. Thus this is a group of insects for which aquatic habitats that do not freeze provide them with an escape to suitable temperatures for the winter. What is fascinating is the plasticity of their responses. Duman *et al.* (1991) found that not only do different populations of the same species exhibit different overwintering mechanisms, but that even the same population may change its overwintering mechanism from year to year.

Because of their need for warmer temperatures in immature stages than that needed by terrestrial insects, most of the aquatic insects spend their egg and immature stages in the water. In fact, warm-water insects avoid the freezing dangers of winter by surviving as eggs. This is particularly true for the blackflies (**Simuliidae**; Figure 51-Figure 53) (Hynes 1970).

Insects rarely spend their entire lives in the water, but some spend larval stages there, pupal stages on land, then return to the water as adults, as in many **Coleoptera** (beetles). Others, particularly some of the **Trichoptera** (caddisflies) overwinter as adults. In fact, some even emerge mid-winter in cold climates. And the adult stonefly *Zapada cinctipes* (**Nemouridae**; Figure 18) re-enters the water when air temperatures drop below freezing (Tozer 1979). However, the stream chironomid *Diamesa mendotae* (Diptera; Figure 32-Figure 33) does things quite differently – its freeze tolerance is actually greater in the larval (stream) stage (Figure 33). Although it has a larval super-cooling-point (SCP) temperature of -7.4°C and pupal SCP of -9.1°C , compared to -19.7°C for the adults (Bouchard *et al.* 2006), the larvae of *D. mendotae* are freeze tolerant, with a lower lethal temperature (99% dead) of -25.4°C , $\sim 10^{\circ}\text{C}$ lower than their minimum super cooling point (-15.6°C). They change from freeze tolerant as larvae to freeze intolerant as adults! Nevertheless, the adults are able to tolerate cold temperatures sufficiently to mate on the snow (Ferrington *et al.* 2010). Furthermore, they can survive under the snow for extended periods of time (Anderson *et al.* 2013).

The often moss-dwelling *Serratella ignita* (Figure 60) overwinters from late summer until late the next spring as an egg (Arnold & Macan 1969). On the other hand, the mayfly *Ameletus inopinatus* (Figure 34) and stonefly *Leuctra hippopus* (Figure 35), a stony bottom dweller, do the most developing in the naiad stage while their stream is iced over, at least in northern Sweden (Ulfstrand 1968b). The low temperatures slow, but usually do not stop, development and growth.

Figure 34. *Ameletus ludens* naiad, member of a genus where some species develop under the ice in streams. Photo by André Wagner, with permission.

It is interesting that in alpine streams that have snow cover for 6-9 months of the year, taxa richness and abundance of the insects seems to have no seasonal pattern. Nevertheless, the species composition differs significantly from summer to winter. Schütz *et al.* (2001) found two strategies for larval survival. The insects either had to be adapted to the extreme conditions of summer or avoid these by developing during the winter (typical of **Ephemeroptera** and **Plecoptera**).

Figure 35. *Leuctra hippopus*, a stonefly that develops in Sweden while the stream is iced over. Photo by Niels Sloth, with permission.

But ice is also a good insulator, so those insects living on the bottom of lakes and ponds are usually able to avoid lethal low temperatures there. Such insects as the **Chironomidae** (Figure 90) typically live in sediments where oxygen content is low. Cold water holds more oxygen, and since these organisms are adapted to low oxygen conditions, there is sufficient oxygen in the cold water. Some **Chironomidae** and **Trichoptera** (Figure 83) actually occur in ice and frozen sediment, as noted in a north Swedish river (Olsson 1981). Olsson found that 80-100% of these frozen insects survived thawing. **Chironomidae** survived exposure to -4°C for five months. Danks and Oliver (1972a) found that in the Arctic **Chironomidae** that overwinter are mature larvae and are ready to emerge as soon as the winter season is over. They take advantage of the warm sun by emerging in the middle of the day when the water temperature is highest (Danks & Oliver 1972b).

It is interesting that **Plecoptera**, **Ephemeroptera**, **Trichoptera**, **Diptera**, and **Coleoptera** have all been recovered alive from **anchor ice** (submerged ice anchored to the bottom; Figure 36). Anchor ice can encase bryophytes as well, and when it breaks loose, it can take the entire patch of bryophytes with it. Hence, it would likewise take all the insect inhabitants as well, moving them downstream to a new location.

Structural

Hynes (1970) summarized the adaptations of stream insects to include flattening, streamlining, friction discs, close application to the surface of stones, and in some the presence of hydraulic suckers. But many of these adaptations pertain to a life on rocks or other relatively smooth substrate. Such characters as flattening, friction discs, close application to the surface, and hydraulic suckers are of little value among the chambers of a bryophyte mat. This leaves us with only one adaptation from his list, that of streamlining (Figure 37), present in the stoneflies [Plecoptera: **Leuctridae** (Figure 37), **Capniidae** (Figure 38), **Chloroperlidae** (Figure 39), and some **Gripopterygidae** (Figure 40)], and mayflies [Ephemeroptera: **Leptophlebiidae** (Figure 41) and **Baetidae** (Figure 45)] – all known from bryophytes. Others have retained the dorsi-ventral flattening, but it is better described as compressing (Figure 42) since these insects do not quite fit the definition of flat. And compression is useful among bryophytes. Other bryophyte adaptations include small size, attachment hooks, and gill covers or gills absent (Glime 1968).

Figure 42. *Ephemerella* naiad showing dorsi-ventral compression. Photo by Bob Henricks, with permission.

Bryophyte-dwelling insects therefore do not necessarily have the same adaptations as stream insects in general. Streamlining helps, but does not need to be as severe. Steinmann (1907, in Muttkowski 1929) found that about 30% of the bryophyte-dwelling taxa were streamlined. But in the streams of the Appalachian Mountains, streamlining was not common (Glime 1994). For example, the common bryophyte-dwelling mayfly *Ephemerella* (Figure 42) is neither flattened nor streamlined (Arnold & Macan 1969), but has a shape more like a terrestrial insect – it is dorsiventrally compressed.

Small size is also an advantage and seems to be the most important characteristic of bryophyte dwellers. Bryophytes provide small spaces where invertebrates can hide, but these same small spaces limit the sizes of the organisms that can occur there. This explains why bryophytes tend to harbor small species and hatchling insects (Figure 43).

Figure 43. *Taeniopteryx* naiad on the edge of a Syracuse watch glass, demonstrating the small size of this bryophyte dweller. Photo by Bob Henricks, with permission.

Dudley (1988) suggested that while the complex structure of bryophytes might interfere with attachment by larger larvae, it reduces frequency of encounter between such predators and the small insect inhabitants. In the Appalachian, USA, streams 70% of the bryophyte dwellers were less than 6 mm long (Glime 1994). Egglishaw (1969) found that a higher proportion of smaller animals occurred on mosses than on stones or riffles. In *Leuctra inermis* (see Figure 37, Figure 44), *Baetis rhodani* (Figure 45), and *Isoperla grammatica* (Figure 46) it was the young (small) stages that occurred among the bryophytes.

Figure 44. *Leuctra inermis* adult, a species whose early naiad instars live among mosses in riffles. Photo by James K. Lindsey, with permission.

Frost (1942) remarked that because of the very young and thus small specimens, identification was both difficult and questionable, forcing identification to genus or subfamily only. Glime (1994) found that *Baetis* sp. was present among mosses (10 per gram) in summer, but were absent in later stages when the larger naiads were present among rocks in the stream bed. Others that moved out of the bryophytes when they got larger were the crane fly *Limonia* (Figure 47), stonefly *Taeniopteryx* (Figure 48), and caddisflies *Lepidostoma* (Figure 49) and *Neophylax* (Figure 50). Similar migration of older stages occurs in Europe (Thienemann 1912; Carpenter 1927; Egglishaw 1969).

Attachment

While torrents bring much-needed oxygen, they also are treacherous, dislodging the insects and sweeping them downstream. Black flies (**Simuliidae**; Figure 51-Figure 53) are among the best adapted of the aquatic insects for surviving this torrential onslaught, living on the upper surface of the bryophyte mats (Niesiolowski 1979). On both rocks and mosses, they are able to anchor themselves with a circle of hooks on the rear of the abdomen (Figure 51) (Arnold & Macan 1969). Furthermore, they manufacture a silken thread that they lay down on their substrate surface as an anchor. When they do become dislodged by chance or choice, they have a tether that prevents them from travelling too far and helps them to gain a "foothold" on their new downstream substrate. Those hooks, on both the abdomen and the single proleg foot (Figure 52), enable blackfly larvae to grab onto the silken mat (Figure 53) they have made. They are able to use these same two sets of hooks to move along their silken mat like inch worms.

Figure 51. **Simuliidae** larva showing anal hooks. Photo by Bob Henricks, with permission.

Figure 53. Simuliidae larvae on leaf where silken threads form a mat, aiding in attachment. Photo by Bob Henricks, with permission.

The net-spinning caddisflies (**Hydropsychidae**) accomplish anchorage by a pair of hooks on the posterior end (Figure 54), a modification of many caddisflies for pulling themselves into their cases. But among the free-living caddisflies like the **Hydropsychidae** and **Rhyacophilidae** [e.g. *Rhyacophila dorsalis* (Badcock 1949)], these hooks (Figure 55) serve as anchors among the bryophytes. Other insects have hooked claws that help them to clamber among the bryophytes, including the beetles (e.g. **Elmidae**, Figure 56) and some mayflies (e.g. **Ephemerellidae**, Figure 60) and stoneflies [e.g. *Nemoura* (Figure 57) and *Acroneuria* (Figure 58)]. Others, like the **Chironomidae**, achieve anchorage by nestling at the leaf bases (Figure 59) where little flow occurs.

Hora (1930) and Ward (1992) suggested that backward pointing dorsal spines (Figure 60-Figure 64) of some moss dwellers, e.g. the **Gripopterygidae** (Figure 61), are adaptations to reduce chances of being swept downstream. Illies (1961) reported large dorsal spines on a moss-dwelling stonefly from Chile. Similar (but smaller) spines are known on the common moss-dwelling mayfly *Ephemerella ignita* (Figure 60; Hynes 1970). Even **Diptera** larvae [e.g. **Psychodidae** (Figure 62), **Tipulidae** (Figure 63-Figure 64)] can have backward-directed spines. But the tipulid larvae of *Phalacrocer* (Figure 63) and *Triogma* (Figure 64-Figure 65) have such projections and live mostly among semiaquatic mosses where there is no flow to dislodge them. This suggests the spines may serve either as camouflage or as trapping devices to prevent would-be predators from pulling them out of the moss mat.

Gill covers help to keep silt from accumulating among the gills, since the mosses often reside where they collect large amounts of silt. The gill covers can also be used to fan the fills, hence moving the water and facilitating oxygen exchange. Gill covers are common among the **Ephemeroptera**, especially in the **Ephemerellidae** (Figure 66-Figure 67) and **Caenidae** (Figure 68).

Behavioral

Behavior often permits organisms to change their locations, providing the best location available to them as the season changes and required resources are in new locations. Behavioral adaptations can help them capture prey, avoid being prey themselves, gain sufficient oxygen, avoid being swept away by the current, and escape cool or freezing temperatures.

Bryophytes provide a series of zones (Figure 69) that permit insects to live in the flow regime they require. As will be seen, oxygen can be a limiting factor, requiring some insects to live near the surface of the bryophyte where torrential waters trap oxygen from the air. Hence, these insects require a means of anchorage lest they themselves become part of the torrent. Others are well adapted to the low oxygen levels and live at the base where detritus accumulates and predators seldom venture. But it is advantageous that they can move about and seek the zone within the stream or lake and within the bryophyte community that best meets their needs.

Figure 69. *Fontinalis* zonation of insects. Redrawn from Niesiolowski 1979.

Aquatic insects tend to avoid light, exhibiting negative phototaxis (Moon 1940; Shelford 1945). Mayflies, in particular, demonstrate a negative phototaxis, preferring darker locations (Wodsedalek 1911; Gros 1923; Percival & Whitehead 1926). This may account for the presence of some taxa among the darker spaces of mosses, particularly in rapid water where rock surfaces may be highly exposed to light. Others may avoid light to be less conspicuous to their prey. On the other hand, *Baetis harrisoni* (Figure 70) chose illuminated stones 112 times compared to 14 for shaded stones, exhibiting strong positive phototaxis (Hughes 1966).

Figure 70. *Baetis harrisoni* naiad, a mayfly that prefers illuminated stones. Photo by Helen James through Creative Commons.

Insects often escape adverse conditions in their environments by modifying the environments themselves. Such modifications may include making shelters (Figure 71), excavating, aggregating (Figure 53), forming colonies, and parental actions (Danks 2002). Although all of these actions may be found among aquatic insects, not all of these occur among those living among bryophytes. The bryophyte itself sometimes makes such actions as excavating and making shelters unnecessary. For example, several families of caseless caddisflies live among bryophytes. But the very tiny **Hydroptilidae** may take advantage of the bryophytes for case-building materials.

Figure 71. *Helicopsyche* case, made by the caddisfly as a shelter. Photo by Mike Quinn, through Creative Commons.

Oxygen Conditions

Ponds can become quite anoxic in winter when the surface is frozen (Nagell & Brittain 1977). Streams are less likely to become anoxic, but within the bryophyte mat water can be quite quiet and oxygen can be used up quickly by decaying organisms. However, insects have a wide array of adaptations to help them through places and times of anoxia (Hoback & Stanley 2001). For example, 10 Arctic species of **Collembola** (springtails) are known to survive anoxia at 5°C for up to 36 days (Hodkinson & Bird 2004). The mayfly *Cloeon dipterum* (Figure 72) is able to survive 3-4 months in anoxic ponds, and naiads survived up to 155 days at 0°C in the lab (Nagell 1977).

Figure 72. *Cloeon dipterum*, a mayfly that can survive 3-4 months in anoxic pond water. Photo by Malcolm Storey, through Creative Commons.

As is obvious from previous studies, oxygen relations in the insects are dependent on temperature (Jacob & Walther 1981). More oxygen can dissolve at low temperatures. In fact, oxygen limitations due to temperature are so important that they set the thermal limits in at least some species of aquatic insects (Verberk & Bilton 2011). Furthermore, since smaller insects use less oxygen, large insects may have been an adaptation to excess oxygen in the Carboniferous Era (Verberk & Bilton 2011). Oxygen limitations may explain in part the presence of small insects among the bryophytes, whereas

the larger stages move to rock faces where flow is uninterrupted and able to replenish the oxygen more easily.

Knight and Gaufin (1966) measured oxygen consumption as a function of temperature in two stonefly naiads that associate with bryophytes: *Hesperoperla pacifica* (Figure 73) and *Pteronarcys californica* (Figure 74). These insects followed the general trend of consuming more oxygen at higher temperatures. This relationship is problematic because gasses are lost from the water at higher temperatures, thus limiting the most available oxygen to winter.

Figure 73. *Hesperoperla pacifica* with its pompom-like gills peeking out from the ventral thorax. Photo by Arlen Thomason, with permission.

Figure 74. *Pteronarcys californica*, probably the largest insect inhabitant of bryophytes. Photo by Bob Henricks, with permission.

Among the common bryophyte dwellers, the mayflies (**Ephemeroptera**) are the least tolerant of low oxygen (Gaufin *et al.* 1974), making them good indicator organisms. These are followed by stoneflies (**Plecoptera**), then caddisflies (**Trichoptera**), flies (**Diptera**), and damselflies (**Odonata**) in that order. Of course there are exceptions within the orders.

Insects living in low oxygen conditions may be adapted by developing enlarged respiratory organs (Figure 75) (Dodds & Hisaw 1924), including enlargement of tracheal gills (Figure 76) (Golubkov *et al.* 1992). Behavior can play an important role, with most species moving away from the anoxic sediments when oxygen becomes limiting (Kolar & Rahel 1993). But moving is not always a good choice because it can result in being swept into the current and usually means becoming more visible, hence being more obvious to predators. The movement itself attracts attention through the excellent vision in the well developed eyes of other arthropods and fish.

Figure 75. Relationship of gill size in seven species of **Ephemeroptera** to oxygen availability in aquatic systems. The outlier species on the right is the genus *Iron*, a genus for which the gills form a suction cup, preventing one side of the gills from functioning in oxygen uptake. Its position when only half the area is used is shown by the square at the base of the dotted line on the right. Redrawn from Dodds & Hisaw 1924.

Gills are a common adaptation to low oxygen, especially in **Ephemeroptera** (Figure 76), **Plecoptera** (Figure 77-Figure 79), and **Trichoptera** (Figure 80). These are placed in almost every position (*e.g.* Figure 78), depending on the genus or family, and are useful taxonomic characters in some groups. But they also tend to be protected, between legs or under gill covers. Others have cutaneous breathing – providing the expanse of the insect's surface and avoiding the danger of collecting sediments.

Figure 80. *Hydropsyche* sp. larva showing gills on ventral side. Photo by Bob Henricks, with permission.

As early as 1907, Babak and Foustka concluded that as the oxygen concentration in the water decreased, movement of the gills of mayflies increased. Dodds and Hisaw (1924) showed a relationship between gill area and oxygen concentration in mayflies. But in the mayfly *Baetis* (Figure 45, Figure 70) used for testing, the gills never beat and it seems that they do not use their gills for oxygen consumption in the range of 5.0 to 8.0 cc L⁻¹ (Wingfield 1939). Rather, these mayflies live in rapid streams where oxygen concentrations are usually above 4 cc L⁻¹ and rapid flow keeps fresh, oxygenated water flowing over the gills. Under these conditions their cuticular respiration is sufficient. Macan (1962) reported on the work of Ambühl (1959). He found that *Baetis vernus* was scarce when the current speed was below 10 cm sec⁻¹ and increased in relative numbers up to 40 cm sec⁻¹. *Ephemera ignita* (Figure 60) was most common at current speeds of 10-30 cm sec⁻¹.

Movements of another type – undulating the body (Figure 81) or fanning the gills (Figure 82) – can increase the rate of oxygen movement across the gills. Undulations typically begin as oxygen levels are low and are also used for swimming, a second way to gain more oxygen. These undulations are easily seen when high-oxygen-requiring mayflies are brought to the lab and put in quiet water. **Ephemereillidae** species accomplish water movement over their gills by moving the gill covers (Figure 82) up and down, fanning the gills. **Trichoptera** (caddisflies) are able to pump water through their cases (Figure 83) to renew oxygen. Humps and projections maintain space between the larva and its case, permitting water (and oxygen)

movement through the case. But these activities require energy and the insects cannot sustain prolonged use of these behaviors (Hynes 1970).

Most of the bryophyte dwellers do not carry oxygen in the air bubble of a **plastron** (Figure 84) or other form of

bubble (Figure 85), as done by a number of free-swimming species. However, the plastron mechanism is useful to some of the **Elmidae** (Figure 84), tiny beetles that clamber among the bryophytes (Arnold & Macan 1969). The plastron is much like a diving bell. The insect traps a bubble of air and carries it beneath the water surface. As the insect breathes, it exchanges its CO_2 for the O_2 in the plastron. Oxygen in the water will diffuse into the bubble as the oxygen is depleted, but as the nitrogen leaves the bubble, the bubble shrinks. The same mechanism applies to other types of bubbles such as the one in Figure 85. Eventually the concentration of oxygen in the bubble is too low and the insect must resurface to grab another bubble, or grab one from a photosynthesizing plant, including bryophytes. The collection of bubbles on plants under water is known as **pearling** (Figure 86).

Obtaining Food

Feeding strategies include shredders, gatherers, scrapers, and detritus feeders. Venturing away from the protective bryophyte substrate is dangerous because the insects can easily be swept away by the current in streams. Thus, it is not any surprise that many of the insects have adapted strategies that permit them to obtain food without venturing away from their safe site. Many are detritus

feeders, and if they have adaptations to get enough oxygen, they can live in the silt or sand. Others such as the net-spinning caddisflies (Figure 87) and the blackflies (Figure 88-Figure 89) trap their food as it flows by them. The very effective anchorage permits the **Simuliidae** (blackflies) to hang from the rear and expose the head fans (Figure 89) into the current to trap organic particles, including diatoms, for food. Some eat their surrounding homes – the bryophytes.

Figure 88. Simuliidae larva head fans closed. Photo by Bob Henricks, with permission.

Figure 89. **Simuliidae** larva showing head fans that are used to capture food. Photo by Bob Henricks.

Others, including some of the net-spinning **Hydropsychidae** (Figure 87), let the bryophytes do the trapping and eat the periphyton and detritus within the bryophyte mat. I base this assumption on finding many more larvae than nets among the mosses. The **Chironomidae** (Figure 90) live in leaf bases where detrital matter accumulates, obtaining both protection and food. In any case, the diet of the aquatic stage is usually quite different from that of the adult.

Who Lives There?

Aquatic bryophytes in mountain streams typically are replete with insects, crawling about and dining on the detritus and algae in the milieu. They find themselves safely out of the torrent above and tucked away from the view of fish and other predators. It seems like they should have a pretty cushy life.

When I began my studies on insects living among bryophytes in Appalachian Mountain, USA, streams, few studies were available for comparison, and most of those

were from Europe. Like the development of keys for bryophytes, the development of keys for aquatic insects lagged way behind what was needed. To further complicate the problem, many of the insects had been described from adults, but studies to link the immature aquatic stages to their adults were lacking for many. It was the insect version of the early *Takakia* classification problem.

As I delved into the many more recent papers to prepare this chapter, I found many unfamiliar names of genera, only to discover that those familiar genera from nearly 50 years ago had gone through reclassification and were now represented under multiple new names, especially at the generic level. To further complicate these changes in generic concepts, the insects, like the bryophytes, comprise many microspecies. Limited dispersal distances for short-lived adult stages, mountain and land barriers, and disconnected stream or lake systems all contributed to the isolation needed for development of differences in physiology, behavior, phenology, and morphology (see for example Hughes *et al.* 1999; Monaghan *et al.* 2002). As bryologists we are well aware of these problems in classifying things separated by great distances, but for these insects the microspecies differences can be manifest over much shorter distances, a phenomenon that has been recognized in some aquatic bryophytes as well (Glime 1987; Shaw & Allen 2000). Nevertheless, there are lessons to learn from the orders, families, and even the genera as we examine who lives among the bryophytes – and why.

Drozd *et al.* (2009) used pitfall traps to compare invertebrate inhabitants related to bryophytes in the mountain areas (384-1200 m asl) of the Czech Republic. In most cases, the **Collembola** were the most abundant group except for the high number of ants at Podolánky. The numbers differed by bryophyte and moisture level (Figure 92). Insects were highest in the dry litter control (within 2

m of moss area). The lowest numbers were in wet *Sphagnum fallax* (Figure 91).

Figure 91. *Sphagnum fallax* with capsules, the species with the lowest number of **Collembola** among bryophytes in the mountainous areas of the Czech Republic. David T. Holyoak, with permission.

Drozd and coworkers (2009) considered several caveats in interpreting their results. Some of the invertebrates move about little and would therefore be poorly represented in the pitfall traps. Others that do move about would move easily between the bryophytes and litter, possibly only passing over the bryophytes in their search for food. Others may reside among the bryophytes as transient visitors, seeking escape from a predator or avoiding the desiccation common in more open areas, but returning to the litter habitat when that environment was safe. In any case, insects that met all their needs within the bryophyte mat would be under-represented in the pitfall traps.

Figure 92. Abundance of taxonomical groups in pitfall traps associated with several species of bryophytes in dry, moist, and wet conditions at five locations in mountains of the Czech Republic. The scale at right is for ant data (**Formicoidea**) from Podolánky. Redrawn from Drozd *et al.* 2009. Controls are litter areas

The insects found among the mosses in streams are mostly **Ephemeroptera** (mayflies), **Plecoptera** (stoneflies), **Trichoptera** (caddisflies), **Diptera** (flies), and

Coleoptera (beetles) (Needham & Christenson 1927; Wesenberg-Lund 1943; Cowie & Winterbourn 1979; Glime 1994; Gislason *et al.* 2001). But moving about

among stems and leaves of mosses is not easy for the weak-legged or swimming insects in the small spaces. Hence, as already noted, most of the inhabitants are small (Thienemann 1912; Glime 1994; Amos 1999; Drazina *et al.* 2011). This also means that young, immature naiads of **Ephemeroptera** and **Plecoptera** are common (Stern & Stern 1969).

Many species overwinter as eggs on the mosses, then begin their immature lives there. Among the **Diptera**, *Dicranota* (Figure 93), *Atherix* (Figure 94), and *Simulium* (Figure 51-Figure 53) are common at this time; likewise, young **Elmidae** (larvae; Figure 95) are common among the mosses (Thienemann 1912).

In a New Zealand stream, Cowie and Winterbourn (1979) found 44 species of invertebrates, mainly immature stages of insects. The moss *Acrophyllum* sp. (Figure 96) hosted the stonefly *Austroperla cyrene* (Figure 97), a species of beetle in the **Helodidae** (Figure 98), and a triclad, *Neppia montana* (Figure 99); the moss *Fissidens* sp. (Figure 100) hosted the stonefly *Zelandoperla fenestrata* (see Figure 101), the caddisfly *Zelolessica cheira* (Figure 102), a fly in the family **Empididae** (Figure 103), and several species of midges (**Chironomidae**; Figure 90); . The moss *Cratoneuropsis* (Figure 104) had only one common taxon, a terrestrial isopod, *Styloniscus otakensis*, suggesting that the streamside *Cratoneuropsis* habitat is more terrestrial than aquatic. In addition to water saturation and flow rates, the ability of mosses to trap detritus was important in determining invertebrate inhabitants.

Suren (1988) examined faunal assemblages in New Zealand alpine streams, with the stoneflies (**Plecoptera**) *Zelandoperla* (Figure 101) and *Zelandobius* (Figure 105) and midge larvae (**Chironomidae**; Figure 90) being dominant. The mosses supported 5-15 times as many invertebrates as did the rocky habitats. In addition to these dominant insects, several non-insect invertebrates were dominant.

One of the interesting questions about bryophyte fauna is whether any species has a unique fauna. So far we have seen little specificity among the other invertebrates. Nevertheless, differences may exist dependent upon the niches of the bryophytes themselves. Some bryophytes occupy fast flow, some occupy areas where they spend part of the year above water, some are deep, and certainly differences exist among growth forms that create differences in the protection they afford. And some **Trichoptera** use liverworts or mosses to construct their cases, forcing them to live with certain species. Coinciding with these differences are the kinds of food the bryophyte habitats provide, again affecting who can survive there.

Paavola (2003) examined the concordance among the macroinvertebrates, bryophytes, and fish to look for possible **surrogates** to describe the system and its state of health. **Surrogates** are groups of organisms that can be used to assess suitability of a habitat for another group of organisms such as fish. When considered across drainage systems, there was strong concordance, but within a single river system that concordance was weak.

Bryophyte locations in the Paavola (2003) study were mainly related to nutrient levels and in-stream complexity, whereas macroinvertebrates correlated with stream size and fish correlated with oxygen levels, depth, and substrate size. But macroinvertebrates also relate to in-stream complexity (Allan 1975; Hart 1978; Trush 1979; Wise & Molles 1979; Williams 1980; Vinson & Hawkins 1998) and to substrate texture (Glime & Clemons 1972). And bryophytes add to that complexity. Some of the genera that inhabit bryophytes are also common in leaf packs – a substrate that provides cover and detritus for food. These include *Baetis* (Figure 45), *Leuctra* (Figure 30), and **Chironomidae** (Figure 90) (Robinson *et al.* 1998).

Due to differences in growing season, ice-free season, winter severity, available food, and flow regime changes from year to year, the fauna assemblage can also change from year to year. This can result in the temporary disappearance of an entire species, or even an entire order (Milner *et al.* 2006). This disappearance is particularly true for **Plecoptera**. Channel stability is important in determining faunal stability, but a normally stable channel can suffer from heavy rains or flooding during snow melt.

And channel stability likewise determines the stability of bryophytes, hence playing a role in the bryophyte fauna.

In my study of the insects inhabiting the bryophytes of mid-Appalachian Mountain streams, I identified 141 species occurring among 10 species of bryophytes in 28 streams, and that does not include the species of the **Chironomidae** (Figure 90), which were identified only to family (Glime 1994). The smallest of the insects occurred on the leafy liverwort *Scapania undulata* (Figure 106) and the largest could be found on various species of *Fontinalis* (Figure 107). As in many other studies, the most abundant insects were midges (**Chironomidae**), the stoneflies *Leuctra* (Figure 30) and *Isoperla bilineata* (Figure 108), and the blackflies (*Simulium tuberosum*; Figure 109).

Heino and Korsu (2008) questioned the species-area concept in aquatic systems, examining rocks and bryophyte cover in two river sites. They found only a weak species-area relationship on stream stones. On the other hand, bryophyte biomass was important both in supporting species richness and in increasing number of individuals of stream macroinvertebrates. They suggested that cover was important in increasing number of individuals and that the species richness was a subsequent passive response. The bryophyte biomass can be expected to increase with time, whereas the area of stones will not. The mechanisms that promote these species-area relationships need to be demonstrated experimentally. These could involve food relationships, sampling methods, niche space, flood disturbance, predation refugia, or flow regime.

Specificity

Many streams have only one dominant bryophyte, and others have the species intermingled. These conditions complicate any attempts to determine insect preference. Nevertheless, some specificity seems to exist, but keep in mind that it might be a preference of both insect and bryophyte for the same stream conditions. The caddisfly *Rhyacophila* cf. *invaria* (Figure 110) was present in 36% of the collections (Figure 118) of *Platyhypnidium riparioides* (Figure 111) in mid-Appalachian Mountain, USA, streams, but totally absent among *Hygroamblystegium fluviatile* (Figure 112), despite the frequent occurrence of these two mosses in the same streams, often on the same rocks (Glime 1994). *Rhyacophila carolina* (Figure 1) reached its greatest abundance in clumps of the leafy liverwort *Scapania undulata* (Figure 106; Figure 118).

Less distinct preferences occurred in the elm mid beetle larva *Optioservus* sp. (Figure 113; Figure 118) [36% of *Hygroamblystegium fluviatile* (Figure 112), 7% of *Platyhypnidium riparioides* (Figure 111)] (Glime 1994). The stonefly *Pteronarcys proteus* (Figure 114) occurred in 24% of the *H. fluviatile*, 7% of the *P. riparioides*, and never in any of the other species, including *Scapania undulata* (Figure 106), *Fontinalis dalecarlica* (Figure 115), and *Hygrohypnum* spp. (Figure 116) (Figure 118).

Figure 113. *Optioservus* sp., a common beetle larva among *Hygroamblystegium fluviatile* and *Platyhypnidium riparioides* in Appalachian Mountain, USA, streams. Photo by Arlo Pelegrin, with permission.

Figure 114. *Pteronarcys proteus*, a stonefly that seems to have some selection in bryophytes it will inhabit. Photo by Jason Neuswanger, with permission.

Figure 115. *Fontinalis dalecarlica*, a large moss but that did not house *Pteronarcys proteus* in Appalachian Mountain, USA, streams. Photo by Kristoffer Hylander, with permission.

The liverwort *Scapania undulata* (Figure 106) has a different form from that of any of the mosses. This flattened habit seems to favor the fast-water members of *Simuliidae*, with *Prosimulium hirtipes* (Figure 117) in

58% of the collections and *Simulium tuberosum* (Figure 109) in 75% of the collections (Figure 118) of this liverwort in mid-Appalachian Mountain, USA, streams (Glime 1994). But *S. tuberosum* also occurred in 78% of the *Fontinalis dalecarlica* (Figure 115) collections (Figure 118).

Figure 116. *Hygrohypnum luridum*, a moss that is not suitable habitat for the large *Pteronarcys* in the streams of the Appalachian Mountains, USA. Photo by Michael Lüth, with permission.

Figure 117. *Prosimulium hirtipes*, a common blackfly on the liverwort *Scapania undulata*. Photo by Janice Glime.

Diversity differs little among bryophyte species (Figure 119), although richness can be higher in the larger *Fontinalis* (Figure 115) species (Glime 1968, 1994). *Fontinalis* species are also the only ones that typically house larger insects. *Scapania* (Figure 106), on the other hand, housed the smallest insects in the Appalachian Mountains, USA, streams.

Figure 118. Frequencies of insects on five bryophyte species sampled in 28 streams in the middle Appalachian Mountains, USA. Only insects with at least 10% frequency on at least one species of bryophyte are included. The bryophyte name appears by the group of species that was most abundant on that bryophyte; the name applies to all groups in that frame. From Glime 1994.

Figure 119. Comparison of mean insect richness and Shannon diversity on a leafy liverwort (*Scapania undulata*) and four species of mosses in 28 mid Appalachian Mountain streams, USA. Redrawn from Glime 1994.

Perhaps the greatest specificity is among some of the case-making caddisflies (**Trichoptera**). Several species in the **Hydroptilidae** make their cases exclusively from bryophytes, including *Palaeagapetus celsus* from leafy liverworts (Flint 1962; Glime 1978, 1994). The flat leaves of *Scapania undulata* seem to be ideal for their method of cutting nearly circular pieces that they cement together for the cases, apparently causing these larvae to live almost exclusively among leafy liverworts (Glime 1978, 1994). Likewise, in the **Brachycentridae** *Adicropheps hitchcocki* (Figure 120) uses bits of *Fontinalis* (Figure 107) leaves or other mosses to construct its cases (Flint 1965; Glime 1994). When it uses *Hygroamblystegium fluviatile* (Figure 112) it may use only costae to make the case, sometimes leaving the ends of the costae dangling from the case (Glime 1994). The **Chironomidae** (Figure 90), as a family, was present in 98-100% of the collections of all species (Figure 118), but these comprised multiple species that could have differed among bryophytes and streams.

The acidity may affect the inhabitants, causing an appearance of bryophyte specificity. Frost (1942) found that the **Plecoptera** and **Coleoptera** were less important in the calcareous stream than in the acid stream, whereas the **Ephemeroptera** and **Trichoptera** reached their greatest density in the more calcareous stream.

Seasons

One reason for insects to live among bryophytes is to escape the cold of winter. To this end, some insects are more abundant in streams in the winter, but many spend the winter as pupae or eggs.

Thienemann (1912) found that young fauna were especially common among mosses in summer. Seasons can

partition niches, with different sizes of insects occupying different niches. This means that larger members of a genus or family can occupy the same moss clump as younger members of other species in that family feeding group because they have different feeding niches. In some cases this niche partitioning is done by a seasonal migration to a different substrate. Hildrew and Edington (1979; see also Muotka 1990) found that early instars of *Hydropsyche siltalai* (Figure 121) and *H. pellucidula* (Figure 122) occupied the same rocks. However, in spring *H. siltalai* migrates to moss beds, but *H. pellucidula* was totally absent among the mosses at that time.

Figure 120. *Adicropheps hitchcocki* showing case made with *Hygroamblystegium*. Note costae protruding near opening. Photo by Bob Henricks, with permission.

Figure 121. *Hydropsyche siltalai*, a caddisfly larva that moves to moss beds as it gets older, avoiding competition with *H. pellucidula*. Photo by Urmas Kruus, with permission.

Figure 122. *Hydropsyche pellucidula*, a net-spinning caddisfly that avoids niche competition with *H. siltalai* by avoiding moss beds when the latter migrates there. Photo by Niels Sloth, with permission.

In the Appalachian Mountain streams, the total numbers diminish in the winter (Glime 1968), but some insects, like the blackfly *Prosimulium hirtipes* (Figure 51-Figure 53; Figure 123), hatch in late fall and spend the winter in the water, emerging as adults in spring.

Figure 123. Relative abundance of the six most common insects among bryophytes in five collecting seasons in Appalachian Mountain, USA, streams. Based on Glime 1968.

In these Appalachian streams, counts do not always track diversity and richness (Figure 127; Glime 1994). What is more interesting is that **Shannon diversity** (following Patten 1962) and species richness do not always agree. This may be the result of the differences in counts, which are reflected in the **Shannon diversity**:

$$H' = -\sum_{i=1}^R p_i \log_2 p_i$$

where p_i = the proportion of individuals belonging to the i th type, or count of the species divided by total count of all species

R = richness, or total number of species

Richness, on the other hand, is simply the number of species present. In these streams, Shannon diversity was highest in March, but richness was highest in July. It is also interesting that these seasonal differences can be different among bryophyte species (Figure 124-Figure 127).

The ever-present **Chironomidae** (Figure 90) often peak among the mosses in winter (Frost 1942), but in the Appalachian Mountain, USA, streams the peak is mid-summer (Figure 123) (Glime 1968). Whitehead (1935) suggested that this might be a behavioral attribute in which the insects seek shelter among the mosses to avoid or respond to the ravages of flooding. But clearly the insects differ among orders, families, and seasons, as seen in these Appalachian Mountain streams (Figure 125-Figure 126).

Figure 124. Seasonal changes in species diversity (H') among mosses (*Fontinalis* spp. —) and liverworts (*Scapania undulata* --) in Appalachian Mountain, USA, streams.

Figure 127. Bryophyte-dwelling insect seasonal richness, species diversity, and counts from handful samples. Redrawn from Glime 1994.

Sampling

Sampling of the fauna of aquatic bryophytes can be a time-consuming process. And sampling used for most terrestrial or stream habitats can introduce strong biases for these sheltered species.

My own methods were to use hand grabs, then determine the dry weight of the bryophytes after the fauna had been removed. This sampling kept the internal fauna intact, and to test for surface losses, I initially placed a net just downstream from my collections. Very few

invertebrates landed in the net, so I proceeded with my hand collections. These were placed in baby food jars with 95% alcohol and a few drops of glycerine added to prevent predation and decay until the jars reached the lab. I removed the insects with microforceps while systematically searching through a dissecting microscope at 10 X.

Frost (1942) was one the early surveyors of bryophyte fauna. Her sample size was 200 g of wet moss. Kamler (1967) cut 10x10 cm samples under water. Maurer and Brusven (1983) were particularly careful. They surrounded the moss with a nylon organdy net of 250 μ m mesh while removing the moss from the stream, then used several washes and hand picking to extract the insects.

Armitage (1961) used the modified square foot sampler, similar to the Surber sampler (Figure 128) used by Gurtz and Wallace (1984), to catch insects from rocks, mosses, sticks, and under rubble in streams. However, most bryophyte dwellers are adapted to clinging to the bryophyte and require more than a little disturbance to free them. This leads to underestimates of the bryophyte fauna relative to those among the rubble of the stream bottom and also to species bias. Wulforst (1994) modified this method slightly, using a box sampler to cut a square of 14 cm^2 to sample mosses in an acid stream. The moss samples were quantified by volume using displacement of water in a graduated cylinder.

In his New Zealand studies, Suren (1988) likewise used a Surber sampler (Figure 128) with 100 μ m mesh to sample 0.01 sq m . Rocky areas were sampled with a 0.02 sq m sampler that had a thick foam flange around the bottom to provide a seal with the substrate. Mosses were scraped into the sampler with a razor blade. This method permitted the same area to be sampled in both rock and moss areas.

Figure 128. Surber sampler being used as drift net for winter stream drift sampling. Photo by Janice Glime.

Preservative

It is important to understand the role of the preservative. Not only does it keep the organisms from decaying and being eaten by cohabitants during the period until the sample can be examined, but it increases the extraction efficiency for flotation techniques (discussed below), at least in a sucrose solution of 1.12 specific gravity (Pask & Costa 1971). In samples preserved for 14 days in 10% formalin compared to those not preserved but examined the same day, the preserved insects had a recovery of 91% whereas those with no preservation had only an 83% recovery rate.

Since any collection of bryophytes will bring significant water with it, it is necessary to use a higher concentration than that used when preserving just insects. I added 95% alcohol to my bryophyte collections (with insects), hoping to achieve a concentration of around 70%.

Extraction

The least bias in extraction can be achieved by careful hand picking while observing through a dissecting microscope. When I first tried to publish my Ph. D. work, the reviewer wanted to know what method I had used to "estimate" the numbers of **Chironomidae**, which could reach thousands in a single handful of moss. But I had removed and counted every single one of them at 10X magnification! Gurtz and Wallace (1984) also hand-picked invertebrates from the mosses at 7X under a dissecting microscope, using a count per dry weight of moss.

There are simpler and less time-consuming methods for those who don't want to spend three years searching among the bryophytes with a microscope. But, these each have their biases. The Tullgren funnel (Andrew & Rodgers 1999) creates a temperature gradient over the sample, typically with a tungsten light bulb above it. Mobile organisms will move away from the higher temperatures and fall into a collecting vessel with alcohol or mixed preservative. But not all insects move quickly, and some may die from the heat and desiccation before falling to their death in the alcohol below. Furthermore, some will die before reaching the lab due to the reduced oxygen.

Fairchild *et al.* (1987) developed a behavioral method for extracting invertebrates from *Sphagnum* (Figure 91). The method includes a vertical temperature gradient coupled with dissolved oxygen gradients in a column of water containing the *Sphagnum* sample. They determined the overall extraction to be 85% efficient ($n=4$). I do have concerns about bias in the species extracted.

Teskey (1969) developed a method especially for sampling the small flies of the family **Tabanidae**. He used a combination of a specially designed sieve with a multiple Berlese funnel (similar to the Baermann funnel in Figure 129) or by using hand searching to sample these larvae. But to identify the larvae, as in many of the aquatic taxa, they had to be reared to adults. Cochrane (1913) used sieves to collect larvae of *Culicoides furensoides* (Diptera: **Ceratopogonidae**) from *Sphagnum* (Figure 91).

Figure 129. Baermann funnel using moss sample and modified from the Berlese funnel setup, using water instead of air. Modified from Briones 2006.

Flotation

Any flotation technique requires that the density of the flotation liquid be greater than that of the insects but less than that of the debris (Lackey & May 1971). The 1.12 specific gravity sucrose solution of Pask and Costa (1971) works well in this regard. The kerosene phase separation extracts more total individuals than those extracted by sugar flotation or the Tullgren funnel, particularly more **Acari** (mites) and **Collembola** (springtails) (Andrew & Rodgers 1999).

Fast (1970) pointed out that calling the flotation techniques "flotation" was a misnomer. While the sugar solution is important, many of the organisms remain lodged at leaf bases or caught among the leaves and stems. He preserved samples with 10% formalin. To separate the organisms, he used 360 g sucrose per liter of water and gave the samples only one immersion in the sugar solution. He then sorted at 3.5X magnification. One problem I found with the flotation method was that tiny creatures like the Chironomidae got trapped in the surface tension. They were almost impossible to pick up, so they needed to be trapped on a filter. By the time you have then picked them off the filter, you might as well sort them directly from the moss and learn about their hideouts and spatial relationships at the same time.

Hribar (1990) reviewed ten methods for sampling biting midge larvae. Some of these will work for aquatic bryophytes. Hribar was successful in extracting larvae of **Ceratopogonidae** (*Alluaudomyia*, *Atrichopogon*, *Bezzia*, *Culicoides*, *Dasyhelea*, and *Forcipomyia*) from *Fontinalis*

(Figure 107) and aquatic liverworts by using a Berlese funnel (see Figure 129). He found that sugar flotation and salt flotation provided similar results, but the sugar flotation caused less mortality. Magnesium sulfate is a slower process but results in fewer deaths than salt solutions. Nevertheless, he considered agar extraction and salt flotation to be the most effective for collecting larvae. Sieving, sieving plus salt flotation, and Berlese funnels worked well for mosses.

In short, unbiased sampling to determine numbers of insects living among bryophytes requires time and patience.

Artificial Mosses

Several researchers have attempted to explain the role of aquatic bryophytes by using artificial mosses. Glime and Clemons (1972) used strips of plastic and bundles of string (Figure 130) as artificial mosses. The plastic permitted colonization by **periphyton** (attached organisms) but lacked the chambering found among mosses; only 13 species occurred on the 33 samples. The string offered a soft substrate with limited chambers; 23 species of aquatic insects occurred on the 35 samples, some of which were not present on the real mosses. The real mosses [*Fontinalis novae-angliae* (Figure 131) & *F. dalecarlica* (Figure 115)] had 25 species among the 46 samples, differing little in overall richness from that of the string mosses. It appeared that density of insects was higher among real mosses, but there was no common base upon which to compare them. It is interesting that the Shannon diversity differed little among the three substrata (1.8 on moss, 1.9 on string, and 1.7 on plastic). Nevertheless, the Shannon diversity (d) on plastic was significantly different from that on mosses or strings. The lack of complexity and smaller surface area of the plastic may have accounted for the limited diversity.

Figure 130. Artificial mosses made of cotton string. Photo by Janice Glime; see Glime & Clemons 1972.

Suren (1988) used nylon twine (5 cm long, 1 mm thick) to weave squares 0.01 m² thick with a pore size of 4

mm. He found no differences in the fauna between artificial and real mosses in a New Zealand stream. The artificial mosses even had abundant periphyton growth [especially *Epithemia* (Figure 132) in winter and spring], but their accumulation of detritus and silt was sparse. This perhaps explains the significantly lower numbers of detritus feeders such as **Acarina** (mites), **Collembola** (springtails), **Tardigrada** (water bears), **Dorylaimoidea** (nematodes), and **Ostracoda** (seed shrimp) on the artificial mosses.

Summary

Aquatic insects are those insects that spend part of their life cycles in the water, usually as a means of escaping the harsher environment on land during one or more seasonal conditions. For most, the immature stages are those requiring such an escape.

Aquatic bryophyte dwellers include the **Collembola** (no longer considered to be insects) that look like miniature adults when born. The **hemimetabolous** insects include the **nymphs** of **Hemiptera** that look like their parents from birth and simply grow larger. The **naiads** of **Ephemeroptera**, **Odonata**, and **Plecoptera** are likewise hemimetabolous, but the naiads often differ from the adults in having gills, different mouth parts, and wing

pads instead of wings. Their life cycle goes from egg/embryo to naiad to adult. The **holometabolous** insects have four distinct stages in the life cycle – **egg/embryo**, **larva**, **pupa**, and **adult**. These orders, among bryophytes, include **Coleoptera**, **Neuroptera**, **Megaloptera**, **Trichoptera**, and **Diptera**. Some have gills as larvae but not as adults.

As an escape from unfavorable conditions, the life cycle stages often respond to environmental cues, including photoperiod, temperature, or available food. Aquatic insects are especially sensitive to temperature, and many of them are in the water for winter to escape the below-freezing temperatures in the terrestrial environment. Some overwinter as dormant eggs or pupae, others as active larvae, naiads, or adults.

Structural adaptations include streamlining, small size, gills, hooks or silk for anchoring, gill covers, and cases or tubes. They move about in the bryophyte clumps to achieve the best oxygen and flow conditions, often leaving as they grow larger. Oxygen may be obtained through gills, cuticle, or a **plastron** that carries an air bubble from the surface or from photosynthesizing plants or algae. Bryophyte dwellers include shredders, gatherers, scrapers, and detritus feeders that prey upon smaller organisms, including periphyton, or eat the detritus gathered by the bryophytes. Some eat the bryophytes. Some make nets to trap food. A few species have a specific requirement for bryophytes for case building, but most simply need a refuge with adequate oxygen, food, and cover.

Sampling is often done with nets, but is best by hand grabs and hand sorting. The faster methods such as nets are commonly used, but they have biases against interior and clinging organisms. Sorting by flotation or Berlese funnels has similar biases. Artificial mosses can sample colonizers but they may not provide the food sources needed and require somewhat lengthy colonization times.

Acknowledgments

For this chapter I must thank the many students who have spent the night in the cold of winter or mosquitoes of summer to sample the streams and their bryophyte dwellers. And a special thanks to Arlene Jim, my sister Eileen Dumire, and many others who spent numerous hours staring through a dissecting microscope and pulling insects out of pickled bryophytes. And in my younger days, my parents, Mildred and Gilbert Glime, chauffeured me to streams throughout the middle Appalachians so that I could study this fascinating group of bryophyte dwellers. My sister often accompanied me on collecting trips and served as the reviewer for this chapter, giving me the perspective of a non-biologist.

In my early days, Lewis Berner, Oliver Flint, Glenn Wiggins, and Ken Cummins encouraged me and helped me in identifications. Jason Neuswanger, Roger Rohrbeck, and Arlen Thomason have been helped me with updating scientific names and suggesting contacts. Jason Neuswanger and Bob Henricks have given me permission to use their large libraries of aquatic insect images. Peter Buchanan gave me permission to use the invaluable

collection of images at Landcare Research, NZ. Throughout the insect chapters, I have constantly appreciated all the photographers, both named and anonymous, who have made their images available through Creative Commons. This project would be far less complete without Google Scholar.

CHAPTER 11-2

AQUATIC INSECTS: BRYOPHYTE ROLES AS HABITATS

Figure 1. Habitat for stream bryophyte dwellers, Wolf Brook, NY, USA. Photo by Jason Neuswanger, with permission.

Potential Roles

Ulfstrand (1967) astutely stated that aquatic insects select their habitats on the basis of factor combinations. While some minimal levels of factors are important – oxygen, temperature, space, stability – the most important factor determining location within this medley of minimums is usually food. And that food works in two directions: enough food to maintain nutrition and avoidance of becoming food themselves. To satisfy both food factors, Ulfstrand found that substrate is especially important; bryophytes are often important choices among those substrates.

Bryophytes are major components in several types of ecosystems, including peatlands, mountain streams (Figure 1), high latitudes, and boreal forest floor. Many researchers have found that bryophytes are important substrata for insects (Percival & Whitehead 1929). Arnold and Macan (1969) found the greatest species richness and number of individuals among mosses, citing their role as cover and source of food by trapping particles.

Bryophytes, both mosses and liverworts, often form extensive cover in rocky and stony reaches of streams (Macan & Worthington 1951). These can have profound effects on the fauna by providing footholds against the current. Mosses with moderate thickness are suitable for the mayflies *Baetis* (Figure 2) and *Ephemerella* (Figure 3) and **Plecoptera** (stoneflies; Figure 20). Fish benefit as well, with the greatest production of fish-food organisms where there are either rooted plants or mosses. For example, **Chironomidae** (Figure 9) are in greatest numbers among thick mosses. And fish certainly eat **Chironomidae** (Mousavi *et al.* 2002). Based on gut contents, Frost (1939) considered moss-dwelling insects to be an important constituent of the diet of trout (Frost 1939) and young salmon (Frost & Went 1940) in the River Liffey, Ireland. Likewise, Minnows appear to crop the moss fauna (Frost 1942). On the other hand, Brusven *et al.* (1990) found that at least in the daytime when salmonid fish feed, the insects drifting in the moss-covered channel (*Fontinalis neomexicana* – Figure 4) did not provide any greater biomass for fish food than in channels where mosses were absent and insect faunal density was much less. Bowden *et*

al. (1999) likewise questioned whether fish actually benefit from the increased abundance of insects in streams where bryophytes are present, citing a lack of evidence.

Figure 2. *Baetis rhodani* on sand, a mayfly that also lives among mosses. Photo by J. C. Schou, with permission.

Figure 3. *Ephemerella dorothea* on moss (*Platyhypnidium riparioides*) in Virginia, USA. Photo by D. N. Bennett, with permission.

Figure 4. *Fontinalis neomexicana*, a slightly amphibious species that provides shelter for moss dwellers. Photo by Belinda Lo, through Creative Commons.

I am aware of no study that demonstrates quantitatively that the increase in number of insects in moss mats benefits fish. It appears that insects may have evolved to drift at night precisely to avoid predation by day-feeding

fish. Bryophytes are a difficult place for fish to locate and catch the insects, perhaps reducing the catchable food from what might have been available if rock-dwelling insects were present instead. The hypothesis that bryophyte dwellers increase available fish food needs to be tested.

Corona (2010) suggested that immature insects in streams stayed together because that behavior would increase survival, a concept already suggested for vertebrates by Elgar (1986), Robinette *et al.* (1995), and Brown and Brown (2004). Bryophytes that provide a stable, protected habitat would facilitate such behavior.

Nearly fifty years after Macan and Worthington (1951) expressed the profound contribution of bryophyte-dwelling insects, Bowden *et al.* (1999) summarized that bryophytes "can profoundly influence both the abundance and community structure of stream invertebrates." But they further stated that "the number of fundamentally important roles of bryophytes in stream ecosystems remain unexamined." I will attempt to pull together what various scattered studies around the world have revealed about the roles of stream bryophytes.

Paddling a Kayak to gain first-hand information, Yamamura (2009) observed the adaptations of aquatic insects to various flow regimes in the rivers of Idaho, following up on studies by Rosentreter (1984). In their studies, Yamamura and Rosentreter found that aquatic insects benefit by having aquatic bryophytes because:

1. Bryophytes **decrease stream velocity** on the rock's surface layer.
2. Bryophytes **trap more detritus** (Figure 5; product of disintegration, especially organic matter produced by the decomposition of organisms) than smooth rock (food for shredder insects).
3. Bryophytes provide hiding cover (**refuges**) from predators.
4. Bryophytes provide better background coloration for **camouflage**.
5. Bryophytes provide **greater surface area**, providing a greater amount of habitat area.
6. Bryophytes provide **more food** since algae can grow upon the greater surface area created by the three dimensions of the moss surface.
7. Bryophytes provide greater **algae retention** and protection when stream flow regimes are low enough to create dry surfaces. The bryophytes **retain water longer** than other substrata in the stream, permitting the algae to dry slowly and acclimate to the encroaching desiccation.
8. Perennial bryophytes such as *Scouleria aquatica* (Figure 6) can provide **long-term stability** to an ephemerally dry rock surface, permitting survival of algae, insect larvae, and eggs.

Yamamura (2009) concluded that insect larval data support the interpretation that larvae in spring-fed streams (streams containing aquatic moss) are larger compared to those in runoff-dominated streams (streams that lacked mosses). He concurred with Rosentreter (1984) that spring-fed (mossy) streams have three cohorts present while most run-off (non-mossy) streams have two cohorts. This raises the question, do mosses in runoff-dominated streams benefit insects enough to produce larger larvae and another generation (cohort) per year? Perhaps the insects benefit

from the added cover of bryophytes – insect predators in Idaho streams include other insects, fish, shore birds, and the American dipper. Mosses provide cover in which to hide from all these predators.

Figure 5. **Detritus**, a common food for aquatic insects and typically accumulated at plant and leaf bases among bryophytes. Photo by James K. Lindsey, with permission.

Figure 6. *Scouleria aquatica* on rock near stream water. Photo by Matt Goff, with permission.

Refuge

Bryophytes serve as refuges in both moving water and lentic systems such as lakes and ponds. In streams, they provide a refuge against the torrents of rapidly flowing water, permitting insects to live where they can take advantage of the higher oxygen and suspended food sources available in flowing water while remaining safely anchored within the moss or clinging to its surface. In both habitats, the bryophyte provides a hiding place from predators, especially fish, but also larger insects, crayfish, and birds.

The importance of bryophyte-dwelling insects as fish food is a subject for speculation. While the bryophytes provide homes for numerous insects, there is no direct evidence that these insects are available as increased fish food. Greig and McIntosh (2008) examined the effect of brown trout (*Salmo trutta*) predation on the caddisfly *Zelandopsycha ingens*, a bryophyte dweller in New Zealand. They determined that these trout can have

positive effects on the size and fecundity of the adult caddisflies by reducing competition among the larvae through predation. The striking revelation of this study was that despite the detritus-based diet of these caddisflies, reduction in the number of larvae still had a positive effect on the adults of the species when compared to those in fishless streams. The adults were larger and the females had 33% more eggs, but the egg size was unchanged. Nevertheless, the increase in number of eggs did not compensate for the loss of larvae.

The study by Greig and McIntosh (2008) suggests that fish have an impact on insects that typically live among the bryophytes, many of whom are detritus feeders. Thus, the bryophyte cover potentially increases the number of insects surviving and the number of adults reproducing, but we are left with the question of whether the bryophytes ultimately produce more available fish food.

Habitat Diversity and Substrate Variability

Habitat diversity offers more niches, hence making the area suitable for more species. Clenaghan *et al.* (1998) identified ecological factors that contribute to macroinvertebrate community composition. Local ecological factors include acidic water, moss, shading, agricultural runoff, longitudinal trends in stream physico-chemistry (distance from headwaters, geology, land use) and season (related to life history patterns of the invertebrates). In their study of a conifer-afforested catchment in Ireland, macroinvertebrate density and richness increased with the distance from the headwaters and the concomitant increases in pH, water hardness, and available nutrients.

Douglas and Lake (1994) demonstrated that habitat diversity was important in increasing species richness in streams. Bryophytes not only add to that diversity, but increase available surface area. Based on a review of the literature, Smith-Cuffney (1987) reported that stream mosses in low order, high elevation streams have a structurally unique community. Measured as respiration rates, the communities among *Fontinalis* (Figure 4) had three times the rates found in the stone community and five times that of the **hyporheic** community. Arnold and Macan (1969) found the largest number of species and individuals of insects inhabited mosses in a Shropshire Hill stream in the UK, where the mosses provided both shelter and trapped food.

Pardo and Armitage (1997) demonstrated the importance of environmental variables in the spatial distribution of aquatic insects based on eight mesohabitats. They found that water velocity and flow dynamics, together with the nature of the substrate were the major determinants of **benthic** (bottom) communities. Heino (2009) looked at the environmental variables somewhat differently, attempting to explain why such things as the influence of altitude varied with geography. He found pH, stream size, and moss cover were the most important variables, with functional diversity increasing with moss cover. These two approaches are not that different, with pH and water velocity both influencing moss cover and moss cover providing safe sites in areas of high flow rates.

Špoljar *et al.* (2012) likewise found that flow velocity and pH had the greatest effect on community structure. In two springs in Papuk Nature Park, Croatia, the

macroinvertebrate taxa numbered only 25. Where the bryophyte cover was dense (90% cover), the community structure was most affected by flow velocity and pH; macroinvertebrate diversity and abundance were higher than in the stream with only 50% bryophyte cover. In the latter stream, algae, protozoa, and **meiofauna** (minute animals living in small spaces in soil or aquatic sediments) reached higher abundance, apparently resulting from suspended organic matter and epiphytes.

Bryophyte communities exemplify the species-area relationship (Gleason 1922). Increased bryophyte cover means an increase in available substrate due to its three-dimensional structure. Heino and Korsu (2008) found a strong relationship between species richness and number of individuals, and both of these were significantly related to the bryophyte biomass. They attributed the relationship to the increased cover provided by greater bryophyte coverage. Heino *et al.* (2005) found that despite the highest congruence between bryophytes and macroinvertebrates among the stream biological groups, that congruence was nevertheless weak. This seems to relate to differences in the stream factors that determine bryophyte locations. Bryophyte diversity followed water color, habitat stability, and stream size, in that order. Macroinvertebrate diversity instead was determined in the order of stream size, water color, and acidity.

Nutrients

Nutrients can affect moss growth in some cases and limit it due to competition for light by encrusting algae in others. In their study of the Kuparuk River, Alaska, USA, Lee and Hershey (2000) found that fertilization with phosphorus increased the growth of mosses (*Hygrohypnum* – Figure 7), but that insects did not respond as extensively as one might expect. Invasion by mosses resulted in an increased density of the mayfly *Ephemera aurivillii* (Figure 8) and **Chironomidae** (midges; Figure 9), but had no effect on densities of the mayfly *Baetis* spp. (Figure 2) or **Simuliidae** (blackflies; Figure 22). Both *Baetis* and *Ephemera* grew larger in fertilized areas, but Lee and Hershey suggested that this was most likely due to the increase in epiphytic diatoms. Only *Ephemera* seemed to be affected by substrate type (bare rock, natural moss, artificial moss), with the greatest densities among the mosses, presumably due to increased habitat complexity. Clenaghan *et al.* (1998) compared several factors and found that mosses were one of the factors explaining the diversity of insects in a catchment stream in Ireland, and that both density and richness increased with moss weight. Voelz and McArthur (2000) likewise concluded that habitat complexity was one of the most important factors in determining species richness in streams.

In my own culturing studies, I have found that enrichment was often detrimental to the mosses. These mosses lost their green color and were covered by algae that presumably intercepted the light – and CO₂. While the bryophytes remained intact, even if dead, this enrichment could benefit the insects by increasing food sources, but such enrichment most likely would make establishment of new mosses or increased coverage by existing ones less likely.

Substrate Size

The biodiversity of macroinvertebrates typically increases linearly with the substrate suitability index [suitability of sediment, **periphyton** (freshwater organisms attached to or clinging to plants, but also used to include other objects projecting above the bottom sediments; *Aufwuchs*), and benthic organic materials] (Duan *et al.* 2009). In large rivers in China (Yangtze River, Yellow River, East River, Juma River), Duan *et al.* found that the macroinvertebrate community was not dependent upon macroclimatic conditions or latitude, but rather responded to the commonality of instream habitat conditions of substrate composition and flow conditions in these rivers.

They found that taxa richness was highest on cobble covered with hydrophytes, high on moss-covered bedrock, and low on clay or cobble where there were no plants. Sandy beds were unstable and thus devoid of benthic macroinvertebrates. As in many stream studies, the EPT insects [**Ephemeroptera** (Figure 8, **Plecoptera** (Figure 20), **Trichoptera** (Figure 13)] dominated the cobble, gravel, and moss-covered bedrock. But contrasting with most stream studies (see Chapter 11-9, Holometabolous Insects – **Diptera**), the **Chironomidae** larvae (Figure 9) reached greatest dominance in the clay beds.

But substrate size apparently does not act alone and importance differs among types of insects (see for example Ulfstrand 1967). Contrasting with other studies, Wise and Molles (1979) found that small substrates supported more insect individuals than did the larger stones. And mixed sizes supported numbers between the small and large sizes.

Stability

I love the expression "A rolling stone gathers no moss," because it so perfectly describes the situation of stability. This expression can be traced to Erasmus' Adagia, first published around 1500, and has since taken on wide usage with somewhat conflicting interpretations. Nevertheless, in the context of a stream, its meaning is clear.

Bryophytes themselves indicate a stable substrate (Yamamura 2009). Such stable areas are present due to stream channel geometry. Rapids can focus the ice scraping at the center of the river, away from the sides where bryophyte populations are able to grow. Hence, some invertebrates may live in those mossy areas simply because they, too, only survive where the substrate is stable and the water has a reduced shearing effect.

Stability is most important for eggs and many pupae that cannot move to a more favorable location when the need arises. Bryophytes will only become well established on stable rocks and boulders, so they signal a stable habitat. Furthermore, as water levels recede, bryophytes maintain water content well beyond the time that a rock can do so, creating a moisture stability. And when the young insects hatch from the eggs, these tiny animals are not only easy prey for larger animals, but they are poor swimmers unable to navigate in the flowing water. The bryophytes provide cover and protection in their small-chambered labyrinth that prevents entry to predators such as fish and large insects and that reduces the flow to near-pool conditions (Glime 1978).

pH Relationships

The **depauperate** (lacking in numbers or variety of species) fauna of some bryophytes may relate more to the preferred habitats of the bryophytes than to the bryophytes themselves. For example, in Wales, Ormerod *et al.* (1987) found that in streams with low pH the bryophytes [liverworts *Scapania undulata* (Figure 10) and *Nardia compressa* (Figure 11)] had few insects; 60% of the *S. undulata* sites had fewer than 20 macroinvertebrate taxa. The pH where Ormerod *et al.* found these liverworts growing was 5.2-5.8. On the other hand, less than 5% of the sites with the red alga *Lemanea* (Figure 12) (pH 5.5-8.5) were so impoverished. In particular, *Hydropsyche*

(Figure 13) was absent at sites with *S. undulata* and *N. compressa*, but present in streams with *Fontinalis squamosa* (Figure 14).

Figure 14. *Fontinalis squamosa* above and below water on rocks, home to several stonefly genera. Photo by Janice Glime.

Research by Willoughby and Mappin (1988) suggests that the insect avoidance of the two leafy liverworts that Ormerod *et al.* (1987) observed may not have been a response to pH, but rather the result of the liverwort terpenes and terpene alcohols in the oil bodies. On the other hand, some insects such as the mayfly *Ecdyonurus* (Figure 15) feed on such acid-tolerant bryophytes as *S. undulata* (Figure 10), but are unable to live in the acid streams at the lower end of the pH tolerance range of this liverwort. Ormerod and coworkers (1987) considered that these mayflies are therefore physiologically restricted from acid streams.

Other factors may affect the choices of many insects to avoid colonizing these acid-tolerant bryophytes. For example, one possibility that Ormerod *et al.* (1987) considered was that the diatom *Eunotia* (Figure 16) that grows in the leaf axils of leafy liverworts (acid-loving) is inaccessible to grazing *Baetis* (Figure 2), whereas the diatom *Cocconeis* (Figure 17) grows on the leaf lamina of the moss *Hygrohypnum* (Figure 7; growing at a higher pH) where it is easily grazed (Sutcliffe *et al.* 1986).

Figure 17. *Cocconeis placentula*, an epiphytic diatom that cements itself to aquatic bryophyte leaves. Photo by Ralf Wagner at <<http://www.dr-ralf-wagner.de/>>, with permission.

Heino (2005) likewise found that functional richness of macroinvertebrates increased with increased pH, with total nitrogen, water color, and substrate particle size also varying with moss cover in 111 boreal headwater streams in Finland. The functional structure depended on these same variables with its dominant pattern being related to increase of shredder-sprawlers and decrease of scraper-swimmers in acidic conditions.

Frost (1942) compared the fauna on the mosses in acid and alkaline streams in her survey of River Liffey, Ireland. *Chironomidae* (Figure 9) constituted 40-54% of the fauna in these streams. In the carboniferous limestone sites,

Fontinalis antipyretica (Figure 18) and *Platyhypnidium riparioides* (Figure 19) dominated in a pH range of 7.4 to 8.4. The stonefly fauna of these mosses was comprised of predominantly *Isoperla* (Figure 20). The dominant caddisfly genus was *Hydropsyche* (Figure 13). Mayflies included *Ephemere*llidae (Figure 8) (mean 533 per sample of 200 g wet weight), *Baetis* (Figure 2), and *Caenis* (Figure 21). The blackfly *Simulium* (Figure 22) was common. In the acid streams (peat bog drainage), the pH ranged 4.4-6.8, and the bryophytes were dominated by *Fontinalis squamosa* (Figure 14) with a small coverage by the leafy liverwort *Scapania undulata* (Figure 10). The stonefly fauna was comprised of *Protonemura* (Figure 104), *Amphinemura* (Figure 105), *Leuctra* (Figure 49), and *Chloroperla* (Figure 23). *Polycentropus* (Figure 24) was the predominant caddisfly.

In a similar study, Willoughby and Mappin (1988) found that growth of the mayfly *Serratella ignita* (Figure 25) was similar when fed on food from acid or alkaline streams. In acid streams they fed on the leafy liverwort *Nardia compressa* (Figure 11) with the filamentous alga *Klebsormidium subtile* (Chlorophyta; see Figure 26), whereas in the alkaline streams they ate the moss *Platyhypnidium riparioides* (Figure 19) with the epiphytic diatom *Cocconeis placentula* (Figure 17). But if the alga *Klebsormidium subtile* was absent in the acid streams, they were unable to subsist on the liverworts alone.

Bryophyte Structure

Not all bryophytes are created equal, despite their frequent treatment as one entity in ecological studies. Their structures can differ greatly, and this has a strong influence on which organisms can live there. This structure is seldom considered in describing the habitat and the influences of the bryophytes on the inhabitants. Let's consider a few and the differences they offer.

Scapania undulata

This is a leafy liverwort whose chemical components of terpenoids have already been mentioned. Its growth form is somewhat layered (Figure 27), and its leaves are **conduplicate** (Figure 28). That is, the leaf is folded over so that the smaller portion is on top. This fold provides a protected area where several small insects such as the stoneflies *Leuctra* (Figure 49) and *Nemoura* (Figure 40) like to hide (Glime 1968). Its layered effect makes it somewhat more open to the water, permitting predators to penetrate more deeply in search of prey, a problem that is avoided by the small insects that can hide within the folds of the leaves.

Figure 27. *Scapania undulata* showing layered effect. Photo by Hermann Schachner, through Creative Commons.

Figure 28. *Scapania undulata* showing folded leaves with smaller lobes on top. Photo by Florent Beck, through Creative Commons.

Hygroamblystegium spp.

This genus, including *Hygroamblystegium fluviatile* and *H. tenax*, forms thick mats on rocks (Figure 29). Its extensive branching provides an array of spaces within the mat, affording protection from both the current and most larger insects and fish. The leaf has a strong costa (Figure 30) that is used by some caddisflies in the construction of their cases (to be discussed later in the **Trichoptera** subchapter). Its small leaves and branches afford small spaces unavailable to larger insects, thus limiting the species and life stages that can live there.

Figure 30. *Hygroamblystegium fluviatile* showing cupped leaves and strong costa used by some caddisflies in construction of their cases. Photo by Hermann Schachner, with permission.

Platyhypnidium riparioides

This species occurs in many of the same streams as those of *Hygroamblystegium fluviatile* (Figure 30). It is a widespread species that forms a chambered mat. It has somewhat larger leaves than *H. fluviatile* but creates a similar habitat with many species in common. It is not unusual to find these two species on the same rock, often intermixed. *Platyhypnidium riparioides* (Figure 31-Figure 32) affords somewhat larger spaces within the mat. Its costa is reduced and much thinner than that of *Hygroamblystegium* species and does not seem to be particularly useful for case building.

Fissidens grandifrons

Fissidens grandifrons (Figure 33) tends to prefer alkaline streams. It is a large moss with flat branches that are layered somewhat like those of *Scapania undulata* (Figure 27-Figure 28), an inhabitant of acid streams. It occurs in very cold water and waterfalls, both conditions that provide it access to more CO₂ than would be available in un-aerated warmer water. I never searched this moss for insects, but my collections of it did not reveal any conspicuous fauna. It is a stiff moss and its preference for torrential water may discourage them.

***Fontinalis* spp.**

Fontinalis species are large mosses (Figure 34). They have a **streamer** growth form in which all stems dangle in the same direction as the flow of water, at least where there is a distinct flow. The end portions of the stems are

exposed, harboring **Simuliidae**. The leaf structure varies among species, thus providing differing suitability for the insects. *Fontinalis antipyretica* (Figure 35) has large, keeled leaves that form a 3-sided branch with well protected interior space. However, this space may be somewhat difficult for many insects to enter due to the close **appression** (state of being pressed close to) of leaves. *Fontinalis hypnoides* (Figure 36) has narrow, more or less flat leaves that do not provide much enclosed space. In between these two extremes are various degrees of enclosure and access to that enclosure. The flat surface of the branch of *F. antipyretica* would be ideal for blackfly larvae, but this *Fontinalis* species is often not successful in the very fast flow needed by these larvae. If the moss is in fast flow, the keel is easily worn away and the leaves become tattered. However, in cool streams there is usually sufficient oxygen for both the moss and blackflies to survive.

Figure 36. *Fontinalis hypnoides* showing flattened, narrow leaf. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Fontinalis squamosa (Figure 37), a European species, is one of the several intermediate species. Its leaves are concave and provide hiding places within the concavities. Like all *Fontinalis* species, it lacks a costa. This species has been indicated as home to numerous insects in many European stream studies.

Figure 37. *Fontinalis squamosa* showing concave leaves. Photo by Michael Lüth, with permission.

Flow Regimes

Flow regimes provide another limitation for bryophyte inhabitants. Many bryophytes live in areas of high flow that is too abrasive for the establishment of **tracheophytes** (plants with lignified vascular tissue, *i.e.*, all plants that are not bryophytes). At the same time, many insects require protection from the rapid flow. Furthermore, insects drift in streams for various reasons – searching for food, making a false move that puts them in the current, overpopulation, finding a site for pupation, and dislodgment due to changes in flow.

Baker *et al.* (1996) found that the hydraulic stability of streams over multiple years determined whether a site was dominated by periphyton, bryophytes, or tracheophytes. Variations within the year can control periphyton biomass, with low velocities favoring both periphyton and tracheophytes that serve as additional substrate for them. Bryophytes, on the other hand, are often restricted to areas of high velocity; these same high velocities restrict colonization and accumulation of detritus.

Bryophytes modify the internal flow of water. The arrangement of sedimentary deposits and fauna below the leaves of submerged stream bryophytes supports this concept of internal current modification (Devantery 1995). Using *Platyhypnidium riparioides* (Figure 19) and colored liquid, Devantery was able to demonstrate that a single leaf of this moss caused symmetrical twirling behind it. Between the leaves he observed a retrocurrent in the direction of the leaf. This current was slowed progressively and directed the water toward the leaf insertion, explaining the accumulation of detritus there. The same hydrodynamics also occurred in a second species of bryophyte that had a different leaf morphology.

Certain insects take advantage of refugia, especially during periods of high flow (Lancaster & Hildrew 1993). Bryophytes are able to provide such refugia and are likely to be especially important for such species as *Nemurella pictetii* (Figure 38) and larger naiads of *Leuctra nigra* (Figure 39), both stoneflies known from bryophytes. Lancaster and Hildrew found that seasonal flow conditions affected the distribution of these two species in streams after high-flow events, but that these seasonal differences in flow seemed to have little effect on the **Chironomidae** or the young **instars** (instar is developmental stage between molts of an insect) of *Leuctra nigra*.

Figure 38. *Nemurella pictetii* naiad, a species that uses bryophytes as refugia. Photo by Urmas Kruus, with permission.

Figure 39 *Leuctra nigra* naiad, a species that uses bryophytes as refugia. Photo by J. C. Schou, with permission.

Flow Rates

One possible role of bryophytes as a habitat for insects and other invertebrates is their ability to provide a refuge with multiple current velocities (Madaliński 1961; Elliott 1967a; Gurtz & Wallace 1984; Suren 1992a, b; Glime 1994). Hence, organisms can migrate within the bryophyte mass to locate the current velocity that meets their needs.

Macan and Worthington (1951) suggested that mosses can "profoundly influence the fauna by providing a foothold for animals which otherwise could be swept away by the current."

Devantery (1987) reminds us of the importance of flow in contributing to the accumulation of food resources in the bryophyte mat. With regard to the moss *Platyhypnidium riparioides* (Figure 19), Devantery considers that the moss increases the spatial uniformity, a perspective that seems to be in contrast with those who consider the moss to increase the complexity of the habitat (Dražina *et al.* 2011). The flow serves as an antagonist with the danger that it can dislodge the bryophytes.

Flow rates approaching the bryophytes influence the insects that make those bryophytes home. The **Chironomidae** (Figure 9) are reduced by higher flow velocities associated with *Fontinalis antipyretica* (Figure 18), whereas the smallest of the **Simuliidae** larvae (Figure 22) are positively influenced (Linhart *et al.* 2002a, b). This may relate to available food, with the Simuliidae trapping fine particles with their head fans and **Chironomidae** living among the detritus that has been trapped by the moss.

Overturned Rocks

The famous statement, "a rolling stone gathers no moss," applies in its literal sense as well as the figurative. Bryophytes cannot grow under an overturned rock, and rolling is abrasive, damaging new stems and knocking off older clumps. For stream ecosystems, these dangers prevail. Englund (1991) found that 16.7% of the moss-covered stones in North Swedish woodland streams had been overturned in the last few years. Small stones rarely had mosses (See also Slack & Glime 1985), a factor most likely related to their instability. But when stone size exceeded more than 12 cm, mosses were abundant even on rocks that were not embedded into the substrate.

Englund (1991) experimented on the effects of overturning not only on the mosses, but also on their invertebrate fauna. Overturning, as expected, reduced both diversity and abundance of fauna as well as reducing the dry weight of mosses. Nevertheless, 3 out of 16 invertebrate taxa increased, predominantly on the moss-covered underside. For the remaining taxa, peak densities occurred on the upper moss-covered sides of control stones, and these densities decreased on the overturned stones. Despite the introduction of insects through stream drift (see below), recovery was still weak 14 months later, probably because of the slow recovery of the mosses.

Life History and Flow

For insects living in streams, the habitat is likely to be too fast at times and too dry at others. Yamamura (2009) concluded that the variability of the flow regime can limit the distribution and the life history traits of aquatic insects.

Some have solved this transient habitat problem by life cycle stages that either are dormant or that do not require water. Among these, the egg stage is a suitable stage for surviving drought in some stoneflies, mayflies, and dipterans (Ward 1992). In the case of the stonefly *Nemoura* (s.l.) (Figure 40), a common moss dweller, in a Welsh stream, the adults emerge at the end of the drought (Hynes 1958; Ward 1992). In their short adult life stage,

they may take advantage of newly formed pools in the stream for oviposition before the stream returns to normal flow.

Figure 40. *Nemoura* naiad, a common bryophyte dweller. Photo by Bob Henricks, with permission.

Mosses may often play an important role in providing moist sites for the aquatic insects during fluctuating conditions, but their role at such times has scarcely been investigated. In a Welsh mountain stream, severe flooding transported large quantities of gravel (Hynes 1968). Gravel-dwelling insects were greatly reduced, and the moss cover was reduced by 80%. But the fauna living among the remaining mosses was not significantly decreased. The stoneflies, caddisflies, and **Elmidae** (riffle beetles; Figure 41) recolonized the area before any reproduction could have contributed to their recovery. Hynes hypothesized that these insects migrated to deep within the benthic zone (away from abrasion) during the flood and then reappeared after the water level returned to normal.

Figure 41. **Elmidae** adult, a rapid colonizer of bryophytes. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Water Level

Water level changes bring problems of not only hydration but also food availability for aquatic insects. Open-water carnivores can easily move and will most likely still have access to smaller insects and other

invertebrates for food. But those that feed on periphyton, and most likely on high quality detritus, may depend on the chambered bryophyte clumps for their dinner. Fortunately, these bryophytes help to provide both hydration and food for herbivores and detritus feeders. As the water level decreases, bryophytes can act like a filter to trap detrital matter from the slow water. In a Québec, Canada, stream, Cattaneo *et al.* (2004) found that many of the invertebrates moved to or remained among mosses (*Fontinalis dalecarlica*; Figure 34) at low water levels. Water depth explained 50-80% of the variation in the invertebrate biomass among the mosses and the biomass was lower on shallow mosses that had more frequent exposure. Grazers were more common in the moss habitat than in the gravel, but carnivores such as **Plecoptera** and **Odonata** were in the gravel.

Stream Drift

Stream drift is a natural occurrence among stream fauna, especially insects (Anderson & Lehmkuhl 1968). Waters (1972) emphasized that this is an episodic event and not a continuous phenomenon. The drift organisms are bottom and vegetation organisms. When stream discharge is reduced by seasonal events, **catastrophic drift** can occur. Two primary organisms in such drift in Oregon, USA, are *Simulium* sp. and *Baetis tricaudatus*, both bryophyte dwellers (Corrarino & Brusven 1983).

Catastrophic drift (Minckley 1964) occurs from a physical disturbance such as flooding, **anchor ice** (ice anchored to bottom) (O'Donnell & Churchill 1954), pollution (Coutant 1964), drought, and high temperatures (Wojtalik & Waters 1970; Reisen & Prins 1972 for *Simulium* - Figure 22). **Behavioral drift** occurs at a particular time of day or night; it may result from crowding, competition, need for food, predation, making a new case, or attempting to reach land at emergence time (Waters 1972). **Constant drift** is comprised of small numbers that are always present as organisms move about and become dislodged from their substrates (Waters 1972).

Most drift occurs at night (Bishop 1969; Elliott 1965, 1968; Holt & Waters 1967), and it always moves the drifters downstream, at least initially. This night-time drift typically has two peaks: one just after darkness begins and one just before dawn (Waters 1972). But in some species, younger individuals may drift in the daytime and older, larger individuals at night (Anderson & Lehmkuhl 1968). Light often suppresses drifting in night drifters (Holt & Waters 1967); a full moon on a clear night can suppress it (Anderson 1966; Bishop & Hynes 1969).

Brusven (1970) found that the riffle beetle *Optioservus seriatus* (Figure 42) was much more likely to drift as an adult compared to its larval form. This species demonstrated the complexity of the drift phenomenon, with drift relating closely to density in one stream but not in the other in this study.

Larimore (1974) studied a very different kind of stream in the Salt Fork Basin, Illinois, USA. This stream ran through farmland where farm runoff was common and rooted macrophytes and bryophytes were absent. Only **Chironomidae** (Figure 9) among the drift organisms matched those found in cooler streams with rocky bottoms discussed above.

Figure 42. *Optioservus seriatus* adult, an insect more likely to drift as an adult than as a larva. Photo from ISUInsects.org, through Creative Commons.

Drift distances are usually not far. McLay (1970) found that the maximum drift in a New Zealand stream was 45.7 m, with a mean of only 10.7 m. Waters (1965) found that *Baetis tricaudatus* (Figure 43) travelled 50-60 m, but Elliott (1971a) showed that this strong swimmer was also capable of dropping out of the drift rapidly. Elliott (1967a) found that when dense macrophyte vegetation was present the maximum drift distance was only about 10 m. Nevertheless, this is sufficient to redistribute the insects and reduce local population competition.

Figure 43. *Baetis tricaudatus* naiad, a drifter that can travel 50-60 m in the drift, or drop out rapidly. Photo by Bob Henricks, with permission.

Many of the species enter the drift as young naiads and larvae, permitting them to disperse and to reduce population competition (Anderson 1967; Elliott 1967a, b; Waters 1969). But more frequently it is the larger stages later in the life cycle that enter the drift (Anderson 1967; Elliott 1967a; Müller 1966; Ulfstrand 1968). While drifting permits macroinvertebrates in streams to seek a more favorable location and to colonize new habitats, it poses its own set of threats (Brittain & Eikeland 1988). The insects may fall prey to predatory fish or fail to stop at a favorable habitat before reaching a quiet area of the stream where drift can no longer help them to relocate.

Some insects enter the drift to avoid or escape from predators. In experiments the net-spinning caddisfly *Ceratopsyche bronta* (Figure 44) moved from one area to another in an artificial stream when the predator stonefly *Acroneuria lycorias* (Figure 45) was present (Michael & Culver 1987). However, it did not exhibit the same drift response to the predator megalopteran *Corydalus cornutus* (Figure 46). Michael and Culver suggested that the caddisfly might have been unable to detect the megalopteran.

Researchers were curious about how the upstream positions got repopulated. Elliott (1971b) marked insects and found that some immature insects were able to move upstream on the stream bottom, especially small naiads of stoneflies and mayflies, small larvae of true flies, and beetle larvae. In winter, upstream movement was about 30% of downstream drift; in spring and summer it fell to only 7-10%. Madsen *et al.* (1973) examined upstream movement in adult mayflies and stoneflies and found that the representative of the common moss-dwelling stonefly genus *Nemoura* (Figure 40) did not move upstream, whereas the mayflies *Caenis rivulorum* (Figure 47), *Baetis rhodani* (Figure 2), *B. vernus* (Figure 48), and *Serratella ignita* (Figure 25) all moved upstream; all three of these mayfly genera are known from bryophytes. Furthermore, females migrated upstream more than males.

Elliott (1971a) divided the drift invertebrates into three groups based on their ability to return to a substrate. The first group apparently had no control over their return to a substrate and did so at the same rate as dead organisms. This group included the *Chironomidae* (Figure 9). The second group includes several bryophyte dwellers, including *Leuctra* (Figure 49) and *Simulium* (Figure 22). These insects travelled shorter distances and were able to return to the substrate more quickly than dead ones at low velocities (10-12 cm sec⁻¹) but not at faster velocities (≥ 19 cm sec⁻¹). The third group, which included bryophyte dwellers such as *Serratella ignita* (Figure 25), *Hydropsyche* spp. (Figure 13), and *Baetis rhodani* (Figure 2), returned to the substrate significantly faster and drifted significantly shorter distances at all velocities tested; *Baetis* and *Simulium* are usually the insects with the highest numbers in the drift (Waters 1972). Caddisflies with cases fall out of the drift very quickly.

Elliott (2003) examined dispersal in nine genera of aquatic invertebrates, most of which occur among bryophytes. He found that dispersal of invertebrates in the streams was not density dependent. Rather, it was a constant percentage of the initial number of each species. The most rapid dispersers, with 70-91% dispersing within 24 hours, were the carnivores *Perlodes* (Figure 50), *Rhyacophila* (Figure 116), and *Isoperla* (Figure 20), travelling up to 13.5 m per day. *Protonemura* (Figure 104) and *Rithrogena* (Figure 51) exhibited about 50% dispersal within 24 hours and travelled only about 8 m per day. The third group, *Ecdyonurus* (Figure 15), *Hydropsyche* (Figure 13), *Gammarus* (Figure 52), and *Baetis* (Figure 2, Figure 48), only had about 33-40% dispersal in 24 hours and travelled only 5.5-7 m per day. All of these genera dispersed upstream. These examples do not answer the question of why drift, but they suggest that some of that downstream drift is compensated by upstream movement.

Lehmkuhl (1969) found that the six mayfly species in his study, including the sometimes moss-dweller *Baetis tricaudatus* (Figure 43), were displaced by winter flooding. He found that in these species drift was not related to habitat. Two of the species that were abundant in the riffle areas were scarce in the drift. In the lab, drift rate did not correlate with ability of a species to hold to its substrate.

Lehmkuhl and Anderson (1972) demonstrated that drift of individual species is seasonal. Within the four species of *Ephemeroptera* studied, some species had peak drift in October and others in May. Winter floods accounted for lesser peaks in drift. Periods of low drifting occur when a species is in its egg state, suggesting that life cycle stages are among the determinants of who is drifting.

Some insects enter the drift at the time of emergence, not by choice, but because they must at that time break through the water-air interface and penetrate the surface tension. If there is no suitable emergent rock or vegetation, this becomes a nearly impossible task. Bryophyte-covered rocks can afford a better place to climb out than a smooth rock. However, there is thus far no study to determine if any insect group might seek out bryophytes as opposed to just rocks for this dangerous endeavor.

The behaviors of the *Hydropsyche* spp. (Figure 13) are worthy of note. This net-spinning caddisfly must live near the water surface where it can trap food in its nets (Edington 1968). When released into the water, larvae would swim with side-to-side movements toward the surface (Edington 1965; Elliott 1971a). When the velocity was slow, they returned to the bottom (Elliott 1971a). When they encountered mosses in swift-flowing areas they made "firm contact." It appears that bryophytes may have a role in catching these drifters.

Elliott (1967a) suggested that aquatic plants served as a natural net for drifting insects. Previously Elliott (1965) examined invertebrate drift in a Norwegian mountain stream where bryophytes formed a dense bottom cover. He did not show a direct link between the bryophyte fauna and drift, but did list the dominant insects in both. Using 400 cm² samples, he found *Baetis* sp. (Figure 2), *Simulium* spp. (Figure 22), *Rhyacophila* sp. (Figure 79), *Polycentropidae* (Figure 24), and *Plecoptera* (Figure 49). When he

calculated those insects in the water column above a square meter of bottom at any time, he found that the values were extremely low, although all the insects among the top taxa in the mosses except *Polycentropidae* were also in the drift.

At least some of the bryophyte dwellers are drift organisms, including *Simulium* (Figure 22), *Isoperla* (Figure 20), and *Ephemerella* (s.l.) (Figure 8) (Minshall & Winger 1968). In these three genera, the drift is suppressed by light, including that of a full moon on a clear night. Density may play a role in the number of individuals entering the drift, as in *Capniidae* (Figure 109), *Ephemerella* sp., and *Hydropsyche* sp. (Figure 13) in a South Carolina, USA, stream (Reisen & Prins 1972; see also Waters 1962, 1966). And, to my surprise, Minshall and Winger (1968) found that reductions in flow cause an increase in drift. The latter may relate to the need for a new location to gain suspended food or oxygen. To this end, *Simulium* larvae may drift at least 100 m (Carlsson 1967). Elliott (2002) calculated the rate of drift and found that most of the organisms had a very constant amount of time spent in a drifting event. For *Serratella ignita* (Figure 25) the mean drift time was 28.8 s, whereas for *Baetis rhodani* (Figure 2) it was 9.4 s, the same drift time as for the amphipod *Gammarus pulex* (Figure 52). For the blackfly *Simulium* it was only 6.4 s, with their choice of rapid water accounting for the 100 m drifting they can accomplish.

In Oregon, USA, Anderson and Lehmkuhl (1968) likewise found known moss dwellers in the drift: the mayflies *Paraleptophlebia* (Figure 53) and *Baetis* (Figure 2), the stoneflies *Nemoura* (Figure 40), *Capnia* (Figure 109), and possibly *Leuctra* (Figure 49) (small *Capnia* and *Leuctra* are difficult to distinguish), dipterans *Chironomidae* (Figure 9) and *Simuliidae* (Figure 22). Dendy (1944) likewise found *Baetis*, *Nemoura*, *Simuliidae*, *Chironomidae*, and *Hydropsychidae* (Figure 13) in the drift in a stream in Michigan, USA, but added significant numbers of the mayfly *Ephemerella* (s.l.) (Figure 8) and caddisfly *Brachycentrus americanus* (Figure 54) to those found by Anderson and Lehmkuhl. To these, Reisen and Prins (1972) added the stoneflies *Isogenus* (probably now *Isogenoides*; Figure 55) and *Isoperla* (Figure 20).

Bryophytes may provide safe sites for drifting organisms, primarily insects. There is a periodicity in stream drift, with light, even strong moonlight, suppressing activity (Albrecht 1968). Numerous organisms, particularly stoneflies, mayflies, and caddisflies, become detached from their substrate and join the water current (Bishop & Hynes 1969). Diptera are day-active and contribute significant numbers to daytime drift. Lest they travel ultimately to a lake or even the distant sea, these drifting organisms must find a suitable substrate where they can cling against a sometimes raging current. Furthermore, it is during these excursions that they are most visible and vulnerable to predation by birds and especially fish.

Bryophytes would seem to provide an ideal location for regaining their composure and taking a more leisurely approach to locating a suitable settling place. The 3-d surface of the bryophyte provides numerous "handles" for hanging on in the current and gives the insects either an instant home or one that can be traversed while maintaining a safe hold to something permanent. On the other hand, one theory for the cause of drift is to decrease population numbers (Müller 1954; Waters 1961, 1962; Pearson & Franklin 1968; Bishop & Hynes 1969). If such is the case, a rock with both smooth surface area and bryophyte cover

would support such loss by forcing at least some individuals to the smooth rock as the bryophyte itself becomes overpopulated. This would seem to eventually provide a selection factor against those organisms that did not do their nightly foraging among the mossy safe site. Is there really a selection factor involved in moss-seeking behavior?

Glime and Clemons (1972) set out to determine the relative importance of bryophytes in catching such insects and constructed artificial mosses to determine how the new colonizers compared to the organisms in the drift. Clemons (unpubl data; Glime & Clemons 1972) used string mosses to determine the use of substrata similar to mosses as a catching net for drifting organisms and compared this substrate to that of real mosses and Visqueen (polyethylene plastic sheeting) strips. In the 24 hours following the placement of 7 of these artificial mosses, insects were found on the strings. These included the mayfly *Baetis* sp. (Figure 2), stoneflies *Amphinemura nigritta* (= *Nemoura venosa*) (Figure 56) and *Leuctra* sp. (Figure 49), blackflies *Cnephia* sp. (Figure 57) and *Prosimulium mixtum* (Figure 58), midges *Chironomidae* (Figure 9), and the caddisfly *Lepidostoma* sp. (Figure 59) occurring in more than one of the string habitats. The Visqueen strips had a smaller and less diverse fauna. While this experiment provides evidence that insects can settle on such substrates rather quickly from the drift, much more study is needed to determine the importance of bryophytes in providing safety nets for drifting insects. Gurtz and Wallace (1984) found that following a major disturbance that dislodged many of the insects, it was moss-covered rock faces that increased in insect density more than any other substrate. Furthermore, they considered that the mosses may enhance the stability of the substrate on which they reside.

In alpine streams the drift pattern may differ. Hieber *et al.* (2003) found no night-day differences in these streams. They found that **Chironomidae** (Figure 9) were the dominant drifting organisms, so one might look at this group in alpine streams as creating more food for fish in streams with mosses than in those without.

The complex structure of bryophytes may not only catch drift, but it may also deter stream drift. Holomuzki *et al.* (1999) found that resettlement choices after drifting by hydropsychid caddisfly larvae depended on the complexity of the algal community. Drift entry of hydropsychids due to stonefly predation increased on rocks with a biofilm, but not on rocks with a thick periphyton mat or macroalgae such as *Cladophora* (Figure 60), with drift inversely related to the amount of *Cladophora* on the rocks. Since bryophytes are even more complex in structure, it is reasonable to assume that they reduce drift.

Figure 60. *Cladophora crispata*, a filamentous alga that keeps **Hydropsychidae** from entering the drift in the presence of predatory stoneflies. Photo by Yuuji Tsukii, with permission.

It is interesting that when Perić *et al.* (2014) sampled the invertebrate drift in a moss-rich **karst** (landscape underlain by limestone that has been eroded by dissolution, producing characteristic landforms) stream system, they did not find the **Chironomidae** (Figure 9) (3.9%) to be the most abundant. Rather, the most abundant insects were the beetles in **Elmidae** (Figure 41) (13.2%) and blackflies **Simuliidae** (Figure 58) (12.2%).

So let's revisit the possibility that other bryophyte dwellers besides **Chironomidae** do not enter the drift as readily as insects on other substrates. Brusven *et al.* (1990) found that in a channel of the South Fork Salmon River, Idaho, USA, the 20% moss-covered portion (*Fontinalis neomexicana*, Figure 4) had 1.6-7.2 times the diversity of the moss-free channel and 1.4-6.1 times the biomass. But the mossy portion did not have any greater numbers in the drift than did the moss-free channel. This, however, does not offer us much on which to base a conclusion because the study only included daytime drift. Their drift organisms were more than 50% **Chironomidae** (Figure 9), a group that drifts equally in day and night (Anderson & Lehmkuhl 1968). The implications for fish are that the bryophytes do not benefit them because the food organisms they house do not increase the daytime drift, at least in this one example.

Safe Sites

For many insects, the mosses offer a safe site, a pool-like environment in which they can forage for food without danger of being swept away by rapidly flowing water. Beetles (**Coleoptera**), scuds (*Gammarus*; Figure 52) and mites occupy only sheltered niches and mosses in the Welsh Dee (Badcock 1949). On vertical faces of waterfalls, the dipteran *Limnophora* (Figure 61) can be found only in moss (Badcock 1949).

Figure 61. *Limnophora* larva, sometimes a bryophyte dweller. Photo by Stephen Moore, Landcare Research, NZ, with permission.

In aquatic habitats, fish are a major predator on insects. The result is that fishless lakes have a higher insect species richness and diversity than lakes inhabited by fish, as demonstrated for chironomids (midge larvae) (Mousavi *et al.* 2002). Bryophytes are typically inhabited by many **Chironomidae** (Figure 9) and when present in lakes or streams they can provide safe sites with loads of detrital food.

Several studies have alluded to the possibilities of bryophytes in providing a **refuge**, a location in the stream where the small organisms can escape predation by larger ones. For example, Parker *et al.* (2007) found twice as many insects on *Fontinalis novae-angliae* (Figure 62) as on *Podostemum ceratophyllum* (Figure 62). One possibility is that the insects are avoided because the moss provides an unpalatable location – an **enemy-free space**. Parker *et al.* (2007) remind us that a number of studies have shown that small herbivores that use plants as both a habitat and a food source may be protected by living on hosts that are chemically defended against wood-be insect consumers. Aquatic mosses may be just such safe sites. To test this hypothesis, Parker and coworkers observed the feeding habits of the Canada goose (*Branta canadensis*, Figure 63-Figure 64) and a crayfish (*Procambarus spiculifer*, Figure 65). In a riverine system where both the riverweed *Podostemum ceratophyllum* (Figure 62) and the moss *Fontinalis novae-angliae* (Figure 62) occurred, both animals consumed riverweed in preference to the moss. This was despite the fact that the moss comprised 89% of the plant biomass. At the same time, there were twice as many macroinvertebrates among the mosses as associated with the riverweed. Examination of the moss chemistry revealed the presence of C₁₈ acetylenic acid, octadeca-9,12-dien-6-ynoic acid, a compound that deterred the crayfish from eating it. Some invertebrates, on the other hand, had different connoisseurial preferences; the amphipod *Crangonyx gracilis* (Figure 66) and the isopod *Asellus aquaticus* (Figure 67) rejected the riverweed, but consumed significant quantities of *Fontinalis novae-angliae*. For periphyton-consuming insects, the same chemical deterrents could protect them without affecting their food source.

But bryophytes are not always selected for their provision of shelter. Using experimental reduction of bryophyte stem density in New Zealand alpine streams, Suren and Winterbourn (1991b) found that only two out of 22 taxa of invertebrates selected the bryophytic home based on shelter as the primary factor in the shaded site; none of them selected it based primarily on its offer of shelter in the sunny site. Rather, periphyton or detrital biomass were the primary influencing factors.

Winterbottom *et al.* (1997) cleverly tested the importance of refugia against the effect of reduction of shear stress during periods of peak flow by creating artificial refugia using cages of different mesh sizes to restrict the flow within cages. They compared a 1.1 mm mesh size that created a reduced flow within the cage with that of a 15 mm mesh size that did not restrict flow. They found that during periods of high flow the invertebrates accumulated more in the flow-restricted refugia than they did there during low-flow periods or in the unrestricted cages. By contrast, in a second stream with lower flow rates generally and during the experimental period, the number of invertebrates did not increase in the refugia during natural spates of increased flow (but less flow than in the first stream), suggesting that the reduced flow in the 1.1 mm mesh cages enabled them to serve as refugia in the first stream during periods of rapid flow. However, the researchers were unable to determine if the accumulation of invertebrates was by active movement to the refugia or by passive collection. Nevertheless, this experiment

demonstrates that bryophytes with different mesh sizes could provide differential refugia for insects during periods of high flow rates.

Biomass and Richness

Many insects hang out among the riffles, taking advantage of the flowing water that brings food and oxygen. Dodd (2011) found that in a river community 516 out of 521 individuals collected occurred among riffles and mosses. These are the sites where biomass and richness usually reach their peaks.

Clenaghan *et al.* (1998) concluded that macroinvertebrate density and richness increased with moss weight. Wulforst (1994) compared the biomass of insects among mosses with those in the interstitial spaces of the substrate (Figure 68). In general, they were orders of magnitude higher (100's of times) in biomass among the mosses. These included **Ephemeroptera**, **Plecoptera**, **Trichoptera** and **Coleoptera** (EPTC).

Figure 68. Combined biomass (mg L^{-1}) of **Ephemeroptera**, **Plecoptera**, **Trichoptera**, and **Coleoptera** at six stations of two brooks in the Harz Mountains in mosses and interstitial spaces of the hyporheic zone at 10 and 20 cm depth. Bars show 95% CI. $N = 14$ for mosses, 28-36 for interstitial spaces. Redrawn from Wulforst 1994.

Linhart *et al.* (2002a, b) examined the **meiobenthos** (meiofauna; between .1 mm and 1 mm in size) of two low-order streams (*i.e.*, small feeder streams) and found that these bryophytes harbored ten times as many organisms as the surrounding mineral bed. In this case, the **Chironomidae** (midge larvae, Figure 9) were the dominant organisms, but a number of other aquatic insects and other invertebrates call this location home, at least in the early stages of their lives.

Brusven *et al.* (1990) studied the effect of bryophyte biomass on macroinvertebrate density in the South Fork of the Salmon River, Idaho, USA. They compared the insect densities on sand, pebbles, cobbles, and the moss *Fontinalis neomexicana* (Figure 4). Insect densities in moss clumps were 4-18 times as great as those in adjacent mineral substrata. Although mosses occupied only 20% of the channel, insect density was 1.6 to 7.2 times as great, with 1.4 to 6.1 times as much insect biomass as the moss-free channel, thus accounting for nearly 50% of the insects in the stream. Midges (**Chironomidae**, Figure 9) typically comprised over 50% of the insect community, whereas

annelids were the primary non-insect invertebrates. The moss seemed to provide a safe site, at least during the day, because despite the greater number of insects present, daytime drift was not greater. Hence, the salmonid fish that feed primarily on drifting invertebrates during the day derive little benefit from the increased numbers in the bryophytes.

On the other hand, Tada and Satake (1994) found that in a cool mountain stream in Japan macroinvertebrates from *Platyhypnidium riparioides* (Figure 19) had 11-13 taxa (species), whereas bare rock bottoms had 13-14. Nevertheless, the caddisfly *Micrasema* sp. (Figure 69) exceeded 100,000 individuals per m² of mosses in November, a level that ranged 2.8-16.3 times as high as that on the bare rock bottom.

Figure 69. *Micrasema charonis* larva, a common genus on bryophytes. Photo by Robert G. Henricks, with permission.

Chantha *et al.* (2000) found that the invertebrate communities of bryophytes and algae in a Quebec, Canada, stream were dominated by **Chironomidae** (especially **Orthocladinae**; Figure 9). The algae and invertebrates formed stable communities during the summer, even sustaining during strong mid-summer flooding. Like many other northern streams, the **Ephemeroptera** and **Coleoptera** were important components. The relative importance of the various taxa changed with the seasons as sizes and life cycle stages changed. Moss biomass explained 43% of the algal spatial variation, but surprisingly the periphyton did not increase proportionally with increase in moss biomass. The epiphytes were less dense per unit of bryophyte biomass as the bryophyte biomass increased in density. Insects in this system became more abundant, but smaller, as the moss biomass increased, with a net result of little change in insect biomass per moss biomass. This may be a function of decreased light for algal growth and decreased oxygen for insects in deeper parts of the moss mat.

Matthaei *et al.* (2006) found that runoff from land use could reduce both aquatic mosses and invertebrate density. The greatest decrease in richness occurred in **Ephemeroptera**, **Plecoptera**, and **Trichoptera**, the three most abundant moss-dwelling orders that move among the open spaces of the bryophyte mats.

Food Sources

Bryophytes harbor a wide variety of invertebrates that can serve as food for the larger members of the bryophyte fauna. Dražina *et al.* (2011) reported 100 taxa of meiofauna among bryophytes in a European study. For example, rotifers averaged 219 individuals per cm³.

Bryophytes are usually predominate in the upper reaches of streams where the flow rate is greater and the stream is shaded. Shredders likewise predominate among the bryophytes in these reaches. Hawkins and Sedell (1981) found that functional groups characterized different stretches of the river continuum. Upstream in shaded reaches the shredders were dominant. Scrapers were most important in the intermediate sections. Collectors increased in importance progressively downstream. Predators were represented equally throughout the stream.

Mosses seem to afford ideal feeding locations for some kinds of insects. In particular, filterers and scrapers can be more common there than elsewhere in streams, showing a positive correlation with such habitats, whereas shredders are negatively correlated, *i.e.*, are moss avoiders (Ely 2005). On the other hand, Zalewski *et al.* (2001) found a significant correlation between **CPOM** (coarse particulate organic matter), bryophytes, and shredders. Smith-Cuffney (1987) found that mosses in streams of a clearcut community supported collector-gatherers, whereas in the forested streams the shredders formed a much larger proportion of the moss fauna.

Cattaneo *et al.* (2004) found that in a Québec stream grazers were more abundant in mosses than among gravel, suggesting that they used the periphyton. The reduction of periphyton when shallow water mosses are exposed may explain why deeper mosses might house more invertebrates.

Wallace *et al.* (1988) found that the mosses retained large amounts of detritus, providing abundant food for collector-gatherers. Like Ely, they found that scrapers reached greatest abundance on cobbles and pebbles that were free of mosses. Smith-Cuffney (1987) found that in a southern Appalachian Mountain stream, mosses in a clearcut community of a forested watershed supported predominantly collector-gatherers with shredders as a minor component. Shredders were a much larger component in the stream that drained the clearcut. Scrapers were more common in the clearcut system where periphyton were abundant. Collector-filterers such as *Parapsyche cardis* (see Figure 70) benefited from the physical environment provided by the mosses.

Although aquatic mosses are seldom eaten by their inhabitants (Haefner & Wallace 1981), they can provide a rich food source through the other inhabitants. Fontaine and Nigh (1983) considered the periphyton (Figure 71) on bryophytes to be an important food source. In New Zealand, periphyton and detritus were primary food sources (Suren 1993). Unfortunately, bryophytes tend to be shade plants and periphyton tends to prefer the sun, so the periphyton is not at its max. Nevertheless, invertebrate densities were higher among mosses containing periphyton than among those with detritus, most likely reflecting the higher food quality of periphyton. Ogbu and Akinya (2001) likewise found that mosses in Nigeria provided a suitable substrate for periphytic algae, especially diatoms.

Figure 71. Stream mosses in Tucquan Creek, Lancaster County, Pennsylvania, USA, laden with a detrital-periphyton complex. It is likely that the schist bedrock is contributing to the light color. Photo by Keith Williams, with permission.

McWilliam-Hughes *et al.* (2009) found *Fontinalis* sp. (Figure 4) abundant in headwater streams and *Drepanocladus* (*s.l.*) sp. (Figure 72) abundant in low-order streams. The scrapers living in low-order streams seemed to depend more on *Fontinalis* as a food source than did scrapers in high-order streams depend on *Drepanocladus* (*s.l.*). They suggested that in low-productivity, nutrient-limited rivers primary consumers might switch to marginal food sources such as bryophytes when more preferred food is limited or unavailable.

The feeding guilds change with the seasons. Habdija *et al.* (2004) found that current velocity and food supply affected the composition of insects inhabiting bryophytes in karst streams. Those inhabiting the bryophytes were predominantly small forms of oligochaetes, **Diptera** (Figure 58), and **Coleoptera** (Figure 41), comprising 64.1-98.7% of the total macroinvertebrate individuals. **Collector-gathers** dominated in spring and summer, whereas in autumn it was **collector-filterers**, and in winter

scrapers reached their maximum. Gregg and Rose (Gregg 1981; Gregg & Rose 1985) found that among the **tracheophytes** (plants with lignified vascular tissue, *i.e.*, all plants that are not bryophytes), shredders, scrapers, and predators were the primary guilds in the autumn and that all guilds had their highest abundances in spring. Bryophytes offer the advantage of being present year-round, and their extensive periphyton growths provide a good winter food source for those insects that remain active in the winter. It is interesting that Gregg found that *Hydropsyche* (Figure 13), *Simulium* (Figure 22), *Baetis tricaudatus* (Figure 43), *Glossosoma velona* (Figure 73), and *Helicopsyche borealis* (Figure 74) avoided macrophytes, whereas all of these genera are known from bryophytes (though *Helicopsyche* is rare there). One problem for these insects was that the tracheophytes reduced the velocity, creating problems for these high-oxygen taxa. The advantage in the presence of tracheophytes seemed to be that of increasing heterogeneity, an advantage also offered by bryophytes.

Thus, we have seen that the reduced water velocity within a bryophyte mat (Devantery 1987; Suren 1991) makes the bryophytes suitable safe sites not only for insects, but also for the periphyton and detrital food components, as shown in New Zealand (Suren 1991), as well as for the insect prey species, as shown in the North Temperate Zone (Elliott 2005).

Bryophytes as Food

Early reports indicated that bryophytes were ingested, but the food value remained in question. Nevertheless, *Fontinalis* (Figure 4) was found in gut contents (Gaevskaya 1969). Jones (1949, 1950) found *Fontinalis* in the guts of the stoneflies *Amphinemura* (Figure 105), *Chloroperla* (Figure 23), *Dinocras* (Figure 75), *Leuctra* (Figure 49), and *Protonemura* (Figure 104), the mayflies *Ecdyonurus* (Figure 15) and *Ephemerella* (s.l.) (Figure 8), as well as in the caddisflies *Hydropsyche* (Figure 13) and *Philopotamus* and the beetle *Oreodytes* (Figure 76).

Figure 75. *Dinocras cephalotes* naiad, a stonefly genus that eats mosses. Photo by Guillaume Doucet <www.guillaume.doucet@yahoo.fr>, with permission.

Jones (1951) considered *Fontinalis antipyretica* (Figure 18) to be one of the main foods for herbivorous insects in his study of the River Towy, Wales. But Dangles (2002) cautions us against categorizing food habits by

generic or higher levels. In his study of four streams in northeastern France he found that two species in the same genus with very similar mouthparts had different diets, one feeding on bryophytes and the other on detritus, including leaf litter.

Figure 76. *Oreodytes septentrionalis*, a genus including bryophyte consumers. Photo by Brian Eversham, with permission.

Caddisflies *Pycnopsyche guttifera* (Figure 77) and *Philocasca alba* both feed on mosses. In an interesting study, Mutch and Pritchard (1984) found that the late-instar larvae of *Philocasca alba* had significantly higher growth rates if their diet of detritus or leaf litter was supplemented with mosses.

Figure 77. *Pycnopsyche guttifera* larva, a consumer of mosses. Photo by Donald S. Chandler, with permission.

Tada and Satake (1994), working with insects on mats of the moss *Platyhypnidium riparioides* (Figure 19) in a cool mountain stream in Japan, found the mayflies *Baetis* (Figure 43) and *Ephemerella* (s.l.) (Figure 8), the stoneflies *Acroneuria* (Figure 45) and *Isoperla* (Figure 20), and the caddisflies *Micrasema* (Figure 69), *Rhyacophila* (Figure 79), and *Palaeagapetus rotundatus* not only live among the bryophytes, but also feed on the leaves of the leafy liverwort *Chiloscyphus polyanthos* (Figure 78) and *Scapania undulata* (Figure 10). Interestingly, they do not feed on leaves of the moss *Platyhypnidium riparioides*, suggesting the possibility of antifeedant compounds in that species.

Figure 78. *Chiloscyphus polyanthos* in the fluctuating water level zone where several kinds of insects eat the leaves. Photo from <www.aphotofauna.com>, with permission.

Even the free-living carnivore caddisfly *Rhyacophila dorsalis* (Figure 79) apparently eats mosses (Slack 1936). One out of nine had *Fontinalis antipyretica* (Figure 18) leaves in the gut. For the mayfly *Ephemerella* (s.l.) (Figure 8), *Fontinalis* is a common food (Jones 1949). *Ephemerella* (s.l.) feeds on the green alga *Ulothrix* when it is available, but feeds on the ever-present moss when the alga is scarce or absent (Jones 1949). On the other hand, in a different study, Jones (1950) found that beetles and mayflies did not eat *Fontinalis* (Figure 18), but the moss was in the gut of *Chloroperla* (Figure 23), *Leuctra* (Figure 49), *Protonemura* (Figure 104), and *Amphinemura* (Figure 105), all stoneflies, and in the gut of the net-spinning caddisfly *Hydropsyche* (Figure 13) – a genus that traps its food with a net. In addition to using the moss for housing, the caddisfly *Micrasema* (Figure 69) eats mosses and associated periphyton (Chapman & Demory 1963; Decamps & Lafont 1974). Chapman and Demory (1963) found that in its preferred food was *Platyhypnidium riparioides* (Figure 19). It is possible that many insects eat the mosses primarily for their associated periphyton, but for *Micrasema* it appears that the primary target is the mosses themselves. Even the filter-feeding blackflies such as *Simulium tuberosum* (Figure 80) will feed on aquatic mosses (Jones 1949), but we need to check to see if they are really digested.

Figure 79. *Rhyacophila dorsalis* larva, a moss consumer. Photo by Walter Pfliegler, with permission.

Figure 80. *Simulium tuberosum* larva, known to have mosses in its gut. Photo by Tom Murray, through Creative Commons.

Most members of the caddisfly genus *Rhyacophila* (Figure 79) are carnivores, although some of these bryophyte dwellers eat bryophytes. Perhaps more importantly is their ability to hide among the mosses to ambush their prey at dusk and dawn [e.g. *Baetis* (Figure 43), *Gammarus* (Figure 52)]. Elliott (2005) found most of the *Rhyacophila dorsalis* (Figure 79) among clumps of the leafy liverwort *Scapania* (Figure 10) and the mosses *Platyhypnidium riparioides* (Figure 19) and *Fontinalis antipyretica* (Figure 18). Although most of the *Rhyacophila* species are carnivores, most of their guts had fragments of bryophytes, but these appeared to be undigested, exhibiting chlorophyll. Older individuals fed primarily at night and diatoms occurred in 29% of the guts of 4th instars; bryophytes occurred in 25%. However, in the 5th instar, only 9% contained diatoms and 7% contained bryophytes. The *Rhyacophila* larvae would disappear into the moss colony to search for food, then return to the bryophyte surface to eat it. These observations suggest that the bryophytes may have been eaten inadvertently when capturing prey.

The inadvertent consumption of bryophytes by carnivores is a likely occurrence in a number of insects. For example, Jones (1950) found *Fontinalis* (Figure 14) in the guts of *Plecoptera* [*Chloroperla* (Figure 23), *Leuctra* (Figure 49), *Protonemura* (Figure 104), *Amphinemura* (Figure 105)] and *Trichoptera* (*Hydropsyche*, Figure 13), but these could have resulted from bits of the moss mixed in with their typical food. *Hydropsyche* is a filter feeder, spinning its own nets to trap food, but bits of drifting moss may get trapped in the net. Nevertheless, Jones did not find any *Fontinalis* in guts of either *Coleoptera* (beetles) or *Ephemeroptera* (mayflies) in these same collections.

Nutritional and Antifeedant Properties

Few protein values are published for aquatic mosses, so we cannot judge if any relationship to protein content is typical. However, it has been a common view among biologists that mosses are avoided as food because of their low food value, among other reasons. Nevertheless, Winterbourn and co-workers (1986), using C^{13} ratios, found bryophytes to be important sources of carbon for the benthic fauna in two British rivers.

Suren and Winterbourn (1991a) examined the gut contents of 23 invertebrate taxa that dwell among bryophytes in two New Zealand alpine streams. Fourteen of these taxa had bryophytes in the guts, but the researchers found that only the tipulid larvae of *Limonia hudsoni* (Figure 81) and caddisfly larvae *Zelandopsycha ingens* (Figure 82) and *Oeconesus similis* (Figure 83) regularly consumed the bryophytes. They found that the bryophytes contained more refractory and indigestible compounds than other riparian plants and were thus less nutritious for the animals. They suggested that the bryophytes might also contain **antifeedant** compounds (compounds that discourage herbivory). Such compounds do exist in aquatic bryophytes, including *Fontinalis* (Liao 1993; LaCroix 1996). But we must keep in mind that modifications of digestive systems and their pH and enzymes make these "indigestible" foods digestible to some specialists (see discussion in Chapter 10-3 on *Asellus*).

Figure 81. *Limonia* larva; some species are regular consumers of bryophytes. Photo courtesy of State Hygienic Laboratory, University of Iowa, with permission.

Figure 82. *Zelandopsycha* larva & case; some species include bryophytes in their regular diet. Photo by Stephen Moore, Landcare Research, NZ, with permission.

But sometimes the consumed mosses carry with them associated periphyton that might be the real food source, as in *Micrasema* (Figure 69) of the Pyrénées (Decamps & Lafont 1974). Dudley (1988) likewise considered that the real food might be the associated periphyton. Suren (1988) similarly concluded that the mosses were not an important food source, citing the similarity of faunal communities on

artificial mosses that became colonized with periphyton. But separating assimilation of moss tissue vs periphyton is a challenging endeavor.

Figure 83. *Oeconesus* larva head; *O. similis* frequently eats bryophytes. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Modern methods have made it somewhat easier to determine the diets of aquatic insects. Using $\Delta^{13}\text{C}$, Winterbourn *et al.* (1986) demonstrated the importance of bryophytes as important food sources. It is surprising that so many invertebrates eat aquatic mosses. Pritchard and Berté (1987) found that the aquatic moss *Leptodictyum* (Figure 84) had the lowest protein content of the five foods tested (wheat flakes, alder, burreed, willow leaves, *Leptodictyum*). Wheat flakes and alder had the most, burreed and willow leaves were next. Nevertheless, Pritchard and Berté (1987) found that despite the low nutritional value in *Leptodictyum*, the caddisfly *Limnephilus externus* (Figure 85) chose mosses second out of the five choices, and the caddisfly *Nemotaulius hostilis* (Figure 86) chose mosses third among these choices. As the larvae grew, they increased their intake of moss, preferring it over alder or willow. Their preference for burreed over moss varied and was sometimes equal. Nevertheless, *N. hostilis* grew more slowly on mosses than on alder or burreed.

Tracing Bryophytes in the Food Chain

If identification of assimilated bryophytes is a challenge, the identification of the role of bryophytes in the food chain is an even greater challenge. To what degree is the assimilated carbon from bryophytes passed upward to predators and top carnivores? Or is it simply stored in the insect tissues and unavailable to them? Or is it mostly lost through **egestion** (process of ridding the body of undigested or waste material; defecation; not to be confused with elimination of nitrogenous waste such as that in urination)?

Identification of unique acetylenic fatty acids in bryophytes, including *Fontinalis antipyretica* (Figure 18) (Anderson & Gellermann 1975; Dembitsky & Rezanka 1995; Sushchik *et al.* 2007), has enabled us to use these fatty acids as markers. These unique acetylenic fatty acid markers are absent in tracheophytes, algae (*e.g.* Sushchik *et al.* 2007), and bacteria, providing us with a tool to trace bryophytes in their consumers (Dembitsky & Rezanka 1995). When testing five aquatic bryophytes, Dembitsky and Rezanka determined that acetylenic fatty acids occurring in the triacylglycerols of bryophytes comprised from 6.6% of the fatty acids in the moss *Calliergon cordifolium* (Figure 87) to 80.2% in the thallose liverwort *Riccia fluitans* (Figure 88). Identification of these unique acetylenic fatty acids opened the possibility of determining if the bryophytes were actually assimilated into tissues of their consumers (Kalachova *et al.* 2011).

Figure 88. *Riccia fluitans*, a thallose aquatic liverwort that contains 80.2% acetylenic fatty acids in its triacylglycerols. Photo by Jan-Peter Frahm, with permission.

Torres-Ruiz *et al.* (2007) used fatty acid content to identify the food groups eaten by several aquatic invertebrates. They found the aquatic primary producers had a higher EFA content for 18:2 ω 6 and 18:3 ω 3 in green algae, 20:5 ω 3 in diatoms, and 20:4 ω 6 in bryophytes. Furthermore, they identified specific markers for diatoms (20:5 ω 3 [eicosapentaenoic acid], 16:1 ω 7, 16:4 ω 4s, 16C-polyunsaturated FAa [PUFAa]), green algae (18:3 ω 3 [α -linolenic acid], 18:2 ω 6 [linoleic acid], 16C-PUFAB), and bryophytes (20:4 ω 6, 20:3 ω 3), permitting them to identify aquatic primary producers as the primary food source for the moss-dwelling mayfly *Ephemerella* (*s.l.*) (Figure 3, Figure 8) and caddisfly *Hydropsyche* (Figure 13). Gladyshev *et al.* (2012) used stable isotope composition of fatty acids to trace a food web from periphyton and mosses, to consumers, including **Trichoptera**, and finally to the secondary consumer fish, the grayling, in the Yenisei River in Siberia.

Kalacheva *et al.* (2009) and Kalachova *et al.* (2011) used similar logic to determine the use of *Fontinalis antipyretica* (Figure 18) as a food source in the Yenisei River. In addition to the differences among fatty acids listed above by Torres-Ruiz *et al.* (2007), green algae and Cyanobacteria synthesize high amounts of α -linolenic acid

(18:3 ω 3); bacteria synthesize odd-numbered, branched fatty acids (Kalacheva *et al.* 2009; Kalachova *et al.* 2011). Bryophytes differ from these and from tracheophytes not only by having highly specific acetylenic fatty acids, but also the levels in the bryophytes maintain a high level of these fatty acids throughout the year (Kalacheva *et al.* 2009).

Kalacheva *et al.* (2009) used fatty acid and stable isotope analyses in a 4-year study on the food sources of macroinvertebrates in the Yenisei River. Using the highly specific biomarkers of acetylenic acids in *Fontinalis antipyretica* (Figure 18), they determined that the lipids of gammarids, **Ephemeroptera**, **Trichoptera**, and **Chironomidae** (Figure 9) all demonstrated the presence of these acetylenic acids in their fatty acids. In some cases, these were seasonal. For example, the amphipod *Eulimnogammarus viridis* exhibited maximum levels of the *F. antipyretica* biomarker in winter and minimum levels in summer. In particular, *Serratella ignita* (Figure 25) and *S. setigera* had the highest level of acetylenic acids A18 and A20 when analyzed. On the other hand, the **Chironomidae** *Prodiamesa olivacea* (Figure 89) and *Pseudodiamesa branickii* (Figure 90) and **Trichoptera** *Apatania crymophila* (Figure 91) had the lowest. The researchers concluded that for most of the aquatic insects the *Fontinalis antipyretica* in the Yenisei River played only a minor role in assimilation. On the other hand, the aquatic insects seemed to have a more depleted ^{13}C content than the biofilms, an indication that the consumption of *F. antipyretica*, which likewise has a lower $\delta^{13}\text{C}$ value than biofilms, contributed to their assimilation. Although the moss was consumed as a minor supplement year-round, consumption in general increased in winter when food sources such as epilithic biofilms were greatly reduced.

Figure 89. *Prodiamesa* sp. larva. *Prodiamesa olivacea* had low levels of bryophyte-derived acetylenic fatty acids, indicating little or no consumption of bryophytes. Photo by Peter Cranston, with permission.

Kalachova and coworkers (2011) raised the question of whether the moss was consumed directly or transferred up the food pyramid by consumption of invertebrates that had eaten it. They concluded that it was direct consumption because of lack of the marker fatty acids in the invertebrates lower in the food pyramid. Perhaps the most important conclusion is that these mosses were assimilated

into the tissues of the mayfly *Serratella* (Figure 25) species and others, a conclusion that cannot be supported by gut analysis alone. This line of research is worth pursuing further in other systems to determine the importance of bryophytes in the food web.

Macroinvertebrates can be flexible in their choices of food. In four acid streams of northeastern France, only 24-36% of the biomass consumed by shredders was comprised of leaf fragments; 44% of their diet was benthic algae and bryophytes (Dangles 2002). Some taxa such as the stonefly *Brachyptera seticornis* (Figure 92) and caddisfly *Chaetopterygopsis maclachlani* (Figure 93), specialized on benthic algae and bryophytes. Even though the caddisfly *Pycnopsyche guttifera* (Figure 77) is a classical shredder, it eats algae and is known to eat even terrestrial mosses (Williams & Williams 1982).

Figure 93. *Chaetopterygopsis maclachlani* adult. The larvae specialize on bryophytes as food. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Few preference experiments have been done with aquatic mosses as a choice. Leberfinger and Bohman (2010) gave detritivores *Limnephilus bipunctatus* (caddisfly, Figure 94) and *Nemoura* sp. (stonefly; Figure 40) the choice of shrubby cinquefoil, birch, Swedish whitebeam, dead and fresh grass, aquatic moss, and algae. Both insects preferred leaves of shrubby cinquefoil; *Nemoura* sp. also ate algae. The dead grass was the least preferred food. The shrubby cinquefoil had the highest nutritional value among the detritus choices. Leberfinger and Bohman considered the high carbon to nitrogen content of the fresh foods to be a contributing factor in their choice.

Figure 94. *Limnephilus bipunctatus* larva in case, a species that preferred aquatic mosses over grass, but less than shrubby cinquefoil. James K. Lindsey, with permission.

The **Tipulidae** (craneflies) are known from both terrestrial and aquatic habitats. In the terrestrial realm they typically live in wet habitats such as cedar swamps. *Tipula oropezoides* (Figure 95) is one such species. And it feeds on both mosses and liverworts. Wyatt and Stoneburner (1989) observed the larvae feeding on the moss *Rhizomnium punctatum* (Figure 96). It would strip the one-cell-thick lamina from the thick costa and leaf borders.

Food when Food Is Scarce

Bryophytes are often considered to be emergency foods for aquatic insects (Dangles 2002; McWilliam-Hughes *et al.* 2009; Kalachova *et al.* 2011). They can be particularly important as a winter food source when other foods become scarce (Kalachova *et al.* 2011). Even within the growing season, the abundance of insects changes and this changes their impact on the bryophytes they consume (Figure 97) (Dangles 2002).

Figure 97. Density and biomass of insect shredders feeding on bryophytes in four streams in four replicate study streams (shown by 4 different symbols and lines) in Vosges Mountains (northeastern France). Modified from Dangles 2002.

Bryophytes can also serve as food in areas of a stream where other food sources are scarce (McWilliam-Hughes *et al.* 2009). Based on $\delta^{13}\text{C}$ values, McWilliam-Hughes and coworkers determined that scrapers in low-order streams were more dependent on *Fontinalis* sp. (Figure 23) than scrapers in high-order streams depended on the *Drepanocladus* sp. (Figure 72) that was dominant there. In fact, 98% of the scraper $\delta^{13}\text{C}$ values were enriched relative to bryophyte $\delta^{13}\text{C}$ values and those two measures correlated well ($r=0.53$). When the values from pool habitats were removed, the correlation increased to $r=0.76$. McWilliam-Hughes and coworkers suggested that in low-productivity rivers, primary consumers might switch to alternative marginal food sources such as *Fontinalis* sp.

Epiphytes and Meiofauna of Bryophytes

In aquatic habitats, bryophytes are typically covered with periphyton. This periphyton coating can serve as food for many kinds of insects. The most common of these are diatoms (Ward 1994; pers. obs.). Amos (1999) found diatoms, desmids, and filamentous algae associated with *Fontinalis* (Figure 62). In New Zealand, Suren (1988) found that as day length increased the mosses were covered with flocculent masses of the diatom *Diatoma* sp. (Figure 98) and the filamentous green alga *Ulothrix* sp. (Figure 99) **Cyanobacteria** included *Placoma* (Figure 100), *Tolypothrix* (Figure 101), and *Chamaesiphon* (Figure 102). Suren (1992b) found that the bryophytes provided an abundant and persistent food source for invertebrates, one that was more stable than that on plain tiles. The bryophytes grew a high biomass of the filamentous diatom *Diatoma hiemale* (Figure 98) in the unshaded site and the crustose diatom *Epithemia sorex* (Figure 103) at the shaded site. The masses of filamentous diatoms were of short duration because they were easily washed away.

Figure 103. *Epithemia sorex*, a common inhabitant on bryophytes in shaded streams of New Zealand. Note the **puncta** (holes) in the cell wall. Photo by Ralf Wagner, with permission.

Diatoms (**Bacillariophyta**) at first appear to be indigestible boxes with glass shells of SiO_2 . However, Ogilvie and Clifford (1986) reported that insects can digest the cytoplasm of diatoms through the tiny holes (**puncta**; Figure 103) in the cell wall. Diatoms and detritus are important foods for the tiny insect inhabitants of bryophytes. But meiofauna, intolerant of high water velocity (Winner 1975), can also reside there, seeking refuge from the high velocity of water on rocks and other substrata in the area.

As already noted, Chantha *et al.* (2000) found that as the moss biomass increased in a Quebec, Canada, stream, the invertebrates became more abundant but smaller. Clumps of moss with greater depth provided more spaces for invertebrates, but the algae did not increase proportionally, presumably due to diminishing light deeper into the mat. Both the algal biomass (5-fold) and invertebrate density (10-fold) was much greater on mosses compared to the nearby rocks, but the overall invertebrate biomass was similar on these two substrates because of the much greater area of bare rock.

Trapping Detritus

The ability of bryophytes to trap detritus (Butcher 1933; Cowie & Winterbourn 1979; Gurtz & Wallace 1984; Suren & Winterbourn 1992a, b) as well as other food resources (Devantery 1987) undoubtedly plays an important role in feeding many kinds of inhabitants. Bryophytes trap **CPOM** (coarse particulate organic matter), **FPOM** (fine particulate matter), and **UFPOM** (ultra fine particulate organic matter) (Habdija *et al.* 2004). The fine particulate matter may be particularly important for the

meiofauna, including such small insects as the **Chironomidae** (Figure 9) (Aguila-S. 1998). Trapping is possible due to the reduced flow within the bryophyte mat, and this same slower flow provides a refuge from flow for stream insects (Madaliński 1961; Elliott 1967a, b; Gurtz & Wallace 1984; Suren 1992a, b; Glime 1994).

Huryñ and Wallace (1987) found that in mountain stream areas where bedrock outcrops are covered with mosses, collector-gatherers consume the FPOM (fine particulate organic matter) collected by the moss colony. Some probably also eat the dung that accumulates there from the many inhabitants (Fisher & Gray 1983).

Cherchesova *et al.* (2012) suggested that small and medium stoneflies living among mosses and other locations where **detritus** (Figure 5) is common probably eat detritus. These include *Protonemura aculeata* (see Figure 104), *Amphinemura trialetica* (Figure 105), *Taeniopteryx nebulosa* (Figure 106), *Taeniopteryx caucasica*, *Brachyptera transcaucasica* (see Figure 107), *Chloroperla* sp. (Figure 23), *Nemoura cinerea* (Figure 108), *Capnia nigra* (Figure 109), *Leuctra fusca* (Figure 110), and *Leuctra hippopus* (Figure 111), all in genera that commonly live among mosses.

Figure 110. *Leuctra fusca*, a probably detritus feeder. Photo by Louis Boumans, through Creative Commons.

Figure 111. *Leuctra hippopus* naiad, a probably detritus feeder. Photo by Niels Sloth, with permission.

Suren (1992b) found that bryophytes increase the periphyton and detritus through increased habitat stability, acting much like debris jams in forested North American streams, but on a micro scale. The variation of periphyton among the bryophytes was much lower than that of plain tiles, suggesting that this food source is more stable than that on rocks. Thus the bryophyte periphyton and detritus provide persistent food sources for the bryophyte inhabitants.

Linhardt *et al.* (2002a, b) found that **Chironomidae** (Figure 9) and rotifers responded negatively to flow velocity, but correlated positively with the fine detrital matter trapped within the moss clump. Within *Fontinalis antipyretica* (Figure 18), the amount of trapped fine matter was dependent on the local flow velocity. Egglishaw (1969) found that detritus was the most important factor determining the structure of the community.

The moving waters provide a continuous renewal of organic particles that serve as food items. This permits the filter feeders among the Trichoptera and the Simuliidae to form large populations there (Galdean *et al.* 2001).

Macan and Worthington (1951) found that the fauna on different bryophyte growth forms differed. The not-so-thick moss housed the mayflies *Baetis* (Figure 43) and *Ephemerella* (*s.l.*) (Figure 8), stoneflies, and the scud *Gammarus* (Figure 52). Thick mosses supported great numbers of **Chironomidae** (Figure 9) (75% of the individuals). These mosses support some of the greatest productivity of the fish food organisms.

In Appalachian headwater streams, Wallace *et al.* (1988) found that thick mats of moss on the bedrock were important in retaining large amounts of organic matter. This seemed to account for the 48% collector-gatherers (insects) in the stream with dense mosses compared to 31% in the one with mostly cobbles and pebbles that were free of mosses. Haddija *et al.* (2000) found a positive correlation between flow velocity and the deposition rate of CPOM in moss mats, the location where most of the CPOM was deposited in an alkaline stream. Miliša *et al.* (2006) found similar relationships in the Plitvice Lakes of Croatia.

It is interesting that some folks in the UK have proposed that the increase of aquatic bryophytes downstream of sheep-dip (insecticide & fungicide mix) or heavy metal mines may be evidence that invertebrates are a major factor controlling aquatic bryophyte abundance (Richard Lansdown, Bryonet 13 January 2008). I wonder if the metals, at least, reduce the growth of periphyton, reducing competition and permitting higher productivity among the bryophytes. On the other hand, it is possible that sheep feces provide a food source, as suggested by Fisher and Gray (1983) in regard to macroinvertebrates living in a moss matrix in a desert stream.

Seasonal fluctuations in water level can present a challenge to stream macroinvertebrates. Wood *et al.* (2016) examined the role of trapped organic matter among the inundated clumps of the leafy liverwort *Porella pinnata* in the Middle Oconee River, GA, USA. This liverwort is generally above the water level, but during periods of high flow it becomes inundated. They found a significant increase in macroinvertebrate biomass, insect density, and organic matter among the *P. pinnata* than on adjoining

bare rock. Thus, the presence of bryophytes explained the additional organic matter, insect biomass, and density. Among these opportunistic insects were the **Diptera** and **Plecoptera** as the most abundant. I would suggest that additionally, the liverworts may have provided "landing sites" for insect that were caught up in the high-water flow.

Detrimental Effects?

But the encroachment of bryophytes is not good for all members of the stream community. Bryophytes displace epilithic algae that would otherwise occupy the rocks. These diatoms and other algae serve as food for the scrapers, some of whom cannot carry out the same feeding strategy on the bryophytes. The soft structure and irregular surface of bryophytes sometimes requires a different scraping apparatus from that used on a rock. Slavik *et al.* (2004) found that added phosphorus in an Alaskan stream increased epilithic algae initially, but that after eight years of fertilization the bryophytes replaced the diatoms as primary producers. This increased moss growth altered ammonia uptake rates, benthic gross primary productivity, habitat structure, insect abundance, and faunal species composition.

The detrimental effects of bryophyte encroachment was apparent in a South African stream when managers chose to transplant *Fontinalis* (Figure 18) into the stream to increase habitat for insects and ultimately increase fish production (Richards 1947). While the idea sounded good, the mosses took over the rock surfaces that had been inhabited by scrapers and insects adapted to clinging to smooth rock surfaces and displaced the native fauna. Unfortunately, I don't know the long-term outcome, which may indeed have increased the number of insects once the bryophyte-adapted species were able to colonize.

Bryophytes vs Tracheophytes

It is clear that bryophytes house numerous aquatic insects. And we know that aquatic insects serve as fish food. But do the insects that live among the bryophytes achieve that role? Bowden *et al.* (1999) found that such a role was unclear. As will soon be seen, bryophytes serve as safe sites for the insects. On the other hand, tracheophytes usually provide a more open habitat than the small chambers of bryophytes. And the tracheophytes can house larger individuals, sheltering fish that seek food there.

Macroinvertebrate biomass, insect density, and organic-matter content were significantly greater in patches of *P. pinnata* than on adjacent bare rock. Bryophyte biomass explained additional variation in organic matter, insect biomass, and density. The most abundant insects in *P. pinnata* patches were Dipterans and Plecopterans.

A legitimate comparison between the bryophyte fauna and that of tracheophytes is difficult because these two plant groups tend to occupy different habitats. In lakes the bryophytes are able to extend into deeper water where there is less light than that needed to support the more rapidly growing tracheophytes. The greater depth furthermore coincides with lower temperatures and less temperature fluctuation. Nutrients and dissolved O₂ also differ. And the meshlike nature of the bryophyte more easily traps detritus that can serve as a food source.

In streams, most tracheophytes are unable to tolerate the rapid flow regime that bryophytes can withstand. Since bryophytes occupy greater flow, their surface interface can have a higher oxygen concentration. And since the bryophytes tend to occupy upstream reaches that are steeper and more rocky, they coincide with a different group of insects adapted to faster water, sometimes lower temperatures, some drying in summer, and different species of predators, especially fish. With such limitations on the comparisons, it should be no surprise that studies designed to compare the inhabitants between bryophytes and tracheophytes are rare.

Harrod (1964) found that in a UK chalk stream four aquatic tracheophytes [*Ranunculus fluitans* (Figure 112), *Callitriche platycarpa* (Figure 113), *Veronica beccabunga* (Figure 114), and *Carex* sp. (Figure 115)] had some inhabitants, present on all four species, that are also known bryophyte inhabitants: *Baetis rhodani* (mayflies; Figure 2) (Frost 1942), *Rhyacophila dorsalis* (free-living caddisflies; Figure 116) (Slack 1936), and *Chironomidae* (midges; Figure 9) (Hynes 1961). *Hydropsyche* sp. (net-spinning caddisflies; Figure 13) and *Ephemerella* (s.l.) spp. (mayflies; Figure 3, Figure 8, Figure 25) preferred *C. platycarpa*. *Simulium ornatum* (blackflies; Figure 117) dominated both *Carex* sp. and *R. fluitans* (Harrod 1964).

Krecker's (1939) model contends that invertebrate abundance varies with macrophyte biomass, but also with plant species. Those plants with finely dissected leaves have more inhabitants than do plants with broad leaves. Cyr and Downing (1988) tested this assumption with macrophytes and found that the dissected *Myriophyllum* spp. (Figure 118) harbored significantly ($p < 0.01$) more epiphytic invertebrates than did the broad-leaved taxa of *Potamogeton amplifolius* (Figure 119), *P. robbinsii* (Figure 120), or *Vallisneria americana* (Figure 121). But they also

found more invertebrates on the large *P. amplifolius* than on the other two broad-leaved species. The numbers of **Trichoptera** (caddisflies; Figure 91) and **Chironomidae** (midges; Figure 90) varied based on plant species. Interestingly, they found that plants with dissected leaves (*Ceratophyllum demersum* (Figure 122) and *Myriophyllum* spp.) did not usually support more invertebrates than did species with large leaves, attesting to the importance of surface area.

Epele *et al.* (2012) conducted a similar study on **Chironomidae** (midge) assemblages in Patagonia. They recorded 35 taxa of **Chironomidae**. The most abundant subfamilies were **Orthoclaadiinae** (20), **Chironominae** (7), and **Podonominae** (4). The five most abundant species represented five genera: *Parametriocnemus* (Figure 123), *Parapsectrocladius*, *Paratrichocladius* (Figure 124), *Pseudochironomus*, and *Rheotanytarsus* (Figure 125) most abundant taxa. *Myriophyllum quitense* (Figure 126) is structurally complex and was inhabited by 11 taxa. *Isoetes savatieri*, a structurally simple plant, hosted only 5 taxa. Among the bryophytes in areas of rapid flow they found **Podonominae**, *Eukiefferiella* spp., *Parapsectrocladius* sp. They found that stability of the substrate was important, with boulders, cobbles, and rooted plants supporting more **Chironomidae** abundance, richness, and diversity than did sand/gravel. They concluded that more complex substrates supported greater diversity.

generally had the highest density of **Chironomidae** (larvae per sq cm on wood or per gram dry weight on all others). On 11 June the density among mosses was more than double that among filamentous algae, with the others having only 1/6 or less density than that among the mosses. But on 21 June, *Hippuris* had 457 midge larvae compared to 268 on mosses; the algae had none, and the other plants had much lower densities than the mosses. By 11 July, the density among the mosses was nearly double that on *Hippuris* with all others trailing behind. Similar results persisted on 31 July, but on 20 August no insects were reported for the mosses! On 1 October the moss inhabitants reached their highest density (1817 per gram), nearly twice that on *Hippuris*. Differences in surface area are likely to account for the generally higher habitation among mosses (Table 1). Could the low numbers on 20 August have been movement of larvae from mosses to a better food source during low flow?

Table 1. Comparison of surface area and volume per weight of three tracheophytes, *Drepanocladus revolvens* (Figure 127), filamentous algae, and willow leaves. From Boerger *et al.* 1982.

Plant type	n	area/wt cm ² g ⁻¹	vol/wt cm ³ g ⁻¹	area/vol cm ² g ⁻¹
<i>Sparganium</i>	8	707±13	19.7±1.2	37.6±2.4
<i>Potamogeton</i>	10	1028±116	14.0±0.9	73.6±7.2
<i>Drepanocladus revolvens</i>	10	1526±136	15.2±1.5	103±9.4
<i>Hippurus</i>	9	2549±638	20.9±2.2	122±9.6
Filamentous algae	5	—	23.5±5.6	—
Willow leaves	9	250±9		

In UK lakes and rivers, Macan and Worthington (1951) found that thick mosses on stones and boulders had a mean of 431,941 animals per square meter, whereas *Potamogeton perfoliatus* (pondweed; Figure 129) had only 243,972 and bare rocks had only 4600. Both rooted plants and mosses increased the food used by fish. Percival and Whitehead (1929) likewise found that bryophytes in UK streams had greater insect densities, with intermediate densities on the alga *Cladophora* (Figure 131) and loose mosses, but with the highest densities on thick moss and river weed (Podostemaceae?).

In Doe Run, Kentucky, USA, Minckley (1963) found intermediate densities on the vascular plants *Nasturtium* (Figure 132), *Myriophyllum* (Figure 118), and *Myosotis* (Figure 133), with the highest densities on mosses. Gregg (1981) found that when the insects were counted on available surface area (3-d, not stream bed), the bare substrate had significantly more insects than did the tracheophytes *Ranunculus* (Figure 134) or *Rorippa* (Figure 135). It seems that the most important role of these tracheophytes was to increase available substrate. It is likely that bryophytes have that role as well.

Unlike the bryophytes that trap large quantities of detritus, the tracheophytes tend to be somewhat cleaner because they have fewer pockets in which to trap things. Soszka (1975) used both laboratory and field experiments to examine how insects in a Polish lake used the tracheophytes. He found that only the larvae of Lepidoptera depended on the tracheophytes for food. Rather, most of the insects ate the epiphytic algae and detritus.

Nearly 60% of the invertebrate taxa associated with macrophytes studied by Krull (1970) occurred on only three or fewer species of macrophytes and 33 invertebrate taxa were associated with only one species. **Odonata** (Figure 136) are relatively common among macrophytes (Corbet 1962) but nearly totally absent among bryophytes (see Chapter 11-4 of this volume). The reasons remain to be explored, but the **Odonata** are large and tend to occur in quiet water where they can lie in wait for prey, whereas bryophytes are more common in rapid water.

Figure 136. A head-on view of the dragonfly *Tanypteryx hageni* naiad lying in wait for its prey. Photo by Greg Courtney, with permission.

The morphology of the plant appears to be of a major importance. Kreckler (1939) found that the lowest number of insects occurred on *Vallisneria* (Figure 121), a plant with smooth, linear leaves. On the other hand, *Myriophyllum* (Figure 118) species (Figure 118) are divided and provide a large surface area. *Potamogeton crispus* (Figure 137) has very wavy leaves and had high faunal densities. Harrod (1964) considered the colonization of aquatic macrophytes to depend on four factors: morphology, position in stream, epiphytes present, and chemical nature. Habitat permanence may be important in lakes (Hargeby 1990). (Hutchinson 1975) suggested that chemical defenses were not well developed in aquatic macrophytes compared to terrestrial plants. Presumably they are also less well developed than in bryophytes.

Figure 137. *Potamogeton crispus* showing dense growth. Photo by J. C. Schou, with permission.

Despite the open nature of most macrophytes, Tarzwell (1936) found more organisms on the tracheophytes than on the mosses in Michigan, USA, streams. Using a relative scale in which 1.0 represented the numbers on sand, he reported individuals on the tracheophytes *Ranunculus* (Figure 134) (194), *Rorippa* (Figure 135) (301), and *Elodea* (Figure 138) (452) to be greater than those on mosses on gravel (111) or mosses on gravel and rubble (140). Similarly, Percival and Whitehead (1929) found that fauna

on a square decimeter of the tracheophyte *Potamogeton* (Figure 129) (2405) exceeded that of both loose moss (709) and thick moss (2140).

Figure 138. *Elodea canadensis* flowering. Note detrital accumulation on substrate but little at leaf bases. Photo by Christian Fischer, through Creative Commons.

The ability to colonize tracheophytes vs bryophytes often depends on the suitability of the morphology. Although bryophytes have a large surface area, most of it is below the interface with flowing water, hence creating surfaces that may be lacking in sufficient oxygen as well as being unsuitable for filter feeders that depend on the flow. This appears to be the case for blackflies. Niesiolowski (1980) found a greater number of blackflies on *Potamogeton* (Figure 137) than on *Fontinalis* (Figure 62). He attributed this to the differences in leaf size and setting. *Potamogeton* leaves are all exposed to the current whereas only tips of bryophyte branches that interface with the water flow are available for these filter-feeding larvae.

Clearly the relationships between aquatic insects and bryophytes are complex and may be indirect. They serve as refuges and food sources, but these roles may change as the seasons change. Their importance in increased diversity is certain, but their role in overall productivity of the habitat is still elusive.

Summary

Bryophytes provide a stable habitat with lots of surface area, a variety of internal spaces with oxygen and flow gradients, a place to hide from predators or escape from flow (enemy-free space/refuges/safe sites), a trap for algae and detritus to serve as food, and a place to hunt for smaller organisms while hiding from larger predators. Bryophytes can also serve as a moist refuge and a place to find food during times of low water. Hence, a rich bryophyte fauna exists to take advantage of these benefits, increasing the functional diversity. The bryophytes provide habitats for insects in streams, rivers, lake margins, deep waters of lakes, ponds, bogs, and fens.

Two strong determinants of the bryophyte faunal composition are velocity and pH. Nutrients can change the dynamic, in some cases increasing moss cover and fauna, but in others increasing algal dominance and reducing bryophyte cover due to competition for light and CO₂.

Some insects specialize on parts of the mosses, with some in leaf axils, some in liverworts, some on the leaf lamina. Morphology of the bryophyte may help to define the faunal community. Other insects specialize on the food types that grow on the mosses – diatoms, Cyanobacteria, filamentous green algae. Some preferences for bryophyte species may relate to the preference of the bryophyte for a particular pH range, flow, or other conditions. Bryophytes can also serve as a trap for drifting insects while helping others to avoid the drift altogether. The bryophytes seem to keep at least some species from joining the drift at emergence by providing a substrate where they can climb out of the water.

Artificial string mosses are colonized by the same dominant insects as are mosses, but Visqueen strips have a smaller, more selective fauna.

New methods using fatty acids have supported the gut analyses that reveal bryophytes in the diets of a number of insects. These fatty acids have been used as tracers to implicate the movement of bryophyte carbon upward in the food pyramid. Antiherbivore compounds may keep some insects from eating the bryophytes; in other cases they keep predators from attacking the insects because they prefer eating among plants that lack these compounds. But it appears that trapped detritus and adhering periphyton may play the most important role in determining bryophyte insect inhabitants.

Although macroinvertebrate density and richness increase with moss weight, lower reaches within the mat may be unacceptable habitats for many, so that area covered is more important. And in some cases, encroachment by bryophytes can eliminate insects adapted to smooth rocks.

Bryophytes offer different advantages compared to those of tracheophytes. They occur in rapid water of streams where tracheophytes are unable to survive, they provide enclosed, protective spaces, they trap more detritus, and they persist year-round. But large-leaved tracheophytes provide better habitats for such taxa as **Simuliidae** because more of their surface area is in direct flow where these blackflies can filter out their food.

Acknowledgments

Throughout this chapter I must thank my sister, Eileen Dumire, for her devoted time to accompany me in the field, to sort insects from the mosses, to make entries in my bibliography, and to review these subchapters. And I thank my parents for taxiing me to my field sites. I thank my advisor, William B. Drew, for his willingness to advise such an interdisciplinary project. Many others have helped in the formation of my perspectives, in providing images, and in general encouragement.

CHAPTER 11-3

AQUATIC INSECTS: BRYOPHYTE HABITATS AND FAUNA

Figure 1. *Sphagnum* blanket bog. Photo through Creative Commons.

Aquatic Bryophyte Habitat and Fauna

Insect distribution and abundance depend on freedom from predation, interspecific competition, and physical disturbance (McAuliffe 1983). Bryophytes offer a refuge from all three of these dangers. Aquatic insect biodiversity depends on gradients in habitat size and acidity (Harrison & Agnew 1962; Heino 2009). Bryophytes can contribute to the acidity, particularly in *Sphagnum* (Figure 1) habitats, and add to both habitat size diversity and complexity. Thus, bryophytes can increase the diversity of insects in streams, lakes, bogs, and springs by creating more niches for occupation.

Moon (1939) summarized his study of aquatic insects as evidence that the substrate provides mechanical support for the fauna and is the surface on which food grows or is

deposited. Bryophytes can contribute greatly to the available substrate, growing periphyton, and trapping detritus. For carnivorous insects, the bryophytes also harbor animal food organisms. Others have reported similar advantages of the moss substrate: increased substrate area (Glime & Clemons 1972), increased algal cell counts (Gurtz & Wallace 1984), replacing scour or sediment-buried algal cover (Hains 1981), protection from scour (Gurtz & Wallace 1984), filtering and trapping detritus (Gurtz & Wallace 1984), providing high prey density (Gurtz & Wallace 1984). The mosses also permit the insects to gain a hold in areas of high velocity where the insects may be able to reduce ventilation needed to gain oxygen, thus saving energy (Johnson 1978; Gurtz & Wallace 1984).

Gurtz and Wallace (1984) found that after a clearcut in the southern Appalachians, USA, the insect fauna increased in density more on the moss-covered (mostly *Hygroamblystegium tenax* – Figure 2) rock faces than on other stream substrates. It was primarily the collector-gatherers and scrapers that increased, whereas shredders declined. They considered that the mosses contributed to the biological stability of their substrates. They were most important in areas of rapid, shallow, turbulent flow. These habitats not only replenished the CO₂ and nutrient supply for the mosses, but provided the flow needed for the net-spinning caddisfly *Parapsyche* (Figure 3).

By experimenting on colonization of *Fontinalis neomexicana* (Figure 4), Maurer and Brusven (1983) found that collector-gatherers were the most numerous (74% of the density), with shredders, collector-filterers, engulfers, and scrapers making up the remainder. Arrival of *Brachycentrus* sp. (Figure 5), a collector-filterer, and *Hydroptila* sp. (Figure 6), a scraper, both caddisflies, changed these percentages after three weeks. Maurer and Brusven believed that fine particulate matter and epiphytic algae may have facilitated the rapid recolonization.

In a Nepalese river system, altitude was an important determinant of the bryophytes and associated fauna (Ormerod *et al.* 1994). Not only did the substrate change, with bryophytes being more common at higher altitudes, but attached diatoms were more common among higher altitude streams. The high altitude springs supported dense

cover of bryophytes, but bryophytes were not well supported by the cold streams of ice and glacial melt.

Ward (1986) studied altitudinal relationships in the Rocky Mountains, USA. As in the Nepalese system, aquatic tracheophytes were absent in the high mountain sites. Rather, bryophytes dominated in the headwaters. The **zoobenthos** (animals that live on the bottom) density experienced a 3-fold to 6-fold increase from the tundra to the plains at lower elevations. Vinson and Hawkins (2003) likewise found that diversity of genera decreased as elevation increased, with only **Plecoptera** (stoneflies; Figure 25) being an exception.

Like altitude, latitude affects stream insect richness. Vinson and Hawkins (2003) examined data on **Ephemeroptera** (mayflies; Figure 8-Figure 9), **Plecoptera** (stoneflies; Figure 25), and **Trichoptera** (caddisflies; Figure 6) from 495 published studies on richness. **Ephemeroptera** showed three richness peaks (~30°S, 10°N, 40°N) with the highest near 5-10°N and 40°N latitude. **Plecoptera** richness was distinctly highest at ~40°N latitude and similarly at 40°S latitude. **Trichoptera** richness showed less latitudinal variation than the other two orders, although it was slightly higher near the equator and at 40°N and S latitude than at other latitudes.

In a study of mosses growing on filter beds, Hussey (1982) found that growth of mosses [*Leptodictyum riparium* (Figure 7) was most common] changed the macroinvertebrate community. Even the thickness of the moss will cause differences among communities (Macan & Worthington 1951). The mayflies *Baetis* (Figure 8) and *Ephemerella* (Figure 9), **Plecoptera** (Figure 25), and the scud *Gammarus* prefer not-so-thick moss, whereas thick moss harbors abundant **Chironomidae** (Figure 15). Macan and Worthington found that of the 431,941 animals per sq m of thick moss, 75% were **Chironomidae**. Despite the small size of the moss inhabitants, they found that rooted plants and attached mosses provide the greatest productivity of fish food organisms. That probably refers to the kinds of organisms that fish eat, not to organisms among the mosses that are actually eaten as these may be unavailable unless they enter the drift. (See Chapter 11-2, Bryophyte Roles as Insect Habitats – Food.)

Streams

Streams can be rich habitats for aquatic fauna. In the Åland Islands of Finland, Autio and Salmela (2010) collected 104 **Diptera** species from 19 sites, using Malaise traps. These sites included open mires, wooded mires, rich fens, Baltic shore meadows, ditches, and a grove. These **Diptera** included the semiaquatic families **Limoniidae**, **Tipulidae**, **Pediciidae**, **Cylindrotomidae**, **Ptychopteridae**, **Psychodidae**, and **Dixidae**. But the species richness was less than that in other parts of Finland, a phenomenon that Autio and Salmela attributed to the absence of brooks and springs.

In a Victorian Australia upland stream the habitats included mossy stones and the tracheophyte *Ranunculus fluitans*, with number of species reaching 19 among mosses compared to 5 in stony riffles (McKenzie-Smith 1987). The densities among the bryophytes were greater than that McKenzie-Smith could explain on the basis of greater surface area, so he concluded that they offered more than just space.

In Appalachian Mountain streams, I found that the insect communities on the leafy liverwort *Scapania undulata* were most similar to those on *Fontinalis dalecarlica* (Figure 16) (Glime 1968). These seem like strange similarities because these two bryophyte species

were the most different from each other structurally. However, they did tend to occur in the same streams, suggesting that conditions of flow, nutrients, and temperature may have been more important for the insects. *Scapania undulata* provided a unique habitat where insects were able to hide within the folded leaves. The large, streaming moss *Fontinalis dalecarlica* may have offered a similar advantage by having a leaf that was somewhat rolled, making it tubular and providing good shelter for the very small.

In many northern streams the bryophytes remain throughout the year, providing a habitat for insects when the tracheophytes disappear. But in English rivers, *Fontinalis antipyretica* (Figure 10), *Fissidens crassipes* (Figure 11), and *Leptodictyum riparium* (Figure 7) decline considerably during winter (Wehr & Whitton 1983; Kelly & Whitton 1987).

Figure 10. *Fontinalis antipyretica*, a species that declines in English winters. Photo by Bernd Haynold, through Wikimedia Commons.

Figure 11. *Fissidens crassipes*, a moss that diminishes in English rivers in the winter. Photo by Michael Lüth, with permission.

As noted earlier, bryophytes in streams increase the heterogeneity of the habitat, increasing the available niches for insects (Allan 1975; Williams 1980). And size matters – sometimes (Bourassa & Morin 1995). Although the taxonomic composition differs among streams, the size distribution is quite similar. But substrate composition in nine Canadian streams did affect overall abundance – more

than it did their size. Eutrophic sites favored higher abundance, but only for organisms larger than 1 mm (approximately 1 μ g dry mass). These small organisms contribute to less than 3% of the respiration of the stream ecosystem, contrasting with the results of Smith-Cuffney (1987 – see above). Does this mean that bryophytes, with their fauna of the smallest organisms, contribute little to the stream ecosystem? I think not, because it is these small organisms that become big ones, and without the shelter of bryophytes they are more likely to be food for predators.

In a Tennessee, USA, springbrook, Stern and Stern (1969) found that the highest number of insects on bryophytes and algae occurred in winter. In February they found 768 individuals per 0.1 m², whereas in July they found only 43 per 0.1 m² (Figure 12). **Diptera** comprised 84.4% of the fauna, Trichoptera 9.6%, **Plecoptera** 3.1%, and **Ephemeroptera** 2.8%. **Coleoptera** comprised only 0.1%.

Following logging in a southern Appalachian, USA, stream, Gurtz and Wallace (1984) found that the stonefly *Amphinemura wui* (Figure 13) increased in numbers, a response they attributed to the particulate accumulation by bryophytes. Baetid mayflies and the spiny crawler mayfly *Ephemerella* (s.l.) (Figure 9) increased most among mosses, correlating with a similarly high increase in diatoms among mosses. And as one might expect, the **Orthocladinae** (**Chironomidae** – midges, Figure 15) increased in response to the increased sediment among the mosses.

One of the uses of bryophytes in stream studies could be to serve as **surrogates** – indicators of the habitat and the organisms one might expect to find there. But it seems that bryophytes do not make very reliable surrogates (Paavola 2003; Paavola *et al.* 2003, 2006). Paavola and coworkers, using 101 boreal stream sites, found that within stream areas, the insect communities correlate primarily with stream size, pH, and water color. Bryophytes, on the other hand, correlate with nutrient levels and habitat heterogeneity, whereas fish correlate with oxygen levels, depth, and substrate size. But the surrogate role is not as dismal as it may seem. At the level of ecoregions, all three respond to acidity and depth as well as spatial coordinates

and the community concordance is much smaller than it is on the level of a single stream or stretch of stream. Nevertheless, these three taxonomic groups had low predictive value. When Virtanen *et al.* (2009) examined bryophyte correlations in 138 boreal springs, temperature was a major driver of communities. The **EPTC** insects [**Ephemeroptera** (Figure 8-Figure 9), **Plecoptera** (Figure 25), **Trichoptera** (Figure 6), and **Coleoptera** (Figure 41-Figure 43), *i.e.* major orders on bryophytes and in fast streams] were not good surrogates for the bryophytes, nor were the **Chironomidae** (Figure 15). Concordance between bryophytes and **Chironomidae** was a little better than with the EPTC group.

Figure 15. **Chironomidae** larva, a common bryophyte inhabitant that is not a good surrogate for bryophytes. Photo by Jason Neuswanger, with permission.

In their study of *Fontinalis dalecarlica* (Figure 16) communities, Cattaneo *et al.* (2004) found that depth was an important contributor to differences in invertebrate biomass. Shallow mosses supported lower invertebrate biomass than did the deeper ones, possibly due to frequent exposure of the shallow mosses.

Streamside

The streamside habitat is one of changing water levels, providing a moisture gradient and a place to leave behind the naiad or pupal stage and crawl to the terrestrial environment for adulthood. Lindegaard *et al.* (1975) examined four zones related to the fauna on the moss *Cratoneuron* (Figure 17). Underlying the moss they found a detritus zone, with numerous flies and earthworms. Above it was a zone of water-covered mosses. The **madicolous** zone occurred just above the water surface and the moss remained constantly wet by splash and capillary water. This madicolous zone and the water zone were suitable for caddisflies, flies, and molluscs. Above that the moss was dry, occupied by springtails, beetles, spiders, and predaceous mites.

Artificial Bryophytes

Artificial substrata provide important information on the role of the moss in the association with invertebrates (Cox 1988). Suren (1988) used mosses constructed from nylon twine woven into squares. These artificial mosses were colonized by the stoneflies *Zelandoperla* (Figure 18) and *Zelandobius* (Figure 19), midges, nematodes, mites, copepods, and ostracods.

Figure 19. *Zelandobius illiesi*, a stonefly that colonized artificial mosses in New Zealand. Photo by Stephen Moore, Landcare Research NZ, with permission.

Glime and Clemons (1972) found that aquatic insects may only colonize mosses as a place to live. In their experiments, insects on artificial string mosses (Figure 20) formed similar communities to those on *Fontinalis* (Figure 16), but the number of species on mosses made of polyethylene strips was more limited.

Figure 20. Artificial string moss used in study by Glime & Clemons (1972). Photo by Janice Glime.

Suren (1987, 1988) found that artificial mosses in high alpine streams of New Zealand provided habitat similar to that of mosses, but some taxa, for example **Collembola**, were not restored due to lack of suitable food. Others can be absent due to lack of suitable materials for building their "houses." Suren did find that these surrogate mosses did develop abundant periphyton in one stream, but in another they collected primarily detritus and silt. For substitute mosses, the right kind of artificial structure must be found to also house the needed food. This most likely would require longer for the dependent organisms to colonize.

Suren (1991b) also found that colonization of artificial bryophytes was rapid, reaching a peak in abundance after only 4 weeks. After two months, the density and richness resembled that of the natural bryophytes. Nevertheless, some taxa did not reach normal levels, with larvae of **Empididae** (Diptera; Figure 21) and the crane fly *Limonia hudsoni* (see Figure 22) having lower numbers. Taxa that were characteristic of riffles, *e.g.*, the mayflies *Deleatidium* sp. (Figure 23) and *Nesameletus* sp. (Figure 24), or stoneflies *Stenoperla prasina* (Figure 25) and *Zelandobius* sp. (Figure 19), did not colonize the "stems" of artificial

bryophytes very well but did colonize the bases of these and the bedrock beneath. TWINSPAN identified a strong similarity between the artificial mosses and the real mosses, but the fauna of the artificial substrates were different from that of the riffles.

Suren and Winterbourn (1992) experimented with artificial bryophytes in shaded and unshaded New Zealand portions of an alpine stream. The artificial mosses consisted of pieces of nylon twine woven into 4 mm pores of nylon mesh cut into 0.01 m² squares. They found that at the unshaded site seven taxa preferred substrata with high detrital and periphytic biomass. Of the 22 taxa there, 8 were influenced by periphyton biomass, three by detrital biomass, and two by exposure time. At the shaded site, only two taxa had a relationship with these food groups. Exposure time was the most important variable for four of these taxa.

Preference Experiment

Corona (2010) experimented with substrate choice of wood, cobble, sand, and moss to help explain the distributions of **Ephemeroptera** (Figure 8-Figure 9), **Plecoptera** (Figure 25), and **Trichoptera** (Figure 6) in streams in the San Bernardino National Forest (SBNF) in Southern California. She placed three of these preference samplers (615 cm² Plexiglass trays) in each of the three streams to determine where the insects chose to live. The actual stream had the leafy liverwort **Porella** sp. (Figure 26), but moss with a similar 3-d structure was chosen

because it was available commercially. Of the possible combinations of substrata, only two pairs were significantly different: large gravel vs sand and sand vs moss. The majority of species had greater species abundance in the liverwort and experimental moss compared to other microhabitats. Species diversity was greater in the experimental moss habitat compared to the sand habitat (Table 1). Corona suggested this could be a response to the greater food source that accumulated in the more complex structure of the mosses. In the stream, *Drunella grandis* (Figure 27) characterized the *Porella* habitat. Other species seemed to be influenced by habitat availability, with *Plecoptera* sp. 1 characterizing sand in the natural habitat, but characterizing the moss in the experimental preference habitat.

Torrents and Waterfalls

The precipice nears and the clump of mosses soon finds itself in a freefall, wet, and being carried by the pounding water and convection currents. Soon it will rejoin the stream below, bumping along until it gets pinned behind a log or rock.

In that same freefall are insects, dwellers of the water, giving in to the strong movement of the water, then drifting with the stream. Like the moss, they await a place where they can lodge. But for them, that lodging place might be the moss itself, a haven out of the torrent that takes them to

unknown destinations. A haven where they can lay their eggs and find algae, bacteria, fungi, or smaller insects to eat. A haven where they can rest safe from larger hungry predators. A place to be until that day when they must climb to the water's surface and take their maiden flight, free from the rushing torrent that made their life so tenuous.

Table 1. Field Tray Results for species contributors with a cut-off at 90% contribution characterizing microhabitats across all depths.

	Moss	Large Gravel	Sand	Wood
Lower Barton Creek				
<i>Baetis tricaudatus</i>	8.24	59.89	100	24.85
<i>Diphetero hageni</i>	28.15	34.76		45.08
<i>Micrasema</i>	8.01			
Nemouridae immature	9.30			
Plecoptera sp. 1	8.01			
<i>Zapada cinctipes</i>	9.61			
Santa Ana				
<i>Baetis tricaudatus</i>	51.87	18.45	74.47	31.99
<i>Ephemerella dorothea</i>	6.51	27.95	12.77	12.52
<i>Lepidostoma errigenum</i>	23.92	25.69	12.77	15.99
<i>Paraleptophlebia</i>	12.12	27.91		35.49
Upper Barton Creek				
<i>Baetis tricaudatus</i>				57.14
<i>Psychoglypha</i>	100			42.86

Thomas (1980) successfully reared the torrential dweller *Porricondyla ramadei* (Diptera: Cecidomyiidae), taken from submerged bryophytes in the turbulent water of a mountain stream in the Pyrénées. There were also hundreds of other strictly torrential invertebrates in the sample. Wallace and Ross (1971) described a new species of caddisfly, *Pseudogoera singularis* (Odontoceridae) from mosses in waterfalls of the Southern Appalachians, USA.

Springs

Virtanen *et al.* (2009) investigated bryophyte inhabitants in 138 boreal springs. They found that water chemistry and temperature determined bryophyte assemblages. By contrast, Ilmonen (2009) found that the macroinvertebrate assemblages correlated with physical habitat but not with changes in chemistry.

Chironomids likewise responded to temperature, but water chemistry had little effect on them in 138 springs in Finland; physical habitat was somewhat important in their distribution (Virtanen *et al.* 2009). The **Chironomidae** (Figure 15) had a closer correspondence with **Ephemeroptera** (Figure 27), **Plecoptera** (Figure 25), **Trichoptera** (Figure 6), and **Coleoptera** (Figure 41-Figure 43) than with the bryophytes. Hence, as in stream habitats, spring bryophytes and insects are relatively poor surrogates for each other. Even when the insect assemblages were similar, the environmental characters differed. As in streams, better concordance occurred when larger geographic areas were included.

Hurny *et al.* (2005) found that springs in the Arctic separated from other stream types based on nutrient concentrations and likelihood of freezing. Glacier and

mountain streams separated from both springs and tundra streams on substrate instability and likelihood of freezing.

Lindegaard *et al.* (1998) concluded that the high variability of substrate within a spring accounted for the low variation among Danish streams. This same variability also made it impossible for Lindegaard and coworkers to correlate environmental variables with fauna. They classified the macroinvertebrates associated with springs and springbrooks into seven groups: (1) **cryobiotic** species restricted to the spring area, (2) **crenophilous** species with maximum abundances in springs, (3) **lotic** species also living in the spring area, (4) **lentic** species found in **limnocrenes**, (5) **ubiquitous** species, (6) **madicolous** species, and (7) **terrestrial** species.

Thorup (1963) described insects from Danish springs. Although I don't know how they correlated with the bryophytes, the genera and some of the species mentioned are known from bryophytes: *Baetis rhodani* (Figure 8), *Brachyptera risi* (Figure 28), *Nemurella picteti* (Figure 29), *Leuctra hippopus* (Figure 30), *Leuctra fusca* (Figure 31), *Agapetus fuscipes* (Figure 32), *Crunoecia irrorata* (Figure 33), *Pericoma* cf. *blandula* (Figure 34), and *Simulium ornatum* (Figure 35).

Unlike other studies on surrogates, Ilmonen (2009) found that a rare spring-dwelling caddisfly (*Crunoecia irrorata*) was a good surrogate for springs that had a high conservation value. These springs had high overall species diversity, including other rare (red-listed) species. But as in other studies cited herein, these relationships held on a regional, but not within-spring system basis. Ilmonen and Paasivirta (2005) found that while there were differences in relative abundances among types of springs, the most common taxa were the same in all of them. The insects were somewhat more abundant in moss carpets and less abundant in sites that were pools. The strongest separators related to water flow and minerogenic substrate, a relationship supported by studies in Spain (Barquin & Death 2009).

Depth is an important factor for some insects. At the Pupu Springs, NZ, the invertebrates on the moss *Cratoneuropsis relaxa* (Figure 36) were 20 times more abundant at 0.6 m depth than at 4.3 m depth (Michaelis 1977). Such depth differences can relate to temperature, oxygen availability, and photosynthetic organisms (algae)

for food. Boulders with bryophytes had more invertebrates than those at similar depths with no bryophytes.

Figure 36. *Cratoneuropsis relaxa*, a moss where depth matters to the insects. Photo by Tom Thekathyl, with permission.

Bottazzi *et al.* (2011) found that springs with mosses served as home for predominately **Chironomidae** (Figure 15) and **Plecoptera** (Figure 29-Figure 31), as well as the crenophilic microcrustaceans in **Harpacticoida** and **Ostracoda**. Only pH and temperature explained the diversity pattern, factors demonstrated as important by (Virtanen *et al.* 2009). Nevertheless, the presence of mosses increased the species diversity of the springs.

Seepage areas differ from other springs by having small flow rates in which the source water has filtered into permeable earth. These are often suitable habitats for bryophytes. In England, these seepage areas provide habitat for the crane fly *Tipula cheethami* (Figure 37) larvae living among the moss *Platyhypnidium riparioides* (Figure 38) and the snipefly *Spania nigra* (Figure 39) larvae on the liverwort *Pellia neesiana* (Figure 40) (Boyce 2002). On cliff seepages, one might find the tiny beetle *Sphaerius acaroides* (Figure 41-Figure 42) among the mosses. *Ochthebius poweri* (Figure 43) (**Coleoptera: Hydraenidae**) live in these seeps, eating the algae there. Some caddisflies occur there as well.

Ward and Dufford (1979) found that mosses and water cress (tracheophyte) had similar macroinvertebrate biomass in a Colorado springbrook-pond system. The tiny caddisfly *Hydroptila* (Figure 6) developed its largest populations on the moss. The crane fly *Limonia* (Figure 22) was present in large numbers and was restricted to mosses; *Euparyphus* (Stratomyiidae; Figure 44), another dipteran, was the second most abundant organism. Surprisingly, the *Coleoptera* (Figure 41) were the most diverse on mosses.

Figure 44. *Euparyphus* sp. larva, a genus that was restricted to mosses in a Colorado springbrook-pond system. Photo from EPA, through public domain.

Bryophytes in springs provide a continuous gradient from land to water, both vertically and horizontally (Lindegaard *et al.* 1975; Thorup & Lindegaard 1977; Bottazzi *et al.* 2011). Thus they provide a wide range of niches that promote a high invertebrate diversity. This transition furthermore makes an easy transition area for insects emerging from their aquatic stage into adults.

Bogs and Fens

Bogs and fens are dominated by bryophytes at the ground level, creating unique and generally favorable habitats for invertebrates. Bogs have a wide temperature range within a single day (Gerson 1969). At the surface, the temperature can have a 30°C span in a single day while the stem layer experiences only a 5°C temperature span. Similarly, the surface humidity can range 40-100% while the stem layer remains at 100%. The pH ranges widely from acid bogs to rich fens, having a strong influence on some members of the insect assemblages.

Bogs have been widely studied for their unusual plant assemblages, but invertebrates have received much less attention, an omission known for a long time (Jewell & Brown 1929). Muttkowski (1912) summarized the insects in trout bogs in Yellowstone National Park, USA. These included *Ephemeroptera* (rare), *Odonata* (rare), *Hemiptera* (few), *Trichoptera* (rare), *Chironomidae* (Figure 15) (common), *Psychodidae* (common), and *Tipulidae* (frequent).

Many insects live in peatlands because of the diversity of habitats present there. For example, Bordoni (1972) found 179 species of beetles (Coleoptera) in a Tuscan fen, but only a few were actually bryophilous. Members of the *Staphylinidae* are known to feed on mosses (Mani 1962) and were well represented in that Tuscan fen. The *Sphaeriidae* (minute bog beetles) live among mosses (Arnett 1971).

A member of the insect order *Grylloblattodea* (crickets and grasshoppers) lays its eggs among mosses (Gerson 1969; Richards & Davies 1977). Crickets and grasshoppers in peatlands even feed on *Sphagnum* (Figure

1) (Vickery 1969). Uvarov (1977) suggested that these insects may eat the mosses to obtain water. Paasivirta *et al.* (1988) found that aquatic sites had greater insect emergence than semi-terrestrial sites in a boreal raised bog of central Finland.

As the hummocks and hollows build, the *Sphagnum* species change. *Sphagnum* (Figure 1) bogs undergo succession and their fauna changes as the *Sphagnum* species change (Murphy 1955). This succession of species is true for oribatid mites (Tarras-Wahlberg 1952-53) and pselaphid beetles (Reichle 1966). The fauna often occupy a specific position relative to the water table, presumably due to a preferred moisture level. Murphy (1955) found that the springtail *Sminthurides malmgreni* (Figure 45) became associated with the most humid hollow and pool species, *Sphagnum cuspidatum* (Figure 46) and *S. subsecundum* (Figure 47). When the mosses *S. papillosum* (Figure 48) and *S. magellanicum* (Figure 49), typical hummock mosses, become available, the springtails *Folsomia brevicauda* (see Figure 50) and *Isotoma sensibilis* (see Figure 51) are likely. Still others are present in the dry *Calluna* (Figure 52) and *Cladonia* (probably *Cladina*) habitat.

Bryophytes play a major role in the fauna of bogs. That fauna is often shared with fauna of surrounding habitats, but some unique organisms prefer that habitat, and others use it seasonally.

Collembola - Springtails

Whereas **Collembola** are not common among submerged bryophytes, a number of species occur among bryophytes, especially *Sphagnum* (Figure 1, Figure 46-Figure 49), in bogs. Ussinger (1974) suggests collecting these bog taxa by submersing the moss in water until the **Collembola** float.

Bright (2002) reported 15 springtail species in Michigan bogs. These included *Bourletiella arvalis*

(Figure 53), *Folsomia prima* (Figure 54), *Heteraphorura subtenuis*, *Hydroisotoma schaefferi* (Figure 55), *Hypogastrura nivicola* (Figure 56), *Isotoma viridis* (Figure 57), *Neelus minutus* (see Figure 58), *Orchesella albosa* (Figure 59), *Sminthurides aquatica* (Figure 60-Figure 61), *Sminthurides malmgreni* (Figure 62), *Sminthurides occultus*, *Sminthurides penicillifer* (Figure 63), *Sminthurinus aureus* (Figure 64), *Sminthurinus bimaculatus* (Figure 65), and *Tomocerus flavescens* (Figure 66).

Coleoptera - Beetles

Crenitis punctatostrata (Hydrophilidae; Figure 67) is a true **bryobiont** (animal exclusively associated with bryophytes) that lives its entire life among *Sphagnum* (Figure 1) and is known from the Jura Mountains (Matthey 1977). This species lays its eggs among the mosses and the larvae remain there. The pupa lives in a cell formed from the bryophytes.

Figure 67. *Crenitis punctatostrata* adult, a species that lays its eggs among mosses and the larva develop there. Photo by Udo Schmidt, through Creative Commons.

For some *Sphagnum* (Figure 1)-associated insects, this moss provides a safe haven during unfavorable seasons. One of the more unusual of these is the tiny water beetle *Hydroporus morio* (quick silver diver; Figure 68) (Jackson 1956 in Gerson 1982). This beetle lives in *Sphagnum* pools in Europe and is sensitive to heat. When these pools dry out in summer, the exposure to heat on a sunny *Sphagnum* mat can be dangerous for *H. morio*. To survive, the beetle bores small round holes into the damp *Sphagnum* in the "dried" pool and **aestivates** (summer equivalent of hibernates) in that protected (and insulated)

location until the rains return. In the southern parts of its range, it is disappearing, apparently due to climate warming (Anderson 2015).

Figure 68. *Hydroporus morio* adult, an insect that lives in *Sphagnum* pools, then bores holes into the mat to aestivate when the pools dry. Photo by Niels Sloth, with permission.

Others find bryophytes a suitable place to survive the winter (Reichle 1966). More than 20 species of beetles in the **Pselaphidae** live in *Sphagnum* (Figure 1) bogs, where they can find a microclimate similar to that of their early postglacial ancestors. Among these are beetles that overwinter as adults in the interstitial spaces of frozen moss mats.

Larson and House (1990) found that small pools were dominated by oligochaetes, beetles, and mosquitoes. Hebauer (1994) listed **Coleoptera** (Figure 68) species he considered to be **tyrphophils**, *i.e.*, living among *Sphagnum* (Figure 1), in middle Europe. These included *Ilybius erichsoni* (Figure 69), *Agabus congener* (Figure 70), *I. wasastjernai* (Figure 71), *Bidessus grossepunctatus* (Figure 72), *Hygrotus novemlineatus* (Figure 73), *Colymbetes paykulli* (Figure 74), *C. striatus*, *Enochrus affinis*, *E. coarctatus*, *E. ochropterus* (Figure 75), *Hydrochus brevis* (Figure 76), *H. megaphallus*, *Hydroporus brevis* (Figure 77), *H. melanarius* (Figure 78), *H. memnonius* (Figure 79), *H. scalesianus* (Figure 80), *H. tristis* (Figure 81). Underground springs with *Sphagnum* housed *Hydroporus ferrugineus* (Figure 82), *H. obsoletus*, and *H. longicornis* (Figure 83). Leng (1913) reported **Parnidae** and **Elmidae** (Figure 84) in *Sphagnum* (Figure 1) bogs.

Reichle (1967) considered temperature and humidity to be the most important variables influencing the pselaphid beetles in bogs. These beetles respond to saturated humidities of 95-100%, and these match the conditions found among the interstices created by the mosses. The temperature stratification created by the mosses could explain the differences in species at different **seral stages** (stages in succession).

For the five species of pselaphids Reichle (1967) studied, these preferences were *Bythinopsis tychoides*, mean 21.5 ± 0.81 , range 25.9 - 15.3°C ; *Decarthron defectum*, 28.5 ± 0.55 , 31.4 - 24.0 ; *Pselaphus bellax* (Figure 85), 19.5 ± 0.86 , 24.7 - 13.0 ; *Reichenbachia borealis* (Figure 86), 21.0 ± 0.99 , 26.2 - 14.4 ; and *Rybaxis clavata* (Figure 87), 28.3 ± 0.41 , 29.9 - 25.1 . These preferences correlated well with the natural conditions of the microhabitats where they resided in the New York bog.

To these species, a report from the New York Entomological Society (Anonymous 1925) added the pselaphid *Pselaphus erichsoni* and the staphylinid *Boreaphilus henningianus*, cohabiting in a New York, USA, bog with *Bythinopsis tychoides*. Mr. Nicholay, at that same meeting, recommended using sifting to locate the **Coleoptera** in such habitats.

Odonata – Dragonflies and Damselflies

The **Odonata** are commonly seen flying about bogs. These strong fliers can easily migrate there. Boudot and Jacquemin (2002) identified 20 species of **Odonata** as tyrphobionts in France. Larson and House (1990) found that **Odonata** dominated, along with **Chironomidae** (**Diptera**; Figure 15), in the large, stable, vegetated pools. With two or more years in their naiad stage, the **Odonata** are important consumers in this habitat and may be a major factor in the insects that survive there. These dragonflies included *Aeshna subarctica* (Figure 88), *Somatochlora arctica* (Figure 89), *Leucorrhinia dubia* (Figure 90), and *Somatochlora alpestris* (Figure 91). The bog habitat influences these dragonflies by its strong *pH* fluctuations, low secondary productivity, few vertical plant structures (needed for emergence), and the isolation of bogs from each other (Dreyer 1988). Goffart and Fichet (2003) observed female *Aeshna subarctica* laying eggs (Figure 88) by inserting them into *Sphagnum* (Figure 1) at the water surface. Sahlén *et al.* (2004) found that *Aeshna subarctica elisabethae* from central and eastern Europe was "strictly" related to *Sphagnum* habitats.

Figure 90. *Leucorrhinia dubia*, a prominent predator in bogs. Photo by L. B. Tettenborn through Creative Commons.

Michiels and Dhondt (1990) observed dragonflies (*Sympetrum danae* – Figure 92) during their egg-laying activities in bogs. This species typically oviposits in flight while still paired in copulation. This behavior seems to make them subject to frog predation – those that were post-

tandem were attacked less frequently by the frogs. The females seemed to prefer *Sphagnum* (Figure 1) as a substrate for their eggs. They avoided warmer sites and often chose sites that already had ovipositing females on them. Michiels and Dhondt reported several threatened and potentially threatened *Odonata* species living in these diminishing habitats. These included *Nehalennia speciosa* (Figure 94), *Coenagrion johanssoni* (see Figure 93), *Aeshna caerulea* (Figure 95), *A. crenata*, *A. subarctica elisabethae* (Figure 88), *Somatochlora arctica* (Figure 89), and *S. alpestris* (Figure 91). In northern Europe where the habitat is common, these species, except *N. speciosa* and *A. crenata*, are likewise common.

The ground cricket *Pteronemobius* sp. (Figure 96) not only eats bryophytes, but also punctures *Sphagnum* leaves with its ovipositor to place its eggs in the resulting cavity (Vickery 1969).

Figure 96. *Pteronemobius heydenii*, a genus of cricket that eats bryophytes and punctures *Sphagnum* leaves to lay its eggs. Photo through Flickr Creative Commons.

Diptera – Flies

If you have ever walked through a forest surrounding a bog on a humid summer evening, you probably have not forgotten the experience of blood-giving. Mosquitoes are not typical bryophyte fauna, but in bogs *Aedes excrucians* (Figure 97) occurs in bog pools and occasionally among the *Sphagnum* (Figure 1) mosses there (Elgmork & Sæther 1970).

Figure 97. *Aedes excrucians* larvae, bog pool dwellers. Photo by Donald S. Chandler, with permission.

The **Tipulidae** (Figure 98) often deposit eggs and live as larvae and pupae among the peat mosses. *Tipula* (Coulson 1962; Freeman 1968) and *Dolichopeza* (Byers 1961) also feed on the mosses. The moss-mimicking tipulid *Phalacrocer* *replicata* feeds on *Sphagnum* spp. (Clymo & Hayward 1982). Other tipulid species burrow into *Sphagnum* (Figure 1) spp.

But bogs often attract human traffic for berry picking and other interests. This traffic can be detrimental to these developing **Diptera**. *Molophilus ater* (Figure 99) (**Limoniidae**) numbers are lower among the peat along a path than in adjacent areas (Duffey 1979). These limoniid crane fly adults seem to spend more time where there is vegetation than on bare ground, although they seem to prefer the bare ground for laying eggs. This same preference for egg laying is not true for large bare areas. Unfortunately, larvae are often crushed along the paths, especially those near the surface.

Figure 98. **Tipulidae** adult, a common family in bogs. Photo by Bob Armstrong, with permission.

Figure 99. **Molophilus ater** adult, a species negatively affected by bog traffic. Photo by James K. Lindsey, with permission.

As in most aquatic moss habitats, **Chironomidae** (Figure 15) are important contributors to the fauna (Muttkowski 1912; Larson & House 1990). Smirnov (1961) did not find any abundant species in *Sphagnum* (Figure 1) bogs to specialize on a food group, but one chironomid, *Psectrocladius psilopterus*, was the only species to eat submerged *Sphagnum*; even so, it ate primarily algae.

Other Insects

The moisture available within a *Sphagnum* habitat, perhaps made safer by the antibiotic properties of the moss, provides a suitable habitat for nests of *Myrmica ruginodis* (Figure 100-Figure 101) and *Formica picea* (Figure 102) (Matthey 1971). These ants also feed on the mosses (Plitt 1907) and become major predators when the bog dries up (Grdović & Sabovljević 2008).

Figure 100. **Myrmica ruginodis** pupa among mosses. Photo by James K. Lindsey, with permission.

Figure 101. **Myrmica ruginodis** adult amid mosses. This species makes its nest of *Sphagnum* fragments. Photo by James K. Lindsey, with permission.

Figure 102. **Formica picea** adult, a species that makes nests of *Sphagnum*. Photo by April Nobile <www.antweb.org>.

On one fortunate adventure into a Michigan, USA, fen I had the privilege of watching ants on one of their nests on a windy day (Figure 103). The light-weight *Sphagnum* pieces were flying off the nest faster than they could grab new ones and repair the nest. This of course created great activity among the ants (Figure 104).

Figure 103. Ant nest in *Sphagnum* in a Michigan fen. Photo by Janice Glime.

Figure 104. Close view of ants repairing nest of *Sphagnum* in a Michigan fen as its bits of *Sphagnum* are being scattered by wind. Photo by Janice Glime.

A number of terrestrial insect types can be found in bogs and fens as well, including crickets and grasshoppers (Vickery 1969), caterpillars of moths (Chapman 1894), and aphids in the genera *Myzodium* (Figure 105) and *Muscaphis* (Figure 106) (Gerson 1969). But aquatic and semi-aquatic types occur there as well, including the biting midge *Forcipomyia* (Figure 107) (Oldroyd 1964) and mayfly naiads (Richardson 1981).

Figure 107. *Forcipomyia* sp. larvae, a biting midge that lives among mosses in bogs. Photo by Tom Murray, through Creative Commons.

Although some of the insects eat *Sphagnum*, Danks and Rosenberg (1987) report that most species in Canadian bogs are generalists. Flannagan and Macdonald (1987) likewise found the **Ephemeroptera** and **Trichoptera** of Canadian peatlands to be generalists. They suggested that the ability for some insects to survive in temporary pools provided adaptations that also permitted them to live in other wet habitats such as peatlands. Mayfly naiads even use *Sphagnum* species for "nests" (Richardson 1981).

Lakes and Ponds

Floating bryophytes can be abundant in small lakes and ponds. The thallose liverwort *Riccia fluitans* (Figure 108) can form dense 3-d mats that provide a protective network. The spaces formed house numerous invertebrates in these floating habitats (Armstrong 2014).

Needham (1901) found layers of shed exuviae of the dragonfly *Gomphus exilis* (Figure 109), with *G. spicatus* mixed in, among mosses on logs at the edge of Little Clear Pond, suggesting the mosses created a preferred site for emergence.

Figure 108. *Riccia fluitans*, home for numerous insects in the floating mats. Photo by Jan-Peter Frahm, with permission.

Figure 109. *Gomphus exilis* female, a species that uses mosses for emergence. Photo by Sheryl Pollock, with permission.

One of the unusual habitats at the edge of lakes is the **moss ball**. Moss balls generally begin on a small pebble that gets moved back and forth across the shoreline as the water gets blown onto the shore and recedes. These are able to develop a special fauna of *Asellus aquaticus* oligochaetes, and leeches on balls formed by *Fontinalis antipyretica* (Figure 10) and *Drepanocladus sendtneri* (Figure 110), but insects were not mentioned (Luther 1979 in Gerson 1982).

Figure 110. *Drepanocladus sendtneri*, a moss-ball former that is inhabited by invertebrates. Photo by Michael Lüth, with permission.

Floating plants provide a habitat that is constantly wet, yet does not require breathing under water. Plants such as those in the flowering plant family Lemnaceae (duckweeds) have their own fauna of insects. And in some lakes and ponds, the floating thallose liverwort *Ricciocarpus natans* (Figure 111) may occur with the duckweeds. In these habitats one might find the springtail *Sminthurides aquaticus* (Figure 112) that eats from the surface, the beetle *Tanysphyrus lemnae* (Figure 113) that completes its entire life cycle in only two weeks on *Lemna* (Figure 113), but it is not yet known from *Ricciocarpus*, and *Mesovelia mulsanti* (Figure 114), a bug known as the water treader, crawling on the surface and in depressions on the surface of this floating habitat (Scotland 1934). The liverwort *Ricciocarpus natans* is also capable of rearing the dipteran *Phytoliriomyza mesnili* (Agromyzidae) (Spencer 1990), but it can pupate on more occasionally inundated species such as *Riccia beyrichiana* (Figure 115) and feed on this and other terrestrial bryophytes (Hering 1966).

Figure 111. *Ricciocarpus natans*, home for springtails and other surface dwellers. Photo by Jan-Peter Frahm, with permission.

Arctic and Alpine

In investigating alpine streams of New Zealand, Suren (1993) found that streambed stability strongly influenced the bryophyte distribution. These communities are dominated by **Nematoda**, **Oligochaeta**, **Copepoda**, and **Chironomidae** (Figure 15). These differed in fauna from bryophytes outside New Zealand, particularly certain families of **Ephemeroptera**, **Plecoptera**, and **Trichoptera** (EPT) that are also present elsewhere in New Zealand. Nevertheless, the invertebrate densities within the bryophytes are higher above treeline than below. The invertebrate densities are higher among bryophytes that have a high periphyton component compared to those with a higher detrital component.

In the alpine area of the South Island of New Zealand, Suren (1988) found that the dominant bryophyte dwellers are the stoneflies *Zelandoperla* (Figure 18) and *Zelandobius* (Figure 19) and the midges (**Chironomidae**, Figure 15). The mosses had 5-15 times as many invertebrates as the rocky areas, but these moss-dwelling invertebrates also include nematodes, mites, copepods, ostracods, and other non-insect invertebrates. The most common mayflies are restricted to rocky areas.

In the Southern Alps of New Zealand, Cowie and Winterbourn (1979) found 44 species of invertebrates among the mosses. These are mainly immature stages of insects, with the fauna varying by moss; the moss species reflects differences in habitat. *Fissidens rigidulus* (Figure 116) grows in the torrential middle channel of the stream and supports *Zelandoperla fenestrata* (**Plecoptera**; see Figure 18), *Zelolessica cheira* (**Trichoptera**; see Figure 117-Figure 118), *Empididae* (**Diptera**; Figure 21) and the ever-present **Chironomidae** (Figure 15). Among the clumps of *Pterygophyllum quadrifarium* (Figure 119) in the saturated inner spray zone Cowie and Winterbourn found *Austroperla cyrene* (**Plecoptera**), and **Helodidae** (**Coleoptera**) as the most abundant species, along with the flatworm *Neppia montana*. *Cratoneuropsis relaxa* (Figure 36), in the outer spray zone, was not a good insect habitat, housing primarily the isopod *Styloniscus otakensis*. Water Saturation, flow rates, and available detritus as a food source seem to have the greatest influence on the locations of these insects.

Robinson *et al.* (2001) studied the glacial streams of the Swiss Alps. These streams experience strong seasonal changes in water chemistry resulting from the seasonal changes in glacial melt, especially in water turbidity, particulate phosphorus, and conductivity. The macroinvertebrates likewise vary seasonally, with winter macroinvertebrate taxon richness being 2-3 times as high as that in summer. These same differences are also reflected in higher numbers and biomass in winter. Although taxa are not delimited by substrate in this study, many of the dominant taxa are species known as common bryophyte inhabitants.

Diptera, common among temperate streams, are even more common in Alaskan streams (Oswood 1989). **Plecoptera** and **Ephemeroptera** are next in abundance, but **Trichoptera** are somewhat rare. The **Hemiptera**, **Odonata**, **Megaloptera**, **Coleoptera**, net-spinning caddisflies, burrowing mayflies, and the stoneflies **Pteronarcyidae**, **Peltoperlidae**, and **Perlidae** are rare or absent. On the other hand, the ever present **Chironomidae** (**Diptera**; Figure 15) and **Nemouridae** (**Plecoptera**) actually increase from south to north in the northern hemisphere.

A similar predominance of **Chironomidae** (Figure 15) is seen in the European Central Alps – comprising 90-95% of the emergence (Füreder *et al.* 2005). As in Oswood's (1989) Alaskan study, **Ephemeroptera**, **Plecoptera**, and **Trichoptera** comprised much fewer numbers. Füreder *et al.* (2001) considered seasonal shifts from harsh summers to less severe autumn and winter conditions in the Tyrolean Alps, Austria, to affect the insect life history patterns and maintain a relatively high insect diversity and productivity in glacier-fed streams. As in glacial streams, the individual alpine streams of the French Pyrénées seem to differ greatly in diversity, displaying distinct benthic macroinvertebrate communities. Within a stream, the 15 most abundant taxa were consistently more stable and persistent from one year to the next than was the entire stream community (Brown *et al.* 2006).

Miller and Stout (1989), working in Alaska, suggested that to be so successful the dipterans that compose the most numerous and variable taxa in the Arctic must have variable **diapause** (period of suspended development; state of physiological dormancy), ability to grow in cold waters, and good dispersal powers.

Disturbance

Disturbance greatly reduces the number of invertebrates, and in some cases the bryophytes, on stones in streams (Englund 1991; Parker & Huryn 2006). Small stones rarely have bryophytes (Slack & Glime), except when they are embedded in the substrate (Englund 1991). Rock size likewise affects the diversity of stream insects (Hart 1978). In Englund's study, following disturbance, several invertebrate taxa increased their density on moss-covered undersides of over-turned stones. The undisturbed moss-covered rocks acquired increased density of invertebrates as a result of the disturbance. On the other hand, on disturbed rocks recovery of lost mosses [*Fontinalis dalecarlica* (Figure 16), *Hygrohypnum* (Figure 120-Figure 121)], and hence invertebrate inhabitants, was poor even 14 months after the stones were overturned.

Figure 120. *Hygrohypnum ochraceum* habitat, a genus that can have poor recovery after disturbance, resulting in loss of insects. Photo by Dick Haaksma, with permission.

Figure 121. *Hygrohypnum ochraceum*, home to many insects. Photo by Michael Lüth, with permission.

In an Alaskan stream, Parker and Huryn (2006) attributed the high macroinvertebrate density in a spring stream to the density of bryophytes there. That biomass was more than 1000 times the density of the mountain stream where disturbance among the loose rocks was great during spring melt.

Disturbance can take the opposite form as well. During the dry season, aquatic insects must find a place of refuge that provides sufficient moisture, or go dormant. In a first-order stream in the Atlantic Forest, Brazil, Rosa *et al.* (2011) found that Chironomidae dominate in both the rainy and dry seasons, but that in the rainy season the Ceratopogonidae are second, whereas in the dry season it is the annelid family Naididae that is second. Rosa and coworkers concluded that the bryophyte habitat provides refuge during spates, minimizing downstream movement of the invertebrate fauna. The density of the fauna is much greater during the rainy season, but the diversity is similar.

Retention

Restoration is not always friendly to mosses. In a headwater stream, the moss cover declined dramatically following restoration (Muotka & Laasonen 2002). This resulted in increases of insects only among the algae-eating scrapers. The mosses were an important retentive feature

for macroinvertebrates, but the restoration techniques knocked them loose from numerous locations, favoring the growth of algae.

Colonization

The rapidity of invertebrate recolonization of mosses can be amazing. Maurer and Brusven (1983) found that insects colonized insect-free *Fontinalis neomexicana* (Figure 4) to capacity within one week. The moss substrate had 5-30 times the densities of insects compared to the mineral substrate. As in many streams, larvae of midges (Chironomidae, Figure 15) were most abundant. Thienemann (1936), in his enumeration of alpine Chironomidae, commented on the importance of mosses as a habitat.

Korsu (2004) found that the restoration procedure in one Finnish stream destroyed almost half of the bryophytes and invertebrate densities plummeted. But recolonization was rapid. The disturbed area was recolonized within two weeks and peak numbers were reached within one month. Korsu found that recovery was especially fast in winter, with bryophytes playing a major role. It is interesting that the density of insects on bryophytes was higher after the restoration than before. The mayfly *Baetis* (Figure 8) had a negative correlation with the bryophytes before restoration, but afterwards (within 1 day!) it had a positive correlation. A similar response occurred for *Hydropsyche siltalai* (Figure 122). Korsu concluded that bryophytes provided refugia during the disturbance and remained a shelter long afterwards.

Figure 122. *Hydropsyche siltalai* larva, a species that increased in numbers after restoration of a stream in Finland. Photo by Urmas Kruus, with permission.

Experimental studies on colonization of mosses are relatively rare. Some of these have been discussed earlier under Artificial Mosses (Chapter 11-1). Maurer and Brusven (1983), however, designed a study using live *Fontinalis neomexicana* (Figure 4) in an Idaho, USA, river. After removing all the insects, they trimmed the moss clumps into 40 X 15 cm plots and arranged them in a natural streambed in five staggered rows with three clumps per row, as well as two comparative samplings. After three weeks of colonization, moss clumps were collected in nylon organdy net (250 µm mesh) to keep insects intact. Insects were removed by washing and hand picking. It

took only one week for insects to reach carrying capacity of the mosses (compared to controls)! The caddisfly *Micrasema* sp. (Figure 123) and mayfly *Dipheter hageni* (= *Baetis parvus*; Figure 124) were especially prevalent among moss clumps during the study. At the same time, the moss cover did not change the insect densities in the underlying hyporheic zone.

Figure 124. *Dipheter hageni* naiad, common among *Fontinalis neomexicana* in Idaho. Photo by Donald S. Chandler, with permission.

Maurer and Brusven (1983) found that the **Ephemeroptera** were the most abundant in both test and control clumps, with **Diptera**, **Trichoptera**, **Coleoptera**, and **Plecoptera** following in that order. The **Chironomidae** (Figure 15) made up ~94% of the **Diptera**. The riffle beetle *Cleptelmis ornata* (Figure 125) was a slow colonizer, reaching carrying capacity only after 4-6 weeks.

Figure 125. *Cleptelmis ornata* adult, a slow colonizer of bryophytes. Image modified from Biodiversity Institute of Ontario, through Creative Commons.

Mackay and Waters (1986) found that mosses provided suitable sites for the **Hydropsychidae** (net-spinning caddisflies; Figure 3) downstream of impoundments. They suggested that the mosses and algae provided suitable sites for attachment of their nets and the location benefitted from the settling effect of the impoundment on abrasive sand.

Streams suffer natural disturbance. In two North Swedish woodland streams nearly 17% of the moss-covered stones were overturned in just a few years (Englund 1991). In experiments, overturning rocks with mosses resulted in a reduction of both ash-free dry weight and diversity. On the other hand, three out of 16 taxa actually increased density on the underside of the overturned stones, living among the buried mosses. All the other taxa decreased in density. Even after 14 months the mosses and invertebrate populations had not recovered.

As already noted, Gurtz and Wallace (1984) found that presence of mosses increased the density of taxa following clear cutting surrounding a southern Appalachian Mountain stream. But disturbance resulting from the insecticide fenitrothion on bogs did not have as favorable a result (Fairchild & Eidt 1993). The poison caused a reduction in insect emergence for the next 6-12 weeks, with the **Chironomidae** (Figure 15) and **Ceratopogonidae** (Figure 126) experiencing more than 50% reduction for at least 1 month after the treatment. Since bog pool insects carry the nutrients to land, this nutrient transfer diminished and more nutrients accumulated in the bog pools.

Figure 126. *Bezzia* larva, in a family (**Ceratopogonidae**) that is quickly reduced by fenitrothion in bogs. Photo from <www.dfg.ca.gov>, through public domain.

It is interesting that in a study of Swedish streams, Malmqvist and Hoffsten (2000) found a negative correlation between macroinvertebrate richness and moss (*Fontinalis* – Figure 10) coverage. In a glacial river in Iceland, Gislason *et al.* (2001) found that distance from glacier, altitude, bryophyte biomass, and Pfankuch Index of channel stability explaining 31% of the variability in the macroinvertebrate data. The **Chironomidae** (Figure 15) predominated, but **Simuliidae** (Figure 35), **Plecoptera** (Figure 28-Figure 31), and **Trichoptera** (Figure 123) were present in low numbers.

In New Zealand alpine streams, bryophytes were confined to stable substrates (Suren 1991a). Suren (1988) found a negative effect on **Collembola** (Figure 45) when real mosses were replaced by artificial mosses in the high

alpine streams of the South Island of New Zealand. Among those moss-inhabited substrates, *Limonia hudsoni* (see Figure 22) and *Zelandoperla* sp. (Figure 18) were typically associated with bryophytes (Suren 1991a).

Not all bryophyte growths bring a positive recovery of the insect fauna. In the Kuparuk River, Alaska, USA, fertilization by phosphorus encouraged the growth of mosses after eight years of increased phosphorus. Persistence of the mosses had both positive and negative effects on the insect populations. It prevented the recovery of *Ephemerella* (Figure 9) (Slavik *et al.* 2004) and midge (Chironomidae, Figure 15) taxa, including the tube-building *Orthocladus rivulorum* (Figure 127-Figure 128) that had been affected by the shifts in primary producers. This shift included the loss of epilithic algae due to human activity, but they subsequently returned within 2-3 years. Once the bryophytes became established, they persisted, changing the morphology of the stream bottom.

Disturbances that remove mosses can greatly affect the invertebrate fauna. Gurtz and Wallace (1984) found that moss (*Hygroamblystegium tenax* – Figure 2) density and leaf detritus were the most important characters determining abundance of aquatic insects following a disturbance. Following clearcutting, the greatest increase in taxon density in the stream that drained the clear-cut watershed occurred in the moss-covered rock face compared to any other substrate. Moss habitats experienced increases of the shredder stonefly *Amphinemura wui* (Figure 13), a response that Gurtz and Wallace attributed to the accumulation of particulate matter

by the moss. The **Baetidae** mayflies likewise increased, experiencing their greatest increase among mosses where there was also the greatest increase in number of diatoms. But the chironomid *Eukiefferiella* spp. (Figure 129) showed the sharpest increase among the insects, occupying mosses on the rock face.

Figure 129. *Eukiefferiella* (arrow) on *Nesameletus ebop-haupapa*. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Forestry practices for logging and drainage often have considerable impact on the bryophytes and their inhabitants. In a small headwater stream where *Fontinalis dalecarlica* (Figure 16) formed the dominant habitat in riffles, forestry disturbances by ditch construction changed these mossy habitats to sand riffles (Vuori & Joensuu 1996). Transplanted mosses in the disturbed sites accumulated considerably more inorganic matter than did undisturbed controls. Subsequently, the invertebrate richness was significantly lower as well. The mosses at the control site supported a dominance of shredder stoneflies whereas the disturbed site was dominated by blackflies (*Simuliidae*; Figure 35).

Pollution Effects

In addition to physical disturbances of flooding and human activities, pollution affects both the bryophytes and their fauna. Winterbourn *et al.* (2000) looked for effects on the food chain in New Zealand streams where mosses were a significant component. Despite the lowering of pH and increases in aluminium and iron in the water, there was not a biomagnification effect in the food web. The metal concentrations in the invertebrates was considerably lower than that in the mosses. It is possible that the bryophytes were able to sequester the metals, thus protecting the invertebrates from those that might have increased in their algal and detrital food.

Geographic Differences

If one were to examine bryophytes in New Zealand streams, the fauna would be significantly different from that of bryophytes in the North Temperature Zone. In New Zealand, instead of the typical mayflies, stoneflies, and caddisflies, the fauna is dominated by nematodes, oligochaetes, and copepods, with the only abundant insect being **Chironomidae** (Figure 15) (Suren 1993). In fact, other types of insects comprise less than 2% of the

invertebrate fauna. This is not due to a difference in bryophytes, but rather the absence of families that typically inhabit the North Temperate bryophyte habitat.

By contrast, Egglisshaw (1969) found that mayflies occupied up to 16% of the invertebrate fauna of Scottish streams. Suren (1993 – updated in Table 2) reviewed studies from other parts of the world and found that the most important bryophyte insects were **Plecoptera** (**Nemouridae**, **Perlodidae**, **Leuctridae**, **Chloroperlidae**),

Ephemeroptera (**Baetidae**, **Heptageniidae**, **Ephemerellidae**), and **Trichoptera** (**Brachycentridae**, **Glossosomatidae**, **Lepidostomatidae**, **Limnephilidae**, and **Sericostomatidae**). These families mesh well with my own studies in bryophytes of Appalachian Mountain streams, eastern USA, except for **Perlodidae**, **Heptageniidae**, and **Sericostomatidae**. Others (**Baetidae**, **Lepidostomatidae**, **Limnephilidae**) were uncommon in the Appalachian streams.

Table 2. Percentages of the contributions by invertebrate taxa > 0.1% of the total invertebrate density in ten studies on invertebrate fauna of stream bryophytes: 1) Percival & Whitehead 1929 from a) thin moss & b) thick moss; 2) Percival & Whitehead 1930; 3) Frost 1942; 4) Egglisshaw 1969; 5) Stern & Stern 1969; 6) Glime & Clemons 1972; 7) Lindegaard *et al.* 1975; 8) Cowie & Winterbourn 1979; 9) McKenzie-Smith 1987; 10) Smith-Cuffney 1987 from a) unshaded and b) shaded streams; 11) Suren 1991a from a) unshaded and b) shaded streams; 12) Vlčková *et al.* 2002; - = not reported with abundances > 0.1% total density. (from Suren 1993). The last two columns indicate the number of studies presented here in which the taxon was represented by >0.1% and the average percent of the community the taxon represented.

Summary

Bryophytes increase the number of niches for occupancy by aquatic insects. They increase surface area, culture algae, collect detritus, provide high prey density, and provide a refugium against the current. At the same time they permit the insects to live in the greater oxygen provided by the rapid flow, saving them ventilation energy. Feeding groups of these insects include collector-gatherers, scrapers, shredders, collector-filterers, and engulfers, with collector-gatherers typically being most abundant.

Altitude and latitude are important determinants of both the bryophytes and the associated fauna. Thickness of the moss mat also is important in determining the fauna, with thicker mats creating more niches.

The most common orders of moss dwellers in streams are **Ephemeroptera** (mayflies), **Plecoptera** (stoneflies), **Trichoptera** (caddisflies), and **Diptera** (flies). Streams in the Arctic and alpine habitats lack most of the **Trichoptera** (caddisflies), but otherwise have similar order representation among stream bryophytes, with even more **Chironomidae**. The associations of insects with the species of bryophytes may be a consequence of both needing similar conditions, as exemplified by the similarities of insect

communities on the moss *Fontinalis dalecarlica* and the liverwort *Scapania undulata*, two species that often occur side-by-side. Nevertheless, bryophytes do not make good surrogates for the stream inhabitants, correlating primarily with nutrient levels and habitat heterogeneity, whereas insects correlate more with stream size, pH, and water color. In fact, clumps of string and other artificial mosses seem to attract communities similar to those on real mosses. On the other hand, the presence of bryophytes will usually indicate a high density of insects.

The bryophytes may serve as a refuge for insects in winter when non-bryophyte plants are absent and the bryophytes are common in fast water where freezing is less common. The bryophytes furthermore serve as a location of collected detritus and a site for winter diatoms.

Within the clump of bryophytes of a stream one can find a detritus zone with little or no flow, a water zone within the moss clump, and a **madicolous** zone just above the water surface but where the bryophytes are still wet. And at the surface of the moss, but submerged, the highest water velocity and therefore the most oxygen exist.

Waterfalls may have specialists that live among the wet mosses, avoiding the torrent itself. Springs often have dense bryophyte cover. **Chironomidae** here

respond to temperature; many insects also respond to nutrient concentrations or pH. Depth of streams, pools, and springs can influence insect community composition, in part because of temperature and oxygen gradients. Bogs and fens have both pool and dry hummock conditions, contributing a wide range of niches that differ in moisture, temperature, and light. Consequently, there is a wide variety of insects, and even flying adults make use of the mosses for egg deposition, mating, and resting. More **Collembola** (springtails) are found in bogs and fens than in most aquatic habitats. **Coleoptera** (beetles) and **Odonata** (dragonflies and damselflies) likewise are common in these habitats. **Hymenoptera** (ants, bees) are absent from streams and lakes, but in bogs and fens ants build nests from the *Sphagnum*. Little seems to be published about insects associated with lake bryophytes. Some of the beetles are associated with floating *Riccia fluitans* and *Ricciocarpos natans* in shallow lakes. In one case, the latter is inhabited by the leaf miner *Phytoliriomyza mesnili*.

Disturbance immediately reduces the number of invertebrates, but if mosses remain or are replaced, they are quickly recolonized by remaining drifting organisms or from egg-laying. Attempts at restoration can cause the bryophytes to break loose and reduce the insect fauna.

If one compares the bryophyte fauna around the world, differences in relative abundance of the orders are apparent. These differences are often the result of evolutionary and distributional differences. For example, the families of the insects are different in Australia and New Zealand from those in North America.

Acknowledgments

My gratitude goes to my sister, Eileen Dumire, for her candid suggestions for improvement of this chapter. I appreciate all the photographers who have kindly given me permission to use their images and to those who have contributed their images to Creative Commons.

CHAPTER 11-4

AQUATIC INSECTS: HEMIMETABOLA – COLLEMBOLA AND EPHEMEROPTERA

Figure 1. *Serratella ignita*, a common moss dweller. Photo by J. C. Schou, with permission.

COLLEMBOLA – Springtails

This group was traditionally considered to be one of the insect orders, but more recently they have been classified in the class **Entognatha**. **Collembola** are quite small and lack wings. They have three pairs of legs, like insects, but have only six abdominal segments (Thorp & Covich 1991). The young (**nymphs**) resemble the adults, changing to adults by breaking their outer covering (**exoskeleton**) and discarding it, then expanding while the new exoskeleton is still soft.. They are unique in having a **furcula** (Figure 3-Figure 5) that forms the spring and a **collophore** (cylindrical ventral tube; Figure 3, Figure 6). When at rest, the furcula bends forward under the abdomen and is held in place by the **tenaculum** (Figure 3), a midventral structure that clasps the furcula. The springtail accomplishes rapid distance movement by releasing the furcula, which springs backward, propelling the springtail forward several centimeters. This can be used even on the

water surface. Some can be seen bouncing around on the snow in winter.

Figure 5. *Dicyrtomina ornata* ventral side showing furcula. Photo by Jan van Duinen, with permission.

Collembola can be sexual or parthenogenetic. Sexual males deposit **spermatophores** in clusters or individually. Females stimulate this deposition by producing pheromones (Waldorf 1974). But among many of the soil *Collembola*, presumably including bryophyte dwellers, females lay eggs (Figure 7-Figure 8) that have not been fertilized, *i.e.*, are produced **parthenogenetically**. Since few reproductive studies exist, I cannot generalize of aquatic bryophyte dwellers. What makes this reproduction so interesting is the role of symbiotic bacteria in the genus *Wolbachia* (Werren *et al.* 1995). These bacteria live in and reproduce in the female reproductive organs and eggs of

the springtail. It is these bacteria that control the parthenogenesis in the colonized species. That is, they feminize the springtails.

Figure 7. *Collembola* eggs. Photo by Jan van Duinen, with permission.

Figure 8. *Sminthurides* eggs in duckweed. Photo by Jan van Duinen, with permission.

The **Collembola** are predominately moist terrestrial organisms, but some can hop on the water surface (Figure 9) or live among wet mosses. Waltz and McCafferty (1979) considered only 10 species as semiaquatic and five as **riparian** (relating to bank of river or other moving water). The waxy cuticle (Chang 1966), coupled with small size, permits them to float on water. The **collophore** (ventral tube) serves a double function: absorption of water and respiration.

The **Collembola** seem to be particularly responsive to drawdown and drainage (Silvan *et al.* 2000). On older drained sites their numbers were up to 100 times as high compared to pre-drawdown. Other invertebrates were typically about ten times as high. The **Collembola** occurred mostly in the top 4 cm of the drained land.

Figure 9. **Collembola** (springtails) on water where they can jump about on the surface tension. Photo by Janice Glime.

In my search for information on the bryophyte-dwelling springtails, I was surprised to find so little that related to aquatic habitats. In my own studies in the Appalachian Mountain, USA, streams, I found representatives of eight families, albeit not frequently. The species in these collections were *Odontella lamellifera* (Figure 10) (**Brachystomellidae**), *Entomobrya griseoolivata* (Figure 11) and *Orchesella quinquefasciata* (Figure 12) (**Entomobryidae**), *Hypogastrura armatus* (see Figure 13), and *Schotella glasgowi* (**Hypogastruridae**), *Hydroisotoma schaefferi* (Figure 14), *Isotoma violacea*, *Isotoma viridis* (Figure 15), and *Isotomurus palustris* (Figure 16) (**Isotomidae**), *Pseudachorutes lunatus* (**Neanuridae**; see Figure 17), *Onychiurus subtenius* (**Onychiuridae**), *Sminthurides aquaticus* (Figure 18) (**Sminthuridae**), and *Tomocerus flavescens* (Figure 19) (**Tomoceridae**). Of these taxa, only *Isotomurus palustris* was present in more than two collections. Nevertheless, I recorded *Orchesella quinquefasciata* in North America for the first time (Toliver Run, Garrett County, MD) (Richard Snider, pers. comm.). The *Hydroisotoma schaefferi* was an atypical blind form from Little Bennett Creek, Montgomery Co., MD. Snider also found this species (not blind) in ponds surrounded with mosses in Michigan, USA (Snider 1967). It is likely that some of these springtails were living at the surface of emergent mosses. But the tiny size of these insects suggests they may have been missed in

collections using insect nets. Others may have "sprung" away from surface locations as the collector approached.

Isotomidae

The family **Isotomidae** was most frequently (almost exclusively among springtails) represented in the publications I found regarding bryophyte fauna. Among these, *Isotomurus palustris* (Figure 16) is most typically considered to be aquatic, although a few other species, including *Sminthurus aquaticus* (Figure 18), have names that suggest they are aquatic.

Isotomurus palustris (Figure 16) is able to float on the water because of their non-wetting waxy epicuticle composed of a lipid monolayer that is extremely impermeable to water (Beament 1960). But Noble-Nesbitt (1963) provided evidence that the presence of wax gives it **hydrofuge** (shedding water) properties. A cementing substance contributes to this hydrofuge ability. The cuticle, combined with surface hairs, provides this springtail with a protective air layer that both makes these springtails **unwettable** (repelling water) and makes them float. Springtails also are very sensitive to desiccation, so the protection by the cuticle is important.

The **collophore** is **wettable** (doesn't repel water) and doubles as both a respiratory and water-taking organ (Noble-Nesbitt 1963). The air layer on the surface also behaves as a **plastron** (breast plate breathing apparatus). These springtails also take water by mouth and this may additionally supply dissolved oxygen. I wonder if they ever get hiccups! This tubule, combined with their small size, would permit them to drink water from the leaves of emergent mosses.

But it appears that the cuticle may also play an important role in their locomotion on the water surface (Noble-Nesbitt 1963). In the water, the furcula is used as a spring, much as it is on land. On the water surface the insect actually walks, using only its limbs.

Isotomurus palustris (Figure 16) is **viviparous**, producing one egg at a time (Chang 1966). These eggs are carried internally and hatched inside the female with the nymph emerging from the genital pore. The female arches its body to permit the emerging nymph to reach the water surface. In observations on newborns of *Isotomurus palustris* (Figure 16) and *Folsomia fimetaria* (Figure 20), Chang found that the newborns stayed close to the mothers for the first two days. The young are able to float, walking on the surface tension with their **non-wetting** (repelling water) claws, but if they are forced to submerge they will sink. The cuticle does not develop until they spend time above water.

Figure 20. *Folsomia fimetaria*, a springtail whose newborns stay close to the mother for two days. Photo by Andy Murray, through Creative Commons.

Antennae are important in assessing the environment in both *Isotomurus palustris* (Figure 16) and *Folsomia fimetaria* (Figure 20). They are the sensory organ, often in consort with the post-antennal organ, that recognizes light intensity, wind direction, and heat. When one or the other of these organs is removed or cauterized, the springtails move about aimlessly or not at all, whereas those with both organs intact wiggle their antennae and exhibit a directional movement in response to the stimulus.

Some **Collembola** like it cold – *Anurida frigida* (**Neanuridae**) occurs under mosses on stones and on stones by melt-water brooks in the high alpine of Swedish Lapland (Fjellberg 1973). The greatest numbers of these were located under mosses that were wet by ice-cold meltwater. In the Nordic countries, *Agrenia riparia* prefers wet mosses, especially on lowland stream banks (Fjellberg 2007b)

Bog Springtails

These tiny creatures seem often to be overlooked, but a treatment of **Collembola** in Michigan, USA, indicates that many species can occur in bogs (Snider 1967):

Hypogastrura nivicola (**Onychiuridae**; Figure 21)

Isotoma viridis (**Isotomidae**; Figure 15)

Lepidocyrtus cyaneus (**Entomobryidae**; Figure 32)

Lepidocyrtus lignorum (**Entomobryidae**; Figure 22)

Lepidocyrtus unifasciatus (**Entomobryidae**)

Lepidocyrtus violaceus (**Entomobryidae**; Figure 23)

– in *Sphagnum*

Neelus minutus (**Neelidae**; see Figure 24)

Orchesella ainsliei (**Entomobryidae**)

Orchesella albosa (**Entomobryidae**)

Pseudobourletiella spinata (**Sminthuridae**; Figure 25)

Sminthurides aquaticus (**Sminthuridae**; Figure 18) – in *Sphagnum*

Sminthurides lepus (**Sminthuridae**)

Sminthurides malmgreni (**Sminthuridae**; Figure 26) – semi-aquatic habitats

Sminthurides occultus (**Sminthuridae**)

Sminthurides penicillifer (**Sminthuridae**; Figure 27)

Sminthurinus aureus (**Sminthuridae**; Figure 28)

Sminthurinus bimaculatus (**Sminthuridae**; Figure 29)

Tomocerus flavescens (**Tomoceridae**; Figure 19) – in *Sphagnum*

Greenslade *et al.* (2006) suggests that *Mesaphorura macrochaeta* may have been introduced to the Southern Hemisphere by human importations of soil and moss peat.

HEMIMETABOLA

The **hemimetabolous** insects are those with **incomplete metamorphosis**. Instead of a larva, they have a **nymph** or **naiad** stage that resembles the adult except for having reduced wings or only wing pads. They lack a pupa stage and pass directly from the nymph or naiad stage to the adult stage. Most of the aquatic Hemimetabola have a stage with gills and wing pads and are distinguished as **naiads**.

EPHEMEROPTERA – Mayflies

As in most of the names of insect orders, *optera* refers to wings. In the **Ephemeroptera**, *ephemera* refers to short-lived. Hence, these are insects that are short-lived in the winged, or adult, stage.

The immature mayflies, known as **naiads**, are all aquatic (Thorpe & Covich 1991). They can be distinguished by their three (two in some) long caudal filaments that are also present in the adults. They are most similar to the stoneflies (**Plecoptera** – see subchapter on Plecoptera in this chapter), but differ in having abdominal gills (lacking in middle abdominal segments of stoneflies) and typically three tails (caudal filaments), which always number two in stoneflies. Most of the naiads are herbivores and some eat bryophytes.

The mayfly naiads are largely night-active and appear most often in the night-time drift (Elliott 1967). Adult mayflies emerge from the naiad first as a **sub-imago** (also known as a **dun**; Figure 35-Figure 40), a stage that often becomes a nuisance to motorists (Figure 36) in the area because of the large numbers that meet their demise (Figure 37) on the windshields. To complete emergence they must climb so they can pump fluids into their new wings (Figure 41). The adult does not eat – in fact lacking mouthparts – and typically lives for only a few days.

Figure 35. *Baetis* male subimago emerging to adult. Photo by Jason Neuswanger at <Troutnut.com>, with permission.

Figure 36. Adult mayflies on emergence day. Photo by Jeff Reutter, through Ohio Sea Grant public domain.

In my own studies in the Appalachian Mountain streams, USA (Glime 1968, 1994), the **Ephemerellidae** was by far the most abundant of the mayflies. Frost (1942) reported the importance of the mayflies *Ephemerella* (*s.l.*) (Figure 45) and *Baetis* (**Baetidae**; Figure 35-Figure 40) among aquatic mosses, where they feed mostly on algae, but occasionally on bryophytes (Hynes 1961; Chapman & Demory 1963). Frost (1942) found about 530 mayfly nymphs per 200 g of mosses in Ireland. In a cool mountain stream of central Japan, Tada and Satake (1994) found that *Baetis thermicus* (Figure 38) and *Ephemerella* (*s.l.*) sp.

were more abundant among the moss *Platyhypnidium riparioides* (Figure 39) than in bare rock areas.

Figure 37. Mayflies that met their end on a travelling car during an emergence in August in Michigan, USA. Photo by Eileen Dumire, with permission.

Figure 41. Emerging **Ephemeroptera**. Mayflies live their immature lives as naiads in the water of streams and lakes. When they emerge as adults, they must climb, like these naiads, so they can pump up their wings once they have exited the naiad exuvia. Photo by Jason Neuswanger at <Troutnut.com>, with permission.

With such a dwarfed lifespan, finding a mate quickly is paramount. This is accomplished by flying in giant swarms, facilitated by coordinated emergence time. At this time, they are a nuisance for motorists and a feast for birds (Figure 42). Those females that survive deposit their eggs, often among mosses.

Figure 42. Hermit thrush (*Catharus guttatus*) with mayfly subimago in its beak, enjoying the brief period of emergence. Photo by Bob Armstrong, with permission.

Increased biomass of bryophytes may increase some insects while having no effect on others. Lee and Hershey (2000) found that a dense growth of the moss *Hygrohypnum* (Figure 43-Figure 44) following stream fertilization in Alaska increased the density of the mayfly *Ephemerella aurivillii* (Figure 45) but not *Baetis* (Figure 46). In the fertilized zone, these mayflies both grew larger, a fact Lee and Hershey attributed to the greater growths of epiphytic diatoms. Furthermore, although the density of *Ephemerella* increased with increased moss density, the highest drift ratios were in the unfertilized zone with lower moss density. In enclosure experiments, they found that bare rock, mosses, and artificial mosses had no effect on any taxa except *Ephemerella*. They considered that the *Ephemerella* benefitted from the increased complexity of the moss habitat.

Jones (1950) did extensive gut analysis of insects from the River Rheidol. Among the **Ephemeroptera**, none of the five species examined had fragments of the common moss *Fontinalis antipyretica* (Figure 47) in the gut. Detritus was the most common food. Gilpin and Brusven (1970) found six mayfly species with *Fontinalis* sp. in their guts, but these all amounted to less than 1% of the gut contents.

Figure 47. *Fontinalis antipyretica*, a moss found in the guts of some mayflies in the River Rheidol. Photo by Kristian Peters, with permission.

It is surprising to find such flattened, rock-adapted genera as *Heptagenia* (Figure 48) among mosses, but Muttkowski and Smith (1929) did find it several times among mosses in trout streams of Yellowstone National Park, USA.

Suborder Furcatergalia

Leptophlebiidae – Prong-gilled Mayflies

This is a family that lives in freshwater streams and lakes where the naiads eat detritus and algae (Leptophlebiidae 2013). Their length is up to 20 mm; they are **nocturnal** (active at night) and are poor swimmers, generally clinging to rocks. Only a few seem to live among bryophytes.

Paraleptophlebia (Figure 49) was a minor component of the bryophyte communities in my own Appalachian, USA, stream studies (Glime 1968). Maurer & Brusven (1983) found *Paraleptophlebia heteronea* (Figure 49) frequently in the clumps of *Fontinalis neomexicana* (Figure 79) in an Idaho stream. In their study of four Appalachian streams, Woodall and Wallace (1972) found this genus where there was moderate or slow current among decaying leaves, bark, and wood. Its food is predominately detritus (Chapman & Demory 1963).

Figure 49. *Paraleptophlebia* sp. naiad, a frequent dweller among *Fontinalis neomexicana*. Photo by Jason Neuswanger, with permission.

Macan (1957) found *Leptophlebia* (Figure 50) among mosses in Ford Wood Beck, UK. Berner (1959) described this genus as one that would live in submerged mossy banks and other quiet areas. The genus is negatively **phototactic** (movement of organism toward or away from source of light), explaining their presence in the secluded shade of streambank mosses. When it is time for the naiads to emerge into adults, they become positively phototactic and crawl upward onto sticks, logs, or other protruding structure, probably including emergent bryophytes.

Vuori *et al.* (1999) considered *Leptophlebia marginata* (Figure 50) to be among the dominant moss dwellers in the Tolvajärvi region of the Russian Karelia. Bengtsson (1981) found that *L. marginata* demonstrated a steady growth rate throughout winter, permitting it to thrive in such northern regions.

Figure 50. *Leptophlebia marginata* naiad on waterweed. Photo by Niels Sloth, with permission.

One advantage enjoyed by some members of this family is tolerance of somewhat low pH. Mayflies in general are indicators of fresh, unpolluted water. They do not generally tolerate extremes, low pH included (Raddum & Fjellheim 1988; Raddum *et al.* 1988; Braukmann 1992; Lingdell & Engblom 1995). Thus the streams that drain *Sphagnum* fens and bogs (Figure 51) are generally **depauperate** (lacking in numbers or kinds of species) of mayflies. However, this habitat is suitable for a few, including *Leptophlebia vespertina* (Figure 52) (Bauernfeind & Moog 2000). This intolerance of low pH may explain its relative rarity among bryophytes in the mid-Appalachian Mountain streams (Glime 1968).

In New Zealand *Austroclima sepia* (see Figure 53) frequently lives among mosses in small waterfalls (Winterbourn & Gregson 1981). Similarly, Towns (1987) reported this species along with *A. jollyae* and *Mauiulus luma* (Figure 54) as 72%, 13%, and 9%, respectively, of the fauna from mosses in rapid flow (where only 4 insect species lived!) on the Great Barrier Island, New Zealand.

Figure 54. *Mauiulus luma* naiad, a mayfly that lives among mosses in small waterfalls in New Zealand. Photo by Stephen Moore, Landcare Research, NZ, with permission.

In his study of the River Rajciana, Krno (1990) found a genus I have not encountered elsewhere – *Habroleptoides*. *Habroleptoides modesta* (Figure 55) is a bryophyte dweller in the river, but like many of the mayfly genera, it is unable to live among the wet mosses above the water level.

Figure 55. *Habroleptoides modesta* naiad, a mayfly that sometimes lives among bryophytes in rivers. Photo by Alfeo Busilacchio, with permission.

Caenidae - Small Squaregill Mayflies

The **Caenidae** are small sprawlers in quiet and sometimes stagnant water as well as streams (Caenidae 2014). They are adapted to the relatively low oxygen of silt.

Caenis (Figure 56) seems to prefer loose mosses (Percival & Whitehead 1929). Frost (1942) found that it was most likely to occur among mosses that had accumulated considerable silt. In the River Rajciana in Slovakia, *Caenis beskidensis* (Figure 56) lives among submerged bryophytes but is not found, like some mayflies, among the wet emergent bryophytes (Krno 1990). In the Appalachian Mountain, USA, streams naiads of *Caenis* were among the lesser of the moss inhabitants, appearing mostly among *Fontinalis dalecarlica* (Figure 69).

Figure 56. *Caenis lactea* naiad, a mayfly that prefers loose mosses. Photo by Niels Sloth, with permission.

Neophemeridae

The rare genus *Neophemera* (Figure 57) sometimes lives deep within submerged moss mats in rapid water in eastern North America (Berner 1959), including

Neophemera compressa (Figure 57) among mosses on submersed parts of trees (Berner 1956). The naiad moves slowly, but when it bends its 3 tails over its abdomen, then suddenly lashes them back, this action propels it forward (see Figure 60).

Figure 57. *Neophemera compressa*, an inhabitant of mosses on submersed parts of trees. Photo by Dana R. Denson, Florida Association of Benthologists, with permission.

In Australia, *Neophemera* (Figure 57) naiads live in protected parts of streams with slow to moderate flow where they hide among debris, plant roots, and mosses (Edmunds *et al.* 1976). These naiads are difficult to dislodge from the mosses, partly because they grip the mosses. The membranous respiratory gills are fragile and they need the protection that is provided by the fused, sclerotized **opercula** (gill covers) (Notestine 1994). This genus relies heavily on these gills for respiration.

Ephemerellidae – Spiny Crawlers

This family occurs throughout North America as well as the United Kingdom (Ephemerellidae 2014). These collector-gatherers occur where there is moving water, including lake shores subject to wave action, but seem to require reduced flow. They are able to live in fast water by accepting the protection of bryophytes.

When these mayfly naiads are threatened by a predator, they raise their three tails like a scorpion, arching them up and over their backs, making them appear larger (Ephemerellidae 2014). They will then project the tails forward to poke the enemy. Spines on the back of the abdomen (Figure 58) may contribute to their protection. One suggestion is that the spines help the mayflies hold their positions when attacked from behind by a predator.

This family takes advantage of the protection of the bryophyte habitat while modulating the oxygen and keeping its tuft of gills clean with its gill covers. When oxygen concentrations become too low, the **Ephemerellidae** move the gill covers (Figure 58) up and down to keep fresh water circulating across the gills (Figure 59) (Ephemerellidae 2014). Their bodies are somewhat flattened dorsiventrally and are adapted to crawling among the chambers of their mossy habitat. When they are in open water and need to move quickly, mayflies in this family flip their tails upward over their backs and down to act like a paddle (Figure 60), thrusting them forward.

Figure 58. *Ephemerella subvaria* naiad gill covers, closed over gills. Photo by Tom Murray, through Creative Commons.

Figure 60. *Ephemerella subvaria* naiad in a swimming position with its tails flipped upward. Photo by Bob Henricks, with permission.

Berner (1959) described some members of this family as living on the tops of rocks, deep within the moss. Arnold and Macan (1969) found that **Ephemerellidae** (Figure 58-Figure 64) were common among mosses in a

Shropshire Hill stream in the UK. In a study of the McKenzie River, Oregon, USA, Hawkins (1984) reported that 5 species [*Serratella teresa*, *C. hystrix* (Figure 61), *Caudatella cascadia* (now a synonym of *C. hystrix*), *C. edmundsi* (Figure 62), and *Drunella spinifera* (Figure 63)] out of 12 **Ephemerellidae** species were common among mosses, including *Fontinalis* sp. (Figure 79) and others. Gilpin and Brusven (1970) likewise found *C. edmundsi* among clumps of *Fontinalis*. Hawkins (1984) found those restricted to mosses were usually at upstream locations where the mosses were abundant. However, two moss dwellers [*Caudatella edmundsi* (100% moss usage - found only on *Fontinalis*), *Drunella spinifera* (54%)] were most abundant downstream, living among mats of the moss *Fontinalis* sp. For other species with more than 5% use of bryophyte habitats he found *Serratella teresa* (85%), *Caudatella cascadia* (46%), and *Caudatella hystrix* (22%).

Brittain and Saltveit (1989) found that river impoundments had "profound" effects on the **Ephemerellidae** (Figure 58-Figure 64) living there. Changes in temperature, discharge, flow patterns, food availability, and predator density all contribute to changes in living conditions for the mayflies. Increased growth of mosses and additional available substrata for periphyton below the dams often favor some of the **Ephemerellidae** while reducing suitable habitat for **Heptageniidae** (Figure 48). The mayflies living under these changeable regimes often have flexible life cycles or shorter periods of rapid growth with a long period of egg development that permit them to survive unsuitable periods.

Figure 61. *Caudatella hystrix* naiad, a common moss dweller in the McKenzie River, Oregon, USA. Photo by Bob Newell, with permission.

Figure 63. *Drunella spinifera* naiad. Photo by Bob Newell at <Troutnut.com>, with permission.

Percival and Whitehead (1929) considered mosses and algae to be the main food of the **Ephemerellidae** (Figure 58-Figure 64). Woodall and Wallace (1972) found *Eurylophella funeralis* (= *Ephemerella funeralis*, Figure 64) to be the most abundant *Ephemerella* species among mosses in the southern Appalachian Mountains, USA, and I found a similar relationship for *E. funeralis* and *E. temporalis* in the middle Appalachian Mountain streams (Glime 1968). The members of *Ephemerella* tended to avoid the heavily shaded hardwood stream where mosses and algae were scarce.

Figure 64. *Eurylophella funeralis*, a common mayfly among mosses in the southern Appalachian Mountain, USA, streams. Photo by Donald S. Chandler, with permission.

Brittain and Saltveit (1989) found that growth of mosses and associated periphyton below dams favored presence of **Ephemerellidae** (Figure 58-Figure 64). They reasoned that flexible life cycles permitted them to survive adverse conditions, including rapid nymphal growth and long period of egg development. Eggs typically form a ball (Figure 65).

Percival and Whitehead (1929) found *Eurylophella funeralis* (= *Ephemerella funeralis*) (Figure 64) to be the most abundant species of the *Ephemerella* genus group in their study of UK streams. The main foods of *Ephemerella* species are algae and mosses (Percival & Whitehead 1929; Jones 1949, 1950; Gerson 1969). This is convenient because this genus is common among mosses, but it also occurs on the pebbles on the bottom. Jones (1949, 1950) found that *Ephemerella* s.l. fed primarily on *Fontinalis* (Figure 47) and the alga *Ulothrix* (Figure 66) in calcareous (having dissolved chalk or limestone) streams of South

Wales. Among 14 specimens examined on 14 July the moss was the primary food, but they concluded that *Ephemerella* feeds on *Ulothrix* when it is abundant but switches to *Fontinalis antipyretica* (Figure 47) when the *Ulothrix* becomes scarce.

Figure 65. *Ephemerella* egg mass with debris stuck to it. Photo by Jason Neuswanger at <Troutnut.com>, with permission.

Figure 66. *Ulothrix*, food for *Eurylophella funeralis*. Photo by Yuuji Tsukii, with permission.

Reproduction in the mayflies involves swarming, a behavior that maximizes contact of males and females that typically live for only one day as adults. In *Serratella ignita* (Figure 67) this swarming occurs in the late afternoon and evening (Elliott & Humpesch 1980). The egg mass is a greenish ball. Once fertilized, eggs are laid in turbulent water, usually where there are mosses. The female flies upstream to deposit the eggs on the water surface. She then usually falls on the surface and is vulnerable to fish predation. The egg mass separates when it enters the water and each egg attaches to the substrate with its polar anchoring cap.

Figure 67. *Serratella ignita* naiad. Photo by J. C. Schou, through Creative Commons.

The family **Ephemerellidae** (Figure 58-Figure 64) seems to have bryological preferences, or preferences that match those of the bryophytes. They reach extremely high numbers among *Hygroamblystegium fluviatile* (Figure 68) in mid-Appalachian streams, but are nearly absent in *Fontinalis dalecarlica* (Figure 69) and *Scapania undulata* (Figure 70) in different streams (Glime 1968).

Figure 70. *Scapania undulata*, a leafy liverwort that has few of the typical moss-dwelling **Ephemerellidae**. Hermann Schachner, through Creative Commons.

D. N. Bennett (pers. comm. 19 April 2011) described her field experience with an aquatic entomologist, Bob Henricks. Henricks was attempting to distinguish between mosses and grasses, so she began looking at the inhabitants of the mosses. When the moss-covered rocks were removed from the stream, the insects began moving about and became more noticeable. There were often 40-50 **Ephemerellidae** naiads on a single moss-covered rock – determined to be *Hygroamblystegium*, probably *H. tenax* (Figure 71-Figure 72). The moss grew on and "under" the rock, and it was the submersed "under" portion that housed the many mayflies. She observed the naiads rolling up the algae from the moss leaf surface, starting at the leaf tip and moving to the stem.

Seasons

Seasonal differences in the life cycle stages spent in the water are often the key to success for these species. Timing differences in emergence times and hatching times can separate realized niches in closely related species. In the **Ephemerellidae** (Figure 58-Figure 64), the life cycle is typically one year with one brood per year (**univoltine**).

For example, *Serratella ignita* (Figure 1) has an annual cycle with the eggs spanning the winter in a dormant state, hatching in April and May in the River Endrick in Scotland (Maitland 1955). The naiads develop quickly, emerging in July and August, and adults typically lay eggs within 24 hours of emergence. These eggs are often laid among mosses in abundance (Percival & Whitehead 1928). The eggs are laid in evening light and are caught by *Platyhypnidium riparioides* (Figure 39) and *Fontinalis* species (Figure 47) where they adhere as a greenish gelatinous mass.

In a Shropshire Hill stream in the UK, Arnold and Macan (1969) found that the longest stage in *Serratella ignita* (Figure 1) was the egg, a stage that remained from late summer one year to late spring the next year, hence overwintering as an egg (Elliott 1967). Rosillon (1988) found that completion of naiad development on a diatom diet required about 950 **degree-days** above a temperature of 3.5°C (range 9.5-18°C). [Degree days for insect development can be calculated by adding the minimum and maximum temperature of the day and dividing by 2. The minimum required for development is subtracted from that number to determine how many degree-days have been added that day. (Townsend *et al.* 2010)]. Those reared on detritus rarely achieved adult stage. Rosillon suggested that poor food quality would reduce **fecundity** (reproductive rate) of females. Furthermore, it appears that under ideal conditions *Serratella ignita* could have a **bivoltine** (2 broods per year) life cycle.

Emergence patterns can be gleaned from the stages of the naiad development of mayflies in samples. Based on such sampling, Gurtz & Wallace (1984) estimated that in a stream in the southern Appalachian Mountains, USA, the moss inhabitants *Ephemerella catawba* (Figure 73) probably emerged from May to July, *E. hispida* from April to June, *E. excrucians* (Figure 81) in May and June, and *Drunella tuberculata* (Figure 74) from June to September. Both *Ephemerella catawba* and *Ephemerella invaria* occurred among mosses in the acidic mid Appalachian streams in my own studies (Glime 1968). *Ephemerella invaria* (Figure 75) increased in Big Hurricane Branch following a clearcut, but no specimens with fully developed wing pads were ever collected, suggesting that nymphs of this species might complete their development farther downstream in Shope Creek (Gurtz & Wallace 1984).

Figure 75. *Ephemerella invaria* naiad. Photo by Bob Henricks, with permission.

Ephemerella invaria (Figure 75) occurred both above and below a hydroelectric plant on the Sturgeon River in northern Michigan, USA, with similar abundance and growth (Mundahl & Kraft 1988). *Ephemerella subvaria* (Figure 76) naiads were 4x as abundant below the plant (136 m⁻² below vs. 33 m⁻² above), but grew more slowly there. Nevertheless, the growth rate increased with distance downstream from the power plant for nearly 10 km. Extensive beds of *Fontinalis* (pers. obs.) may have

contributed to the improved growth rates, with the mosses serving as traps for **seston** (swimming or floating living organisms and non-living matter) being released from the reservoir. Both of these species occur among bryophytes in streams of the mid Appalachian Mountains, USA (Glime 1968).

Food

The **Ephemerellidae** (Figure 58-Figure 64) are the most commonly reported mayflies among the bryophyte consumers (Table 1). *Caudatella hystrix* (as *C. cascadia*; Figure 61) varies its diet depending on the site (Coffman *et al.* 1971; Hawkins 1985). Detritus is important in its diet, but the proportion decreases when that of moss increases (Hawkins 1985). The naiads of *Caudatella edmundsi* (Figure 62, Figure 101) feed primarily on diatoms, but also include detritus and mosses in their diet. Hawkins found that as size increased in the **Ephemerellidae**, especially in *Caudatella edmundsi* and *Ephemerella dorothea infrequens* (Figure 80), the consumption of both animal matter and mosses increased. Hawkins found that eight species demonstrated a correlation between moss consumption and size. López-Rodríguez *et al.* (2008) likewise found that the proportion of mosses in the diet increases in **Ephemerellidae** as naiads age. Several researchers (Hynes 1941; Chapman & Demory 1963; Gaevskaya 1969) found that mosses are eaten by members of this family more often than other aquatic macrophytes (not including algae). But it is not clear if the moss is eaten for its own food value or for the attached periphyton. Percival and Whitehead (1929) found that two species in this family ingested large amounts of moss, suggesting that the moss itself was an important food source. Among the members of **Ephemerellidae** studied by Hawkins (1985), *Caudatella edmundsi*, *C. heterocaudata*, *C. hystrix*, and *Serratella teresa* were moss shredders. Others living among the mosses and ingesting them were detritus shredders, including *Attenella margarita* (Figure 77), *Ephemerella dorothea infrequens*, *E. excrucians* (Figure 81), *E. velmae*, *Serratella tibialis* (Figure 84), and *Timpanoga hecuba* (Figure 78). *Drunella pelosa* is a diatom scraper, permitting it to eat the many diatoms adhering to the moss leaves.

Table 1. Correlations between size (mm) and percent composition of major food items in the gut. Values are correlation coefficients (r). * = $P < 0.05$; ** = $P < 0.01$. Percentages arcsine-transformed prior to analysis. From Hawkins 1985.

Ephemerella

Ephemerella and its segregates are usually the most common mayflies among mosses. Needham & Christenson (1927) reported *Ephemerella* s.l. from moss-covered boulders in streams of northern Utah, USA. In their study of colonization of *Fontinalis neomexicana* (Figure 79) in Idaho, USA, Maurer and Brusven (1983) found *E. dorothea infrequens* (Figure 80) to be common among these mosses. In the St. Maries River of Idaho, USA, Gilpin and Brusven (1970) occasionally found *E.*

excrucians (Figure 81) and *E. dorothea infrequens* clinging to *Fontinalis* and other vegetation, but mostly they were on submerged logs and rocks. Nevertheless, mosses comprised 8% of the diet of this variety (Hawkins 1985).

Figure 81. *Ephemerella excrucians*, a common inhabitant of *Fontinalis neomexicana* in streams of Idaho, USA. Photo by Jason Neuswanger, with permission.

In Straffan, UK, *Ephemerella notata*, a species once considered close to *Serratella ignita*, lived among mosses (Frost 1942; Kimmins & Frost 1943), including *Fontinalis* (Figure 47) (Kimmins & Frost 1943). Although *Ephemerella* sometimes eats a considerable diet of bryophytes, Jones (1950) did not find moss tissue in the guts of any of the five species of mayflies, including *Ephemerella notata*, in the River Rheidol, UK.

Bob Henricks reported 40-50 spiny crawlers (*Ephemerella*) on a mossy rock in a stream. He noted that in this stream the mosses held tiny sand grains and minute rocks instead of fine silt. In the mountain streams the mosses held fine silt and organic matter with many fewer of these mayflies. They avoid the mosses that grow on the tops of rocks and that float on the surface where the moss reaches the air. Rather, they tend to be on the under-surface of the mosses that wrap around the rocks in the water (Figure 82).

Figure 82. *Ephemerella* on rock with mosses. The mayflies blend with the algal-detrital mat on the mosses. Photo by D. N. Bennett, with permission.

Bengtsson (1981) found that *Ephemerella mucronata* (Figure 83) demonstrated a steady growth rate throughout winter in Sweden. This species has an interesting niche in the River Rajcianska, Slovakia, where it occurs among the wet emergent bryophytes but not among the submerged ones (Krnó 1990).

Figure 83. *Ephemerella mucronata*, a mayfly that continues to grow throughout winter in Sweden. Photo by Biodiversity Institute of Ontario, through Creative Commons.

Serratella

Serratella tibialis (Figure 84) is a collector-gatherer, feeding on detritus (Aquatic Insects 2008). Both early instars and mature naiads are common among mosses, including *Platyhypnidium riparioides* (Figure 39) and *Fontinalis antipyretica* (Figure 47) (Langford & Bray 1969). *Serratella teresa* occurs on mosses and other vegetation in swiftly-flowing streams (Allen & Edmunds 1963). In the McKenzie River, Oregon, USA, Hawkins (1984) found that 85% of the individuals of this species sampled were in clumps of *Fontinalis* sp. (Figure 79). Furthermore, 17% of the food for *S. teresa* in Oregon was mosses (Hawkins 1985).

Figure 84. *Serratella tibialis*, a naiad common among mosses in both its young and older stages. Photo by Bob Henricks, with permission.

In Straffan, UK, Frost (1942) found that *Serratella ignita* (Figure 67) lived among mosses. Percival and Whitehead (1929) found that mosses form the primary habitat for *S. ignita*, and that the moss also is its dominant food, an observation consistent with that of López-Rodríguez *et al.* (2008). Langford and Bray (1969) found this species among *Fontinalis antipyretica* (Figure 47) and *Platyhypnidium riparioides* (Figure 39) as well as on bare sand and tracheophytes in Britain.

Macan (1957) found that among the streams he studied in Ford Wood Beck, UK, the abundance of *Serratella ignita* (Figure 1, Figure 67) increased as the flow became more sluggish and the vegetation became thicker. In all

streams, this species was more common when either tracheophytes or mosses were present. In faster streams, this relationship with mosses might explain the presence of this species. Furthermore, this species is able to move about in the wet moss mats above the water level (Krnó 1990). *Serratella ignita* is among the species that not only live among mosses, but it also eats them (Percival & Whitehead 1929).

Serratella ignita (Figure 1, Figure 67) usually lays its eggs where moss is present in fast-flowing water (Elliott 1978). The development time for the eggs depends on the temperature, with hatching time decreasing with increasing water temperature in the range of 5.9-14.2°C. However, at higher temperatures the hatching time increases with temperature. Correlations of naiad numbers with moss coverage may be a correlation with temperature.

Serratella ignita (Figure 67) prefers a flow of 10-30 cm sec⁻¹ (Macan 1962). Willoughby and Mappin (1988) were unable to find it in upland streams of the River Duddon where the pH was low (4.8-5.2), but it did occur in lowland streams with pH values of 6.6 and higher. But it appears that the pH was not the direct cause of its absence. In the lab, it was very tolerant of low pH and low ion content, and growth rates were equally good whether food supplied was that available in low pH streams (liverwort *Nardia compressa* (Figure 85) plus the filamentous alga *Klebsormidium subtile* (Charophyta; see Figure 86) or that available in high pH streams [moss *Platyhypnidium riparioides* (Figure 39) with the epiphytic diatom *Cocconeis placentula* (Bacillariophyta; Figure 87). Nevertheless the absence of *K. subtile* as a food at the higher pH seems to account for the absence of *S. ignita* there. Percival and Whitehead (1929) found mosses in the guts of *Serratella ignita* in Great Britain. But are the mosses really a preferred food? In preference experiments, Rosillon (1988) found that *S. ignita* preferred diatoms over detritus. In these experiments, the growth rate was significantly higher on the diatom diet than that on the detritus diet, no matter what the temperature. In fact, larvae reared on the detritus diet had slower development and usually failed to reach the adult stage. If diatoms are the preferred food, eating the moss may simply be the most efficient means of obtaining them.

Figure 87. *Cocconeis placentula*, a common epiphyte on aquatic bryophytes and important food for *Serratella ignita*. Photo by Ralf Wagner, with permission.

Rosillon (1988) demonstrated that temperature was an important factor in determining mortality for *Serratella ignita* (Figure 67). Furthermore, as the temperature increased, mortality was higher on the detritus diet than on the diatom diet. The bryophytes are more likely to be abundant in the cooler habitats, often being overtaken by algal and microbial growth where it is warmer.

Serratella serratoides (Figure 88) occurs primarily among *Hygroamblystegium fluviatile* (Figure 68) – *Platyhypnidium riparioides* (Figure 39) mats in Appalachian Mountain, USA, streams (Glime 1968). In the southeastern USA it burrows into the moss mats a few cm below the surface (Berner & Allen 1961).

Figure 88. *Serratella serratoides* naiad. Photo by Bob Henricks, with permission.

Even for this common moss-dwelling genus, other substrata are often acceptable as well. *Serratella spinosa nevadensis* (as *Ephemerella ikonovici nevadensis*) only occurred in soft water in Spain, living at margins or midstream where roots, moss, algae, or other form of vegetation, along with detritus, was present (Alba-Tercedor 1990; López-Rodríguez *et al.* 2008). Unlike most of the **Ephemerellidae** that increase moss consumption with size, the naiads of *S. spinosa nevadensis* increase the percentage of detritus in the diet as they grow larger.

Some **Ephemerellidae** take advantage of ecosystem engineering by other insects. They are poor swimmers that need to cling to vegetation or other objects for support in the current (DEP 2014). *Serratella setigera* prefers slow flow (Nakano *et al.* 2005). In field experiments on artificial substrata, this species took advantage of the flow reduction in retreats of the net-spinning caddisfly *Hydropsyche orientalis* (Figure 89). In the experiments, those living on experimental plates with no caddisflies were mostly lost during high flow events, whereas none of the naiads in the caddisfly retreats were lost. It is likely that bryophytes provide similar retreats on rocks for some members of this genus. The researchers suggested that in the complex habitat created by mosses, the advantages provided by the *Hydropsyche* retreats would weaken. *Hydropsyche orientalis* occurs in moss mats of *Platyhypnidium riparioides* (Figure 39) in Japan (Takemon & Tanida 1992), but I could find no documentation that *Serratella setigera* likewise occurs there.

Teloganopsis

Teloganopsis (= *Serratella*) *deficiens* (Figure 90- Figure 91) is known from bryophytes in eastern North America (Allen & Edmunds 1963; Glime 1968). In the southeastern states it lives primarily among mosses and other plants in rocky, swift streams, but in Michigan it also occurs among detritus (Allen & Edmunds 1963). Among the mosses they are protected from the current and find a sufficient food supply.

Figure 91. *Teloganopsis deficiens* naiad, a *Fontinalis* inhabitant. Photo by Bob Henricks, with permission.

Cincticostella

In Japan, the narrowly distributed *Cincticostella nigra* (Figure 92) occurs in mats of *Platyhypnidium riparioides* (Figure 39) (Takemon & Tanida 1992). This species is restricted to Honshu, Japan (Allen 1971).

Figure 92. *Cincticostella nigra* naiad. Photo from Shiiba Research Forest. Permission pending.

Drunella

Allen and Edmunds (1962) did not report any bryophyte dwellers among the North American species of *Drunella* they examined. But Muttkowski and Smith (1929) did find *Drunella* twice among the mosses of strong rapids in Yellowstone National Park, USA. Hawkins (1984) found only 2% of two *Drunella* (Figure 93) species [*D. pelosa*, *D. coloradensis* (Figure 93)] among mosses in western Oregon, USA. But *D. spinifera* (Figure 94) was collected primarily (54%) in mats of *Fontinalis* (Figure 79). *Drunella allegheniensis* (see Figure 95) occurs among bryophytes in the Appalachian Mountain, USA, streams (Glime 1968). Gilpin and Brusven (1970) found *D. grandis* (Figure 96) among *Fontinalis* clumps in Idaho, USA, as well as in other habitats with protective cover. *Drunella spinifera* was common on *Fontinalis*. And Barton (1980) found the latter species to be abundant on moss-covered stones in riffles and rapids of a stream in northeastern Alberta, Canada.

Figure 96. *Drunella grandis* naiad, a *Fontinalis* dweller. Photo by Bob Newell, with permission.

Drunella grandis (Figure 97) was a characteristic species among clumps of the leafy liverwort *Porella* (Figure 98) in California, USA (Corona 2010). This species seems to be adapted to its bryological habitat by large dorsal projections on the head, thorax, and abdomen. These projections reduce the chance of being swept away by rapid current in the locations of the liverwort, hooking the mayfly on the branches (Hora 1930).

Caudatella

Although the records of the members of this genus inhabiting bryophytes are limited, Hawkins (1985) reported that four species of *Caudatella* had three of the four highest percentages of bryophytes in the gut among all the **Ephemerellidae** in Oregon, USA. The moss percentage in the diet of these species, which we must presume were associated with mosses, were *C. hystrix* (Figure 99-Figure 100) (15% + 20% listed as *C. cascadia*), *C. edmundsi* (Figure 101) (19%), and *C. heterocaudata* (15%).

Figure 99. *Caudatella hystrix* naiad, a mayfly for which mosses comprise 35% of the diet in Oregon, USA, streams and rivers. Photo by Bob Newell, with permission.

Figure 100. *Caudatella hystrix* adult. Naiads live in fast riffles in Idaho, USA, clinging to *Fontinalis*. Photo by Bob Newell, with permission.

Figure 101. *Caudatella edmundsi*, a naiad that sometimes occurs exclusively on *Fontinalis*. Photo by Bob Newell, with permission.

In the St. Maries River of Idaho, USA, *Caudatella hystrix* (Figure 99-Figure 100) typically occurred in fast riffles where it would cling to *Fontinalis* (Figure 79) or the alga *Prasiola* (Maurer & Brusven 1983). These substrata did an effective job of concealing the naiads. *Caudatella edmundsi* (Figure 62, Figure 101) occurs in streams with lower mean summer temperatures at higher elevations and coincides with higher moss coverage (Jacobus *et al.* 2006; Hogue & Hawkins 2008). Hawkins (1984) found *Caudatella edmundsi* exclusively among *Fontinalis* in western Oregon, USA.

Attenella

I am only aware of two species in this genus that live among the bryophytes. *Attenella margarita* (Figure 77) is a detritus shredder that also eats bryophytes and lives among them. In Appalachian Mountain streams, *A. attenuata* lives among the bryophytes, particularly *Fontinalis dalecarlica* (Figure 69), but its use of bryophytes for food is unknown (Glime 1968).

Torleya

This is one of the many genera that have been split off from *Ephemerella*. *Torleya major* is a bryophyte dweller in the River Rajciana in Slovakia, where it lives below the surface but is not found among the emergent wet bryophytes (Krno 1990).

Leptohyphidae – Little Stout Crawler Mayflies

This is a family of small mayflies (3-10 mm) that are clingers and sprawlers (Leptohyphidae 2015). They are widespread in North America, but most are not common among bryophytes. They do crawl about on plants.

Tricorythodes (Figure 102) burrows among the stems and rhizoids of mosses (Armitage 1961). In North America Berner (1959) found it in streams with a perceptible current where it lived among mosses or other plant growth on large stones or amid fine sand and gravel. They eat mostly plants (Leptohyphidae 2015). These naiads rarely swim, but rather move by crawling (Berner 1959). Their gill covers protect the gills, keep them clean, and move water across them when the current is insufficient to provide the needed oxygen.

Figure 102. *Tricorythodes* sp. naiad, a genus that burrows among moss stems and rhizoids. Photo by Bob Henricks, with permission.

Suborder Pisciforma

Ameletidae – Combmouthed Minnow Mayflies

Unlike the **Leptophlebiidae**, the **Ameletidae** are fast swimmers. They are mostly limited to clean, cold water (Henricks 2011) of North America and Europe (Ameletidae 2015) where they feed by scraping algae (Zuellig *et al.* 2006). Some members of this univoltine family may be **parthenogenetic** (reproducing with an unfertilized egg). They range 7-21 mm in length (Zloty & Pritchard 1997).

Ameletus (Figure 103) is not generally a moss dweller, preferring more open waters with a stream substrate free of silt (Schwiebert 2007). Nevertheless, mosses can play a role in its location. It is among the few mayflies able to tolerate acid water, permitting it to live downstream from a lake acidified by *Sphagnum* (Figure 51) (Bauernfeind & Moog 2000). *Ameletus inopinatus* (Figure 104) lives in such a habitat at higher altitudes. In my Appalachian Mountain streams it was an infrequent occupant of the bryophytes (Glime 1968).

Figure 103. *Ameletus ludens* naiad. Some members of this genus are able to tolerate the acidified outflow from *Sphagnum* lakes. Photo by Jason Neuswanger, with permission.

Figure 104. *Ameletus inopinatus* naiad, a species that is able to live in the pH extremes of outflow from *Sphagnum* fens and bogs at higher elevations. Photo by André Wagner, with permission.

Baetidae – Blue-winged Olives

The **Baetidae** are distributed throughout the cooler (but not polar) parts of both the Northern and Southern Hemispheres (Hebert 2012). They are among the smallest mayflies, usually <10 mm, and mostly members of the open water column, hanging out on the stream bottom or darting into the flow (Baetidae 2013). They are strong swimmers, but feed mostly on algae. Nevertheless, the youngest naiads can be found sheltered among the bryophytes, out of the flow that is beyond their ability for controlled swimming at that early stage (Hynes 1961; Glime 1968). They leave the bryophytes when their swimming skills develop, but when it is time to emerge, the **Baetidae** may once again use the bryophytes to facilitate their break through the surface tension safely. And once above water, they may cling to bryophytes to escape their naiad skin (Figure 105).

Figure 105. **Baetidae** newly emerged adults on wet moss. Photo by Jason Neuswanger, with permission.

Despite their open water nature, *Baetis* species are common among bryophytes in the River Rajcianka in Slavakia (Krno 1990). Those on submerged bryophytes include *Baetis alpinus* (Figure 106), *B. fuscatus* (Figure 107), *B. lutheri*, *B. muticus* (Figure 108), *B. rhodani* (Figure 111), *B. scambus*, *B. vardarensis* (Figure 109), and *B. vernus* (Figure 110). Among these, naiads of *Baetis lutheri*, *B. muticus*, *B. rhodani*, and *B. scambus* are also able to move about among the wet emergent bryophytes.

In a Welsh mountain stream Hynes (1961) found the very small (under 3 mm) members of *Baetis* (Figure 105-Figure 112) among mosses. I found a similar relationship of early instars among the mosses in Appalachian Mountain, USA, streams (Glime1968). Macan (1980) found that naiads of *Baetis rhodani* (Figure 111) in the River Lune, England, were common and abundant in the moss-covered area of the stream in winter. Naiads of four species of mayflies lived there spring to autumn, then overwintered in the egg. Hence, in the summer these other species appeared to displace *Baetis rhodani* from the mossy area. Wallace and Gurtz (1986) found that the biomass and production of *Baetis* were more than twice that of the weighted stream biomass and production. They suggested that part of this surge in biomass might be due to the large diatom count on mosses. Galdean (1994) further supported the importance of food among the mosses. On boulders where the velocity had increased in a stream, and the mosses on these boulders formed a felt that lacked detritus, *Baetis rhodani* was rare.

The mayfly *Baetis* (Figure 105-Figure 112) is well adapted to living where water levels fluctuate in streams. It can crawl to deeper water as the water level recedes, and it can relocate by entering the drift (Corrarino & Brusven 1983). When *Baetis* is in the drift, it swims to the surface, does a somersault, and hopefully is able to establish a hold on a substrate (Hughes 1966). Its streamlining makes it a good swimmer, and it is among the few insects that can swim against a current. It is positively phototactic and exits from its dark enclosures when there is light.

In their experiments on effects of pH on mayflies, Willoughby and Mappin (1988) found that *Baetis muticus* (Figure 108) and *Baetis rhodani* (Figure 111) are directly sensitive to the low pH of the water, whereas *Serratella ignita* (Figure 1) was tolerant but absent in low pH water due to an inadequate food supply. Water acidity accounted for the absence of these *Baetis* species in the Upper Duddon, UK.

Figure 111. *Baetis rhodani*, a species that is sensitive to low pH. Photo by J. C. Schou, with permission.

Figure 112. *Baetis tricaudatus* naiad, a common mayfly among *Fontinalis neomexicana* in Idaho, USA. Photo by Tom Murray, through Creative Commons.

Frost (1942) found that *Baetis*, including the common *B. rhodani* (Figure 111), often makes its naiad home among mosses. In their study of colonization of *Fontinalis neomexicana* (Figure 79) in an Idaho stream, Maurer and Brusven (1983) found *Baetis tricaudatus* (Figure 112) to be common among the mosses.

The food of *Baetis* is typically diatoms, desmids, and filamentous algae (Butcher 1933; Percival & Whitehead 1929). But Brown (1961) found that detritus was the primary food of *B. rhodani* (Figure 111), a sometimes moss-dweller. Food of *B. rhodani* varied somewhat with habitat and season, also including algae. On the other hand, *Baetis* is frequent prey for fish. Frost (1942) found that 71% of the fish examined at Ballysmuttan and 59% at Straffan had *Baetis* in their guts. Such consumption is likely because of their frequent ventures into the open water.

Lee and Hershey (2000) found that *Baetis* (Figure 105-Figure 112) did not increase in numbers in fertilized reaches of the Kuparuk River in Alaska when the moss *Hygrohypnum* (Figure 43-Figure 44) increased in density. However, they grew larger in the fertilized zone, a fact Lee and Hershey attributed to greater abundance of epiphytic diatoms.

Wulfhorst (1994) compared naiads of *Baetis* (Figure 105-Figure 112) on mosses and in the **interstitial** spaces (spaces between individual sand grains in the soil or aquatic sediments) in the **hyporheic** zone (region beneath and alongside a stream bed) of two streams in the Harz Mountains, West Germany. There the mosses were home to many more of these mayflies than the interstitial spaces of the stream bed (Figure 113). On the other hand, Arnold and Macan (1969) found that *Baetis*, in addition to inhabiting mosses, occurred on unstable bare stones on the stream bottom.

Figure 113. Mean abundance \pm 95% CI of *Baetis* naiads in moss clumps in two streams in the Harz Mountains, West Germany. Redrawn from Wulfhorst 1994.

In the Arctic, conditions that favor mosses do not always favor the insects. Cold temperatures require life cycles that protect them in the winter. Among those species known to occupy mosses elsewhere, Giberson *et al.* (2007) found *Ephemerella aurivillii* (Figure 45) and *Baetis tricaudatus* (Figure 112) in the Arctic streams of Nunavut, Canada. The **Baetidae** was the most common family there. *Baetis bundyae* (Figure 114) naiads hatched within 2-3 weeks of ice-out and completed their development in 2.5-4 weeks. Giberson *et al.* considered the female-biased sex ratio to be an indication they might experience parthenogenesis. The Arctic **Baetidae** species are able to survive by having freeze-tolerant eggs, good dispersal, and a female-biased sex ratio that promotes greater reproduction.

Figure 114. *Baetis bundyae* naiad, a species with a female-biased sex ratio that is possibly parthenogenetic. Photo by Donna Giberson, with permission.

When we enter the Southern Hemisphere, the fauna changes, but major groups tend to remain the same. In Africa, baetid *Acanthiops elgonensis* (= *Afroptilum erepenscan*) attaches to mosses, barely covered by water, in the spray of water falls (Gillies 1990).

Siphonuridae - Primitive Minnow Mayfly

This family generally occurs in slow water. In St. Maries River in Idaho, USA, Gilpin and Brusven (1970) found *Siphonurus occidentalis* (Figure 115) typically clinging to *Fontinalis* (Figure 47) growing at the stream margins.

Figure 115. *Siphonurus occidentalis* naiad. Photo by Bob Newell, with permission.

Heptageniidae – Clinger Mayflies

This family is widespread in the Holarctic, Oriental, and Afrotropical regions, as well as Central American Tropics and extreme northern South America (Heptageniidae 2014). Most of them occur in very fast flow where they anchor themselves on rocks by using their collective gills as a suction cup.

Because of this suction cup arrangement, bryophytes are not friends to the **Heptageniidae**. For example, when mosses increased in growth downstream from impoundments, the **Heptageniidae** diminished or were eliminated completely (Brittain & Saltveit 1989). Bottová and Derka (2013) reported that *Rithrogena semicolorata* avoided mosses in a karstic spring in the West Carpathians,

despite its high coverage of mosses. But in the moderately eutrophic River Rajcanka in Slovakia *Rithrogena ferruginea* did occur among the bryophytes, despite the family's adaptations for smooth rock surfaces.

This is a family of flattened mayflies adapted to living on rock surfaces, typically with gills arranged along the abdominal segments to form a suction cup. Nevertheless, Jones (1949, 1950) found all of the guts with identifiable contents from 22 *Ecdyonurus venosus* naiads (Figure 116) contained the moss *Fontinalis antipyretica* (Figure 47). Winterbourn *et al.* (1986) likewise found that this species ate mosses in two British river systems. In the St. Maries River of Idaho, USA, *Cinygmula* sp. (Figure 117) occasionally occurred in clusters among *Fontinalis* (Gilpin & Brusven 1970). Among bryophytes in mid-Appalachian Mountain, USA, streams, I only found *Epeorus* (Figure 118-Figure 119) representing this family (Glime 1968).

Isonychiidae

The **Isonychiidae** are mostly North American, with scattered records in Asia (Isonychiidae 2015). These active swimmers are 8-17 mm long and occupy rapid currents (Waterbugkey 2015). They filter algae and diatoms from the water by using the long hairs on their forelegs, but they also eat smaller insects.

In the Appalachian Mountain streams I (Glime 1968) found *Isonychia* (Figure 120-Figure 121) occasionally among the bryophytes.

Figure 120. *Isonychia bicolor* naiad, member of a genus that sometimes occurs among bryophytes. Photo by Jason Neuswanger, with permission.

Figure 121. *Isonychia bicolor* naiad, showing fibrillate gills with gill covers. Photo by Jason Neuswanger, with permission.

Oligoneuriidae – Brushleg Mayflies

This is mostly a river family, but occasionally they are associated with bryophytes. In the Sierra Nevada Mountains in southern Spain, young naiads of *Oligoneuriella marichuae* (Figure 122) require physical support and a way to capture food in the absence of a well developed filtering device (Alba-Tercedor 1990). For this they use roots, filamentous algae, and mosses. After they grow, they are able to move into the current.

Suborder Carapacea

Baetiscidae – Armored Mayflies

This small family of North American mayflies has a distinctive morphology (Figure 123) – the **notum** (Figure 124) covers the thorax and part of the abdomen (Edmunds 1960). These mayflies are medium sized (4-14 mm long) and live in pools or flowing water of sandy streams (Baetiscidae 2015b). Hence their occurrences among bryophytes are rare. Their feeding strategies are gatherers and scrapers (Baetiscidae 2015a). When they swim, they tuck their legs under the body and move by undulating the abdomen and caudal filaments (Baetiscidae 2015b).

I am delighted to report this unusual-looking family as having at least occasional moss dwellers. In fact, both *Baetisca obesa* (Figure 123) and *B. rogersi* (Figure 124) are moss dwellers. Berner (1955, 1956) found *B. obesa* among mosses that grew on submersed parts of trees in slow streams in North America. Later, Pescador (1973) found *B. rogersi* early instars in thick mats of the moss *Leptodictyum riparium* (Figure 125), likewise in slow water. In Appalachian Mountain, USA, streams, I found *B. callosa* and *B. carolina* among bryophytes, but infrequently (Glime 1968).

Summary

The **Collembola** are no longer considered insects and are now placed in the class **Entognatha**. Few live in the water and small numbers may mean they have fallen in. But some can occur in large numbers on the water surface, wet bryophytes of bogs, fens, and streambanks, and emergent bryophytes. They possess a **furcula** that propels them forward like a spring. The **collophore** facilitates respiration and absorption of water. Antennae recognize light intensity, wind direction, and heat.

The **Isotomidae** is the most frequent aquatic family, especially *isotomurus palustris*. This species is **viviparous**.

The **Hemimetabola** have **incomplete metamorphosis** with egg, nymph or naiad, and adult. Naiads typically have gills.

Ephemeroptera (mayflies) live only about one day as adults, emerging, mating, and dying, but not eating. Mating is accomplished in swarms. All the immatures (*naiads*) are aquatic. Some are **univoltine** (one brood per year) and some are **bivoltine** (two broods per year).

Most mayflies have high oxygen requirements. Mayfly naiads have gills, and those with gill covers are able to increase movement of water and oxygen across the gills by beating the gill covers. Some use body undulations to increase contact with oxygenated water.

The most common mayfly family among bryophytes is the **Ephemerellidae**. This is the family that most commonly eats bryophytes, and consumption of mosses increases as the naiads age. However it is not clear if they eat the mosses to assimilate them or if they only assimilate the attached algae and bacteria.

Baetis (**Baetidae**) seems to use bryophytes as a nursery and a stopping point when they enter the drift, a usage common among a number of other families.

Acknowledgments

Juan Carlos Villarreal helped me obtain the information on the oviposition of *Epiophlebia superstes*. D. N. Bennett shared her fauna stories and passed on to me the information from Bob Henricks on ecology of some of the insects, especially *Ephemerella*. Richard J. Snider verified identifications of the **Collembola** from my mid-Appalachian Mountain study and Lewis Berner verified the species of **Ephemerellidae**. My sister Eileen Dumire helped me make this more layperson friendly and caught many proof-reading errors.

ODONATA – Dragonflies and Damselflies

This order contains both dragonflies (**Anisoptera**; Figure 2-Figure 4) and damselflies (**Zygoptera**). You can recognize adult dragonflies by their wings at rest (Figure 2) – they are spread horizontally; the term *anisoptera* means uneven wings. The damselflies, by contrast, usually fold the wings together above the body at rest (Figure 5); their wings are of equal size (**Zygoptera**). Both dragonflies and damselflies have an aquatic stage, the **naiad** (gilled nymph). Dragonflies can be recognized in the naiad stage by having internal anal gills and relatively stout bodies (Figure 3). Damselflies have three blade-like external anal gills and slender bodies (Figure 6).

Both groups are predators (Thorpe & Covich 1991) and the naiads have a large, scooplike **labium** (mouth part; Figure 4 & Figure 8, Figure 7) that extends to capture the prey. These giant jaws are formidable and the **Odonata** are efficient in catching prey.

The naiads climb out of the water and must climb up rocks or vegetation before they split their exoskeleton and emerge (Figure 1). They must then pump fluids into their wings before they fly away. Unlike the mayflies, the dragonfly naiads live as long as 5-6 years and adults for 5-6 months (Dragonfly 2015). Dragonflies are among the strongest fliers in the insect world – just try to catch one!

Bryophytes are not the usual homes of **Odonata** naiads in lakes, ponds, and streams. In a Québec, Canada stream, **Odonata** preferred gravel to the moss *Fontinalis dalecarlica* (Figure 9) (Cattaneo *et al.* 2004). These carnivores preferred places where they could remain hydrated as the water level decreased and were not tied to the bryophytes for obtaining the periphyton required by many other orders.

Figure 9. *Fontinalis dalecarlica*, a moss often less preferred than sand, at least in Quebec streams. Photo by J. C. Schou, with permission.

But bryophytes do seem to hold importance for some **Odonata**. In my studies of Appalachian Mountain, USA, streams, the dragonfly genus *Cordulegaster* (**Cordulegastridae** – spiketail dragonflies; Figure 10) was occasionally present among bryophytes (Glime 1968). The gomphids *Gomphus* (**Gomphidae** – clubtail dragonflies; Figure 11) and *Octogomphus* (**Gomphidae**; Figure 12) also occurred among the bryophytes, both rarely, representing the dragonfly naiads (Glime 1968).

The presence of exuviae provides indirect evidence that the **Odonata** use bryophytes for emergence (Needham *et al.* 1901). Both *Gomphus exilis* (dragonfly; **Gomphidae**) (Figure 13) and *G. spicatus* (Figure 14) exuviae (Figure 15) appeared in layers among mosses at the edge of a pond in the Adirondack Mountains of New York, USA.

Suborder Zygoptera – Damselflies

Specific records of damselfly naiads living among bryophytes outside of bogs and fens are few, partly because they do not tend to inhabit the types of habitats where many of the aquatic bryophytes grow. But it seems more likely that the bryophytes do not afford a suitable habitat for their elongate labium to catch prey.

In the Red Cedar River, East Lansing, MI, I found a number of damselfly naiads early in the spring in large clumps of *Fontinalis* (Figure 16). *Teinobasis ponapensis* (see Figure 17), in the **Coenagrionidae** – narrow-winged damselflies, a damselfly from the eastern Caroline Islands

of Micronesia, occurred as adults only near mosses (Paulson & Buden 2003).

Figure 16. *Fontinalis antipyretica*, home for damselfly naiads in early spring. Photo by Michael Lüth, with permission.

Figure 17. *Teinobasis sjupp* (damselfly; **Coenagrionidae**) adult, relative of *T. ponapensis* that is known as adults only near mosses in the Caroline Islands of Micronesia. Photo by V. J. Kalkman, through Creative Commons.

But there appear to be interesting relationships still waiting for us. Two new species of the genus *Argiolestes* (**Argiolestidae** or **Megapodagrionidae**; damselflies; Figure 18) in Papua New Guinea are known only from shaded areas of water courses; *Argiolestes fornicatus* avoids sunny areas of the watercourses and occurs primarily in areas with high moss cover (Michalski & Oppel 2010). *Argiolestes tuberculiferus* (Figure 19) and *A. verrucatus* were discovered only recently in Papua New Guinea. Other bryophyte relationships most likely remain for discovery in less studied parts of the world.

Suborder Anisoptera – Dragonflies

Direct usage of bryophytes by **Odonata** naiads is not well documented, but there seems to be more usage for the dragonflies than for the damselflies. It appears that mosses, as well as other protective pond locations, can protect some species when their ponds dry up. *Somatochlora semicircularis* (Corduliidae – emerald dragonflies; Figure 20-Figure 21) uses mosses, as well as rocks, logs, and deep in the bases of sedge clumps, to escape the drying conditions of exposure when their Colorado, USA, ponds dry up in late August and September (Willey & Eiler 1972). This species has the further advantage that it loses water more slowly than other dragonflies such as *Aeshna interrupta interna* (Figure 79-Figure 80) and *Libellula quadrimaculata* (Figure 22), neither of which seems to live among bryophytes.

Figure 20. *Somatochlora semicircularis* (dragonfly; Corduliidae) adult whose survival could depend on naiads seeking shelter in mosses when their ponds dry up. Photo by Belinda Lo through Creative Commons.

Even if **Odonata** are unable to live among bryophytes where their large size would make movement and prey capture more difficult, they may still take advantage of them for cover. *Somatochlora provocans* (dragonfly; Corduliidae) (Figure 23) occurred in a small lake inlet in southeastern USA, where *Sphagnum* (e.g. Figure 24) provided a border (Tennessen 1975). The naiads were common in the flowing water, but were hanging out near that *Sphagnum* cover.

Figure 24. *Sphagnum* peatland in Alaska, USA. Photo by Vita Plasek.

Oplonaeschna armata (Figure 25), a member of the **Aeshnidae** – hawkers or darners, may not live among mosses, but the species still finds them useful. Some individuals of this dragonfly left traces of their behavior behind as exuviae clinging to mosses 0.8-1.25 m above the water on vertical rocky walls of a canyon (González Soriano & Novelo Gutiérrez 1998).

Life Cycle Considerations

Bryophytes can actually provide several functions for **Odonata**, from wet habitats in waterfalls to safe sites or cover at the margins of streams, ponds, and lakes. The most important of these uses seems to be for egg depositories.

Mating and Egg-Laying

Mosses may not house naiads in many habitats, but they are a preferred site for egg deposition in many bogs and fens. *Aeshna subarctica* (dragonfly; **Aeshnidae**) (Figure 27) in northwestern Wisconsin flies along the northwest shoreline, the sunny side, where there is a mat of

floating mosses and sedges (DuBois *et al.* 1999). While they submerge the ends of their abdomens into the moist *Sphagnum* (Figure 27) they are not ready for a quick getaway. Naiads of this species require submerged mosses in their habitat. *Aeshna sitchensis* (Figure 61) does not distinguish between *Sphagnum* bog pools and pools of fens with *Drepanocladus* (Figure 59) (Cannings *et al.* 2004). In the muskeg, *Aeshna coerulea septentrionalis* (dragonfly; **Aeshnidae**) (Figure 62) uses wet moss patches between tufts of scant grass as well as the muskeg "slime" as deposition sites in small pools, or in the creamy-pink muskeg slime bordering small pools (Whitehouse & Walker 1941). During mating and oviposition is a good time to catch the **Odonata** because they are occupied in laying eggs and not in flying.

The female of *Argia moesta* (damselfly; **Coenagrionidae**; Figure 26), in Ohio, USA, deposits her eggs on submerged mosses, logs, and algae-covered stones (Kellicott 1899). *Tanypteryx hageni* was once thought to insert eggs into plant tissues, but in a closer examination Svihla (1959) found that these were deposited below the water among mosses, liverworts, and other bog plants.

Figure 26. *Argia moesta* adult, a species that lays its eggs on submerged mosses. Photo by Richard Murphy through Creative Commons.

Corbet (1999) specifically reports naiads of *Thaumatoneura inopinata* (**Megapodagrionidae**), the giant water damselfly, as moss dwellers. This species oviposits among mosses that grow adjacent to, but not within, the main current.

Leucorrhinia hudsonica (dragonfly; **Libellulidae** – skimmers; Figure 29) at a black spruce *Sphagnum* bog (Figure 30) in Québec, Canada, uses that habitat for egg deposition (Hilton 1984). The males first establish territories, then perch there except for short attack flights against intruders. Females visit those sites to deposit eggs and are intercepted by the males who enter into tandem formation and copulate with them. Unlike many of the other **Odonata**, they perch near the egg-laying sites during copulation. Once copulation is completed, the females dip their abdominal tips in rapid succession into the small pools of water associated with the saturated *Sphagnum* (Figure 51). Males hover nearby to guard the females during this process, chasing off competing males. In Illinois, USA, when females of *Leucorrhinia* are pursued by too many males, they land on the mosses and deposit their eggs (Needham & Hart 1901).

Figure 27. *Aeshna subarctica* (dragonfly; **Aeshnidae**) female laying eggs in *Sphagnum*. Photo by Guillaume Doucet <guillaume.doucet.free.fr>, with permission.

Some species use terrestrial mosses for egg deposition. For example, one female *Tetracanthagyna plagiata* (**Aeshnidae**; Figure 28), the heaviest of all extant **Odonata**, deposited eggs on a moss-covered log adjacent to a stream, arching its abdomen to insert its ovipositor into the soft substrate (Leong & Tay 2009).

Figure 29. *Leucorrhinia hudsonica* (dragonfly; **Libellulidae**) female adult. Photo by Richard Orr, with permission.

Figure 30. Spruce bog in Pennsylvania, USA. Photo by Nicholas A. Tonelli, through Creative Commons.

One smart dragonfly in Oregon, USA, used mosses to make egg-laying a safer venture. Using her legs to cling to streambank mosses, *Octogomphus specularis* (dragonfly; **Gomphidae**) (Figure 31) dipped her ovipositor into the stream water, avoiding the danger of being washed away and helpless against the current (Opler 2013).

Figure 31. *Octogomphus specularis* (dragonfly; **Gomphidae**) clinging to moss while ovipositing in the water. Photo by Jim Johnson, with permission.

Temperature plays a major role in the timing and coordination of emergence in *Somatochlora alpestris* (dragonfly; **Corduliidae**) (Figure 34) and *S. arctica* (Figure 35-Figure 36) (Sternberg 1995). Eggs can hatch the same season or go into diapause and remain in their aquatic habitat throughout the winter. This is a facultative response that causes eggs deposited late in the season to increase from 0 diapausal eggs early in the season to 37% later in the season in *S. alpestris* and from 0 to 18% in *S. arctica*. Depending on the temperature during development, egg development requires 17 to 38 days. Dark mosses and dark bog water help to increase the ambient temperature and hasten development.

Few studies have identified egg-laying locations in streams. Bryophytes would seem to be ideal, even if the naiads leave soon after hatching to chase food items in open water. Askew (1988) did in fact observe *Caliaeschna microstigma* (**Aeshnidae**; Figure 32-Figure 33) depositing eggs in mosses on boulders of a stream in Europe.

Figure 32. *Caliaeschna microstigma* adult. Photo by Cosmin O. Mancu, with permission.

Figure 33. *Caliaeschna microstigma* exuvia. Photo by Cosmin O. Mancu, with permission.

Emergence

Donnelly (1990) reported with implied amazement a finding of naiads of a species of the damselfly *Nesobasis* (Coenagrionidae; Figure 37) crawling over wet mosses near a stream in the Fijian Islands, but it was not clear if they lived there or were seeking an emergence site to climb. It appears that mosses are among the sites used for emergence (Walker 1923). Exuviae from several species of the dragonfly *Ophiogomphus* (Gomphidae; Figure 38-Figure 40) were present on mosses under underhanging foliage at Godbout, Quebec, Canada, where they were a meter or more from the present waterline.

Figure 40. *Ophiogomphus cecilia* (dragonfly; **Gomphidae**) adult, a genus that apparently uses mosses for emergence. Photo by Varel, through Creative Commons.

Somatochlora elongata (dragonfly; **Corduliidae**) (Figure 41) sometimes sheds its exuvia on mosses at the edge of ponds (Needham *et al.* 1901). *Somatochlora semicircularis* (Figure 20) faces imminent danger as it emerges. First, it must find a suitable site for climbing out of the water, and if these sites are scarce, they may all be occupied (Willey 1974). Then, it is vulnerable while it is emerging because it can neither fly nor return to the safety of cover. At this time it is especially vulnerable to birds, and its relatively large size can make a hearty meal. Once free of its nymphal skin, its maiden flight easily draws the attention of hungry predators. At this time, it gains the advantage of safety in numbers. Emergence is highly synchronized, and although many die, the emergence of 50% of the adults within the first three to six days prevents birds from capturing all of them. Considerable space is needed for catching these strong fliers in the air, limiting the number of predators. Life cycle processes from naiad to adult to egg laying can be seen in Figure 42-Figure 48.

Figure 41. *Somatochlora elongata* (dragonfly; **Corduliidae**) male adult, a species that may shed its naiad exuvia on mosses bordering ponds. Photo by Denis A. Doucet, with permission.

Safety in Numbers

The dragonfly *Sympetrum vicinum* (Libellulidae – skimmers; Figure 49) typically uses wet mosses at the edge of a lake for depositing eggs (Whitehouse & Walker 1941). Mating and egg laying can be particularly dangerous for the **Odonata**. These able fliers are at a disadvantage when coupled during mating and when dipping into the water to lay eggs. One strategy for reducing chances of becoming frog dinner is for the mating pair to join other mating pairs, with up to seven pairs of *Sympetrum vicinum* (Figure 49) grouping together in a single 1 m² plot (McMillan 2000). Interestingly, frogs attacked lone pairs more frequently than they attacked pairs in aggregations. On the other hand, the presence of multiple pairs may have signalled a safe site against the predation.

Figure 49. *Sympetrum vicinum* (dragonfly; Corduliidae) adults mating. Photo by Phil Myers, through Creative Commons.

Sympetrum danae (dragonfly; Corduliidae) (Figure 50-Figure 52) does not remain in tandem pairs (compare to Figure 48) like *S. vicinum* (Figure 49). In the field, 14% of females that started oviposition while still in tandem and 10% of those that had separated from the males were killed by frogs (Michiels & Dhondt 1990). A curious observation is that separated ovipositing females were attacked less often by the frogs than were those females that were not observed mating previously. Females of this species preferred sites with *Sphagnum* (Figure 24), but when non-aquatic mosses with a similar structure were substituted, they were selected equally, suggesting that selection was based on surface characteristics of the mosses. Within the bog, temperature played a role in oviposition location. In the cooler part of the season the females selected the south-facing side of a hummock, whereas in the warmer part of the season they selected the cooler north-facing side of the hummock.

Figure 52. *Sympetrum danae* (dragonfly; **Corduliidae**) mating. Once mating is completed, this species separates and does not fly in tandem. Photo by Tim Faasen, with permission.

Bogs and Fens

Bogs and fens in many ways offer ideal conditions for adult **Odonata**. These strong fliers prefer bright sunshine and become quiet when the weather is cloudy. Sunny, open bogs are thus best suited for them, compared to other kinds of habitats. As discussed earlier regarding bog habitats (Chapter 11-2), the adults are easily seen flying about in bogs (Boudot *et al.* 1990).

Some **Odonata** seem to prefer bogs as adults, using them as a place to forage and for "sport" (Needham *et al.* 1901). One such dragonfly is *Cordulia shurtleffi* (American emerald – **Corduliidae**; Figure 53) in the Adirondack Mountains of eastern North America.

Figure 53. *Cordulia shurtleffi* (American emerald dragonfly) adult, a species that forages and plays around bog pools. Photo by Richard Orr, with permission.

But is this habitat equally suitable for the naiads? As Krebs (2001) reminded us, habitat heterogeneity provides more ecological niches, and bogs fit that heterogeneity of moisture and temperature as well as differences in microtopography. Some of these may use the mosses as occasional cover in the naiad stage (Figure 54).

Figure 54. *Cordulia aenea* (downy emerald dragonfly) naiad with mosses. This species is a relative of *C. shurtleffi*, a bog species. Photo by Tim Faasen, with permission.

In Ontario, Canada, naiads of *Williamsonia fletcheri* (**Corduliidae**; Figure 55) live among the dead *Sphagnum* stems (Charlton & Cannings 1993). They matched the *Sphagnum* and rarely moved, giving them excellent camouflage. In Maine, USA, the males perch on *Sphagnum* hummocks in spruce bogs.

Figure 55. *Williamsonia fletcheri*, a species whose naiads live among dead *Sphagnum* stems. Photo by Diana-Terry Hibbitts, through Creative Commons.

Odonata can have a strong impact on the communities where they live. The naiads are efficient carnivores with highly specialized scoops for capturing prey. Larson and House (1990) concluded that they may be the principal organism determining abundance and distribution of potential prey organisms in the bog pool system.

Normally bogs and fens have rather different flora and fauna from each other. But Cannings and Cannings (1994) concluded that there were no clear differences between the **Odonata** in these two habitat categories. Rather than responding to acidity or nutrient levels, they seem to respond to the form and structure that is similar in these two habitats.

In a study of the northern Cordilleran peatlands, Cannings and Cannings (1994) found that of 40 species there, 8 are obligate peatland inhabitants and another 4 almost always occur there. The most common genera there are *Aeshna* (**Aeshnidae**; Figure 56-Figure 62) – 11 species) and *Somatochlora* (**Corduliidae**; Figure 20-Figure 21) – 10 species, both dragonflies. The peatlands serve as **refugial** habitats (having isolated populations of once more widespread species, *i.e.* **relict populations**), with 25

species that are restricted to boreal regions and six that are **Holarctic** (majority of habitats found throughout the northern continents of the world).

Figure 56. *Aeshna juncea* (dragonfly; **Aeshnidae**) depositing eggs among the *Polytrichum* plants. It is common in small acid pools of bogs. Photo copyright by David Kitching <<http://www.brocross.com/dfly/dfly.htm>>, with permission.

Aeshna juncea (dragonfly; **Aeshnidae**) (Figure 56-Figure 57) prefers the acid water of bog pools and lays its eggs among the bog bryophytes (Figure 56). *Aeshna subarctica* (Figure 27) likewise lays its eggs among *Sphagnum* (Figure 24), but in the northern Cordilleran peatlands, *A. subarctica* (Figure 58) is more commonly associated with *Drepanocladus* (*s.l.*) (Figure 59) and *Scorpidium* (Figure 60) (Cannings & Cannings 1997). Its males patrol only the floating mats in search of females; the females lay their eggs directly on these mats. *Aeshna sitchensis* (Figure 61) lives where the peatlands have filled-in depressions. The mossy fen ponds of the Yukon include *Aeshna septentrionalis* (Figure 62) and *A. subarctica* among their fauna. *Aeshna septentrionalis* females use the sedge-moss habitat for oviposition.

Figure 62. *Aeshna caerulea* (dragonfly; **Aeshnidae**) male adult. Photo by Guillaume Doucet <guillaume.doucet.free.fr>, with permission.

In the Czech Republic, *Aeshna caerulea* (Figure 62) is a relict, living in bogs that are drying up, suffering from nitrogen deposition, suffering from global warming – all factors contributing to the disappearance of the bogs that serve as its habitat (Dolný 2013).

Mossy fen ponds in the Yukon, Canada, provide us with some idea of the dominant **Odonata** in northern habitats (Cannings & Cannings 1997). In addition to *Aeshna* species, their distinctive fauna includes the damselfly *Coenagrion interrogatum* (**Coenagrionidae**; Figure 63-Figure 64) and dragonfly *Somatochlora sahlbergi* (**Corduliidae**; Figure 65; see Figure 66 for *Somatochlora* naiad). *Coenagrion interrogatum* is only common where the aquatic mosses are abundant. Where the peatlands have filled in depressions the habitat is characterized by *Aeshna sitchensis* (Figure 61), *Somatochlora franklini* (Figure 67), *S. kennedyi* (Figure 82), *S. whitehousei* (Figure 83), and *Leucorrhinia patricia* (**Libellulidae**; Figure 84). These dragonfly males patrol the floating mats of mosses that include *Drepanocladus* (*s.l.*) (Figure 59) and *Scorpidium* (Figure 60). *Leucorrhinia patricia* (Figure 84) is restricted to water bodies that have aquatic mosses either floating or near the surface. In Sweden, *Leucorrhinia rubicunda* (Figure 85-Figure 86) hunts for its food in bogs as adults (Scholl 2002). In the boreal ecosystems this species occurs only in transitional mires, but in the Netherlands it is the most abundant species of **Odonata** in the spring in degraded and rewetted mires (Desrochers & van Duinen 2006).

Figure 67. *Somatochlora franklini* (dragonfly; **Corduliidae**) adult, a bog dweller. Photo by Larry deMarch, through Creative Commons.

In northern British Columbia, Canada, species are similar to those of the Yukon. In standing open water with submerged mosses provides a suitable naiad home for many species with wide ecological tolerances: *Coenagrion interrogatum* (Figure 63-Figure 64), *Aeshna septentrionalis* (Figure 62), *A. subarctica* (Figure 27), *Somatochlora kennedyi* (Figure 82), *S. septentrionalis*, *Leucorrhinia patricia* (Figure 84). In slender sedge fens with *Drepanocladus* (Figure 59), one can find *Lestes disjunctus* (Figure 101), *Coenagrion interrogatum*, *C. resolutum* (Figure 68), *Nehalennia irene* (Figure 69), *Aeshna juncea* (Figure 56-Figure 57), *Aeshna subarctica*, *Leucorrhinia hudsonica* (Figure 29), *L. proxima* (Figure 70), and *Sympetrum obtrusum* (Figure 71-Figure 72) (Cannings *et al.* 2004). In shallow sedge-moss fens, typical of patterned fens with *Drepanocladus*, *Lestes disjunctus*, *L. congener* (Figure 73), *L. forcipatus* (Figure 102), *Enallagma boreale* (Figure 74), *Coenagrion resolutum*, *Nehalennia irene*, *Aeshna septentrionalis*, *A. sitchensis* (Figure 61), *A. tuberculifera* (Figure 75), *Somatochlora brevicincta*, *S. franklini* (Figure 76), *S. kennedyi*, *S. semicircularis* (Figure 87), *S. whitehousei* (Figure 83), *Leucorrhinia hudsonica*, and *Sympetrum danae* (Figure 50-Figure 52) occur. The outer coastal bogs have a communities of *Pinus contorta* – *Empetrum nigrum* – *Sphagnum austini* (Figure 77) and *Juniperus communis* – *Trichoporum cespitosum* – *Racomitrium lanuginosum* (Figure 78). These are suitable habitats for *Lestes disjunctus*, *Enallagma boreale*, *Aeshna interrupta* (Figure 79-Figure 80), *Aeshna sitchensis*, *Cordulia shurtleffii* (Figure 53), *Somatochlora albicincta* (Figure 88), *Leucorrhinia hudsonica*, *Libellula quadrimaculata* (Figure 22), and *Sympetrum danae*. The seepages and springs of coastal fen associations with *Eriophorum angustifolium* and *Sphagnum* are typical habitats for *Tanypteryx hageni* (Figure 81), which burrows into the seepage.

Figure 83. *Somatochlora whitehousei* (dragonfly; Corduliidae) adult, a species that patrols the *Sphagnum* mats to find a female. Photo by Jim Johnson, with permission.

Somatochlora franklini (Figure 76) patrols over *Sphagnum* (Figure 24) in bogs and over water-soaked mosses in fens, preferring spring-fed *Sphagnum* fens. *Somatochlora sahlbergi* (Figure 65) naiads (see Figure 66) live where the water is underlain with mosses. As adults they drop their eggs into the water, but again in sites underlain with mosses. Both *S. semicircularis* (Figure 87) and *S. albicincta* (Figure 88) prefer mossy substrata, the former in a sedge-moss marsh and the latter in mud-bottomed, mossy fen ponds. *Somatochlora semicircularis* (Figure 89) flies low over bogs in search of egg-laying sites among the pools; naiads develop in the spring pools and swamps (Usinger 1974).

Figure 89. *Somatochlora artica* (dragonfly; **Corduliidae**) adult; the female flies low over bogs to find a suitable place to lay eggs. Naiads develop in pools there. Photo by Guillaume Doucet <guillaume.doucet.free.fr>, with permission.

Dragonflies often deposit their eggs among bryophytes (Macan 1963), with the naiads subsequently living there (Gerson 1982). These bryophyte dwellers include *Leucorrhinia dubia* (**Libellulidae** – skimmers; Figure 90-Figure 93) from Europe (Matthey 1971) and *Calicnemia miles* (**Platycnemididae** – white-legged damselflies; Figure 94) from the Himalayan Mountains (Kumar & Prasad 1977).

Macan (1962) attempted to explain why (and how) *Leucorrhinia dubia* (Figure 90-Figure 93), a **Libellulidae** dragonfly, chose bog pools for laying eggs. He found that this genus was attracted to a white surface on the ground, but that hardly explained anything since *Leucorrhinia* species lay eggs by flying and dipping to deposit the eggs in the water during flight. Schiemenz (1954) found that it preferred a *Sphagnum* (Figure 51) pool (68%) to tap water, but considered this to be inconclusive. It is likely that water chemistry plays a role.

Figure 90. *Leucorrhinia dubia* (Libellulidae) naiad, a dragonfly species that changes color in late naiad stages to blend with the surrounding *Sphagnum* (Figure 51). Photo by Tim Faasen, with permission.

Figure 94. *Calicnemis miles* (Platynemididae) adult female damselfly who often lays eggs among wet mosses in the Himalayas. Photo by Davidvraju, through Creative Commons.

The dragonfly *Leucorrhinia dubia* (white-faced darter; dragonfly; Libellulidae) (Figure 90-Figure 93) is so well adapted to the *Sphagnum* (Figure 24) habitat that the late instar naiads (immature stages) actually change color to blend with the brown and green color of *Sphagnum* (Figure 95) (Henrikson 1993). These naiads show preference for the *Sphagnum* substrate over debris in laboratory tests, a behavior that seems to permit them to be more successful in preying on aquatic pillbugs, *Asellus aquaticus* (Figure 96). Henrikson suggested that the complex habitat of *Sphagnum* serves both as shelter and as a foraging site; the *Sphagnum* apparently provides a safe habitat against predators – where large mats of this moss exist, *Leucorrhinia dubia* is able to coexist with the fish without becoming dinner.

Figure 96. *Asellus aquaticus*, food of *Leucorrhinia dubia*. Photo by Niels Sloth, with permission.

Tanypteryx hageni (Figure 97-Figure 99) (dragonfly; **Petaluridae** – petaltails) adults are most common in alpine bogs. Naiads have been found in mosses in seepage along the west coast of USA (Usinger 1974).

Figure 97. *Tanypteryx hageni* (dragonfly; **Petaluridae**) naiad clinging to mosses. Photo by Greg Courtney, with permission.

Figure 99. *Tanypteryx* (dragonfly; **Petaluridae**) burrows amid mosses and swamp litter. Note the holes. Photo by Greg Courtney, with permission.

Damselflies (**Zygoptera**) seem less common among the bog fauna than dragonflies. The common genus *Lestes* (**Lestidae** – spreadwings; Figure 100-Figure 102), a damselfly, includes bogs among its many habitats. In British Columbia, Canada, *Lestes disjunctus* (Figure 101) is common in several bog types whereas *L. forcipatus* (Figure 102) is uncommon in one type and absent in the others (Cannings & Simaika 2005). *Lestes forcipatus* is most common in the cold sedge and moss fens and is relatively rare in warmer habitats.

Summary

The **Odonata** are **hemimetabolous**, having egg, naiad, and adult stages. They are comprised of dragonflies (**Anisoptera**) and damselflies (**Zygoptera**). Neither is common among bryophytes, most likely due to their large labium used for catching prey and to their large size. Nevertheless, some occur among the bryophytes as naiads, some lay their eggs there, and some gather on bryophytes to emerge to the adult stage.

The **Odonata** are common in bogs and fens, with naiads living among the many pools, sometimes darting into the dangling mosses for cover. The form and structure of the bryophytes may be important determinants in where they live. At mating time, some of the **Odonata** increase the safety of the species by forming aggregations – safety in numbers. *Aeshna* and *Somatochlora* are the most common genera in the bogs. In both the naiad and adult stages the **Odonata** are voracious carnivores and thus have a major impact, especially in the bog ecosystem.

The typical bog inhabitants include members of **Aeshnidae**, **Coenagrionidae**, **Corduliidae**, **Lestidae**, **Libellulidae**, **Platycnemididae**, and **Petaluridae**. Other families that may be found among bryophytes include **Argiolestidae**, **Cordulegastridae**, and **Gomphidae**.

Acknowledgments

Juan Carlos Villareal helped me obtain information on oviposition of *Epiophlebia superstes*. My sister Eileen Dumire helped to sort the insects from the bryophytes, maintain the bibliography, and most importantly she proofread the chapter and offered a non-biologist's perspective on its readability. Thank you also to Bob Marr for reviewing the chapter and making several suggestions to improve clarity.

CHAPTER 11-6

AQUATIC INSECTS:

HEMIMETABOLOUS INSECTS –

PLECOPTERA

Figure 1. *Taeniopteryx* sp. naiad, a common inhabitant of stream bryophytes, especially in early stages. Photo by Bob Henricks, with permission.

PLECOPTERA – Stoneflies

Like the other **hemimetabolous** (incomplete metamorphosis with egg, naiad, and adult) aquatic orders, the **Plecoptera** (Figure 1) have an aquatic immature stage known as a **naiad**. They differ from the **Ephemeroptera** (Chapter 11-4) in that they consistently have only two tails (**caudal filaments**). Their gills occur in various locations but are not found in the middle of the abdomen. The gills are usually not extensive and are absent in many (Dodds & Hisaw 1924; Pennak 1953), so **Plecoptera** naiads require water with high oxygen levels (Needham 1901; Dodds & Hisaw 1924; Macan & Worthington 1951; Pennak 1953; Ward & Whipple 1959), making them good indicators of relatively clean water.

The naiads reach their greatest numbers in fast, cold mountain streams (Thorpe & Covich 1991). Although most occur in streams, a few occur in cold, **oligotrophic** (low nutrient) lakes. The naiads must climb out of the water to emerge from their exoskeleton and become adults. The adults are short-lived, but live longer than mayflies, usually several days to two weeks (Thorpe & Covich 1991). The

naiads are largely night active and appear most often in the night-time drift (Elliott 1967).

Krno and Žiak (2012) found that the number of stoneflies in West Carpathian calcareous **submontane** (ecological zone pertaining to lower slopes of mountains) rivers increased with an increase in mosses, with several genera maintaining their highest density on mosses. **Plecoptera** can use bryophytes in a number of ways. The most obvious is their use as a substrate and shelter from the flowing water. They are especially common there as young instars when the bryophytes can protect these less able swimmers from the flowing water. Many are able to obtain food there, either by preying on smaller invertebrates, by using the collected **detritus** (dead organic matter and debris) and **periphyton** (attached algae and other microorganisms), or less often by eating the mosses themselves. When it is time to emerge, they can use the bryophytes to help them climb through the surface tension and sometimes even provide a surface on which to emerge from naiad to adult, spread their wings, and fly away (Figure 2). Finally, these adults may return to the mosses to lay their eggs (Figure 3).

Figure 2. *Isoperla* sp. emerging, using emergent vegetation for support and to pump fluids into its wings. Photo by Richard Bartz, through Creative Commons.

Figure 3. **Plecoptera** eggs, laid here on a rock. Photo by Wendy Brown <www.gunnisoninsects.org>, with permission.

But the presence of some stoneflies as major inhabitants among bryophytes may be the preference of both the stonefly and the bryophyte for the same habitat. Two of the most common families, **Leuctridae** and **Nemouridae**, prefer cooler upstream stations in a southern Ontario, Canada, stream (Harper 1973), a habitat type also very suitable for bryophytes. Both benefit from clean, cool water with rapid flow and a rocky substrate.

Predation Retreat or Restaurant?

Many of the stoneflies are carnivores on a microscale. Since they are small, living in water torrents, they need a food source that is close by. For many, bryophytes can provide that habitat, a place where they can move about, safe from the current, and find an abundance of yet smaller prey items. For them, it is a restaurant with an impressive menu, but it is also a retreat from larger predators. For the yet smaller insects – well, it might be easier to escape predators, but it might also be a trap where they are eaten.

Elliott (2003) used *Baetis* naiads as experimental prey items to determine the effect on stonefly interactions, including three known bryophyte dwellers [*Perlodes microcephalus* (Figure 80), *Isoperla grammica* (Figure

75), *Dinocras cephalotes* (Figure 42)]. They found that feeding was density dependent, with the number of *Baetis* being eaten dependent on the number provided (between 20 and 200). Handling time was not affected by predator density or presence of other predators. However, attack rate decreased as predator density decreased. As expected, prey consumption also decreased as predator density decreased, with the severity of competition with a paired species being similar to that with the same species.

Food Relationships

Gerson (1982) suggested that **Plecoptera** may feed on aquatic bryophytes, but Stern and Stern (1969) found that detritus was the most common food for stoneflies, and detritus is common among the mosses. Jones (1950) examined the gut contents of **Plecoptera** naiads in the River Rheidol. Four of the six species studied had mosses (*Fontinalis antipyretica*, Figure 4) in the gut: *Chloroperla tripunctata* (see Figure 15-Figure 16), *Leuctra hippopus* (Figure 5), *Protonemura meyeri* (Figure 20), *Amphinemura sulcicollis* (= *A. cinerea*; Figure 19). The highest number with mosses in the gut was 12 out of 100 for the species *Protonemura meyeri*. But the question remains, were the mosses digested or just eaten for their adhering periphyton and detritus?

Small streams in the Tolvajärvi region of the Russian Karelia are characterized by higher nutrient and iron concentrations as well as a large amount of organic matter compared to the lake outlet. These small streams are dominated by the mosses *Fontinalis* (Figure 4) and *Hygrohypnum* (Figure 6) like the lake outlet habitats, but also the leafy liverworts *Scapania* sp. (Figure 7), *Marsupella* spp. (Figure 8), and *Jungermannia* sp. (Figure 9). The dominant moss inhabitants are stonefly shredders in the genera *Nemurella* (Figure 10-Figure 11), *Nemoura* (Figure 12-Figure 13), and *Leuctra* (Figure 5). Shredders typically eat leaf litter. Unfortunately, we have no data to indicate what they were shredding among the bryophytes.

Typical Fauna

When I examined the bryophytes from the Appalachian Mountain streams in Pennsylvania, Maryland, and West Virginia, USA, I found that the stoneflies were mostly small members in the genera *Nemoura* (Figure 12-Figure 13), *Allocapnia* (Figure 14), and *Leuctra* (Figure 5). Berthélemy (1966) found the moss-dwelling species generally to be smaller than those living among stones. Stern and Stern (1969) likewise found that the bryophytes

served the smaller stoneflies, especially *Nemoura* (Figure 12), and acted as a nursery for the young of other Plecoptera.

Figure 14. *Allocapnia* naiad, common among stream bryophytes in its early (small) stages. Photo by Bob Henricks, with permission.

Frost (1942) found that the moss fauna differed between acid and alkaline waters of the River Liffey, Ireland. In the acid areas, *Protonemura* (Figure 20),

Amphinemura (Figure 19), *Leuctra* (Figure 5), and *Chloroperla* (Figure 15-Figure 16) dominated the mosses, whereas in the alkaline waters only *Isoperla* (Figure 17) was common. This is consistent with my finding of *Nemouridae* and *Leuctra* among bryophytes in the acidic Appalachian Mountain, USA, streams (Glime 1968).

In a study of a cool mountain stream of central Japan, Tada and Satake (1994) found that the density of many **Plecoptera** was greater among bryophytes than in bare rock areas. These included *Scopura* sp. (**Scopuridae**; Figure 18) (also known from glaciers), *Amphinemura* (Figure 19), *Protonemura* (Figure 20), *Isoperla towadensis* (see Figure 21), and *I. nipponica*.

Reproductive Use

Stoneflies can use bryophytes for emergence and egg laying. But in some cases the bryophytes are used in mating behavior. Some stoneflies have an interesting way to attract females. They wait on the shoreline of streams or lakes for the females to emerge from the water and escape their naiad skins. Then they drum their abdomens on such available objects as rocks, dry leaves, and mosses, presumably to attract females (Erman 1984). Mating takes place on the ground (Brinck 1949).

Life cycles are typically attuned to the climate, permitting the insects to overwinter or survive dry spells. These life cycle needs thus dictate part of the required niche. Hynes and Hynes (1975) reported that the life cycle of Australian species were less rigid than those of stoneflies in the Northern Hemisphere. Hence, they tend to have broader ecological niches.

Capniidae – Small Winter Stoneflies

This family of medium-sized stoneflies (usually 5-10 mm) is poorly represented among bryophytes, despite being one of the largest families with about 300 species (Capniidae 2014). In the mid-Appalachian Mountains I found only *Allocapnia* (Figure 22) represented among the stream bryophytes (Glime 1968). *Allocapnia* adults (Figure 23-Figure 24) emerge in winter (Ross & Ricker 1971). The males are wingless, and these stoneflies often can be seen on the snow (Figure 23), wandering as much as 100 m from their naiad stream. Even the females have reduced wings, poorly developed wing venation, and reduced **thoracic sclerites** (plates forming the outer cover of an arthropod thorax) associated with the flight muscles, so their dispersal ability may be more limited than in other genera. Nevertheless, they do have the ability to disperse downstream, with **gravid females** (females carrying eggs) occurring in the drift and riding on floating ice. And adults may disperse upstream by **planing** – climbing up trees and structures, then gliding to a new location.

Figure 24. *Allocapnia pygmaea* female adult, a winter emerger that can ride the ice downstream. Photo by Donald S. Chandler, with permission.

Bryophytes can be an important location for finding food for some members of the **Capniidae**. Production of *Capnia vidua* (Figure 25) naiads in the High Tatra of

Slovakia is dependent on the detritus collected by the mosses, making the mosses a suitable habitat for them (Krnó & Sporka 2003). This genus also contains members that emerge and flit about on the snow (Figure 26).

Figure 25. *Capnia* naiad, a frequent bryophyte dweller. Photo by Jason Neuswanger, with permission.

Figure 26. **Capniidae** adult on snow. Photo by Bob Armstrong, with permission.

Leuctridae - Rolled-winged Stoneflies

This is likewise a family of medium size (5-13 mm). They are long, narrow stoneflies of streams. Berthélemy (1966) suggested that *Leuctra* (Figure 5, Figure 30-Figure 31) might be a **muscirole** (living in association with mosses). The genus is known as the rolled-wing stoneflies because of the manner in which the wings curve around the adult body (Figure 27). However, a number of species are **apterous** (without wings) as adults.

Figure 27. *Leuctra fusca* adult showing rolled wings. Photo by Malcolm Storey <www.discoverlife.org>, through Creative Commons.

The genus *Leuctra*, along with the **Nemouridae**, are among the most common naiads among the European bryophytes (Carpenter 1927; Frost 1942; Illies 1952).

In the mid-Appalachian Mountain, USA, streams, *Leuctra* was a fairly common bryophyte inhabitant, occurring among *Fontinalis dalecarlica* (Figure 78), *Hygroamblystegium fluviatile* (Figure 89) – *Platyhypnidium riparioides* (Figure 62), and most abundant on the leafy liverwort *Scapania undulata* (Figure 7) (Glime 1968). These naiads are relatively small, and those on bryophytes tend to be the youngest, *i.e.* smallest, making species identification nearly impossible. In Toliver Run, Garrett Co., MD, USA, this genus reaches a peak in June, but reaches a secondary peak in December, suggesting the presence of two different species. Mackereth (1957) likewise reported seasonal peaks that differed among species in this genus. I also found one adult in my collections, suggesting that they may emerge among the bryophytes (Glime 1968).

Wulfhorst (1994) examined the relative abundance of **Leuctridae** in mosses and in **interstitial** (spaces between individual sand grains in the soil or aquatic sediments) spaces in the **hyporheic** zone (beneath the bed of a river or stream) of two streams in the Harz Mountains of West Germany. She found that the **Leuctridae** were more abundant among the mosses at most collection stations, but that they were also abundant in the interstitial spaces of the **hyporheic** zone at 10 and 20 cm depths (Figure 28).

Figure 28. Mean abundance \pm 95% CI of **Leuctridae** in moss clumps compared to depths of the hyporheic zone in two streams in the Harz Mountains, West Germany. Redrawn from Wulfhorst 1994.

Several species of *Leuctra* [*L. armata* (Figure 29), *L. autumnalis*, *L. pusilla*] contribute to the production of Hincov Brook, High Tatra, Slovakia (Krno & Sporka 2003). Krno and Sporka concluded that these detritivorous stoneflies depend on the mosses to trap the coarse **benthic** (bottom) organic matter needed for their diet. The cold period produces higher productivity, attributable to reduction in feeding by brown trout.

In Radíkovský Brook in the Czech Republic, Jezberová (2003) found that substrate explains a large fraction of the data variability for **Ephemeroptera** and **Plecoptera**. Bryophytes play an important role for several species of *Leuctra* in that stream. Among these *Leuctra albida* and *L. teriolensis* highly prefer a bryophyte substratum.

Figure 29. *Leuctra armata* adult, a species whose naiads depend on mosses to trap detritus for their food. Photo from Zoologische Staatssammlung Muenchen, through Creative Commons.

Leuctra is herbivorous (Frison 1929). Jones (1949) found that *Leuctra fusca* (= *L. fusciventris*; Figure 30) and *L. geniculata* (Figure 31) had *Fontinalis antipyretica* (Figure 4) leaf fragments in about half the gut analyses from calcareous streams in South Wales. In the River Rheidol, UK, Jones (1950) found *Fontinalis* fragments in 8 of the 20 guts in which contents could be identified. Percival and Whitehead (1929) reported that several species of UK *Leuctra* had mosses in their guts. Dangles (2002) considered members of this genus to be generalist feeders, including bryophytes among their food choices.

Figure 31. *Leuctra geniculata* naiad, a consumer of *Fontinalis*. Photo from Zoologische Staatssammlung Muenchen, through Creative Commons.

In the River Rajcianka, Slovakia, submerged bryophytes are home to *Leuctra hippopus* (Figure 5), *L. inermis* (Figure 32), and *L. rauscheri* (Krno 1990). Most are restricted to the submerged portions, but *L. rauscheri* is able to live above the water surface among emergent bryophytes.

Figure 32. *Leuctra inermis* adult, a species whose naiads live among bryophytes in River Rajcianska, Slovakia. Photo by James K. Lindsey, with permission.

Nemouridae – Spring Stoneflies

This is a family of small to medium stoneflies (5-20 mm). Wulfhorst (1994) examined the relative abundance of **Nemouridae** in mosses and in interstitial spaces in the hyporheic zone of two streams in the Harz Mountains of West Germany. She found that the **Nemouridae** were much more abundant among the mosses at all collection stations (Figure 33) than on other substrata. Furthermore, she found that most of them avoided 10 and 30 cm depths.

Figure 33. Mean abundance \pm 95% CI of **Nemouridae** (*Amphinemura*/*Protonemura*) in moss clumps in two streams in the Harz Mountains, West Germany. Redrawn from Wulfhorst 1994.

In the Appalachian Mountain streams I studied, **Nemouridae** (Figure 34-Figure 37) were the most frequent and abundant of the Plecoptera, reaching their greatest numbers on turfs of *Scapania undulata* (Glime 1968, 1994). The species included *Nemoura sinuata* (Figure 34), *Soyedina vallicularia*(?) (Figure 35-Figure 36), and *Amphinemura nigritta* (Figure 37). These occurred at all instar stages and most likely emerged to adulthood from the bryophyte mat.

Figure 37. *Amphinemura nigritta* naiad, a common nemourid among Appalachian Mountain stream mosses. Photo by Tom Murray, through Creative Commons.

In subarctic Fennoscandia, some members of *Nemoura*, such as *N. viki*, deposit their eggs on damp mosses, although most are deposited in the water (Lillehammer 1986, 1988). *Nemoura viki* and *N. arctica* differ in their life cycles and in their preferred biotopes, effectively separating their niches. The temperature tolerance range of the eggs of *N. arctica* is wider. For the latter, temperature nevertheless has a profound effect on naiad development time. After 700 days at 4°C, the naiads still are not ready for emergence. On the other hand, at 16°C, the naiads can reach maturity in 120 days.

Wu (1923) reported that *Nemoura* (Figure 12) was a herbivore, eating mostly desmids and diatoms; he never found animal tissue in the diet. On the other hand, Chapman and Demory (1963) found that *Nemoura* in two Oregon, USA, streams consumed mostly detritus. Leberfinger and Bohman (2010) found that *Nemoura* sp. chose algae and shrubby cinquefoil when offered leaves of birch, Swedish whitebeam, shrubby cinquefoil, dead and fresh grass, moss, and algae. The least consumed food was dead grass, despite its being the most abundant food in the stream. Even though the fresh food had the highest carbon to nitrogen content, it was the dead leaves of the shrubby cinquefoil that was the food of choice, suggesting that perhaps fungal or bacterial decomposer organisms might have been important in the diet. A word of caution – the genus *Nemoura* has since been divided into multiple genera, so these generic designations may be misleading; The designation by Leberfinger and Bohman (2010) is recent and is most likely reflective of modern nomenclature.

Nemoura flexuosa (Figure 38), *N. marginata*, and *N. monticola* all live among bryophytes in the River Rajciana, Slovakia (Krno 1990). *Nemoura monticola* seems to be restricted to submerged bryophytes, whereas the other two species are able to move about within the wet bryophyte clumps above that water line.

Figure 38. *Nemoura flexuosa* naiad, a bryophyte dweller in Europe. Photo by Niels Sloth, with permission.

Nemoura cinerea (Figure 39-Figure 40) survives low oxygen levels better than *Diura bicaudata* (Perlodidae; Figure 41) and *Dinocras cephalotes* (Perlidae; Figure 42) (Benedetto 1970), perhaps explaining the ability of *N. cinerea* to live among mosses with heavy sedimentation. Furthermore, *N. cinerea* was the only species among the four tested that did not display undulations as oxygen levels became low (Benedetto 1970). *Amphinemura* has a cluster

of pompon-like gills in each side of the neck (Figure 43). But *N. cinerea*, like all *Nemoura* species, lacks this group of gills and does not have the ability to acclimate and change its low oxygen response to temperature (Nagell & Fagerstrom 1978).

Figure 39. *Nemoura cinerea* mating, a species whose naiads are unable to acclimate to low oxygen but that is a better survivor in these conditions than *Diura bicaudata* and *Dinocras cephalotes*. Photo by James K. Lindsey, with permission.

Figure 45. *Protonemura intricata* adult, a species whose naiads live among bryophytes. Photo by Zoologische Staatssammlung Muenchen, through Creative Commons.

Nemouridae (Figure 39-Figure 43) are very tolerant of low temperatures, achieving a growth rate of 1.6% per day at a mean water temperature of only 0.6°C in a subalpine lake in the Jotunheimen Mountains of southern Norway (Brittain 1983). This is also a typical stream temperature in northern Appalachian Mountain streams of New Hampshire in winter (Glime, unpubl data).

Krno (1990) reported several species of *Protonemura* on submerged bryophytes in the River Rajcianka, Slavakia: *Protonemura auberti*, *P. autumnalis*, *P. hrabei* (Figure 44), *P. intricata* (Figure 45), *P. praecox* (Figure 46-Figure 48). Of these, *Protonemura auberti*, *P. autumnalis*, *P. hrabei*, and *P. intricata* also occurred on emergent wet bryophytes. Krno and Žiak (2012) reported that *Protonemura* was one of the taxa that was greatest on bryophytes in calcareous submontane rivers of the West Carpathians. *Protonemura* is likewise abundant among mosses in the Pyrénées (Berthélemy 1966), causing Berthélemy to consider *P. pyrenaica* to be a **muscirole** (living in association with mosses).

Figure 46. *Protonemura praecox* emergent female adult before wings are inflated. Photo by Walter Pfliegler, with permission.

Figure 48. *Protonemura praecox* female adult with fully inflated wings. Photo by Walter Pfliegler, with permission.

Protonemura meyeri (Figure 20) is common on *Fontinalis* (Figure 4) and other mosses in Europe (Hynes 1941; Costello 1988). This is a species that not only lives among bryophytes below the water surface, but also is able to go above the water level in the protective moisture of the bryophytes (Krno 1990). Frost (1942) concluded that *P. meyeri* lives among mosses throughout its entire naiad life. Not only did Hynes (1941) find that moss is the primary habitat for *P. meyeri*, but Frost (1942) found that in the River Liffey it feeds almost entirely on mosses. However, Jones (1950) found *Fontinalis* in the guts of only 12 out of 32 *Protonemura meyeri* and in 2 out of 43 *Amphinemura sulciollis* (Figure 19) in the River Rheidol, UK. Availability of moss vs other food choices influence which the stoneflies will eat.

On the other hand, Dangle (2002) considered *Protonemura* to be a generalist, including mosses among its food selections. But Dangle also cautioned against making generalizations from one species to another within a genus, even when the mouth parts were essentially the same. Krno and Sporka (2003) found that mosses were important for *P. montana* and *P. nimborum* because of the coarse benthic organic matter that accumulated there, providing both a stable habitat and a detrital food source.

Kamler (1967) found large numbers of *Protonemura nitida* among mosses in the early naiad stages. Bottová and Derka (2013) found that *P. nitida* was a significant contributor to the biomass in a **karstic** (limestone terrain characterized by sinks, ravines, and underground streams) spring in the West Carpathians. Its numbers reached 13,585 per m² in moss there, making them the most abundant stonefly. Steiner (1991) was surprised to find that when the surface film in *Fontinalis antipyretica* (Figure 4) was removed, small *P. nitida* fed on the leaf interior, but larger naiads tore the leaves, becoming moss shredders.

In the calcareous submontane rivers of the West Carpathians, *Amphinemura* was in its greatest abundance on mosses (Krno & Žiak 2012). Percival and Whitehead (1929) found *Amphinemura sulciollis* (Figure 19) would occupy both thick and loose mosses, but it is much more abundant in the tracheophyte *Potamogeton* (Figure 49). Butcher *et al.* (1937) commented that it is probable that all the naiads belonged to this species, alluding to the difficulty in identifying the young instars. Frost (1942) found only two individuals of this species among the mosses in the alkaline station, but over 2000 at the acid water station. In their experiments, Willoughby and Mappin (1988) found that the tolerance of low pH by *Amphinemura sulciollis* from acidic streams in the watershed of the River Duddon was similar to that of the mayfly *Serratella ignita* (Figure 1). It is interesting that *A. sulciollis* slightly increases the percentage of detritus in its diet as it grows rather than increasing the moss component, as is common among other stoneflies and mayflies (López-Rodríguez *et al.* 2008). Nevertheless, mosses appear to be important components of the habitat for *A. sulciollis* as evidenced by its presence in thirteen localities on the Isle of Man where mosses or overhanging grass were present (Hynes 1952). In North America, *A. nigrilla* (Figure 50) occurs among bryophytes in the mid-Appalachian Mountain streams, inhabiting all the major bryophytes there: *Fontinalis dalecarlica* (Figure 78), *Hygroamblystegium fluviatile* (Figure 89) – *Platyhypnidium riparioides* (Figure 62), and *Scapania undulata* (Figure 7) (Glime 1968).

In streamside mosses like *Cratoneuron* (Figure 51), the stonefly *Nemurella pictetii* (Figure 10-Figure 11) may reach 16,500 individuals per square meter in a Danish spring (Lindegård *et al.* 1975), and Thorup (1963) considered it to prefer mosses as a substrate. This species not only occurs in springs, but is among the few moss dwellers that are also common in lakes (Kamler 1967). Its adaptability to climate changes and habitat differences is seen in its ability to have both **bi-** and **trimodal** emergence patterns (having 2 and 3 peaks, respectively), coupled with partial **bivoltinism** (two broods per year), in Central Europe (Wolf & Zwick 1989), representing the only confirmed multivoltinism in a stonefly. Its emergence threshold temperature of 8°C prevents it from emerging when freezing danger is still likely. Rather than relying on seasonal life cycle cues, this species seems to be regulated by temperature, registered as accumulated degree days and an emergence temperature threshold.

Figure 51. *Cratoneuron filicinum* where *Nemurella pictetii* lives on springs and streamside. Photo by Michael Lüth, with permission.

Zapada cinctipes (= *Nemoura cinctipes*; Figure 52) was most abundant in the upper reaches of Trout Creek, Utah, USA, where the substrate was densely covered with the moss *Hygrohypnum bestii* (Figure 53) (Hales & Gaufin 1971). *Zapada columbiana* (Figure 54), a native of subalpine streams in Calgary, Canada, has a three-year life

cycle (Mutch & Pritchard 1984, 1986). The naiads live primarily on boulders and cobble among mosses (Clifford 2014). Despite their long life cycle, they only grow during the ice-free season (Mutch & Pritchard 1986). The females do not move upstream to lay eggs (Mutch & Pritchard 1984). Of the six females examined, their egg production ranged 800-1200 eggs each (Mutch & Pritchard 1986). These eggs hatch before winter so that the young naiads spend the first winter living among the mosses. Nevertheless, the eggs of these stoneflies develop best at lower temperatures.

Figure 54. *Zapada columbiana* adult on snow. Photo by Bob Newell, with permission.

Although *Zapada columbiana* (Figure 54) lives for three years in the rocky streams of the Alberta, Canada, Rocky Mountains, some naiads may complete their life cycle in two years (Mutch & Pritchard 1984). Important to these naiads is the food available to them. Mutch and Pritchard found that at any time during their growth season (June to November) at least 50% of them were living among the mosses covering the boulders or cobble in riffles. Furthermore, mosses are the predominant food in the gut for these shredders, but during winter highly conditioned conifer detritus becomes the predominant component. In experiments these naiads grow better on a moss diet than on the leaves of the willow *Salix glauca*.

Notonemouridae

This New Zealand/southern Africa family is another stonefly addition to the moss fauna and is not known from the Northern Hemisphere. All the genera are endemic to New Zealand except *Notonemoura* (McLellan 1991). They are typical of cool, high elevation lakes and rivers (Notonemouridae 2015), but some have terrestrial naiads and others have naiads that spend their early instars in the water and later instars on land, and some live in lowlands (McLellan 1991). They are herbivores and detritivores. Their enlarged hind femora helps them to climb vertical surfaces against flowing water (Notonemouridae 2015). The females lay their sticky eggs in the crevices of logs and rocks. These are small stoneflies (5-8 mm) and are mostly leaf shredders (Picker *et al.* 2004).

Notonemoura latipennis occurs in bog pools and bog outlet streams (McLellan 1991). *Spaniocercooides hudsoni* (see Figure 55) naiads live in *Sphagnum* bogs (Figure 56-Figure 57) (McLellan 2005). *Spaniocerca zelandica* naiads live in streams under stones or fallen logs or hidden among mosses or leaf litter (Winterbourn 1968).

Figure 55. *Spaniocercooides philpotti* naiad, member of a genus that lives in bogs and in streams among mosses. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Chloroperlidae – Green Stoneflies

Members of this family are medium in size (10-20 mm) and typically green as adults (Figure 58). *Chloroperla tripunctata* (see Figure 59) occasionally eats fragments of *Fontinalis* (Figure 4), but Jones (1950) reported only 3 specimens out of 113 with this moss in their guts in the River Rheidol, UK.

Figure 59. **Chloroperlidae** naiad, a family where some members occasionally eat *Fontinalis*. Photo by Bob Henricks, with permission.

In the High Tatra of Slovakia, *Siphonoperla neglecta* (Figure 60) depends on mosses that trap the coarse benthic detritus that serves as their food (Krno & Sporka 2003). The moss helps them to avoid predation by the brown trout until the cold season when the trout cease feeding actively.

Figure 60. *Siphonoperla torrentium* mating; *Siphonoperla neglecta* escapes brown trout predation by hiding among mosses. Photo by James K. Lindsey, with permission.

Taeniopterygidae – Winter Stoneflies

The Taeniopterygidae are among the small to medium (10-20 mm) bryophyte-dwelling stoneflies. These shredders and detritivores prefer cold, clear running water of large streams and rivers (Entz 2006). They emerge in winter and are not among the bryophytes year-round because they are very sensitive to warm temperatures and require high oxygen levels.

The genus *Taeniopteryx* (Figure 61) commonly develops among mosses (Berthélemy 1966). It is common in some mid-Appalachian Mountain streams among *Hygroamblystegium fluviatile* (Figure 89) – *Platyhypnidium riparioides* (Figure 62) clumps, seemingly either abundant or absent. (Glime 1968). This species disappears from the bryophytes as it grows and is never present in older stages. Krno and Žiak (2012) reported that *Taeniopteryx auberti* is one of the taxa that reaches its greatest abundance on mosses in calcareous submontane

rivers of the West Carpathians. Tiny naiads of *Taeniopteryx nebulosa* (Figure 61) are common among *Platyhypnidium riparioides* in Britain (Langford & Bray 1969). Hubault (1927) considered *Taeniopteryx hubaulti* to be a strong muscicole.

Figure 61. *Taeniopteryx nebulosa* naiad, member of a genus that is common among *Platyhypnidium riparioides* in the UK. Photo by Niels Sloth, with permission.

Figure 62. *Platyhypnidium riparioides*, home of *Taeniopteryx nebulosa*. Photo by Michael Lüth, with permission.

Brachyptera risi (Figure 63) in a Dartmoor stream was confined to mosses on the sides of boulders in the stream (Elliott 1967). Costello (1988) found it both widespread and abundant among mosses in Irish streams. Langford and Bray (1969) found larger nymphs of this species throughout the year on the mosses *Platyhypnidium riparioides* (Figure 62) and *Fontinalis antipyretica* (Figure 4), two species that usually did not occur together, in British lowland streams. Dangles (2002) reported *Brachyptera seticornis* as specializing on algae and bryophytes for its food.

Figure 63. *Brachyptera risi* naiad, a species confined to mosses in a Dartmoor stream. Photo by Guillaume Doucet <guillaume.doucet.free.fr>, with permission.

Perlidae – Common Stoneflies

The **Perlidae** are larger than members of the previous families, reaching 20-50 mm as adults. Although their distribution is nearly worldwide, they are most abundant in eastern North America (Perlidae 2013). Although they typically occur in cool, clear medium-sized to large streams, they can occur in quiet waters. When water is not moving over their bodies, they undulate the body to increase oxygen exchange. They are predators that engulf their prey.

Krno and Žiak (2012) reported that the perlid genus *Dinocras* reached its greatest abundance among mosses, compared to other substrata, in calcareous submontane rivers of the West Carpathians. Berthélemy (1966) considered *Dinocras* to be a muscicole, suggesting that the mosses help to stabilize the habitat for *Dinocras cephalotes* (= *Perla cephalotes*) (Figure 42). *Dinocras cephalotes* is one of the largest stoneflies in the Shropshire Hill Stream, UK, and is found mostly in streams and rivers where mosses cover stable stones (Arnold & Macan 1969). Hynes (1941) similarly found that it was much more common where the substrate was stable and moss-covered. And *Dinocras cephalotes* occasionally ingests mosses, including *Fontinalis antipyretica* (Figure 4) (Percival & Whitehead 1929; Jones 1949). But more importantly, at least in North Wales, the *D. cephalotes* hung out near where the triclads (flatworms) were abundant, forcing the triclads to live exclusively in dense patches of moss (Wright 1975).

In trout streams of Yellowstone National Park, USA, one could find *Hesperoperla pacifica* (Figure 64) among mosses and the green alga *Cladophora* (Figure 65) (Muttkowski & Smith 1929). This medium-sized species is a carnivore, but Muttkowski and Smith did find mosses in many of the guts, perhaps taken along with a grab for an insect prey.

Figure 65. *Cladophora*, habitat, along with mosses, for *Hesperoperla pacifica*. Photo by Yuuji Tsukii, with permission.

In the eastern USA, one can find a different array of **Perlidae** among the stream bryophytes. In the Appalachian Mountains, I found *Acroneuria* (Figure 66), *Agnatina capitata* (Figure 67), *Perlesta placida* (Figure 68-Figure 69), and *Paragnetina* (Figure 70) (Glime 1968). *Acroneuria carolinensis* (Figure 66) in Panther Creek, West Virginia, USA, clings to mosses, sand, rocks, and stems of *Rhododendron* (Schmidt & Tarter 1985). I often found this genus among the bryophytes in Appalachian Mountain streams (Glime 1968).

Perlodidae – Springflies & Yellow Stones

Like the **Perlidae**, the **Perlodidae** tend to be somewhat larger than the previous families (10-50 mm). The adults hatch in April to June and the eggs provide **diapause** (period of suspended development; physiological dormancy) during the warmer months, making the naiads absent from their native streams at that time because they have only one generation per year (Perlodidae 2014). Like the **Perlidae**, they are mostly engulfing predators, but some are scrapers and collector-gatherers. In addition to their diet of small invertebrates, at least some eat plant material, especially when they are young.

This is not a common family among moss dwellers, but in their study of an Idaho, USA, stream, Maurer and Brusven (1983) found a species of *Cultus* (Figure 71) to be common in clumps of *Fontinalis neomexicana* (Figure 72) as well as on the mineral substrate. Naiads climb out of the water and emerge on nearby rocks and vegetation (Figure 73).

Figure 72. *Fontinalis neomexicana* in a dry streambed; home of *Cultus verticalis* naiads. Photo by Janice Glime.

Figure 73. **Perlodidae** emerged on rock at edge of stream. Photo by Janice Glime.

Krno and Žiak (2012) reported that *Isoperla* is one of the taxa that is at its greatest abundance on mosses in calcareous submontane rivers of the West Carpathians. *Isoperla petersoni* is abundant in the upper 100 m of a Utah stream where the moss *Hygrohypnum bestii* (Figure 74) provides heavy cover on the substrate (Hales & Gauvin 1971). *Isoperla grammatica* (Figure 75) seems to be more common elsewhere than among mosses, but in her study of the River Liffey, Ireland, Frost (1942) found it to be the dominant moss-dwelling stonefly in the alkaline station of her study. Percival and Whitehead (1929) likewise found it to form denser populations among mosses than among stones. Langford and Bray (1969) reported it to have its largest numbers among the moss *Platyhypnidium riparioides* (Figure 62) in Britain, citing Brinck's (1949) comment that it has the widest ecological amplitude of all Swedish **Plecoptera**. This is a species that is common among submerged bryophytes in the River Rajcianka, Slovakia, but unlike some stoneflies, it is absent among the wet emergent mosses (Krno 1990). The same relationship of confinement to submersed bryophytes is true for *Isoperla oxylepis* and *I. sudetica*. Krno and Sporka (2003) found that *Isoperla sudetica* in the High Tatra of Slovakia depends on the detritus collected by mosses. This stonefly is most productive in winter when the brown trout is not actively feeding.

Figure 75. *Isoperla grammatica* naiad, a stonefly whose preference for mosses varies among streams. Photo by Urmas Kruus, with permission.

In the Nearctic, Nelson and Kondratieff (1983) found *Isoperla major* only at the source of a stream where naiads hid under large, moss-covered cobble. In Appalachian Mountain streams, *Diploperla duplicata* (Figure 76) and *Isoperla bilineata* (Figure 77) both occur among mosses (Glime 1968). The former is the most common, occurring among all the major bryophytes [*Fontinalis dalecarlica* (Figure 78), *Hygroamblystegium fluviatile* (Figure 89) – *Platyhypnidium riparioides* (Figure 62), *Scapania undulata* (Figure 7)]. What is surprising here is that these are mature naiads, not the tiny young ones.

Figure 76. *Diploperla duplicata* naiad, a common bryophyte inhabitant in Appalachian Mountain streams. Photo by Bob Henricks, with permission.

Figure 78. *Fontinalis dalecarlica* habitat Highlands, NC. Photo by Janice Glime.

In the Sturgeon River, northern Michigan, USA, *Isoperla signata* (Figure 79) had similar growth above and below a hydroelectric power plant, but the naiads were six times as abundant below the power plant (46 m^{-2} vs 7 m^{-2}) (Mundahl & Kraft 1988). Mundahl and Kraft suggested that the greater abundance below the dam may be from the rich growth of *Fontinalis* below the dam. These mosses were able to trap the detritus released from the dam and thus provide both cover and food for the stoneflies.

Figure 79. *Isoperla signata* naiad, a species that thrives on detritus collected by *Fontinalis*. Photo by Royce Bitzer <Iowa State Entomology Image Gallery>, with permission.

In the High Tatra, Slovakia, *Diura bicaudata* (Figure 41) is dependent on detritus that collects among mosses (Krno & Sporka 2003). This species is common in both stream mosses and in lakes (Kamlet 1967).

In Estonia *Perlodes microcephalus* (Figure 80) occurs in stony and gravelly bottoms where *Fontinalis* (Figure 4) grows (Timm 2000). *Perlodes intricatus* in the High Tatra of Slovakia depends on the detritus that accumulates among mosses in streams (Krno & Sporka 2003). The mosses also provide them with shelter from the predatory brown trout.

Figure 80. *Perlodes microcephalus* naiad, a species that hangs out near *Fontinalis* in stony streams of Estonia. Photo by Niels Sloth, with permission.

Susulus venustus from California, USA, is one of the species that drums on mosses and other substrates to attract females (Bottorff *et al.* 1989). The male drumming call is 1-3 groups of bi-beats and is a unique pattern among the **Perlodidae**. After mating, the females fly to the dark detritus and moss substrate, then walk into the shallow water where they release their eggs.

Peltoperlidae – Roachflies

This family (~8-20 mm) did not appear in any of the published studies I found. This is understandable because their preferred habitat is flowing streams characterized by sediments, vascular plants, and detritus (Peltoperlidae 2014). However, I did find *Peltoperla* (Figure 81) occasionally among all the major bryophytes [*Fontinalis dalecarlica* (Figure 78), *Hygroamblystegium fluviatile* (Figure 89) – *Platyhypnidium riparioides* (Figure 62), and *Scapania undulata* (Figure 7)] I studied in the Appalachian Mountain, USA, streams (Glime 1968). It typically preferred the mat habit.

Figure 81. *Peltoperla* naiad, an occasional dweller among bryophytes in streams in the Appalachian Mountains, USA. Photo by Bob Henricks, with permission.

Gripopterygidae

This family has become terrestrialized to the degree that the naiads usually live among damp substrata on land (McLellan 1977). But the naiads of *Zelandoperla fenestrata* (10-14 mm; see Figure 82) are widely distributed, especially among mosses, in stony streams in the mountains of New Zealand (Winterbourn & Gregson 1981). This species is most abundant among the *Fissidens rigidulus* (Figure 83) in the torrential water mid stream (Cowie & Winterbourn 1979). These naiads feed on the diatoms and detritus collected there.

Figure 82. *Zelandoperla pennulata* from the Takitimu Mountains, N. Z. Photo by Brian Patrick, with permission.

Figure 83. *Fissidens rigidulus*, home to *Zelandoperla fenestrata* in New Zealand. Photo by Bill & Nancy Malcolm, with permission.

Cardioperla nigrifrons occurs in large numbers among surface mosses in a fast waterfall (45° angle) in Tasmania (Dean & Cartwright 1992).

South American Plecoptera, like those from New Zealand and Tasmania, are often different from the ones found in the Northern Hemisphere. *Alfonsoperla flinti* occurs among mosses in high waterfalls in Chile (McLellan & Zwick 2007). Illies (1963) found this species among mosses on the stream beds.

Zelandobius (Figure 84-Figure 85) is one of the common small stoneflies in New Zealand, starting its life at about 0.6 mm length, with adults 7-11 mm (Death 1990). It is amphibious and is able to climb out of the water and move about among the emergent wet mosses of streams (Auckland Council 2011).

Figure 84. *Zelandobius* sp. naiad, a genus that can climb out of the water to explore among emergent mosses. Photo from Landcare Research, through Creative Commons.

Figure 85. *Zelandobius illiesi* naiad, a genus that can climb out of the water to explore among emergent mosses. Photo from Landcare Research, through Creative Commons.

Pteronarcyidae – Giant Stoneflies

This family has the largest members (15-70 mm) among the **Plecoptera**, hence the common name. The largest stonefly I have encountered among mosses is *Pteronarcys biloba* (Figure 86) (Glime 1968, 1994). The large size of older individuals seems to preclude their habitation among smaller mosses like *Platyhypnidium riparioides* (Figure 62) and *Hygroamblystegium fluviatile* (Figure 89). But within the larger spaces among branches of *Fontinalis* species (Figure 4) the genus is able to move about more freely. One feature that may contribute to its ability to hide deep within the streaming *Fontinalis* away from the rapid current is its possession of numerous thoracic tufts of gills that resemble pompoms (Figure 88). These gill tufts facilitate obtaining oxygen and permit the stoneflies to live deep within the clump, out of the rapid flow that brings oxygen to surface dwellers. On the other hand, small individuals (early instars) of *Pteronarcys proteus* (Figure 87-Figure 88) are able to live among the smaller spaces of *Hygroamblystegium fluviatile* (Figure 89).

Figure 86. *Pteronarcys biloba* naiad, a *Fontinalis* dweller in the Appalachian Mountain streams. Photo by Donald S. Chandler, with permission.

streams in Yellowstone National Park, USA. The researchers were surprised that this large stonefly was a vegetarian, with only 4% of its diet consisting of animals; instead the guts contained over 50% detritus.

Figure 89. *Hygroamblystegium fluviatile* in the Appalachian Mountains, USA, a moss that provides spaces too small for *Pteronarcys biloba*, but houses smaller individuals of *P. proteus*. Photo by Janice Glime.

Figure 87. *Pteronarcys proteus* naiad, an occasional occupant of *Hygroamblystegium fluviatile* in the Appalachian Mountains. Photo by Jason Neuswanger, with permission.

Figure 88. *Pteronarcys proteus* naiad, an occasional moss dweller, showing well-developed thoracic gills. Photo by Jason Neuswanger, with permission.

Muttkowski and Smith (1929) found mosses, along with diatoms (especially *Epithemia*, Figure 90) in the guts of five out of six *Pteronarcys californica* (Figure 91) examined from among mosses in strong rapids of trout

Figure 91. *Pteronarcys californica* naiad, a bryophyte consumer. Photo by Bob Henricks, with permission.

Several researchers have attempted to explain these diet preferences. *Pteronarcys pictetii* (Figure 92) and *P. californica* (Figure 91) have a diet that is 50-80% detritus during most of the year (Martin *et al.* 1981). Lechleitner and Kondratieff (1983) found that *P. californica* naiads switch from a diet of 40% algae in October to one with more mosses and blackflies in December. However they increase their moss intake when their normal food is insufficient. Martin and coworkers (1981) found that the midgut **proteolytic** (breaking down of proteins into simpler compounds) activity of the naiads is very high, similar to that in other aquatic detritivores. But the conditions differ from those of detritus-feeding **Diptera** and lack the digestive systems that are adapted for digesting proteins that are bound to **polyphenols** (compounds such as tannic acid composed of multiple phenol structures and that have toxic, metabolic, and other biological properties). They furthermore are poorly adapted for digesting the major **polysaccharides** (carbohydrate such as starch, cellulose, or glycogen whose molecules consist of a number of sugar molecules bonded together) present in detritus. Polysaccharide digestion is presumed to be restricted to α -1,4-glucans, the primary storage polysaccharide of higher plants, algae, and presumably bryophytes. But there seemed to be little enzymatic activity on the major structural polysaccharides of higher plants, suggesting that organisms that accompany the food items may help in the digestion.

Figure 92. *Pteronarcys pictetii* naiad, a detritus feeder. Photo from <Plecoptera.SpeciesFile.org> through Creative Commons.

Pteronarcella badia (Figure 93) is generally a detritus feeder in its early stages, but in later instars the naiads make mosses a substantial portion of their diet (Fuller & Stewart 1979). The other eight stonefly species examined from several Colorado, USA, rivers ate predominantly animals – **Chironomidae** (Figure 94), **Simuliidae** (Figure 95), and **Ephemeroptera** (see Chapter 11-4). Even though diets shifted for these other species as they developed, only *Pteronarcella badia* shifted to mosses (Fuller & Stewart 1977).

Figure 93. *Pteronarcella badia* naiad, a species that switches to feeding on mosses as it gets older. Photo by Arlo Pelegrin, with permission.

Figure 94. **Chironomidae** larva, a typical part of stonefly diet. Photo by Bob Armstrong.

Figure 95. **Simuliidae** larvae on rock, common food for stoneflies. Photo by Jason Neuswanger, with permission.

Hassage *et al.* (1988) examined feeding behavior in the shredder species *Pteronarcella badia* and found that in small groups (1-4) the naiads distributed themselves in proportion to the available surface area. However, when the group was increased to 14, they formed aggregations that often involved body contact. Addition of the predator *Claassenia sabulosa* (Figure 96) cause them to exhibit a random distribution. It would be interesting to see if this behavior differs on rocks vs bryophytes.

Figure 96. *Claassenia sabulosa* naiad, a predator on *Pteronarcys badia*. Photo by Bob Henricks, with permission.

Summary

The **Plecoptera** (stoneflies) are **hemimetabolous**, having eggs, naiads, and adults. Some have gills and others are gill-less, requiring high oxygen concentrations. This requirement for oxygen makes them more common in cold, rapid streams. The naiads are mostly night active. Many of the smaller **Plecoptera** are moss dwellers, especially in young stages, where they eat mostly **detritus** and **periphyton**, but some eat bryophytes.

The stoneflies use the bryophytes for depositing eggs, escaping the drift, protection and food source during early instars, and emergence. Adults of some use the bryophytes as a substrate for attracting females – the males drum their abdomens on the mosses. Some stoneflies, however, emerge in the winter, often climbing out of the water on emergent bryophytes, and can be seen on the snow.

The **Nemouridae** and **Leuctridae** are the most common families among bryophytes, although in some locations the **Taeniopterygidae** are abundant. The **Notonemouridae** is a somewhat terrestrialized moss-dwelling family restricted to the Southern Hemisphere. In New Zealand one can find **Gripopterygidae** among stream mosses, although this stonefly family is mostly terrestrialized. Large stoneflies like the **Pteronarcyidae** are usually absent in the small spaces of most bryophytes, but they are able to maneuver among the larger branches of *Fontinalis*. Other families that include regular moss dwellers are **Capniidae**, **Chloroperlidae**, **Perlidae**, **Perlodidae**, and **Peltoperlidae**.

Acknowledgments

Allen Knight and Dennis Heiman verified my identifications of the Plecoptera for my mid-Appalachian Mountain study and T. Wayne Porter verified the *Microvelia*. Bob Henricks and Jason Neuswanger have been particularly helpful in contributing images and

personal experiences. Eileen Dumire proofread and made suggestions for greater clarity.

CHAPTER 11-7

AQUATIC INSECTS:

HEMIMETABOLA – HEMIPTERA

Figure 1. *Pachybrachius luridus*, a species of bogs and fens. Photo by Tristan Bantock, with permission.

HEMIPTERA – True Bugs, Cicadas, Hoppers, Aphids, and Allies

Aquatic bryophyte dwellers are rare in this insect order. Most members are either free swimming or skate on the top of the surface tension. However, bogs and bog pools do provide a suitable habitat for some species. Rédei *et al.* (2003) found no specificity for species among *Sphagnum* (Figure 2) or any species that was characteristic for that moss. *Ceratocombus coleoptratus* (Figure 6-Figure 7) and *Hebrus ruficeps* (Figure 13) had the highest dominance in that habitat, with *Cryptostemma pusillum* (Figure 3), *Saldidae* (Figure 27-Figure 31), and *Miridae* (Figure 4) also occurring here. They considered the similarity of the bog community to that of the soil moss community to be due to the low relative dominance of larvae from the large family *Lygaeidae* (Figure 32-Figure 37) in both habitats.

Members of this family lack gills and their immature stages are nymphs, placing them in the **Hemimetabola**. Some breathe by a **plastron** (mechanism for carrying an air layer next to the body).

Figure 2. *Sphagnum fuscum*, a genus that is home for a few members of the **Hemiptera**. Photo by Michael Lüth, with permission.

Figure 4. *Campyloneura virgula* (Miridae), a dominant species in bogs. Photo by Valter Jacinto, through Creative Commons.

Cicadellidae – Leafhoppers

This family was previously placed in the Homoptera, but is now included in the order **Hemiptera**. It is not, however, a true bug.

This is the second largest hemipteran family. The members live primarily on land (Leafhopper 2015). They use the hairs on their legs to facilitate a secretion over their bodies that acts as a water repellent and carrier of pheromones. They obtain their food by sucking sap from a variety of plants.

Megophthalmus scanicus (Figure 5; 3-4 mm) is a widespread species in the UK where it overwinters among mosses (Edwards 1874-1879). This is a species of wide habitat variety, including both wet and dry habitats.

Figure 5. *Megophthalmus scanicus* nymph, a species that overwinters among mosses. Photo from <www.biolib.cz>, through public domain.

Ceratocombidae

The **Ceratocombidae** is mostly tropical and lives primarily in leaf litter along water margins. This is a group of small bugs, 1.5-3.0 mm, mostly dull-colored, from yellowish to dark brown (Livermore & Rider 2015). These insects require permanently damp conditions such as those provided by the wet mosses close to running water. Members of this family overwinter as adults, requiring the permanent wetness of habitats like wet mosses near running water (Howe 2004). *Ceratocombus brevipennis* (see Figure 6) is one of these moss dwellers in central and southern Europe (Michael Münch personal communication 30 October 2014).

Figure 6. *Ceratocombus coleoptratus*, an inhabitant of wet mosses in Europe. Michael Münch <www.insekten-sachsen.de>, with permission.

Ceratocombus coleoptratus (Figure 7) was rare in the UK even as early as the 1870's (Edwards 1874-1879). It lives among mosses, perhaps being under-collected and accounting for its presumed rarity. Fortunately it still

exists, living in moss cushions, needle litter, and dead plant material at the edges of forests (Münch 2012). It also occasionally lives in moss beds in swampy meadows.

Figure 7. *Ceratocombus coleoptratus* wending its way through its moss home. Photo by Michael Münch, with permission.

Dipsocoridae – Jumping Ground Bugs

This family (Figure 3) of tiny bugs (2-3 mm) is found mostly among wet mosses by running water in Wales (Howe 2004). These bugs, despite their small size, are predators with rapid movements that typically live near streams and rivers.

In particular, some species of the genus *Pachycoleus* are closely associated with bryophytes in central and southern Europe (Michael Münch pers. comm. 30 October 2014). In Wales, it is *Pachycoleus waltli* that is common among the wet mosses (Howe 2004). Kment *et al.* (2013) found *P. waltli* among wet mosses that covered dead branches along a stream. This species is typical of permanently wet to very wet moss [*Sphagnum* (Figure 2), *Hypnum* (Figure 8), *Brachythecium* (Figure 9), *Cratoneuron* (Figure 10)] and may stay fully submerged.

Figure 8. *Hypnum cupressiforme*, a home for *Pachycoleus waltli*. Photo by Li Zhang, with permission.

Figure 10. *Cratoneuron commutatum*, a wet habitat where one might find members of the genus *Pachycoleus*. Photo by Michael Lüth, with permission.

Using Berlese funnels to sample in Hungarian bogs, Rédei *et al.* (2003) found *Cryptostemma pusillum* (Figure 3) among the common Hemiptera.

Gerridae – Water Striders

The most distinctive feature of the **Gerridae** is their ability to skate about on the water surface. They are larger (~4-18 mm) than the other surface bugs described here. Their skating ability is possible due to hydrofuge (water-repelling) hairs, retractable claws, and long legs (Ward 1992). The hairs are arranged in hair piles with more than 1000 microhairs per mm. They cover the entire body, repelling water drops that could otherwise weigh them down.

Gerris is not a genus that finds mosses important in the water, instead skating on its surface. To my surprise, I read an old report of *Gerris lacustris* (Figure 11) hibernating under a terrestrial moss nearly a km from water! (Butler 1886). This species is a water strider – the spider-like insect that skates on the surface tension of quiet pools of ponds and streams. Furthermore, *Gerris argentatus* (Figure 12) occurs among wet mosses (Edwards 1874-1879).

Figure 11. *Gerris lacustris* on pond, a species that hibernates under terrestrial mosses. Photo by Jakub Rom through public domain.

Figure 12. *Gerris argentatus*, a species that can be found among wet mosses. Photo by Niels Sloth, with permission.

Hebridae – Sphagnum Bugs, Velvet Water Bugs

The **Hebridae** are small insects (1.3-3.7 mm) of semiaquatic habitats, living mostly in moist detritus or among floating plants, wet moss, or margins of still waters (McClarín 2006). The **Hebridae** are most common among wet mosses (Howe 2004) and the genus *Hebrus* lays its eggs among mosses, hiding them in leaf axils, or between closely spaced leaves, where it uses a gelatinous glue to adhere them (Polhemus & Chapman 1979a). In the bogs and fens of Hungary the diversity of **Hemiptera** is very low when a large spatial area is considered (Rédei *et al.* 2003). This is because one wet moss species, *Hebrus ruficeps* (Figure 13), dominates, comprising 90% of the **Hemiptera** fauna!

Figure 13. *Hebrus ruficeps*, a moss dweller in *Sphagnum* bogs that is able to survive the winter frozen in ice at the water surface. Photo by Ruth Ahlburg, with permission.

Members of *Hebrus* are small bugs, only 1.3-3.7 mm long (Ramel 2014). Their preferred habitat is ponds with *Sphagnum* (Figure 14) or along margins of streams. Although the genus has about 150 species worldwide, mostly in tropical environments of Southeast Asia, the UK has only two species, both moss dwellers.

Figure 14. *Sphagnum cuspidatum*, in a genus that is home to *Hebrus* in ponds. Photo by Blanka Shaw, with permission.

Hebrus concinnus was observed laying its eggs between the leaves of mosses where the eggs were partially concealed (Hungerford 1920). Edwards (1874-1879) reported *Hebrus pusillus* (Figure 15) from wet moss. Münch (2013) likewise considered *H. pusillus* a moss dweller, but that it also lives on the water surface and at the edge of the water where it reproduces. Howe (2004) reported that it is associated with *Sphagnum* (Figure 2, Figure 14) and other mosses.

Figure 15. *Hebrus pusillus* on a moss. Photo by Michael Münch, with permission.

But not all members of *Hebrus* live along streams. *Hebrus pusillus* (Figure 15) and *H. ruficeps* (Figure 13) both occur among *Sphagnum* (Figure 2) in bogs (Butler 1886). *Hebrus ruficeps* is able to survive the winter frozen in ice at the water surface (Ramel 2014). Butler (1886) recommended tearing a handful of the moss into small pieces and examining each carefully to find these tiny bugs.

The genus *Merragata* (Figure 16), like *Hebrus*, lays its eggs on moss leaves, or under algae, where they incubate for 8-12 days (Polhemus & Chapman 1979a).

Figure 16. *Merragata hebroides*, a genus that lays its eggs on moss leaves or under algae. Photo by Don Loarie, through Creative Commons.

Mesoveliidae – Water Treaders

These are small usually greenish or yellowish surface bugs of about 2-5 mm length. *Mesovelia mulsanti* (Figure 17) prefers lakes and bogs with lots of surface vegetation where they live on mosses and other floating plants (Figure 18; Menke 1979). They feed on lily pads and easily run on the surface of the water. *Mesovelia amoena* (Figure 19), on the other hand, occurs on mosses in hot spring caves of Death Valley and avoids the water unless disturbed (Hungerford 1917; Polhemus & Chapman 1979b). At least some populations must be **parthenogenetic** (giving birth without fertilization) because only the female of *Mesovelia amoena* occurs in Hawaii.

Figure 19. *Mesovelia amoena*, a moss dweller, including those in a hot spring cave. Photo by Dana R. Denson, Florida Association of Benthologists, with permission.

Veliidae – Small Water Striders, Riffle Bugs

The family **Veliidae** (1-12 mm) is best adapted for surface activity, walking easily on the surface tension. The surface tension facilitates their detection of food items (small arthropods) by vibrating as the prey organisms move about (McLeod 2005).

In my studies of Appalachian Mountain, USA, stream bryophyte inhabitants, *Microvelia* (Figure 20-Figure 22) was the only member of **Hemiptera** that I found (Glime 1968). The genus *Microvelia* has a unique means of locomotion. Instead of clambering about on the water surface by paddling with its middle legs like other **Hemiptera**, it exudes a fluid that reduces the surface tension in the water behind it. This causes the surface there to expand and push it forward.

Microvelia and *Paravelia* species lay their eggs on such floating objects as moss, duckweed, and living or dead leaves just above or below the water surface (Polhemus & Chapman 1979d). *Microvelia reticulata* (Figure 20) overwinters as an adult (Ramel 2014). It lays eggs in mosses and feeds on tiny invertebrates, including mosquito eggs.

Figure 20. *Microvelia reticulata*, a species that lays its eggs among mosses. Photo by Niels Sloth, with permission.

Microvelia buenoi (Figure 21) lives among mosses at the edge of a pond in Indiana, USA (Bamd 2007), where it was sampled using a Berlese funnel. In Florida, Herring (1950) found *Microvelia hinei* (Figure 22) in mats of *Sphagnum* (Figure 14) in acid swamps and bog streams. This species illustrates a short incubation time of only 6.41 days (mean) (Taylor & McPherson 2003). Nymphal development requires only 25 days for its 5 instars (developmental stages).

Figure 22. *Microvelia hinei*, an inhabitant of *Sphagnum* mats in bogs. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Macroveliidae – Macroveliid Shore Bugs

This new world family never exceeds 5 mm in length. *Macrovelia hornii* (Figure 23; ~4.2 mm) nymphs and adults live among mosses and other floating vegetation at the water's edge in protected niches behind rocks or logs or among debris (Uisinger 1956; Menke 1979). Polhemus and Chapman (1979c) consider this species to be common among the mosses of California springs and seeps. They lay their eggs glued to wet mosses (Menke 1979).

Figure 23. *Macrovelia* sp. Some species live among mosses in crevices at the water's edge. Photo by Paul A. Rude, through Creative Commons.

Corixidae – Water Boatmen

This family ranges 2-14 mm and is free-swimming in ponds and slow-moving streams (Corixidae 2014). Thus, they are not typically among the bryophyte dwellers. Unlike most aquatic Hemiptera, they are predominantly herbivores, feeding on algae and aquatic plants. And, Macan and Maudsley (1968) report *Micronecta poweri* (Figure 24) to be associated with vegetation, including *Fontinalis* (Figure 25). The Corixidae inject enzymes into the plants (or animals) through the strawlike mouthparts (Figure 26), then suck the cell contents back through that same straw (Corixidae 2014).

Figure 24. *Micronecta poweri*, a water boatman that sometimes lives among *Fontinalis*. Photo by Urmas Kruus, with permission.

Figure 25. *Fontinalis antipyretica*, a genus that is home to *Micronecta poweri*. Photo by Bas Kers, through Creative Commons.

Figure 26. **Corixidae** eating mosquito pupa. Photo by Bob Armstrong, with permission.

Saldidae – Shore Bugs

The **Saldidae** are small to medium in size (2-8 mm) (Saldidae 2013). *Salda* (Figure 27) is known as a bog-moss dweller at pond margins (Butler 1886). *Salda morio* and *S. muelleri* live in bog pond margins (Spunġis 2009) among mosses (Michael Münch pers. comm. 30 October 2014). *Salda littoralis* occurs in salt marshes and tidal zones, where it hides under marine algae at low tide and migrates to the edge of the water in high tide, but it also lives in freshwater habitats (Spunġis 2009) where it often associates with bryophytes, including living among *Sphagnum* (Figure 14) in a mountain lake in the Italian Alps (Michael Münch pers. comm. 30 October 2014). It will occasionally submerge into the water (Polhemus 1976).

Figure 27. *Salda lugubris*, member of a genus that has bog moss dwellers. Photo by Dana R. Denson, Florida Association of Benthologists, with permission.

Saldula pallipes (Figure 28) lays its eggs at the bases of mosses or in between their leaves at the edges of ponds (Usinger 1956).

Figure 28. *Saldula pallipes* lays its eggs at the bases or between leaves of mosses at the edges of ponds. Photo by Charlie Eiseaman, through Creative Commons.

Chartoscirta cocksii (= *Salda cocksii*; Figure 29) lives in ponds, mossy areas, and wetlands. Michael Münch (pers. comm. 30 October 2014) found it in a swamp among a taller moss (not *Sphagnum*). In early surveys, *Chartoscirta cocksii* was the primary hemipteran among *Sphagnum* (Figure 2, Figure 29) in the UK (Butler 1886). This tiny black bug has huge eyes and stout antennae, making a striking find. Butler recommends putting mud, mosses, and dead leaves in a box to watch how many saldids will hatch out. This species will also take an occasional dip in the pools of the bog (Polhemus 1976).

Figure 29. *Chartoscirta cocksii* on *Sphagnum papillosum*. Photo by Barry Stewart, with permission.

Chartoscirta elegantula (Figure 30) occurs between tide marks, but it also can be common among *Sphagnum* (Figure 2) (Michael Münch pers. comm. 30 October 2014). Like *Gerris lacustris*, it migrates to overwinter in dry moss or leaves on land far from its summer habitat.

Figure 30. *Chartoscirta elegantula elegantula*, a species that often migrates from the intertidal zone to overwinter among dry mosses. Photo by Sanjo, through Creative Commons.

Ioscytus nasti (Figure 31) occurs in bogs in North America (Usinger 1956). This is a poorly known genus and may provide some surprises in the bogs.

Figure 31. *Ioscytus nasti*, a bog inhabitant. Image from Smithsonian Institution, through Creative Commons.

Lygaeidae – Seed Bugs, Cinch Bugs

This family of bugs, ranging 4-20 mm (Lygaeidae 2015), feeds primarily on seeds. Hence, bryophytes do not provide an ideal habitat. Nevertheless, the family has several bog and fen dwellers (Michael Münch pers. comm. 30 October 2014). Among these are *Scolopostethus pilosus* (Figure 32) in calcareous fens, *Cymus glandicolor* (Figure 33) in fens, *Ligyrocoris sylvestris* (Figure 34) in hill moors, *Pachybrachius luridus* (Figure 35) in bogs and fens, *P. fracticollis* (Figure 36) rare in bogs, fens, and wet meadows (Spunġis 2009), all among mosses (Michael Münch pers. comm. 30 October 2014). *Scolopostethus puberulus* (Figure 37), on the other hand, lives primarily in deciduous forests, but also in **mesic** meadows (environment with moderate amount of moisture) (Spunġis 2009), as a moss dweller (Michael Münch pers. comm. 30 October 2014).

Figure 37. *Scolopostethus puberulus*. Photo by Michael Münch <www.insekten-sachsen.de>, with permission.

Rhyparochromidae – Dirt-colored Seed Bugs

Like the Lygaeidae, the **Rhyparochromidae** feed primarily on seeds, making bryophytes less than ideal habitats. *Rhyparochromus pini* (Figure 38) has adults 7-8

mm in length (British Bugs 2015). Most in Great Britain live in heathland, often under the heath; others live on sand dunes. However, Spunģis (2009) found that this species also lives in bogs and fens.

Figure 38. *Rhyparochromus pini* nymph, an inhabitant of bogs and fens. Photo by Tristan Bantock, with permission.

Summary

The Homoptera have been moved into the order **Hemiptera** and the family **Cicadellidae** has a few members that use wet mosses to overwinter.

The true bugs have more aquatic members, but few are true bryophyte dwellers. The families **Ceratocombidae** and **Dipsocoridae** require permanently damp conditions and therefore many live in wet mosses. The surface-dwelling **Gerridae** sometimes spend the winter far from water among bryophytes. The **Hebridae** are frequent bryophyte dwellers among wet mosses and some lay their eggs there; others live in bogs. **Mesoveliidae** occur in lakes, bogs, and among mosses of hot spring caves. Some **Veliidae** lay their eggs on mosses and live among them in pools, acid swamps, and bog streams. Macroveliidae are more terrestrial but may live among mosses as nymphs. The **Saldidae** have some species that prefer bog pond margins among the mosses; others live among the taller bog bryophytes. Even the **Lygaeidae** and **Rhyparochromidae** occur among mosses in bogs. The larger, free-swimming **Corixidae** can occur among *Fontinalis* in slow-moving water.

Acknowledgments

Allen Knight and Dennis Heiman verified my identifications of the Plecoptera for my mid-Appalachian Mountain study and T. Wayne Porter verified the *Microvelia*. Bob Henricks and Jason Neuswanger have been particularly helpful in contributing images and personal experiences. Michael Munch was very helpful in providing me names of Hemiptera he has found in association with bryophytes, as well as providing a number of images. Eileen Dumire has helped with sorting insects,

maintaining the bibliography records, and reviewing the written chapter.

CHAPTER 11-8

AQUATIC INSECTS: HOLOMETABOLA – NEUROPTERA AND MEGALOPTERA

Figure 1. *Nigronia serricornis* larva (Megaloptera), a species that sometimes pupates in mosses. Photo by Jason Neuswanger, with permission.

HOLOMETABOLA

The **holometabolous** insects are those with a complete life cycle – egg/embryo > larva > pupa > adult. These insects typically spend only part of the life cycle in the water. Some lay their eggs near water and larvae develop in the water. Some have eggs, larvae, and pupae in the water, but their emerging adults break through the water surface and climb onto land to emerge. For most, adult life and mating occur on land.

NEUROPTERA – Net-winged Insects

Neuroptera literally means nerve wings, so-named because of the prominent wing veins of the adults. This order is not well represented among bryophytes, and only the larvae are associated with aquatic habitats.

Osmylidae

On continents other than North America a small family, the **Osmylidae** (Figure 2-Figure 6), occurs among mosses and organic matter in and near streams (Flint 1977). *Osmylus fulvicephalus* (Figure 2) is the only species known in the UK, likewise living among mosses of streambanks (Elliott *et al.* 1996) and seeking food there (NatureSpot 2015). The adults (Figure 3; 25 mm long including wings) don't stray far from water but are not aquatic. The females lay their eggs on overhanging plants, tree trunks, or stones (Osmylidae 2014), and especially on

mosses (Elliott *et al.* 1996) near water, laying about 30 eggs either singly or in pairs. Larvae leave the egg site within 1-3 days to burrow into mosses. Larvae may live in or out of water, but pupation is on land, lasting 7-18 days. If the larvae are submersed, they crawl out of the water (Ward 1965). If the moss is submersed, they burrow deeply into it, but within 8-28 days of submersion they die. Adults live two weeks to three months, depending on species and location.

Figure 2. *Osmylus fulvicephalus* larva, a species that lives among mosses on streambanks and feeds there. Photo by Walter Pflieger, with permission.

Figure 3. *Osmylus fulvicephalus* adult that lays its eggs on overhanging vegetation. Larvae live among streambank mosses. Photo through Creative Commons.

Figure 4. Phenological events (cyclic and seasonal natural phenomena, especially in relation to climate) of the life cycle of *Osmylus fulvicephalus*. From Elliott *et al.* 1996.

Osmylus fulvicephalus (Figure 3) is controversial in that its larvae live in wet mosses, but drown in 8-28 days of submersion (Elliott *et al.* 1996). Nevertheless, they do enter the water in search of food. It seems safe to say, however, that their relationship with mosses is damp, but not aquatic. The larva feeds among these mosses. When movement is detected, it jabs at it with the long proboscis, then injects it with a salivary secretion that paralyzes it. A chironomid larva is paralyzed within 10 seconds. The *O. fulvicephalus* then sucks out the interior of the prey. The larvae stop eating during mid autumn and burrow down to the moss rhizoids to hibernate for the winter. Fortunately, in this state they can survive occasional submersion in water, thus surviving **spates** (sudden flood in a river, especially one caused by heavy rains or melting snow). In spring they spin a silken cocoon, sometimes incorporating bits of moss in the cocoon. Just before pupation the long jaws break off (Figure 5). The pupa becomes immobile during pupation. It grows a pair of mandibles that it uses to cut its way out of the cocoon.

Figure 5. *Osmylus fulvicephalus* larva showing large jaws. Photo by Walter Pfliegler, with permission.

Like *Osmylus fulvicephalus* (Figure 2-Figure 5), *Kempynus* sp. (Figure 6) in the Southern Alps of New Zealand is somewhat amphibious, living at the edge between water and land (Cowie & Winterbourn 1979). In springbrooks it lives in clumps of the mosses *Acrophyllum quadrifarium* (= *Pterygophyllum quadrifarium*; Figure 7) and *Cratoneuropsis relaxa* (Figure 8).

Chrysopidae

There are a number of reports of the larvae of the green lacewing *Leucochrysa pavida* (Figure 9-Figure 12) using bits of lichen as camouflage (Tauber *et al.* 2009; Moskowitz & Golden 2012). In fact, Wilson and Methven (1997) found that the larvae at their Illinois, USA, site were somewhat specific in the species of lichens they chose. But Slocum and Lawrey (1976) found that this insect was not totally specific. In addition to the lichens, it also includes pieces of bark, angiosperm pollen, fungal spores, insect debris, and (of course) bryophyte gametophytes. Slocum and Lawrey demonstrated that the lichens, at least, are still alive and that they have photosynthetic rates equal or greater than those same lichen species still growing on a bark substrate. Furthermore, these lichen propagules are still viable when the cocoons are attached to the bark, giving the lichens the opportunity and establish in this new location. Unfortunately, there are no similar studies on the bryophytes in this camouflage arrangement, but it at least provides the possibility for a means of dispersal.

MEGALOPTERA – Dobsonflies and Alderflies

Megaloptera means large wing; one adult is known with a wingspan of 21 cm, the largest of any aquatic insect in the world (Megaloptera 2014). The order is relatively small, and is close to the **Neuroptera**. Its members have

aquatic larvae, but they pupate on land in damp soil or under logs. The pupae are fully mobile and can defend themselves against predators with their large mandibles. Female adults lay 1000's of eggs on overhanging vegetation where larvae can drop into the water (Figure 13). The adults often live only a few hours and usually don't eat.

Figure 13. *Sialis fuliginosa* eggs. Photo by James K. Lindsey, with permission.

Sialidae – Alderflies

This is a small family that can be up to 25 mm long (Alderfly 2014). They occur sparsely worldwide with a concentration of known species in Europe (Sialidae 2015).

I have only found reference to one genus of bryophyte dwellers, *Sialis* (Figure 13-Figure 17) (Lithner *et al.* 1995). I likewise found this genus occasionally among bryophytes in Appalachian Mountain, USA, streams (Glime 1968). It has aquatic larvae, but adults are terrestrial and lay eggs near water (Alderfly 2014). Fully grown larvae of *Sialis* pupate in soil, mosses, under stones, and other locations, usually near water. In Canada, after about one month the adults appear. *Sialis nigripes* prefers mosses for egg laying (Elliott *et al.* 1996). *Sialis lutaria* (Figure 15-Figure 17) was used in a study comparing heavy metal accumulation in mosses (*Fontinalis* spp.; Figure 18), insects, and fish (Lithner *et al.* 1995).

Figure 14. *Sialis* adult, a genus that sometimes pupates and lays eggs among streamside bryophytes. Photo by Patrick Coin, through Wikimedia Commons.

Figure 16. *Sialis lutaria* adult. Photo ©entomart, through Creative Commons.

Figure 17. *Sialis lutaria* adults mating. Photo by James K. Lindsey, with permission.

On the South African Cape, pupae of **Sialidae** along streams or waterfalls live in *Sphagnum* (Figure 19) and other mosses (Barnard 1931). These pupae require a wet, but not submersed, habitat, so the mosses must be soaking wet.

Figure 18. *Fontinalis antipyretica*, home to numerous kinds of insects and useful for comparing heavy metal accumulation. Photo by Malcolm Storey, through Creative Commons.

Figure 19. *Sphagnum fimbriatum*, a genus that lives in Africa and is a potential home for pupae of *Sialidae*. Photo by Blanka Shaw, with permission.

Corydalidae- Dobsonflies and Fishflies

This family occurs mostly in the Northern Hemisphere and in South America, including both temperate and tropics (Corydalidae 2014). Their body size is usually greater than 25 mm and ranges up to 80 mm (Penny *et al.* 1997; Bartlett 2004). The larvae are aquatic, are called hellgrammites, and are predators.

Nigronia, an aquatic member of the **Corydalidae**, is not typically a moss inhabitant, although I did occasionally find larvae of this genus among Appalachian Mountain stream bryophytes (Glime 1968). But like many other aquatic insects, *Nigronia serricornis* (Figure 20-Figure 21) pupates among mosses as well as under stones and logs (Needham *et al.* 1901). Likewise, *Chauliodes pectinicornis* (Figure 22) and *C. rastricornis* (Figure 24-Figure 24) pupate in these habitats. Pupation lasts about 2 weeks in these **Corydalidae**.

Figure 24. *Chauliodes rastricornis* adult, a species that lives in the water as larvae and pupates among mosses. Photo by Stephen Cresswell, with permission.

Summary

The **Holometabola** have a complete life cycle with egg, larva, pupa, and adult.

The **Neuroptera** are represented among aquatic bryophytes by only one family, the **Osmylidae**. The larvae of *Osmylus* may live among bryophytes in streams or on streambanks and obtain food there. Some species lay their eggs on mosses that overhang streams. Larvae bore into mosses in or out of the water. *Kempynus* species often live among mosses in springbrooks.

The **Megaloptera**, like the **Neuroptera**, have few aquatic bryophyte dwellers. *Sialis* (**Sialidae**) larvae occasionally occur among stream bryophytes; the pupae are often among terrestrial mosses. Some species lay eggs among mosses. Wet *Sphagnum* along streams or near waterfalls serves as a home for some **Sialidae**. Some members of *Nigronia* and *Chauliodes*, both in the **Corydalidae**, pupate among mosses.

CHAPTER 11-9

AQUATIC INSECTS: HOLOMETABOLA – COLEOPTERA, SUBORDER ADEPHAGA

Figure 1. *Lancetes angusticollis* adults on moss, South Georgia in the Antarctic. *Lancetes angusticollis* has a two-year life cycle, with overwintering possible in three life stages – aquatic larvae, terrestrial pupae (not proven), and aquatic adults. Note the air supply at the tip of the abdomen. This external air supply makes it necessary for these beetles to cling to vegetation, when they are not swimming, to avoid floating to the surface, hence their use of mosses. Photo by Roger S. Key, with permission.

COLEOPTERA BACKGROUND

The Coleoptera seem to have a somewhat closer relationship to terrestrial life than other aquatic bryophyte dwellers. First of all, they get their air from the atmosphere or underwater plants where they grab an air bubble (Figure 2). They can accumulate air as bubbles under the **elytra** (hardened forewings; wing covers), through the **plastron** (breast plate breathing apparatus; Figure 3) (Oliveira de Sousa *et al.* 2012), or an anal bubble. The **plastron** is a ventral structure that acts as a physical gill by using various combinations of hairs, scales, and undulations projecting from the cuticle. This apparatus holds a thin layer of air along the outer surface of the body (Figure 3). In all three

of these mechanisms, the nitrogen in the air bubble diffuses into the water slowly while the replacement oxygen diffuses into it 2-3 times as fast (Rich Merritt, pers. comm. 28 January 2015). Thus, as the insect uses up the oxygen from the bubble, the water replaces it by oxygen diffusion for a reasonable period of time. The CO₂ from respiration enters the bubble and rapidly diffuses into the water, having little effect on bubble size. Many beetles attach an anal gas bubble (Figure 1, Figure 18-Figure 19) that uses this diffusion mechanism. They may have hairs that help hold the bubble in place. (See **Elmidae** in Coleoptera, Suborder Polyphaga, for details of the plastron functioning in that family.)

Figure 2. *Berosus luridus* adult on moss where air bubbles from photosynthesis can be used to replenish the air supply. Photo by Tim Faasen, with permission.

Figure 3. *Chaetarthria siminulum* adult with plastron. When the plastron is full of air, the beetle must cling to vegetation in order to descend into the water column. Photo by Gerard Visser <www.microcosmos.nl>, with permission.

Nearly all aquatic **Coleoptera** go to land to pupate (Leech & Chandler 1956; Pennak 1978; Erman 1984), then return to the water as adults. Others clamber about on the surface of the plants. Some of these are associated with floating plants, including *Ricciocarpus natans* (Figure 4) (Scotland 1934). To get below the surface requires muscle action to break the surface tension (Leng 1913).

Figure 4. *Ricciocarpus natans*, a floating liverwort. Photo by Jan-Peter Frahm, with permission.

Percival and Whitehead (1930) noted that the mosses in streams in the UK were very important to both larvae and adults of the small **Coleoptera**. In 1949, Badcock indicated that beetles were more common among mosses than associated with stones, especially loose stones. Ogbogu (2000) found **Coleoptera** among the insects associated with *Fontinalis* (Figure 5) in an intermittent reservoir spillway in Ile-Ife, Nigeria. Many of the **Coleoptera** in rivers of northwest Spain prefer moss as a substrate, as indicated by both species richness and abundance (Fernández-Díaz 2003; Sarr *et al.* 2013). They attributed this to the abundance of food available for the herbivores (Passos *et al.* 2003; Sarr *et al.* 2013). This applied particularly to the **Elmidae** and **Hydraenidae**.

Figure 5. *Fontinalis antipyretica* on rocks of a stream bed. Photo by Betsy St. Pierre, with permission.

Among the most common of these bryophyte dwellers are the **Elmidae** (Figure 6), small beetles only a few mm in length (Percival & Whitehead 1930; Glime 1994). But many studies miss the small **Coleoptera** that live among the bryophytes, necessitating special collecting techniques for such habitats as submerged roots, wood, and mosses (Zařoviřová *et al.* 2004). Zařoviřová and coworkers found 13-61% more species when they used qualitative sampling that included these habitats.

Figure 6. **Elmidae** adult, one of the most common of beetle families among bryophytes. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Whereas mosses in streams and lakes are not especially important for beetles, bogs and fens have greater

species numbers. Some live in the acidic pools, some burrow into the moss mats, and some run about the surface. The **Dytiscidae** (Figure 18-Figure 55) are particularly important in the pools. These bog dwellers, although often not adapted to a submerged aquatic habitat, will be included here.

Jones (1950) did extensive gut analysis of insects from the River Rheidol and found that none of the **Coleoptera** had mosses (*Fontinalis antipyretica*, Figure 5) in their guts, although **Plecoptera** and **Trichoptera** did. Rather, these **Coleoptera** were all carnivores.

Suborder Adephaga

This suborder is comprised of a group of highly specialized beetles.

Carabidae – Ground Beetles

The **Carabidae** forms a large family (>40,000 species) (Ground Beetle 2015), ranging 0.7-66 mm long (Bartlett 2004a). Despite this large number of species, they are mostly either shiny black or metallic and have ridged elytra (Ground Beetle 2015). Their distribution is worldwide, but records from Africa and Asia are scant. Typical homes are under tree bark, under logs, and among rocks or sand by the edge of ponds and rivers. Many expel an especially noxious and painful liquid for their defense. They are predators, often rapidly chasing their prey, usually at night (Bartlett 2004a).

These are not aquatic beetles, but they do live in bogs (Boyce 2011). In Dartmoor, UK, *Agonum ericeti* (Figure 7) prefers mires that have both *Sphagnum* (Figure 7) hummocks and warm, bare peat. Here they run around on the bog surface and are one of the most "important" species in the bog. They occur only where there are abundant bog mosses.

Figure 7. *Agonum ericeti* adult, a mire dweller, on *Sphagnum*. Photo by Niels Sloth, with permission.

Pterostichus rhaeticus (Figure 8) prefers to live among *Sphagnum* (Figure 7) of a blanket bog (Boyce 2011). *Pterostichus diligens* (Figure 9) likewise lives in blanket bogs, but lives in litter as well as among mosses. *Acupalpus dubius* is sometimes restricted to the moss *Drepanocladus aduncus* (Kopecky 2001).

Gyrinidae – Whirligig Beetles

This family is aptly named for its behavior of skating in whirling patterns on the water surface. The most unusual feature of this family is the eyes. They are divided so that two eyes are above the water and two are below, protecting the beetles from predators above and permitting them to see what is beneath them (Gyrinidae 2015). Their size ranges 3 to 18 mm long (Whirligig Beetles 2014). They eat insects that fall into the water, sensing the vibrations of their struggles by using their antennae. They are worldwide, with a heavy concentration in Europe.

But even these insects sometimes use mosses. At least some members of the **Gyrinidae** (Figure 12-Figure 14) use mosses as hiding places during the day (Leng 1913). And in the Appalachian Mountain, USA, streams, the mosses may provide a refuge for *Dineutus* (Figure 12-Figure 14) during times of high flow (Glime 1968).

Figure 13. *Dineutus assimilis* adult showing split eyes. Photo by Joyce Gross, with permission.

Figure 14. *Dineutus* larva, a genus that sometimes occurs among bryophytes when it is resting. Photo by Bob Henricks, with permission.

Haliplidae – Crawling Water Beetles

The **Haliplidae** are clumsy swimmers, alternating the motion of their legs (Haliplidae 2014). Hence, they move about mostly by crawling. The adults are convex on the dorsal side and range 1.5-5.0 mm long. The hind legs have large coxal plates and are immobile. The primary function of these legs seems to be that of storing air, supplementing the air stored under the elytra. The larvae eat only algae, but the adults are omnivorous. They live among aquatic vegetation around the borders of small ponds, lakes, and quiet streams. Their worldwide distribution is similar to that of the **Scirtidae**, with the greatest diversity known in Europe (Haliplidae 2015).

These are mostly not bryophyte dwellers, but the genus *Haliplus* (Figure 15) still benefits from the presence of *Sphagnum* (Figure 7). *Haliplus variegatus* (Figure 16) in Poland lives in canals that are created by beavers in floating *Sphagnum* mats (Buczyński *et al.* 2014).

Figure 15. *Haliplus* larva. Some members of this genus live in bogs and *H. variegatus* lives in beaver canals in floating *Sphagnum* mats. Photo by Dana R. Denson, Florida Association of Benthologists, with permission.

Figure 16. *Haliplus variegatus* adults, inhabitants of beaver canals in floating *Sphagnum* mats of Poland. These color phases and the spots can help to camouflage the beetles among the mosses. Photo by Stefan Schmidt, through Creative Commons.

In my own studies (Glime 1968) in the Appalachian Mountain, USA, streams, I found the genus *Brychius* (Figure 17). The generic name suggests a possible moss habitat, but I was unable to find additional information on the habitat.

Figure 17. *Brychius elevatus* adult, a genus with moss inhabitants in Appalachian Mountain, USA, streams. Photo by Udo Schmidt, through Creative Commons.

Hygrobiidae – Squeak Beetles

This small family has only one genus, *Hygrobia*, with six species, and is distributed in Europe, North Africa, China, and Australia (Hygrobia 2014). *Hygrobia* adults make a grating noise, earning them their name of squeak beetles (Pendleton & Pendleton 2014). Their size is moderate (8.5-10 mm). They are most common in stagnant water, where they walk or swim; they do not dive (Watson & Dallwitz 2003a). They obtain their oxygen from the air collected and stored under the elytra. *Hygrobia hermanni* (Figure 18) reaches large populations at pond margins where it lives among the submerged *Sphagnum* (Figure 39) (Denton 2013).

Figure 18. *Hygrobia hermanni* adult, an inhabitant of submerged *Sphagnum*. Note the anal air bubble. Photo by Trevor and Dilys Pendleton, with permission.

Dytiscidae – Predaceous Diving Beetles and Noteridae – Burrowing Water Beetles

The *Noteridae* are often included with the *Dytiscidae* and I will do so here because it makes the discussion easier. The larvae of *Dytiscidae* are known as water tigers. They

are passive predators, waiting quietly until a prey organism passes nearby (Dytiscidae 2014). On the other hand, several members of the family are eaten by humans in China, Japan, and Mexico, as well as other places in the world. This worldwide family has a large range of sizes (1.2-40 mm long) (Bartlett 2004b). They are distributed throughout the world, but with the best known concentrations in North America, Europe, and Australia (Dytiscidae 2015). The larvae live in the water, but they climb to land and bury themselves in the mud for pupation, returning to the water as adults.

The adult *Dytiscidae*, like other beetles, lack true gills. Instead, they carry a bubble of air with them as they descend down the water column. This bubble is either held against the body or stored under the **elytra** (outer hardened wings) (Figure 1). As oxygen is used up, nitrogen maintains the size of the bubble so that oxygen can diffuse into the bubble. When the bubble becomes too small, they must obtain another bubble from plant surfaces or the water surface by exposing the tip of the abdomen (Figure 19).

Figure 19. *Rhantus suturellus* adult replenishing air supply at surface. Photo by Niels Sloth, with permission.

Based in my own studies on moss-dwelling aquatic insects in the Appalachian Mountains, USA, it seemed that the predaceous diving beetles (*Dytiscidae*) do not typically hang out among the bryophytes. But many of the species occur in mossy wet areas, especially associated with bogs and fens. Usinger (1974) describes three types of ovipositors in the *Dytiscidae*. Those with a long ovipositor are able to inject their eggs into moss mats growing in the water. And some species even ingest mosses occasionally (Jones 1949).

Roger Key (pers. com. 31 October 2014) considers the primary role of bryophytes in the life of the predaceous aquatic beetles to be that of a structural component, a place for cover to escape predators. But these beetles are mostly predators themselves (Figure 20). In some cases the mosses are important as a place to hang or climb to avoid being carried to the surface by their air supply – the plastron apparatus or air layer under the elytra. For example, *Lancetes* in South Georgia may make use of mosses, among other anchored substrata, to get back under the surface or to stay there when it is not actively swimming. In places like South Georgia, mosses are the predominant, if not the only, vegetation at the margins of streams, hence providing these roles for aquatic beetles there.

Figure 20. *Dytiscus* larva eating young fish. Photo by Roger S. Key, with permission.

Graphoderus zonatus (spangled diving beetle; Figure 21) occurs where *Fontinalis* (Figure 5) provides the major vegetation in a heathland mire in Hampshire, UK (Roger S. Key, pers. comm. 31 October 2014). This diving beetle is frequently found associated with the mosses and can be collected by shaking the mosses over a container. The bryophyte role, as suggested above, is one of cover.

Oreodytes davisii (Figure 22) and *O. sanmarkii* (Figure 23) both live among aquatic bryophytes in a stream in Yorkshire, UK (Gilbert *et al.* 2005). *Oreodytes rivalis* may occasionally even ingest mosses such as *Fontinalis antipyretica* (Figure 5) (Jones 1949), perhaps in their attempts to capture one of the other invertebrates dwelling there.

Figure 21. *Graphoderus zonatus* adult in a heathland mire in Hampshire, UK. Photo by Roger S. Key, with permission.

Foster (1992) found *Hydroporus umbrosus* (Figure 24) among mosses at the edge of a pond in Inner Hordaland, Norway. Usinger (1974) describes the small members of the genus *Hydroporus* as able to occupy moss-covered seepages no bigger than a hand. Buczyński *et al.* (2014) reported *H. incognitus* (Figure 25) from *Sphagnum*

bogs (Figure 26) in Poland. In spring-fed boggy areas one can find *Hydroporus longulus* (Figure 27) among mosses and leaves (Denton 2013).

Moors, Bogs, and Fens

These three habitats are partially aquatic, providing wet or damp bryophytes and pools where there may be submerged bryophytes. **Moors**, a term used more commonly in Europe, are upland habitats including heathlands and fens and characterized by low vegetation and acidic soils (Moorland 2014). The term **bog** has a mixed history, with North Americans using a much broader definition than that of the northern Europeans. Until relatively recently, North Americans tended to include any wetland with *Sphagnum* as a bog. English language dictionaries go even further to define a bog as any muddy or spongy wetland. The more restrictive European definition is a habitat that is dominated by *Sphagnum* and receives only precipitation as a source of new nutrients. By contrast, a **fen** may have *Sphagnum* or other dominant bryophytes, but it receives nutrients through surface or ground water in addition to precipitation. Most of the habitats that North Americans have called bogs (including most current definitions and websites on the internet) are actually **poor fens**, *i.e.*, wetland habitats with low nutrients, ground or surface water, and *Sphagnum* species similar to those of true bogs.

Fens and bogs provide habitats for a number of **Dytiscidae** and provide the most common associations with bryophytes. The genus *Agabus* is among these common inhabitants (Nelson 1996). *Agabus affinis* (Figure 29) can be considered a characteristic species, a **tyrphobiont** (species living only in peat-bogs and mires) in high moors (Hebauer 1974), often accompanied by *A. unguicularis* (Figure 30), in the moss lawns of lowland fens and bogs of Ireland (Nelson 1996) and flooded *Sphagnum* (Figure 39) (Denton 2013). In Scotland *A. unguicularis* occurs in peaty water with mosses or other dense vegetation (Knight 2014). *Agabus melanocornis* is less common and occurs in mossy drains, fens, and bogs (Nelson 1996). *Agabus melanarius* (Figure 31) is easily overlooked in North Hampshire, UK, where it lives in shallow water with mosses.

Figure 29. *Agabus affinis* adult with *Sphagnum*. Photo by Tim Faasen, with permission.

Figure 31. *Agabus melanarius* adult, a species from shallow water among mosses. Photo by James K. Lindsey, with permission.

In contrast to other bryophyte habitats, bogs are a mix of terrestrial and aquatic microhabitats that provide homes for a number of **Dytiscidae**. Brink and Terlutter (1983) found *Dytiscus lapponicus* (Figure 32-Figure 34), *Hydroporus tristis* (Figure 35), *H. erythrocephalus* (Figure 36), and *Acilius canaliculatus* (Figure 37), as well as **Noteridae** (burrowing water beetles, sometimes included in the **Dytiscidae**) – *Noterus crassicornis* (Figure 38), to be acid **tyrphophiles** (characteristic of bogs but not confined to them) associated with *Sphagnum cuspidatum* (Figure 39). *Acilius* is one of the genera with a long ovipositor that permits egg-laying among mosses and other substrata (Unger 1956). These eggs are laid in the water and sometimes out of water. From Dartmoor, UK, Boyce

(2011) also reported *Hydroporus tristis* in small, peaty pools that had *Sphagnum* (Figure 39). Boyce also found *Hydroporus gyllenhalii* (Figure 40) among *Sphagnum* in bogs and in small peat pools that likewise had at least some *Sphagnum* in both undisturbed and eroded blanket mires. *Hydroporus obscurus* (Figure 42-Figure 43) was more restricted, living only in relatively pristine blanket bogs where it lived in small *Sphagnum*-dominated peat pools.

Figure 39. *Sphagnum cuspidatum*, home for some *Dytiscidae* and *Noteridae*. Photo by Jan-Peter Frahm, with permission.

Figure 40. *Hydroporus gyllenhalii* adult, a species that lives among *Sphagnum* in bogs and bog pools. Photo by Niels Sloth, with permission.

In his studies in Central Europe, Hebauer (1974) similarly found *Hydroporus pubescens* (Figure 41) to be a tyrphobiont, as well as such tyrphobionts as *Hydroporus obscurus* (Figure 42-Figure 43) and *H. melanocephalus* in the high moors (Hebauer 1994).

The smallest member of Irish *Hydroporus* is *H. scalesianus* (Figure 44) (Nelson 1996). In the Appalachian Mountain, USA, streams, this genus lives among stream mosses (Glime 1968), whereas in Ireland it lives exclusively among mossy carpets of undisturbed fens, mires, and lake basins.

Figure 41. *Hydroporus pubescens* adult among *Sphagnum*. Photo by Tim Faasen, with permission.

Figure 42. *Hydroporus obscurus* adult on *Sphagnum*. Photo by Tim Faasen, with permission.

Figure 43. *Hydroporus obscurus* adult climbing on a moss. Photo by Niels Sloth, with permission.

Figure 44. *Hydroporus scalesianus* adult, the smallest *Hydroporus*, on *Sphagnum*, from the high moors of Europe. Photo by Tim Faasen, with permission.

Other tyrphobionts in the high moors included *Rhantus suturellus* (Figure 19, Figure 45) (Hebauer 1974), a species also found in Poland in peaty pools (Boyce 2011). In Ireland, *Graptodytes granularis* (Figure 46) lives in mossy carpets of undisturbed fens, mires, and lake basins, but requires permanently wet mosses (Nelson 1996).

Ilybius crassus and *I. aenescens* (Figure 47-Figure 48) are tyrphobionts in European high moors (Hebauer 2004). *Ilybius aenescens* also occurs in flooded *Sphagnum* (Figure 39) of heathlands of North Hampshire, UK, but it is rare (Denton 2013). Boyce (2011) found that *Ilybius montanus* usually occur in shallow bog pools where there are dense growths of *Sphagnum*. *Ilybius fuliginosus* (Figure 49) is quite ubiquitous and thus might be found hiding among the mosses (Tim Faasen, pers. comm. 20

October 2014). But *Ilybius* is not restricted to bogs and moors, appearing among mosses in Appalachian Mountain, USA, streams (Glime 1968).

Figure 45. *Rhantus* larva. Photo by Dana R. Denson, Florida Association of Benthologists, with permission.

Laccornis oblongus (Figure 50) is a flightless beetle that lives in Irish fens that lack open water (Nelson 1996). It occurs among wet moss carpets, especially those associated with clumps of sedges. *Hydaticus seminger* (Figure 51) is a dweller of typical mossy fens. This species is not frequent in North Hampshire, UK, but it does occur among flooded *Sphagnum* and in detritus pools (Denton 2013).

Figure 50. *Laccornis oblongus* adult, a flightless beetle known from moss carpets in Irish fens. Photo by Niels Sloth, with permission.

Figure 51. *Hydaticus seminger* adult, a mossy fen dweller. Photo by Tim Faasen, with permission.

Floating moss carpets are often associated with bogs and fens. *Bidessus grossepunctatus* (Figure 52) is one of the inhabitants of these moss carpets in small lakes, ponds, fen pools, and mires (Nilsson & Holmen 1995).

Figure 52. *Bidessus grossepunctatus* adult, an inhabitant of floating moss carpets, on *Sphagnum*. Photo by Tim Faasen, with permission.

Special techniques can facilitate collecting bog and fen species. Since bryophytes in these habitats are typically underlain by water, these semi-terrestrial beetles can be collected by depressing the mosses, creating a depression until they are covered by water (Nilsson & Holmen 1995; Knight 2014). The beetles can then be swept from the water with a tea strainer. Knight (2014) considers this technique especially useful for sampling **Hydraenidae** and small **Hydrophilidae**.

In the Japanese rice fields, many invertebrates find refuge. Some of these fields even have peat mosses. Such communities include *Cybister japonicus* (Figure 53-Figure 54) (Ohba 2009), a species eaten by humans in Japan (Dytiscidae 2014). These carnivores feed on insects such as Odonata in early instars, but starting in the third instar they feed on small vertebrates such as amphibia as well. In the last larval stage, they burrow into the peat moss and enter the pupation period.

Figure 53. *Cybister japonicus* adult, a species that hides among peat mosses in Japanese rice fields. Photo through Creative Commons.

Figure 54. *Cybister japonicus* larva, a species that hides among peat mosses in Japanese rice fields. Photo through Creative Commons.

Liodessus cantralli (Figure 55) lives in small pools in North America, but also lives in moss mats of fens (less often in bogs) (Larson & Roughley 1990). They are particularly associated with *Drepanocladus* s.l. (Figure 56) in depressions in the moss mats.

Figure 55. *Liodessus* adult; *L. cantralli* lives in moss mats of fens. Photo © Stephen Luk through BugGuide non-commercial use, with permission.

Summary

Coleoptera can live in the water as larvae and as adults, but the pupae are generally on land. The aquatic adults gain oxygen by using a **plastron**, accumulating air under the forewings, or from an anal bubble. Some live on the surface and may crawl over plants such as *Ricciocarpus natans*. Smaller beetles live among mosses in streams. But the greatest number of aquatic bryophyte associations for beetles occurs in bogs and fens.

The order **Coleoptera** (beetles) has two sub orders: **Adephaga** and **Polyphaga**. In the **Adephaga** the families **Carabidae**, **Gyrinidae**, **Haliplidae**, **Hygrobiidae**, and **Dytiscidae**. The **Dytiscidae** are especially common and diverse in bog pools and this is the only family of **Adephaga** frequently associated with bryophytes.

Acknowledgments

Tim Faasen not only gave me permission to use his wide collection of insect images, he also helped me to understand the ecology of some of the species and provided me with additional images I needed. Thank you to Roger S. Key not only for his permission to use his images but for sharing his experiences with me regarding beetle use of bryophytes. Ronald Willson verified my beetle identifications for the mid-Appalachian Mountain study. And thank you to Amy Marcarelli, Wayne Minshall, and especially Rich Merritt for helping me with my query about the anal air bubble in aquatic beetles. Eileen Dumire proofread the chapter and suggested changes to provide more clarity.

CHAPTER 11-10

AQUATIC INSECTS: HOLOMETABOLA – COLEOPTERA, SUBORDER POLYPHAGA

Figure 1. *Ilybius erichsoni* adult on *Sphagnum*. Photo by Niels Sloth, with permission.

Suborder Polyphaga

This suborder includes more than 90% of the **Coleoptera** species. As its name suggests, it eats a tremendous variety of foods.

Helophoridae

This is a family of North America and Europe and has only one genus, *Helophorus* (Helophoridae 2014). They are relatively small (2-9 mm) (Helophoridae 2014) and live primarily in wetlands (Helophoridae 2015). Most adults live in shallow standing water where they are **saprophagous** (Fikáček 2009) (organism that feeds on decaying organic matter). Larvae, on the other hand, live in terrestrial, but moist, habitats near water and are predators on small invertebrates.

Helophorus grandis (Figure 2) occurs among the aquatic mosses in a stream in Yorkshire, UK (Gilbert *et al.* 2005). In Canada, *Helophorus orientalis* (Figure 3) occurs in wet mosses beside small streams (Majka 2008).

Helophorus strigifrons (Figure 4) lives in bogs in North Hampshire, UK, among moss and litter (Denton 2013).

Figure 4. *Helophorus strigifrons* adult, a bog dweller in North Hampshire, UK, among moss and litter. Photo by Zoologische Staatssammlung Muenchen, through Creative Commons.

Hydrochidae

Although this family is worldwide, it has only one genus, and most of the records are from Europe (Hydrochidae 2015a). Adults and larvae live in both quiet and flowing water where they are herbivores – shredders (Hydrochidae 2015b). The adults range 4-60 mm long. Some of these are associated with bryophytes.

Hydrochus ignicollis (Figure 5), a very rare species in Ireland, appeared in collections only twice between 1988 and 1996 (Nelson 1996). Both finds were from mossy calcareous fens adjacent to **marl lakes** (calcium carbonate or lime-rich lakes). These are alkaline lakes with unconsolidated calcium carbonate or lime-rich mud or mudstone which contains variable amounts of clays and silt (Figure 6-Figure 7).

Figure 5. *Hydrochus ignicollis* adult, a rare inhabitant of mossy calcareous fens in Ireland. Photo by Tim Faasen, with permission.

Figure 6. Marl lake in Jasper National Park, Canada. Photo by Janice Glime.

Figure 7. Marl at margin of marl lake in Jasper National Park, Canada. Photo by Janice Glime.

Hydrophilidae – Water Scavenger Beetles

This is a worldwide, mostly aquatic family, typically in open water (Cotinus 2005). The larvae often emerge from the water to pupate, usually hanging from moss at the edge of the water (Water Beetles 2014). The final larval skin is found beneath the pupa. The adults (1-40 mm) are mostly scavengers, but some are predators; larvae are often predators (Cotinus 2005).

Some **Hydrophilidae** join the **Dytiscidae** as common beetles swimming in bog waters. *Enochrus* (Figure 8-Figure 9) is a common genus there (Denton 2013). *Enochrus affinis* (Figure 10) is often abundant in *Sphagnum*-dominated (Figure 51) areas of acidic heathland pools (Figure 11) of North Hampshire, UK. *Enochrus coarctatus* (Figure 12) is a mire dweller, preferring older detritus pools but also living in *Sphagnum*-filled large bog pools. *Enochrus ochropterus* (Figure 13) does not occur in areas of pure *Sphagnum* where the *Enochrus* is exclusively *E. affinis*. However, it does occur in richer areas with *E. coarctatus*. The importance of the *Sphagnum* in its habitats may be due to its role in acidification. *Enochrus fuscipennis* (Figure 14) lives in the *Sphagnum*-choked shallow pools of undisturbed blanket bogs in Dartmoor, UK (Boyce 2011). *Enochrus hamiltoni* (Figure 15), on the other hand, lives in wet mosses next to small streams on Prince Edward Island, Canada (Majka 2008). In the Appalachian Mountain streams, eastern USA, the genus *Enochrus* can occasionally be found among mosses, as well as the genus *Tropisternus* (Figure 16-Figure 17) (Glime 1968).

Figure 8. *Enochrus* larva, common among bog bryophytes. Photo by Dana R. Denson, Florida Association of Benthologists, with permission.

Figure 17. *Tropisternus natator* adult, an occasional moss inhabitant in Appalachian Mountain, USA, streams. Photo by Donald S. Chandler, with permission.

The genus *Laccobius* (Figure 18-Figure 19) associates with mosses in both stream and mire habitats. *Laccobius reflexipennis* (see Figure 18) live in wet mosses next to small streams on Prince Edward Island, Canada (Majka 2008). *Laccobius atratus* in Ireland and Great Britain occurs in *Sphagnum* (Figure 51) bogs and other peatlands (Friday 1987; Nelson 1996; Denton 2013). *Laccobius ytenensis* adults live among mosses around the tiny pools that occur in the seepage lines of UK bogs (Denton 2013).

Figure 18. *Laccobius* sp. adult, a genus with several species that live in water or bog mosses. Photo by Gerard Visser <www.microcosmos.nl>, with permission.

Figure 19. *Laccobius* adult with open wings showing the membranous wings under the hardened elytra. Photo by Michael Schmidt, through Creative Commons.

Chaetarthria siminulum (Figure 20) can be present in "huge" numbers among mosses at the edges of ponds (Denton 2013). It also lives among mosses in fens and in fen litter.

Figure 20. *Chaetarthria siminulum* adult with plastron. When the plastron is full of air, the beetle must cling to vegetation in order to descend into the water column. Photo by Gerard Visser, with permission.

Hebauer (1994) found *Crenitis punctatostrata* (Figure 21) in the high moors, living as a tyrphobiont. *Hydrobius fuscipes* (Figure 22-Figure 23) on Prince Edward Island (Majka 2008) occurs in *Sphagnum* (Figure 51) bogs and other peatlands.

Figure 21. *Crenitis punctatostrata* adult, a beetle that lives in bogs of the high moors. Photo by Udo Schmidt, with permission.

Figure 22. *Hydrobius fuscipes* adult, a species of *Sphagnum* bogs. Photo by Tim Faasen, with permission.

Figure 23. *Hydrobius* larval head showing large mandibles. Photo by Dana R. Denson, Florida Association of Benthologists, with permission.

Friends are wonderful, and I recently received this story and all the images from Andrea Ares. She found an "amazing place" covered with the leafy liverwort *Jungermannia vulcanicola* (Figure 24-Figure 25) in Chatubomigoke Park, Gunma Prefecture, Japan. Soon she also discovered a small (6-7 mm) black beetle wending its way upon and within the "big, robust carpet" of the liverwort in this acid stream. This beetle was identified by Itouga san as *Hydrobius pauper* (Figure 26-Figure 28), the only member of the genus in Japan. There was not just one, but the bases of the liverworts were "full" of them.

Figure 24. Cushions of *Jungermannia vulcanicola* (chartreuse-colored cushions) in Chatubomigoke Park in Japan. Photo courtesy of Angela Ares.

Figure 25. Habitat of *Jungermannia vulcanicola* (chartreuse-colored cushions) in Chatubomigoke Park in Japan. Photo courtesy of Angela Ares.

Figure 26. Cushion of *Jungermannia vulcanicola* with its inhabitants, *Hydrobius pauper*. Photo courtesy of Angela Ares.

Figure 27. Disturbed cushion of *Jungermannia vulcanicola* showing bases of plants with its inhabitants, *Hydrobius pauper*. Photo courtesy of Angela Ares.

Figure 28. *Hydrobius pauper* adult. Photo by Itago san.

Berosus luridus (Figure 29, Figure 30) is tyrphophilic, living among *Sphagnum* (Figure 51), but can also be found in other places (Tim Faasen, pers. comm.). I have found no other records of it living among *Sphagnum*, but it is rare in the Netherlands and may be rare elsewhere. Perhaps the *Sphagnum* provides a relict habitat, a safe site where conditions are still tolerable.

Figure 29. *Berosus luridus* adult on moss, a rare beetle in the Netherlands, but present in bogs among *Sphagnum* there. Note the air bubbles on the moss; these can be used to replenish the air supply. Photo by Tim Faasen, with permission.

Figure 30. *Berosus* larva, a moss dweller in bogs of New Zealand. Photo by Stephen Moore, Landcare Research, NZ, with permission.

In tropical Africa, the genus *Anacaena* is probably more common than is recognized. Komarek (2004) described nine new species. Among these, four were from mosses. *Anacaena capensis* occurs among the mosses and leaf litter of mountain rivulets in South Africa. *Anacaena glabriventris* lives among mosses in small streams; *A. reducta* likewise lives among mosses in small streams, but with steep channels. *Anacaena tenella* lives among **hygropetric** mosses (mosses growing on vertical rock faces where a thin film of water flows) in mountain streams. *Anacaena limbata* (Figure 31) lives in wet mosses next to small streams on Prince Edward Island, Canada (Majka 2008).

Figure 31. *Anacaena limbata* adult, an inhabitant of wet mosses adjacent to streams. Photo by Tim Faasen, with permission.

Anacaena globulus (Figure 32) lives among *Sphagnum* (Figure 32) in bogs in Europe and can be collected by squeezing the moss (Buczyński *et al.* 2014). However, Faasen (personal communication) does not find them typically in *Sphagnum* bogs in the Netherlands, but considers them widespread, occasionally occurring in bogs.

Also in Dartmoor, UK, *Helochaeres punctatus* (Figure 33) is an obligate mire species, living among saturated *Sphagnum*, particularly *S. cuspidatum* (Figure 34), of pools and acid flushes.

Figure 32. *Anacaena globulus* adult on *Sphagnum*, one of its many habitats. Photo by Tim Faasen, with permission.

Figure 33. *Helochaeres punctatus* adult on moss. Photo by Niels Sloth, with permission.

Figure 34. *Sphagnum cuspidatum*, home for *Helochaeres punctatus*. Photo by David T. Holyoak, with permission.

Nelson (1996) found several additional species of **Hydrophilidae** in Irish mossy fens. These included *Cercyon convexiusculus* (Figure 35-Figure 36) in mossy fens. In North Hampshire, UK, Denton (2013) found this species to be abundant in detritus and rotting leaf litter, but also among mosses that bordered richly vegetated sites. *Cercyon marinus* similarly occupied mosses or decaying organic matter at the water's edge in Ireland (Nelson 1996). *Cercyon ustulatus* (Figure 37) occurs in mossy areas of ponds and also occurs among mosses growing on sewage filter beds (Denton 2013).

Figure 35. *Cercyon convexiusculus* adult, an inhabitant of mossy fens. Photo by Tim Faasen, with permission.

Figure 37. *Ceryon ustulatus* adult, an inhabitant of mossy areas of ponds and filter beds. Photo by Tom Murray, through Creative Commons.

Paracymus scutellaris (Figure 38) occurs among peat mosses in Ireland (Nelson 1996).

Figure 38. *Paracymus scutellaris* adult, a peat moss dweller in Ireland. Photo by Udo Schmidt, with permission.

Hydraenidae – Minute Moss Beetles

Adults of **Hydraenidae** (Figure 39), known as minute moss beetles (1-3 mm length), are aquatic, but the larvae drown if completely submersed (Watson & Dallwitz 2012). Even adults are poor swimmers (EOL 2014); most eat plants, but a few are carnivorous or **saprophagous** (feeding on decaying organic matter) (Hydraenidae 2014). They are sparsely distributed worldwide with a concentration in Europe (EOL 2014).

Sarr *et al.* (2013) found that *Hydraena* was correlated with a moss substrate in Northwest Spain. Berthélemy (1966) found this family commonly among mosses in the Pyrénées, including *Hydraena gracilis* (Figure 40), *H. minutissima*, and *H. pygmaea* (Figure 41), with the latter two being considered **musciholes** (thriving among mosses). He also considered *Hydraena pulchella* (Figure 42) and *Hadrenya* to be **musciholes**. Nelson (1996) reported *Hydraena gracilis* as a common and widespread species in Britain where it lives on mossy rocks in fast-flowing streams and rivers.

Figure 42. *Hydraena pulchella* adult, a tiny beetle that lives among stream mosses in Europe. Image through Creative Commons.

Hydraena nigrita is a tiny beetle that lives among mosses at the edges of streams, but it will climb out if the moss is placed under water (Anderson 2014). It is considered vulnerable because of siltation and loss of habitat (Foster *et al.* 2009). *Hydraena rufipes* (Figure 43) lives among mosses (Nelson 1996; Knight 2014) and fine **shingle** (mass of small rounded pebbles) along rivers (Nelson 1996).

Figure 43. *Hydraena rufipes* adult, a species that lives among mosses along rivers. Photo from Zoologische Staatssammlung Muenchen, through Creative Commons.

Hebauer (1994) found similar species representation from this family in middle Europe. Among the stream mosses he found *Hydraena minutissima*, *H. pygmaea* (Figure 41), and *H. pulchella* (Figure 42). Several more used mosses or algae as a substrate: *Ochthebius granulatus* (Figure 44), *O. metallescens* (Figure 45), *O. exsculptus* (Figure 46), *O. melanescens*, *O. colveranus*, and *O. halbherri*. Eggs of *Ochthebius* are either naked or somewhat covered by loosely applied silk provided by the mother; the eggs hatch in 7-10 days. In rivers in Northwest Spain, Sarr *et al.* (2013) found that *Ochthebius heydeni* was likewise correlated with a moss substrate.

Limnebius nitidus (Figure 47) is among the smallest of the water beetles and in addition to wet mud, it makes mosses in swamps and at the edges of pools and streams its home (Nelson 1996). Adults are a mere mm long, so these scavengers of dead plants and animals are easily overlooked (Hilsenhoff 1975). Eggs of this genus are either naked or somewhat covered with loosely applied silk and hatch in 7-10 days (Usinger 1956). In my studies in the Appalachian Mountain streams of the eastern US, this genus likewise occurred among submerged mosses (Glime 1968).

Figure 47. *Limnebius nitidus* adult, one of the smallest of all water beetles and a moss dweller in swamps. Photo through United States public domain.

Hygrotus decoratus (Figure 48) lives in shallow, mossy fens in North Hampshire, UK, where mosses may provide safe sites for larvae and adults (Denton 2013). *Hygrotus novemlineatus* was reared with **Chironomidae** larvae as a food source (Nilsson 1983). Mosses were provided in the culture chamber. After a few days, the beetles laid eggs, attaching them to branches of mosses. But is this a normal substrate for egg-laying in nature? The habitat seems suitable, providing lots of **Chironomidae** larvae as food. This genus should be sought among bryophytes in other fens.

Ptiliidae – Featherwing Beetles

This is a large, worldwide family of minute (0.3-2 mm long) beetles (Ptiliidae 2015). The egg size is half the length of the body and only one is developed at a time, permitting the female to store a large energy supply in the egg. Their wide-ranging habitats include moist leaf litter, under bark of dead trees, along sand and gravel banks of rivers and streams, beneath seaweed on beaches, in mammal nests, on dung, rotting cacti, ant and termite colonies, and other habitats containing rotting or damp organic material. And some seem to live their entire lives in bogs.

The small size of several **Ptiliidae** beetles – *Tychobythinus bythinoides* (Staphylinidae or Ptiliidae; Figure 65), *Ptiliopycna moerens* (Figure 49), *Acrotrichis* (Figure 50) – and other small beetles in bogs seems to correlate with a high incidence of **parthenogenesis** (reproduction from an unfertilized egg) in **relict** (habitat that survived from an earlier period) bogs (Dybas 1978), most likely having poor dispersal as an additional selection factor.

Figure 49. *Ptiliopycna moerens* adult, a parthenogenetic inhabitant of relict bogs. Photo © Stephen Luk for non-commercial use, with permission.

Figure 50. *Acrotrichis* sp. adult, a parthenogenetic inhabitant of relict bogs. Photo by Joyce Gross, with permission.

Ptiliopycna moerens is minute, less than 1.0 mm long, and lives in the northeastern United States and adjacent Canada (Dybas 1978). It lives in *Sphagnum* in bogs and swamp forests, confined within the limits of Wisconsinian glaciation. Males are seemingly restricted to the northern part of the range. More southern locations have parthenogenetic females, a common character of small beetles in relict bogs. (See the chapter on Terrestrial Insects – Coleoptera for further discussion of beetles in bogs.)

Silphidae – Large Carrion Beetles

This family is predominantly in the Northern Hemisphere, although scattered records exist in the Southern Hemisphere (Silphidae 2015a). Ranging in size from 7-45 mm, the family is rare in the tropics where ants might out-compete them (Silphidae 2015b). As the common name implies, the family feeds on decaying organic matter. Because of this feeding behavior, forensic scientists use their stage of development to determine how long a body has been dead.

Despite the need to find new carcasses as their carcass home ages, the **Silphidae** use walking as their primary means of locomotion (Silphidae 2015b). Most of their activity occurs at night.

The **Silphidae** have a variety of defenses (Silphidae 2015b). These include color warnings from **aposematism** (use of bright colors to advertise danger or unpalatability) to **Batesian mimicry** (mimicking coloration or behavior of poisonous or unpalatable species), chemical defenses, and parental care. And many of them use camouflage, having dark colors with a mix of gold, black, and brown to blend with their environment.

Some carrion beetles (**Silphidae**) occur in bogs. Beninger and Peck (1992) described the resource use by *Nicrophorus* species (carrion beetles, **Silphidae**) in a *Sphagnum* (Figure 51) bog near Ottawa, Canada, and found that resource use differed little from resource use in forested habitats. However, *Nicrophorus vespilloides* (Figure 52) used only small carrion (Figure 53) in the bog for reproduction, whereas the closely related *N. defodiens* (Figure 54) went to the nearby forest for reproduction. Likewise, *N. sayi* (Figure 55), *N. orbicollis* (Figure 56), and *N. tomentosus* (Figure 57), also bog inhabitants, were rarely associated with the small carrion of the bog, but rather reproduced mostly in the forest.

Staphylinidae – Rove Beetles

These beetles are distinctive in having short wings that cover less than half the abdomen (Bartlett 2004). This large family has about 58,000 species, ranging in size from 1 to 35 mm, but mostly 2-8 mm (Rove Beetle 2014). Distribution is worldwide, but records are lacking in vast areas of Asia and Africa. They live in every imaginable type of habitat and likewise eat everything – except living plants! There is now one exception to that – a recent discovery of a herbivore.

Like the *Carabidae*, the *Staphylinidae* are not aquatic, but likewise inhabit bogs (Boyce 2011). In Dartmoor, UK, *Gymnusa brevicollis* (Figure 58) is **stenotopic** (able to tolerate only a restricted range of habitats or ecological conditions). Its preferred habitat is saturated *Sphagnum* (Figure 51) in extremely wet acid mires where they can be found at the edge of bog pools.

Figure 58. *Gymnusa brevicollis* adult, a beetle that lives among saturated *Sphagnum* at the edge of bog pools of wet acid mires. Photo from Zoologische Staatssammlung Muenchen, through Creative Commons.

Myllaena kraatzi (Figure 59), a nationally (UK) rare species, is restricted to very high quality acid mires with abundant bog mosses (Boyce 2011). It is collected by shaking the *Sphagnum* (Figure 51) and litter, suggesting close ties with these two substrates. *Oxypoda procerula* (Figure 60) is likewise sampled by shaking the litter and *Sphagnum*, indicating that it is directly a moss dweller.

Figure 59. *Myllaena vulpina* adult. *Myllaena kraatzi* is a rare species of high quality acid mires in the UK. Photo by Reginald Webster, Jan Klimaszewski, Georges Pelletier, and Karine Savard through Creative Commons.

Figure 60. *Oxyptoda procerula* adult, a *Sphagnum* and litter dweller. Photo by Udo Schmidt, through Creative Commons.

Philonothus nigrita (Figure 61) is a characteristic species in *Sphagnum*-dominated (Figure 51) acid mires (Boyce 2011). It can be found by treading on the moss cushions, causing it to float out of the saturated *Sphagnum*. *Stenus brevipennis* (see Figure 62) lives among *Sphagnum* in blanket bogs. *Stenus kiesenwetteri* (Figure 63) is rare in the UK, occurring in very wet *Sphagnum* (Butler 1886).

Figure 61. *Philonothus nigrita* adult, a species that characterizes *Sphagnum*-dominated acid mires. Photo by Marko Mutanen, through Creative Commons.

Figure 63. *Stenus kiesenwetteri* adult, a rare beetle inhabiting very wet *Sphagnum*. Photo by Udo Schmidt, through Creative Commons.

Unlike the other *Staphylinidae* discussed here, *Dianous coerulescens* (Figure 64) lives where water trickles over mosses and liverworts (Butler 1886).

Figure 64. *Dianous coerulescens* adult on leafy liverwort. Photo by Malcolm Storey, through Creative Commons.

The *Pselaphinae* beetles are represented along the postglacial fringe in the central and eastern United States where they inhabit *Sphagnum* (Figure 51) bogs (Reichle 1966). More than 20 species of pselaphids characterize these bogs. They are relict species with specific habitat requirements and poor dispersal ability. Some have very specific temperature range requirements: *Tychobythinus bythinoides* (= *Bythinopsis tychoides*; Figure 65), 21.5 ± 0.81 , 25.9 – 15.3°C ; *Decarthron defectum*, 28.5 ± 0.55 , 31.4 – 24.0 ; *Pselaphus ulkei*, 19.5 ± 0.86 , 24.7 – 13.0 ; *Reichenbachia borealis* (a short-winged mold beetle; Figure 66), $21. \pm 0.99$, 26.2 – 14.4 ; *Rybaxis clavata* (Figure 67), 28.3 ± 0.41 , 29.9 – 25.1 (Reichle 1967). The moss microhabitats provide them with both the required near-saturation humidities and the multiple temperature ranges they require. Changes in temperature stratification regimes result in different species occurring at different seral stages in the bogs.

Scirtidae (=Helodidae) – Marsh Beetles

This is a worldwide family, but is most diverse in the temperate region (Murray 2005). The larvae live in both stagnant and flowing water where abundant decomposing plant material is present. Adults live on vegetation and on rotting vegetation. The **Scirtidae** are soft-bodied relative to other beetles and are slightly flattened to nearly **subglobular** (almost globe-shaped) (TOL 2011). Their sizes range 1-15 mm long. Some females secrete substances that may be pheromones used to stimulate males into courtship (Ruta 2008).

This is typically a beetle of open water, but in a subalpine springbrook in the southern Alps of New Zealand, **Scirtidae** (Figure 68) are most abundant in the moss *Acrophyllum quadrifarium* (= *Pterygophyllum quadrifarium*; Figure 69) at the edge of the inner spray zone where the mosses are saturated (Cowie & Winterbourn 1979).

Cyphon (Scirtidae; Figure 70-Figure 72) has been collected from wet mosses at the edge of a cold spring (Usinger 1974). *Cyphon hiliaris* (Figure 71) in Dartmoor, UK, prefers bog pools that have *Sphagnum* (Figure 51) (Boyce 2011). In North Hampshire, UK, *C. hiliaris* occurs infrequently in wetlands with peaty soils, acidic bogs, and fens (Denton 2013). *Cyphon padi* (Figure 72), also in North Hampshire, prefers peaty areas in wooded sites where the *Sphagnum* is flooded.

Elmidae – Riffle Beetles

These are small beetles (1-8 mm) (Gordon & Post 1965). The **Elmidae** have a distribution similar to that of the **Silphidae**, but there are more known locations, including southern Africa (Harrison 2009). As the common name describes, these beetles usually live in the riffles of cool, rapid streams (Arnett *et al.* 2002; Harpootlian 2005). They feed mostly on decaying plants and algae (Epler 2010).

Only three species of **Elmidae** are considered to be frequent aquatic bryophyte dwellers: *Promoresia tardella* (Figure 73), *Atractelmis wawona* (Figure 74), and *Cleptelmis addenda* (Figure 75) (Brown 1972; Shepard & Barr 1991; Bowles *et al.* 2003; Elliott 2008a), all from North America where the family has many more species (80 species) than in Europe (46 species) (Elliott 2008a). But if one looks among the liverworts in the Pacific states of USA, a fourth genus, *Bryelmis* (Figure 108-Figure 110) is lurking (Bowles *et al.* 2003 – see below); further searching among submerged leafy liverworts may expand this *Bryelmis* distribution. Nevertheless, a number of species use bryophytes at some stage in their lives. Both larvae and adults of some **Elmidae** are able to feed on mosses (Usinger 1974). When disturbed, **Elmidae** may play dead for a number of hours before attempting to relocate (Usinger 1956). *Cleptelmis* (Figure 75) may wait for 12-15 hours before moving. Such patience!

Elmidae colonize mosses when insect-free mosses are introduced, but some of the elmids may be slow to colonize. This is no surprise since they creep and don't swim. For example, Maurer and Brusven (1983) found that the elmid *Cleptelmis ornata* (Figure 76) was the only insect that was slow to colonize insect-free test clumps of *Fontinalis neomexicana* (Figure 77) during a field experiment in Idaho, USA.

Elliott (2008a) summed up some of the characters that define the bryophyte dwellers. Their larvae have a triangular cross section. Among this group he included *Elmis* (Figure 87-Figure 86), *Esolus* (Figure 84-Figure 85), and *Oulimnius* (Figure 88-Figure 89), none of which were considered by earlier researchers mentioned above to be the frequent bryophyte dwellers. All members of the family have aquatic larvae and most have aquatic adults. The pupae are terrestrial. This means that the newly emerged adults must re-enter the water – no small feat for such a small insect. They must break through the surface tension – easy for us, but nearly impossible for them unless they have something to cling to and provide leverage for them to break through (see Figure 78). Bryophytes, plants, and rocks can help here.

Figure 78. *Dryops auriculatus* (Dryopidae) adult entering water by clinging to a plant. Note the rings in the water and depression of the surface by the beetle body. Photo by Tim Faasen, with permission.

The aquatic adults use the **plastron** for oxygen availability (Thorpe & Crisp 1949) – they are air breathers. The plastron apparatus is seen as a silvery layer (Figure 79) on the ventral side of the beetle. Some members include the antennae as part of the apparatus that holds the air bubble. They groom the plastron with brushes on the femur of the leg and also use these brushes to add air bubbles to the plastron apparatus by smearing bubbles over the plastron. Most do not need to return to the surface, using the mouthparts to capture oxygen bubbles emitted by plants. If the plastron air layer is thick, it has a silvery sheen and is called a **macroplastron** (Figure 116). When air diminishes from the macroplastron to the normal, smaller plastron, air exchange with the water is generally adequate to maintain the duller-looking air bubble and meet their needs. This low need for fresh air is likely possible because these beetles do not swim, requiring less oxygen for their clambering movements.

In a tributary of the Danube, *Elmis maugetii* and *Riolus subviolaceus* (Figure 80) were abundant in high flow areas among coarse mosses, whereas *Esolus parallelepipedus* (Figure 81) and *Limnius volckmari* (Figure 82-Figure 83) were among algae in moderately flowing water (Dietrich & Waringer 1999). *Esolus*

angustatus (Figure 84-Figure 85) and *Oulimnius tuberculatus* (Figure 88-Figure 89) were more common in moderate flow with abundant moss-covered pebbles.

Figure 85. *Esolus angustatus* adult, member of a genus that is common among bryophytes. Photo by Tim Faasen, with permission.

In British streams and rivers, *Elmis aenea* (Figure 86-Figure 87), a moss dweller in rapid streams and rivers (both above and below water), occurred among bryophytes as both adults and larvae, but larvae were more abundant among small stones or under larger ones (Elliott 2008a). In these rivers and streams, *Oulimnius tuberculatus* (Figure 88-Figure 89) preferred tracheophytes.

Figure 86. *Elmis aenea* larva, a species whose distribution is related to elevation. Photo by Niels Sloth, with permission.

Figure 87. *Elmis aenea* adult, a moss dweller in rapid streams and rivers. Photo by Tim Faasen, with permission.

In a 39-month study, Elliott (2008b) examined the effect of density on drift rate. Most of the larvae and adults of **Elmidae** drift at night with very few drifting in daytime. Elliott found that the **Elmidae** in the study, including the bryophyte dwellers, did not drift on the basis of density. Drift losses accounted for only about 0.07% of total losses in the benthos. The exception to this was the high drift, during a heavy rainfall, of early stages of immature adults of *Elmis aenea* (Figure 87), *Oulimnius tuberculatus* (Figure 88-Figure 89), and *Esolus parallelepipedus* (Figure 81), all species known from bryophytes. For *Elmis aenea*, the highest drift density was in the earliest life stage soon after egg hatching; for *O. tuberculatus* it was the start of the larval overwintering period. Frost (1942) found that *Oulimnius tuberculatus* lives among mosses (and other habitats); moving to land for pupation most likely subjects this insect to the drift.

Figure 88. *Oulimnius tuberculatus* adult, a European moss dweller. Photo by J. C. Schou, with permission.

Figure 89. *Oulimnius tuberculatus* larva, an aquatic moss dweller. Photo by J. C. Schou, with permission.

Nelson (1996) described *Elmis aenea* (Figure 86-Figure 87) as a species from moss-covered rocks in rapid rivers and streams. Berthélemy (1966) found larvae (Figure 86) and adults (Figure 87) of *E. aenea* and *E. maugetii* were often abundant among mosses and liverworts in the Pyrénées. The moss-dwelling species were generally smaller than those among stones. Nelson found that the proportion of *E. aenea* vs *E. rioloides* (Figure 90) among mosses was related to elevation.

Figure 90. *Elmis rioloides* adult, a moss dweller whose distribution is affected by elevation. Photo through Creative Commons.

Gurtz and Wallace (1984) found larvae of the elmid *Promoresia* in only one sample in Big Hurricane Branch.

They had learned from J. Haefner (personal communication) that these larvae in Sawmill Branch occurred almost exclusively among aquatic mosses (Haefner & Wallace 1981). I found *Promoresia elegans* (Figure 91-Figure 92) frequently among the bryophytes [*Fontinalis dalecarlica* (Figure 93-Figure 94), *Hygroamblystegium fluviatile* (Figure 95), *Scapania undulata* (Figure 112)] of Appalachian Mountain, USA, streams. This is a genus that exhibits the triangular cross section that Elliott (2008a) suggested to be characteristic of bryophyte dwellers.

Figure 94. *Fontinalis dalecarlica* showing the dangling streamers. Photo by Jan-Peter Frahm, with permission.

Figure 95. *Hygroamblystegium fluviatile*, home to several species of Elmidae. Photo by Janice Glime.

In addition to *Elmis*, Berthélemy (1966) found *Riolus cupreus* (Figure 96-Figure 97), *Esolus parallelepipedus* (Figure 81), and *Oulimnius tuberculatus* (Figure 88-Figure 89) among mosses in streams in the Pyrénées. *Elmis* and *Oulimnius* were strong **muscoles** (living among or in association with mosses). Hebauer (1994) found *Elmis obscura*, *E. rioloides* (Figure 90), and *Oulimnius tuberculatus* among mosses in streams in Central Europe.

Figure 96. *Riolus cupreus* larva, an inhabitant of Pyrénées stream mosses. Photo by Urmas Kruus, with permission.

Figure 97. *Riolus cupreus* adult, an inhabitant of Pyrénées stream mosses. Photo by Urmas Kruus, with permission.

The **Elmidae** spend their larval life in the water, pupate on land, then after their initial dispersal flight they return to the water. The interesting note here is that once they return to the water, they lose their ability to fly (Ward 1992). This locks them into their habitat no matter what the water conditions. For those inhabiting stream mosses, this means that if the water level drops, they must remain in the habitat of the mosses, unable to disperse for any significant distance. But for them it seems to be no problem because they have a high drought tolerance (Larimore *et al.* 1959; Iverson *et al.* 1978).

Steffan (1961) suggested that the mosses such as *Fontinalis* (Figure 94) were necessary for some **Elmidae** and **Dryopidae** to make the transition from water to land (and back to the water) during their amphibious life. Bryophytes would permit them to gain a firm hold while breaking through the surface tension in either direction.

In Louisiana, USA, the endangered riffle beetle *Heterelmis comalensis* (Figure 98-Figure 99) lives on submerged roots and aquatic mosses (Barr & Chapin 1988). In this same habitat, *Microcyloepus pusillus* (Figure 100-Figure 101) likewise uses these substrata. In the Appalachian Mountain streams, USA, I found a species of *Microcyloepus* among the submerged mosses (Glime 1968).

Figure 101. *Microcyloepus pusillus* adult, an inhabitant of submerged roots and mosses. Photo by Mike Quinn, through Creative Commons.

My experience with **Elmidae** among the stream bryophytes in the Appalachian Mountains, USA, differs from that in many of the reports cited here (Glime 1968). I found six species, and among these only *Microcylloepus* (Figure 100-Figure 101) and *Promoresia elegans* (Figure 91-Figure 92) (both larvae and adults) have been reported in the other studies cited herein. The numbers of *Promoresia elegans* actually exceeded the numbers of **Chironomidae** among bryophytes in one stream in March; in winter I found only two adults. In addition I found two species of *Optioservus* (Figure 102-Figure 103) on *Hygroamblystegium fluviatile* (Figure 95); on *Fontinalis dalecarlica* (Figure 93-Figure 94), I found *Stenelmis crenata* (Figure 105-Figure 104) and one species of *Dubiraphia* (Figure 106-Figure 107).

It is no surprise that new species remain to be discovered among the bryophytes. But one such recent discovery in the western states of the USA was not just a new species, but a new genus, widespread, and with multiple species! And these were among aquatic bryophytes, particularly leafy liverworts (Barr 2011). These three species were *Bryelmis idahoensis* (Figure 108), *B. rivularis* (Figure 109), and *B. siskiyou* (Figure 110) from streams and springs in the states of Washington,

Oregon, California, and Idaho. Once Barr alerted her colleagues in neighboring states of her find, they began searching this new habitat, the leafy liverwort *Chiloscyphus polyanthos rivularis* (Figure 111). After searching through 652 adult and over 200 larval specimens from museum and new collections, she distinguished three species, all previously unknown. And now all these people know the difference between a moss and a liverwort – the latter houses *Bryelmis*.

Figure 111. *Chiloscyphus polyanthos*, primary home to the recently discovered genus *Bryelmis*. Photo by Jan-Peter Frahm, with permission.

Barr had found *Bryelmis idahoensis* in association with aquatic bryophytes on rocks, but some also occurred on water-soaked wood. *Bryelmis rivularis* preferred *Chiloscyphus polyanthos rivularis* (Figure 111) and *Scapania undulata* (Figure 112) and tended to avoid both of the mosses *Fontinalis neomexicana* (Figure 77) and *Platyhypnidium riparioides* (Figure 113). By targeting aquatic liverworts she discovered another new species, *B. siskiyou*.

Figure 113. *Platyhypnidium riparioides*, a habitat rejected by *Bryelmis*, a leafy liverwort inhabitant. Photo by Hermann Schachner, through Creative Commons.

In Mexico, Central America, and the West Indies, *Lara avara* (Figure 114-Figure 115) spends 4-6 years as larvae, going through seven instars (Spangler & Santiago-Fragoso 1992). The larvae leave the stream water in spring and move to mosses at the stream bank in their last instar. In their last instar they burrow into small "cells" under mosses at water's edge (Spangler & Santiago-Fragoso 1992) or under mosses on the upper surface of emergent logs (Elliott 2008a). When the moss dries in early summer the larvae begin pupation (Spangler & Santiago-Fragoso 1992). This pupation lasts only two or more weeks.

Dryopidae – Long-toed Water Beetles

The **Dryopidae** are mostly Northern Hemisphere (Dryopidae 2015), but the scant records in the Southern Hemisphere may reflect limited collecting rather than absence of beetles. This is an interesting family in that the larvae are mostly terrestrial, living in decaying plant material, rotting wood, and soil, whereas the adults (3.5-5.5 mm long) return to running water to lay eggs (Watson & Dallwitz 2003). They are unable to swim and clamber about by clinging to plants. They eat plants as adults, but larvae may also prey on small animals. The **Dryopidae** occur on every continent except Antarctica and Australia, but they are most common in the tropics (Dryopidae 2015). They use hairs to create a **plastron** apparatus (see introductory information), enabling them to breathe under water.

The **Dryopidae** (Figure 116) seem seldom to be reported among the bryophytes of aquatic habitats. Nevertheless, Percival and Whitehead (1930) found that the **Helminae** (**Dryopidae**) reached 1244 per dm² in the mossy area of streams in the UK, whereas among stones with no mosses they reached only 10-15 per dm². Buczyński *et al.* (2014) reported that in Poland *Dryops anglicanus* (Figure 117) lives in canals created by beavers in floating

Sphagnum (Figure 51) mats. In rivers of Northwest Spain, *Dryops luridus* preferred moss substrata (Sarr *et al.* 2013). In the Appalachian Mountain, USA, streams, I found a species of *Helichus* (Figure 118) (Glime 1968).

Figure 118. *Helichus lithophilus* adult, member of a genus with bryophyte dwellers in Appalachian Mountain, USA, streams. Photo by Mike Quinn, through Creative Commons.

Chelonariidae – Turtle Beetles

These are relatively small beetles (adults 2.5-10 mm long) and somewhat resemble turtles in that their heads are hidden and their legs can be tucked into depressions in the abdomen made for them (Harpootlian 2006). They are best known from eastern North America, western South America, and Central America, but there are some records from eastern Asia (Chelonariidae 2015). They reach their greatest diversity in the Neotropics.

Sometimes it is hard to determine if the insects are aquatic or terrestrial. Perhaps it is just a wide niche with a wide water tolerance. In other cases, entrance into the aquatic world may be accidental. Such seems to be the case with *Chelonarium* (Figure 119), a genus that inhabits damp moss (Spangler 1980). From these damp mosses, they may occasionally get washed into the nearby stream by rain or high water (Brown 1972). The larvae, once considered aquatic, lack gills (Spangler 1980). Members of the genus are often associated with the roots of terrestrial **epiphytes** (plants that grow on other plants but are not parasitic) and often feed on ants and termites.

Figure 119. *Chelonarium lecontei* adult, a species once thought to have aquatic larvae. Note how the legs fit into the exoskeleton. Photo through Creative Commons.

Lampyridae – Lightning Bugs

"When night closes in, fireflies flicker with an ethereal and haunting light" (WWF 2011). This is the family of fireflies (Figure 120) that delighted us as children. And one of them, *Luciola ficta* (see Figure 121), lives in the water as a larva and uses mosses (Ho *et al.* 2010)! The adults court, mate, and females oviposit on mosses (or under leaf litter, in root gaps, or in soil clefts), but on land. The young hatchlings must make their way to the water. This unique Asian beetle is in danger of extinction because its habitat is disappearing. However, the Chinese are attempting to save it by learning its development (Ho *et al.* 2006) and creating small pools for it (WWF 2011).

Figure 120. **Lampyridae** adult showing the portion that lights up. Photo by Andy Deans, through Creative Commons.

Figure 121. *Luciola lusitanica* adult. *Luciola ficta* is a species with aquatic larvae and adults that oviposit on terrestrial mosses. Photo by Tim Faasen, with permission.

Latridiidae – Minute Brown Scavenger Beetles

Minute it is, with sizes up to 3 mm (McClarín 2005). The family mostly eats fungi and slime molds, frequenting decaying vegetation (Latridiidae 2015). Records of this family are concentrated in Europe, with scattered records in North America, South America, Africa, and Australia. But this family is even present in the Antarctic region.

In South Georgia (southern Atlantic Ocean) bryophytes often play an important role as habitats for insects. One such inhabitant is *Aridius malouinensis* (Figure 122) (Arnold & Convey 1998).

Figure 122. *Aridius malouinensis* adult, a moss dweller on the island of South Georgia. Photo by Roger S. Key, with permission.

Curculionidae – Weevils

Despite the fact that **Curculionidae** (Figure 123) is the third largest animal family (Curculionidae 2014), its presence is missing among aquatic mosses. Its distribution is worldwide, although records are lacking in vast areas of Asia and Africa (Curculionidae 2015). Adults range 1-40 mm long and are plant feeders.

Figure 123. *Cionus hortulanus* adult, showing one of many thousands of bizarre forms present in this family. Photo by Lukas Jonaitis, through Creative Commons.

This terrestrial family has limited associations with the water. The marine weevil *Palirhoeus eatoni*, on the Prince Edward Islands south of Africa, lives among tufts of algae as larvae (Doyen 1976). When it pupates it goes above the high water level among clumps of the shoreline moss *Grimmia amblyophylla* (Jeannel 1940, 1953).

Lagriidae

Our records of bryophyte dwellers from Africa seem to be rare, so it is pleasing to see a study on bryophagy in South Africa (Chown 1993). Chown found that members of the **Lagriidae** in the Afromontane forest fed on both green and brown parts of the moss *Braunia secunda*. This is a family with poorly known feeding habits, and the species discovered here was unnamed.

Figure 124. *Lagria hirta* adult, a beetle that eats the moss *Braunia secunda*. Photo by Udo Schmidt, with permission.

Figure 125. *Braunia secunda*, home for some members of the Lagriidae. Photo by Efrain De Luna, with permission.

Summary

The suborder **polyphaga** includes a number of families of beetles that live among bryophytes, especially the small members.

These include **Helophoridae** that live in both bogs and streams among bryophytes. **Hydrochidae** live among bog mosses. **Hydrophilidae** are common in

bog pools, where diversity is high, but some also occur among stream bryophytes. The **Hydraenidae** are tiny beetles that live primarily among bryophytes in streams and fast rivers. Some small members of the **Ptiliidae** are **parthenogenetic** and live in **relict** bogs. The **Silphidae** are carrion feeders and those in bogs breed on small carrion such as frogs. The **Staphylinidae** are not typical bryophyte dwellers, and are not aquatic, but they live in bogs. The **Scirtidae** find suitable habitat in the saturated mosses of the spray zone of the streambrooks in the Alps of New Zealand.

The best adapted family of the beetle bryophyte dwellers is the **Elmidae**. They use a **plastron** to breathe and are small enough to clamber about among the bryophyte stems and leaves. The **Dryopidae** are similarly adapted and both families can be found among stream bryophytes.

Some species of the **Chelonariidae** live among wet mosses of stream banks and seem to occasionally fall in. The species *Luciola ficta* is a firefly in the family **Lampyridae**. Its larvae live in the water and the adults deposit their eggs on mosses and other substrata near water. The **Latridiidae** are among the insects in South Georgia where one species lives among the bryophytes. The **Curculionidae** are weevils and few are associated with aquatic habitats. Some live on floating plants and one species leaves its water home to pupate among shoreline mosses.

Acknowledgments

Tim Faasen not only gave me permission to use his wide collection of insect images, he also helped me to understand the ecology of some of the species and provided me with additional images I needed. Thank you to Roger S. Key not only for his permission to use his images but for sharing his experiences with me regarding beetle use of bryophytes. Ronald Willson verified my beetle identifications for the mid-Appalachian Mountain study. Eileen Dumire proofread the chapter and offered suggestions to improve clarity.

CHAPTER 11-11

AQUATIC INSECTS: HOLOMETABOLA – TRICHOPTERA, SUBORDER ANNULIPALPIA

Figure 1. *Fontinalis antipyretica* in a small stream. This moss is often home to many kinds of insects, including even larger Trichoptera. Photo by Betsy St. Pierre, with permission.

LEPIDOPTERA – Moths and Butterflies

This predominantly terrestrial order has a number of aquatic members whose larvae live on tracheophytes. These include such families as the **Pyralidae** (Figure 2) and **Noctuidae**. Larvae of some aquatic species possess gills (Bouchard *et al.* 2004). The aquatic **Pyralidae** are the only **Lepidoptera** with aquatic pupae.

I have not been able to find any records of this order on bryophytes. However, on one occasion I found a caterpillar of the **Nymphalidae** in a bed of *Fontinalis* in the Red Cedar River, East Lansing, MI. Unfortunately, I was there for a different purpose and don't have any further details.

TRICHOPTERA – Caddisflies

The **Trichoptera** are distinguished as adults by the hairs on their wings (Figure 3) and the resting position that looks like a pup tent (Figure 4). Their distribution is worldwide and size varies greatly. Most build cases that serve as retreats for both larvae and **pupae** (immature stages, often immobile) between larvae and adults).

Figure 3. *Brachycentrus appalachia* adult wings showing hairs. Photo by Jason Neuswanger, with permission.

Figure 4. *Limnephilus frijole* adult showing wings folded like a pup tent. Photo by Bob Newell, with permission.

Caddisflies are common inhabitants among mosses (Oswood 1979; Glime 1994; Ogbogu 2000; Ogbogu & Akinya 2001). Berg and Petersen (in Macan 1963) found a mean of 260 Trichoptera in just 1 sq meter of *Fontinalis* (Figure 1) in Lake Gribso. And Frost (1942) found 492,200 individuals per gram of mosses in Ireland. Several families of caddisfly larvae have members that use bryophytes in the construction of their homes (Glime 1978).

In North America, caddisfly larvae are closely associated with mosses such as *Fontinalis* (Figure 1) (Ogbogu 2001a). As the density of these mosses increases, so does the density of the caddisfly larvae. Ogbogu suggested that use of the mosses as part of their life cycle strategy permits these larvae to survive in the unstable habitats of streams.

Krno (1990) found that some Trichoptera were able to climb out of the water to move about among the wet emergent mosses. However, the fauna there was not as rich as that among submerged mosses. Galdean (1994) found that some caddisflies were common on the mosses lining the walls of the Somequell Cald Gorges. These mosses were clean, lacking **detritus** (organic matter produced by the decomposition of organisms), and formed a felt on the walls.

Some insect assemblages even partition the moss into several habitats. The caddisfly *Brachycentrus* (Brachycentridae; Figure 5) uses mosses (as well as rocks

and sticks) for attachment; *Tricorythodes* (Ephemeroptera: Leptohyphidae) burrows among the stems and rhizoids; and the caddisfly *Chimarra* (Philopotamidae; Figure 6) lives in the gravel and sand at the base of the mosses, all in the riffles of one Wyoming river (Armitage 1961).

Figure 6. *Chimarra tsudai* larva, member of a genus that lives in gravel and sand at the bases of mosses in riffles. Photo by Takao Nozaki, with permission.

In the case of *Helicopsyche sperata* (Helicopsychidae; Figure 7), the aquatic surroundings are achieved by living on mossy rocks out of the stream but in the sun in locations kept wet by constantly dropping water (McLachlan 1880).

Drift

Unlike most of the drifting aquatic insect species, many species of Trichoptera are day-active and do most of their drifting during the day (Waters 1972). This makes this group more vulnerable to predation by fish (White 1967), and this would particularly apply to the caseless caddisflies that are the most common caddisflies among bryophytes. However, Brusven (1970) found that among the caseless net-spinning caddisflies, *Arctopsyche* (Figure 8) drifted mostly at night and *Hydropsyche* (Figure 9) was rare in the drift. It is reasonable to assume that the bryophyte habitat may help to keep these caddisflies anchored as they move about, hence offering a safe refuge.

Figure 9. *Hydropsyche pellucidula* larva (Hydropsychidae), a rare drifter that can be found among bryophytes. Photo by Niels Sloth, with permission.

Food

Slack (1936) compared the food of twelve species of caddisflies. Among these, all but three had bryophyte leaf fragments in the gut. Those with more than half the larvae having bryophyte fragments were **Limnephilidae**: *Glyptotaelius* sp. (Figure 10), *Limnephilus rhombicus* – an opportunist in using a variety of materials to build its case (Figure 11), *Stenophylax* sp. (Figure 12), and *Halesus* sp. (Figure 13) and **Sericostomatidae**: *Sericostoma personatum* (Figure 14). Among common bryophyte dwellers, *Hydropsyche* sp. (Figure 9) had none and

Rhyacophila dorsalis (Figure 15) had bryophyte fragments in only one out of nine larvae. An image on Garden World Images by Dave Bevan (Bevan 2014) suggests that some *Stenophylax* species eat mosses. (The image looks like either protonemata or a filamentous alga.)

Trichoptera is a large order, surpassing Ephemeroptera, Odonata, and Plecoptera in the number of genera (Wiggins & Mackay 1978). Most of the filter-feeders are in eastern North America in the deciduous forest biome. In addition to filter feeders, they are represented by grazers, especially upstream in the mountains where waters are cool. Shredders, especially in the **Limnephilidae**, can be found in lakes, ponds, streams, and even terrestrial habitats. Shredder-collectors are more common upstream and grazer-collectors are more common downstream. Some are predators.

Cairns (2005) reported that some caddisfly larvae consumed stream mosses. Kalachova *et al.* (2011) used

acetylenic acids as biomarkers of *Fontinalis antipyretica* (Figure 1) to demonstrate consumption of this moss by Trichoptera in the Yenisei River.

Case Building

Case building provides most species of Trichoptera with a mobile home that protects them from predation. Some of these case-builders use bryophytes in their construction, including the New Zealand genus *Zelolessica* (**Helicophidae**; Figure 16) that sometimes uses bryophytes exclusively (Suren 1988). Frost (1942) found that a rather dominant caddisfly in her acid site on the River Liffey, Ireland, made cases from fragments of *Fontinalis* (Figure 1), but the larvae were too small for identification.

Figure 16. *Zelolessica*, a caddisfly that sometimes uses bryophytes in case construction. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Elliot and Spribille found that in a northwest Montana fen caddisfly larvae use living *Scorpidium scorpioides* (Figure 17) to build cases. The larvae harvest small tips of branches (*ca.* 2 cm) of the *S. scorpioides* from plants that grow submerged in shallow water and attach them to their cases. Elliot and Spribille suggested that the moss provides a "buoyant platform" from which the caddisfly can emerge, prey on the invertebrate fauna, and then fly off without being trapped by the surface tension.

SUBORDER ANNULIPALPIA

Hydropsychoidea

Ecnomidae

This is a relatively small family with worldwide distribution (Holzenthal *et al.* 2007). Although records of this family are worldwide, their main distribution is Gondwanan (Ecnomidae 2014). The larvae are of moderate size (5-10 mm) and live in retreats that they construct of silk in slow-water streams or lakes. They are predators, but some eat algae and detritus.

From Ceylon, Schmid (1958) reported *Ecnomus ceylanicus* (see Figure 18) and a new species, *Ecnomus vaharika*, from large, mossy rocks in the torrent.

Figure 18. *Ecnomus tenellus* adult, member of a genus in which some species live in mossy torrents in Ceylon. Photo by Dick Belgers, through Creative Commons.

Hydropsychidae – Net-spinning Caddisflies

This worldwide family occupies a wide range of rivers and streams, always requiring flowing water to obtain its food (Hydropsychidae 2014). For example, in Ceylon Schmid (1958) reported *Pseudoleptonema ceylanicum* (see Figure 19) from a small, mossy creek in the jungle.

Figure 19. *Pseudoleptonema supalak* adult. In Ceylon, larvae of *P. ceylanicum* live in a mossy creek. Photo from Biodiversity Institute of Ontario, through Creative Commons.

The larvae can be relatively large, ranging 5-25 mm (Hydropsychidae 2015). The larvae of this family build retreats from plant and mineral fragments. These retreats open into the nets used to catch their food, including algae, detritus, and small animals. When another caddisfly attempts to occupy the retreat, the current occupant uses its hind legs, rubbing them under the head, to produce stridulations that warn the intruder to vacate (Jansson & Vuoristo 1979).

Larvae of *Hydropsyche angustipennis*, *H. siltalai*, *H. nevae*, and *H. pellucidula* will enter any suitable retreat when forced to leave their own, and it need not be their own species or unoccupied. When it is already occupied, a vigorous fight will ensue. Larger defenders lost more fights as the size of the intruder increased. Stridulation increased the likelihood of a defender winning the fight.

Several researchers have supported the importance of mosses in the habitats of net-spinning caddisflies (Sprules 1947; Tanaka 1968). Oswood (1979) found that in a lake outlet stream in Montana, USA, larvae of **Hydropsychidae** had greater densities on moss-covered substrata (up to >1400 0.2 m⁻²) than elsewhere. In a gorge of the Some River, Galdean (1994) considered the mosses on the walls of the gorge to create the conditions needed for the **Hydropsychidae** to develop. The boulders were cleaned by the river velocity on the concave bank, permitting the mosses, hence the **Hydropsychidae**, to develop there.

Parapsyche cardis preferred substrata in the order of mossy rock face > cobble riffle > pebble riffle > sandy reach (Gurtz & Wallace 1986). This relationship held true for all instars (larval stages) in both studied streams. Thus, mossy rock faces accounted for 94.8% of the total production of *Parapsyche* (Figure 20) in Hugh White Creek (with 36.5% rocky channel) and 87.3% in Big Hurricane Branch (with 16.8% rocky channel) in the southern Appalachian Mountains, USA. Haefner and Wallace (1981a, b) likewise found that the distribution of *P. cardis* was highly correlated with the distribution of moss in Sawmill Branch. In several Maryland, USA, streams, *Parapsyche apicalis* occurred among bryophytes, mostly *Fontinalis dalecarlica*, and at the time were new records for Maryland, but it was not one of the more common **Hydropsychidae** represented among the mid-Appalachian bryophytes (Glime 1968).

Figure 20. *Parapsyche apicalis* larva, a species I collected among bryophytes in several Maryland streams. *Parapsyche cardis* distribution is correlated with moss cover. Photo by Donald S. Chandler, with permission.

Wulfhorst (1994) examined the relative abundance of the caddisfly larva *Diplectrona* (Figure 29) in mosses and in **interstitial spaces** (spaces between individual sand grains in soil or aquatic sediments) in the **hyporheic zone** (region beneath and alongside a stream bed, where mixing of shallow groundwater and surface water occurs) of two streams in the Harz Mountains of West Germany. She found that *Diplectrona* was more abundant among the mosses at most collection stations, but that they were also abundant in the interstitial spaces of the hyporheic zone at 10 and 30 cm depths (Figure 21).

Figure 21. Mean abundance \pm 95% CI of *Diplectrona* spp. in moss clumps in two streams in the Harz Mountains, West Germany. Numbers of samples are shown at the bottom. Redrawn from Wulfhorst 1994.

The high density of **Hydropsychidae** among stream mosses is supported by their ability to colonize that habitat rapidly. Smith-Cuffney (1987) found that artificial mosses reached their capacity of these net-spinning colonizers in only 7 days; Georgian and Thorp (1992) found that 6-9 days provided enough time for them to reach their constant colonization density among the artificial mosses. Mosses provide a particularly easy place to colonize relative to other stream habitats because their rough surface makes it easy to gain a hold that rescues them from the speeding water.

The **Hydropsychidae** can be considered ecosystem engineers (Nakano *et al.* 2005). In Japan, *Hydropsyche orientalis* (Figure 22, Figure 23) make their larval retreats on the upper surfaces of stones. These retreats provide a safe site for naiads of the mayfly *Serratella setigera*, providing them with the slower flow that they prefer. It is likely that in the absence of these caddisflies and their nets that mosses could play a similar role in creating a suitable refuge. And in some cases it appears that the hydropsychids use the mosses in place of some, but not all, nets (Figure 24).

Ogbogu (2000) found **Hydropsychidae** associated with *Fontinalis* (Figure 1) in Nigeria and reported that the density of larvae increased when the moss grew. Both *Cheumatopsyche* (Figure 45) and *Amphipsyche* formed close associations and Ogbogu (2001a, b) suggested that the moss served as a **refugium** (area in which population of organisms can survive through period of unfavorable conditions, even glaciation) during vulnerable life cycle stages.

Pupal Sites

Frost, in her 1942 study of the River Liffey, Ireland, found that few Trichoptera pupae were present among the mosses. She considered this an expected absence because the caddisfly larvae usually seek another type of environment instead of mosses for **pupation** (period of development of pupa). For example, *Ceratopsyche morosa* (Figure 25) lives among moss and algae in young larval stages (Stern & Stern 1969), but just prior to pupation it moves to stones.

Temperature can signal that it is time to pupate. At least some *Hydropsyche* species cannot live below 8°C (Kaiser 1965). Instead, they build loose cases and go into the pupa state in autumn. Sleight (1913) found *Hydropsyche* pupae (Figure 26-Figure 28) among mosses in strong currents in the eastern USA. At maturity, these pupae moved to the surface where the pupal case would split and adults would emerge. The larval hooks made it possible for these caddis larvae to climb over the vegetation to find a suitable place for the pupa.

Crowding and Niche Separation

It appears that mosses might separate the niches of co-habiting net spinners. Late instar *Diplectrona modesta* (Figure 29) has a somewhat uniform occupancy among substrata in Big Hurricane Branch (Gurtz & Wallace 1986). The first three instars are most abundant on the (mossy) rock face and the fourth and fifth are more evenly distributed. But in Hugh White Creek, the rocks have a lower density of moss, and *D. modesta* is less common than in Big Hurricane Branch, where the moss is thicker. In fact, in Hugh White Creek, *D. modesta* is most abundant in the cobble riffle and least abundant in the rock face samples, while first instars are most common on sand. Gurtz and Wallace suggested that the lower density of moss in the Hugh White Creek may not provide enough microhabitats and that differences in available substrata

could account for the differences in productivity. Mosses provide a suitable substrate for attaching the nets (Figure 30) and retreats of these caddisflies while providing a range of current velocities. The nets themselves do not, however, appear to contribute directly to their food; none were found in the gut analysis (Haefner & Wallace 1981a). The larvae are also relatively common among *Hygroamblystegium fluviatile* (Figure 31), *Platyhypnidium riparioides* (Figure 32), and *Fontinalis dalecarlica* (Figure 33) in Appalachian Mountain streams (Glime 1968).

Figure 33. *Fontinalis dalecarlica*, home to some larvae of *Cheumatopsyche*. Photo by J. C. Schou, with permission.

When *Cheumatopsyche* sp. (Figure 34) reaches high densities it becomes more aggressive (Glass & Bovbjerg 1969). This aggressiveness dictates a pattern of **dispersion** (pattern of distribution of individuals within a habitat) that is a function of density. Hildrew and Edington (1979) found that larvae are able to make ultrasonic sounds to discourage intruders when they approach. Fortunately, for overlapping generations of the same species larval sizes differ at a given point in time, permitting them to use different net sizes (Figure 35-Figure 36) and avoid competition for food.

Figure 34. *Cheumatopsyche* larva, a caddisfly that becomes less aggressive when it has shelter. Photo by Bob Henricks, with permission.

Figure 36. Nets of the net-spinning caddisfly, *Cheumatopsyche*, on *Fontinalis*. The number of larvae usually greatly exceeds the number of nets on the *Fontinalis*, suggesting that they may be using the mosses as nets to gather detritus and diatoms. Photos by Janice Glime.

Williams and Hynes (1973) suggested that mossy habitats provide the greatest number of protected sites. Furthermore, the rapid flow typical of locations where mosses grow will bring more food per unit of time. *Cheumatopsyche* (Figure 37) larvae are common among the mosses *Hygroamblystegium fluviatile* (Figure 31), *Platyhypnidium riparioides* (Figure 32), and *Fontinalis dalecarlica* (Figure 33) in the mid-Appalachian Mountain streams (Glime 1968). And *Cheumatopsyche* (Figure 34) larvae seem to be less aggressive when shelter is readily available (Glass & Bovbjerg 1969). Williams and Hynes (1973) found that the hydropsychids *Cheumatopsyche oxa* (Figure 37) and *Ceratopsyche sparna* (Figure 38) occupied the mossy areas of boulders, whereas the philopotamid

Chimarra aterrima (Figure 39), a potential competitor, occupied the spaces under large stones. The two hydropsychid species share the same sites, eat the same foods, and have similar life cycles. In contrast to *Chimarra aterrima*, these net-spinning caddisflies have mechanisms in their gut for crushing diatoms, important constituents of the diet and one that separates their niche from that of *C. aterrima*.

Figure 39. *Chimarra aterrima* larva, a species that occupies spaces under rocks in preference to that of mosses. Photo by Stroud Water Research Center, Stroud Water Research Center, through Creative Commons.

Hydropsyche pellucidula (Figure 40-Figure 41) occurs among submerged mosses in the River Rajcianka (Krno 1990). Elsewhere, when *Hydropsyche pellucidula* and *H. siltalai* (Figure 42) occur together, the moss cover is important in permitting these two caddisflies to partition the rocks into two functional feeding (net-spinning) niches and co-exist throughout their larval lives (Hildrew & Edington 1979). In late winter and early spring, there is rapid growth of moss (particularly *Fontinalis antipyretica*, Figure 43) on boulders and bedrock in rapids. *Hydropsyche siltalai* (but not *H. pellucidula*) migrates onto the moss in spring. Although large numbers of *H. siltalai* occupied the moss, not a single *H. pellucidula* could be found there. Plastic artificial grass, similar to moss mats, proved to be a suitable surface for net-spinning.

Figure 40. *Hydropsyche pellucidula* larva, a species that occurs among mosses in the River Rajcianka of Slovakia. Photo by Niels Sloth, with permission.

Figure 41. *Hydropsyche pellucidula* larva showing the large jaws. Photo by Niels Sloth, with permission.

Figure 42. *Hydropsyche siltalai* larva, a species that migrates to mosses to avoid competition from *H. pellucidula*. Photo by Urmas Kruus, with permission.

Figure 43. *Fontinalis antipyretica*. Photo by Bernd Haynold, through Wikimedia Commons.

Hydropsyche siltalai (Figure 42) filters its food with a fine-meshed net (mean $100 \times 70 \mu\text{m}$) while *H. pellucidula* (Figure 40-Figure 41) is larger and uses nets with a mean mesh of $370 \times 240 \mu\text{m}$ (Hildrew & Edington 1979). Migration of *H. siltalai* onto mosses (*Fontinalis antipyretica*; Figure 43) in spring further separates their niches. Englund (1993) observed that whereas small IV instar larvae were able to construct nets on the mosses, the physical structure seemed unsuitable for the larger V instar larvae to do so.

Food

Although Frost (1942) reported several studies in which *Hydropsyche instabilis* ate primarily Chironomidae, and Slack (1936) found that it ate diatoms, it also ingests mosses. In Great Britain (Percival & Whitehead 1929) and in calcareous streams in South Wales, *Hydropsyche instabilis* (Figure 44) ingested *Fontinalis antipyretica* (Figure 43) (Percival & Whitehead 1929; Jones 1949). Frost (1942) found that *Hydropsyche instabilis* (Figure 44) lived primarily among mosses in an acid stream, but in the alkaline stream it was *Cheumatopsyche lepida* (Figure 45) that was dominant among the mosses, in this case where there was more silt. Jones (1950) did extensive gut analysis of insects from the River Rheidol; among the Trichoptera, only *Hydropsyche instabilis* of the six species examined had fragments of *Fontinalis antipyretica* (Figure 43) in the gut (7 out of 27). Fragments of this moss were present in nine of the 23 analyses with identifiable gut contents (Jones 1949). Algae and detritus were the most common foods.

Figure 44. *Hydropsyche instabilis* adult, a species whose larvae sometimes eat mosses. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Figure 45. *Cheumatopsyche lepida* larva, a dominant caddisfly among mosses with lots of silt in an alkaline stream. Photo through Creative Commons.

On the other hand, occurrence of net-spinning caddisflies among mosses may offer the advantage of a greater number of prey organisms. Although these insects trap their food on finely constructed nets, they are also carnivores. Haefner (1980) found a significantly higher (2x) density of prey organisms (*Baetis* spp., *Ephemerella* spp., *Nemoura* spp., *Hydroptila* sp., and *Chironomidae*) in rock face samples, where mosses were typically dense. These organisms are common among stream mosses – *Hydroptila* less so (Glime 1994), thus the abundance of prey invertebrates may account for the greater productivity of *Parapsyche cardis* (see Figure 20) there.

Although *Diplectrona modesta* (Figure 29) had little correlation with mossy rocks in one of two Appalachian Mountain streams, and few such rocks existed in the other (Haefner & Wallace 1981a,b), this and other studies (Gurtz & Wallace 1986) suggest that the mosses provide a variety of niches that benefit both the potential prey organisms and the net-spinning caddisflies.

In a study to determine the source of foods for aquatic invertebrates, Torres-Ruiz *et al.* (2007) used the distinctive fatty acids for green algae, diatoms, and bryophytes, each of which also differed from fatty acids of terrestrial food sources. They determined that *Hydropsyche* spp. (Figure 40-Figure 42) consumed primarily **autochthonous** (originating from within the stream system) food sources, not the terrestrial **allochthonous** (originating from elsewhere) food such as leaf litter. In Appalachian Mountain streams the **Hydropsychidae**, including species of *Hydropsyche*, seemed to use the mosses instead of constructing nets to capture their food (Glime 1968). There always seemed to be many more larvae than nets.

Gut pH is often important in determining the digestible food sources. *Hydropsyche betteni* (Figure 46-Figure 47) had a gut pH close to neutral but somewhat alkaline (Barlocher & Porter 1986). Hence, this species was unable to **hydrolyze** (break down a compound by chemical reaction with water) proteins of maple leaves that were not yet conditioned by decomposer organisms. They could, however, digest starch and laminarin (storage product in many seaweeds). Unlike those in the crane fly *Tipula*, the fungal **carbohydrases** (enzymes that break down carbohydrates) ingested with decomposing leaves remained active in the guts of this species.

Figure 46. *Hydropsyche betteni* larva, with a gut pH that is alkaline. Photo by Bob Henricks, with permission.

Figure 47. *Hydropsyche betteni* larva showing ventral gills. Photo by Donald S. Chandler, with permission.

Role of Water Velocity

The larvae of the **Hydropsychidae** are able to partition the niches of the most immature from those of the nearly mature (Osborne & Herricks 1987; Muotka 1990). Osborne and Herricks (1987) found that *Hydropsyche* (Figure 40-Figure 42) species in their study separated the larger larvae into communities at higher velocities, whereas the smaller, less mature larvae sought areas of diminished flow. The same size distribution occurs between species. These larvae seek out depressions where they can gather passing detritus but where sedimentation is minimal. Turbulence seems to play a role in determining distribution, perhaps contributing to food availability and preventing

sedimentation. Larger larvae are apparently able to occupy greater velocities; this is coupled with the construction of a larger mesh size, hence dividing the feeding niche from that of smaller larvae.

The net-spinning caddisflies prefer a habitat with a stable substrate and high water velocity. Georgian and Thorp (1992) showed that 96% of the **Hydropsychidae** larvae selected artificial moss substrates that had high velocity water flowing over them. They estimated that a prey item would be consumed within 5.5 m of travel in the drift. It appears that one advantage afforded these moss dwellers is that they can take advantage of high-flow rates while themselves finding a flow-rate suitable for their own safety.

Current speed also influences net-spinning activity, with a greater percentage of larvae spinning nets at 20 cm sec⁻¹ (73%) than at 10 cm sec⁻¹ (10%) (Edington 1965). Edington found that hydropsychid larvae formed tunnels into the moss mats with nets at the moss surface. When the nets were removed (and when they were not) and the flow was artificially reduced, the larvae moved to a different area. When something restricts the flow, the larvae move to a new location and construct new nets (Edington 1965, 1968).

Muotka (1990) considered that it was the flow pattern, rather than the flow velocity itself, that determined the pattern of occupancy by filter-feeding caddisfly larvae. He based this on the ability of multiple sizes of caddisflies, including **Hydropsyche** (Figure 40-Figure 42) to coexist at the same flow rates. Nevertheless, he concluded that species were often ecologically closer to other species than to other instars of their own species. In their study, many of the sites were covered with bryophytes [mosses *Fontinalis antipyretica* (Figure 43), *Cratoneuron commutatum* (Figure 48), leafy liverwort *Jungermannia exsertifolia* (Figure 49)] and the uneven surface of this substrate would create multiple flow patterns. It is noteworthy that in the stream that lacked bryophytes only one filter-feeding caddisfly was present – **Hydropsyche saxonica** (Figure 50) – whereas seven species occurred in the two streams with heavy bryophyte cover.

Figure 50. *Hydropsyche saxonica* larva, the only filter-feeding caddisfly in a stream with no mosses. Photo by Niels Sloth, with permission.

Food capture is important in the location of nets, and water velocity helps to determine the food available. Mosses on the rocks actually prevent some insects from living there. The caddisfly **Leucotrichia** (**Hydroptilidae**; Figure 51) is unable to live on a substrate dominated by heavy moss growth and instead the net spinner **Hydropsyche** (Figure 40-Figure 42) occupies those locations (McAuliffe 1983). The larvae arrange their nets very evenly downstream but are often crowded across the substrate, preventing the water from being filtered by a net above them.

Figure 51. *Leucotrichia pictipes* larva, a genus that cannot live on a substrate with heavy moss cover. Photo by Stroud Water Research Center, through Creative Commons.

As I already noted in the Appalachian Mountain streams, some caddisflies actually use the mosses to help them gather food. Hildrew and Edington (1979) found that favorable situations for net-spinning caddis larvae (**Hydropsychidae**), such as moss covered rocks, often seem to be occupied to capacity. I have observed the same relationship, but it appeared that the caddisflies in some cases took advantage of the collecting ability of the moss and did not make nets. This would be useful for those species that eat primarily small invertebrates living among the bryophytes (Ross & Wallace 1983), but it could also take advantage of the bryophytes as filter traps.

Role Below Impoundments

Mosses are important habitats at impoundments. In Valley Creek in Minnesota, USA, **Hydropsychidae** caddisflies use mosses and filamentous algae as sites for attachment and building materials for retreats, with the mosses providing an environment that protects the larvae from the abrasive sand deposited by the impoundment (Mackay & Waters 1986).

Ogbogu (2000; Ogbogu & Akinya 2001) likewise found that **Fontinalis** (Figure 1) was important to the **Hydropsychidae** in an impoundment at Ile-Ife, Nigeria. They occupied the spillway, among the **Fontinalis**, in large numbers when sampled in August (1233 m⁻²), September (900 m⁻²), and November (1178 m⁻²). The moss provided refuge from the rapid water of the spillway, protection from predators, and food (epiphytic diatoms and other algae) trapped among the mosses.

Polycentropodidae – Tube Maker Caddisflies

Members of this worldwide family are relatively small to moderate in size, with the forewing reaching 6-13 mm (Hickin 1967). Larvae live in both quiet and flowing waters and trap their food in a tube (Murray 2006).

Polycentropus (Figure 52) is not a caddisfly one thinks of as a moss dweller because of its long, tubular net. But in both Ballysmuttan and Straffan, UK, it does occur among mosses, as well as other locations (Frost 1942). Percival and Whitehead (1929) found that **Polycentropus flavomaculatus** (Figure 52) was most abundant in thick mosses compared to other types of substrate. In mid-Appalachian Mountain streams, larvae of this genus are occasional inhabitants of bryophytes (Glime 1968).

Figure 52. *Polycentropus flavomaculatus* larva, a species that is more abundant in thick mosses than elsewhere. Photo by Dragiša Savić, with permission.

In one location in the Pyrénées Décamps (1967) found that **Plectrocnemia scruposa** (see Figure 53) comprised 4.5% of the **Trichoptera** fauna among mosses. Edington (1965) found that **Plectrocnemia conspersa** (see Figure 53) spun more nets at a flow rate of 10 cm sec⁻¹ (80% of the larvae) than at 20 cm sec⁻¹ (4%), a relationship just the opposite of that of **Hydropsyche instabilis**. Furthermore, in both species, those few making nets at the less favorable flow rate had a tendency to construct aberrant nets.

Figure 53. *Plectrocnemia geniculata* larva, member of a genus in which some larvae live among mosses. Photo from Biodiversity Institute of Ontario, through Creative Commons.

From Ceylon, Schmid (1958) reported **Nyctiophylax devanampriya** (Figure 54), **Pseudoneureclipsis watagoda** (Figure 55), and **P. thuparama** from large, mossy rocks in the torrent.

Figure 54. *Nyctiophylax* sp. larva; *N. devanampriya* occurs among mosses in torrents in Ceylon. Photo by Dana R. Denson Florida Association of Benthologists, with permission.

Figure 55. *Pseudoneureclipsis* adult, a genus whose naiads can live on mossy rocks in torrents. Photo by Biodiversity Institute of Ontario, through Creative Commons.

But this family relies primarily on food trapped in its funnel-shaped net. Ross and Wallace (1983) demonstrated that 80% of the food for this family in a southern Appalachian Mountain, USA, stream was fine detritus. Another 15% was diatoms. So why do we find them among bryophytes at all?

Psychomyiidae – Net Tube Caddisflies

The **Psychomyiidae** are widespread, but are concentrated in the Oriental Region and absent in the Neotropical Region (Kjer 2010a). The adults are of moderate size (5-8 mm long forewings) (Watson & Dallwitz 2003). This family traps its food in a silken tube (Figure 56), with the diet consisting of algae, leaves, and animal matter (Neuswanger 2015). Grazing may occur both on the tubes and nearby, therefore consisting mostly of diatoms and other algae (Holzenthal *et al.* 2007; Kjer 2010a). Females dive to the bottom of the stream to lay their eggs (Neuswanger 2015).

Figure 56. **Psychomyiidae** net. Photo by Janice Glime.

Mosses occurred in the guts of *Psychomyia pusilla* (see Figure 57) and *Tinodes waeneri* (Figure 58-Figure 59) in UK streams (Percival & Whitehead 1929), attesting to their residence among bryophytes.

Philopotamoidea

Philopotamidae – Finger-net Caddisflies

The larvae of this worldwide family build nets that can require more than 1 km of silk (Wallace & Malas 1976); these are used to trap small particles for food (McLeod 2005). To use them, the larvae are restricted to fast-flowing water of rivers and streams. The adult body is 5-9 mm long.

The net-building behavior would seem to preclude mosses as a substrate, but exceptions occur. *Philopotamus montanus* is not typically a bryophyte inhabitant and captures its food with a tube net. But this net can trap bits of mosses travelling downstream, and of the 15 guts with identifiable contents, two had *Fontinalis antipyretica* (Figure 43) (Jones 1949).

Chimarra (Figure 39; Figure 60-Figure 65) lives among mosses but prefers the gravel and sand at their bases (Armitage 1961). Williams and Hynes (1973) suggested that the affinity of *C. aterrima* (Figure 39) for moss-covered rocks may have been more related to the large size of those rocks rather than the presence of the moss. For example, in a wooded Ontario, Canada, stream, *Wormaldia moesta* (Figure 66) preferred bare stones, whereas *Rhyacophila minor* (Rhyacophilidae) preferred moss-covered stones in the same area (Singh *et al.* 1984). *Wormaldia moesta* grazed on diatoms when its primary food supply, detritus/seston (living organisms and non-living matter swimming or floating in a water body), became scarce. In my own studies of the fauna of bryophytes in the Appalachian Mountain streams, *C. aterrima* was occasionally present, but in small numbers, among *Fontinalis dalecarlica* (Figure 33) in larger streams (Glime 1968). It was absent in the other bryophytes.

Another occasional visitor to bryophytes in Appalachian Mountain, USA, streams was *Dolophilodes distinctus* (Figure 67) (Glime 1968). In this case, it occurred among all four of the primary bryophytes in the study: *Hygroamblystegium fluviatile* (Figure 31), *Platyhypnidium riparioides* (Figure 32), *Fontinalis dalecarlica* (Figure 33), and *Scapania undulata* (Figure 68), preferring the mats and turfs over *Fontinalis* streamers.

Summary

Lepidoptera apparently do not use aquatic bryophytes.

Trichoptera, on the other hand, are among the common inhabitants. Those that enter the drift may use bryophytes as a means to get out of the drift. Some larvae use the bryophytes for food and many use them as a safe site for capturing food, using both filtering strategies and predation of smaller inhabitants. The mosses themselves may serve as filter traps for caddisfly food, including drifting algae, bacteria, decomposing organic matter, and detritus. For some caddisflies the bryophytes themselves serve as food and may be a seasonal staple when other foods are unavailable. Some build their cases from bryophytes and live among the bryophytes to capture food.

Larvae of most **Trichoptera** are aquatic, and many may also use the bryophytes as a site for pupation and emergence. The most common families among bryophytes are The **Hydropsychidae** and **Rhyacophilidae**. These are both caseless caddisflies, and the bryophytes may provide some of the protection otherwise afforded by cases.

Hydropsychidae take advantage of the bryophytes to partition their niches and avoid competition for food. In some cases this is the result of changing diets at later instar stages. Others use differences in flow within the bryophyte mat. They seem to be able to use the bryophytes to trap food, and the bryophytes create locations with a variety of flow regimes. Still other caddisflies are selective about which species of bryophytes they use, with a few selecting leafy liverworts only and others avoiding them.

The importance of the bryophytes as food remains a mystery. It is possible they are ingested along with adhering periphyton and detritus without being digested.

Acknowledgments

As a graduate student I relied heavily on the expertise of Oliver Flint, Glenn Wiggins, Tom Waters, and Ken Cummins for both encouragement and identification help in my novice years. Thank you so much to Donna Bennett for making a special trip to photograph live *Micrasema wataga* eating and showing the mosses sprouting on the case, just for this chapter! She also made additional trips to the field to determine the identity of the moss. David Tempelman helped me to obtain some of the images and permission for use and provided me with references on *Ptilocolepus*. Eileen Dumire proofread for me and made suggestions to improve clarity.

CHAPTER 11-12

AQUATIC INSECTS: HOLOMETABOLA – TRICHOPTERA, SUBORDERS INTEGRIPALPIA AND SPICIPALPIA

Figure 1. *Adicrophleps hitchcocki* (Brachycentridae), a larva that makes its case from mosses. Note the "furry" portion near the opening. Photo by D. N. Bennett, with permission.

SUBORDER INTEGRIPALPIA

Leptoceroidea

Odontoceridae – Mortarjoint Casemakers

This worldwide family lives in springs and small to medium streams and rivers, typically with slow flow; some are associated with waterfalls (Holzenthal *et al.* 2010c). Also known as the strong case-maker caddis, the larvae make very strong cases from bits of rock with more than usual amounts of the silk glue (Henricks 2011).

Although I never found *Pseudogoera* in my studies of stream insects among bryophytes in the mid Appalachians, *P. singularis* (Figure 2) is associated with mosses in waterfalls in the southern Appalachians, USA (Wallace & Ross 1971).

Figure 2. *Pseudogoera singularis* larva, a species that lives in mosses of waterfalls in the southern Appalachian Mountains. Photo by BIO Photography Group, through Creative Commons.

In the mid-Appalachian Mountain streams, I found two species of *Psilotreta* (Figure 3) among *Hygroamblystegium fluviatile* (Glime 1968). This genus has forewings of 6-17 mm (Parker & Wiggins 1987), representing one of the larger of the bryophyte dwellers.

Limnephiloidea

Goeridae

This family occurs on all continents except Australia and South America (Holzenthal *et al.* 2007). Adults have a forewing length of 6-9 mm and are typically light brown (Figure 6) (Houghton 2012). The larvae (Figure 7) live in cool, flowing water and graze on **periphyton**. Their larval cases consist entirely of rock fragments, sometimes with larger rocks on each side of the case (Figure 8).

Figure 6. *Goera pilosa* adult, demonstrating the light brown wings typical of the family **Goeridae**. Photo from Biopix, through Creative Commons.

Figure 7. *Pseudogoera singularis* larva. Photo by BIO Photography Group, through Creative Commons.

Figure 8. *Goera calcarata* larva showing large rock fragments on sides of case. Photo by Bob Henricks, with permission.

Goerita is a small genus with only three species and is restricted to the Appalachian Mountains and Allegheny Plateau in eastern North America (Parker 1998). The larvae are **bryobionts**, in this case living on rocks covered with mosses and liverworts where the rocks can be dry or covered by a film of water. The larvae do not eat the bryophytes, but instead feed on detritus and diatoms growing there.

Goerita semata lives on the undersides of rocks (Flint 1960), but in western North Carolina, Huryn and Wallace (1985) found the larvae among liverworts and mosses on vertical rock faces; fewer than 2% were found on other substrata. *Goerita betteni* lives in a similar habitat (Wiggins 1973). Huryn and Wallace (1985) suggested that the bryophytes may offer the larvae some protection from desiccation. Pupae typically occur on these same rocks with mosses and a thin film of water. Ultimately, females lay their eggs away from water on bare rock, mosses, and liverworts. Food of the larvae consists primarily of fine amorphous detritus (65%), and diatoms (32%), but diatom composition increases to an average of 64% in spring. Bryophyte clumps are typically good sources of both. Although the mechanisms of desiccation resistance are unknown in larvae of this species, it is likely that they are adapted behaviorally by living among the bryophytes.

In the River Rajcianka in Slovakia, *Lithax niger* (Figure 9) is a bryophyte dweller, living under water, but not in the wet emergent bryophytes (Krno 1990). This is a mountain species, occurring in the Alps and Balkans.

Figure 9. *Lithax niger* adult, a species whose larvae live among mosses in the River Rajcianka. Photo by Paul Frandsen, through public domain.

The larvae of *Archithremma ulachensis* move to a layer of *Sphagnum* (Figure 10) on the bank of a spring to pupate (Levanidova & Vshivkova 1984). These pupae are morphologically reduced, lacking long **setae** (hairs) and projections used to clean the silk disks that close the case. They also lack swimming legs. The larvae live in streams that have low water temperatures (3-5°C) in summer.

In a cool mountain stream of central Japan Tada and Satake (1994) found that *Pseudostenophylax ondakensis* (Figure 12) was significantly more abundant on mats of the moss *Platyhypnidium riparioides* (Figure 13) than in bare rock areas. Décamps (1967, 1968) found *Rhadicoleptus spinifer* (see Figure 14) to be abundant among mosses in the Pyrénées; at one station it comprised ~15% of the moss **Trichoptera** fauna (Décamps 1967).

Limnephilidae – Northern Caddisflies

The **Limnephilidae** encompasses a wide variety of case-making caddisflies in a wide range of habitats. Their ingenuity in making these homes could challenge some of our most creative artists. This is one of the largest caddisfly families, with recent segregate families diminishing its numbers. Although it occurs worldwide, its records are concentrated in Europe and North America (Limnephilidae 2015). In North America it is often the dominant group in higher elevation streams. But these are mostly large caddisflies (15-35 mm) (Houghton 2012), making navigation difficult among bryophytes. *Fontinalis* (Figure 11), on the other hand, is a large enough moss with a streamer habit that permits these larger larvae to navigate (Glime 1968, 1994). Their dependence on terrestrial litter makes the larvae vulnerable to deforestation (Houghton 2012).

Figure 14. *Rhadicleptus alpestris* adult. *Rhadicleptus spinifer* larvae are abundant among mosses in the Pyrénées. Photo by Niels Sloth, with permission.

The larvae of *Chaetopterygopsis maclachlani* (Figure 15) typically occur among clumps of *Fontinalis* (Figure 11) in the Vosges Mountains, eastern France, mostly in areas with slower or laminar flow (Lehrian *et al.* 2010). The mosses constitute ~65% of their diet, with the remainder being coarse leaf detritus (Dangles 2002). Dangles warned that some species, including this one, are

able to shift their diet based on availability, causing misinterpretations based on the general feeding guild classification of these insects. Dangles (2002) considered *Chaetopterygopsis maclachlani* (Figure 15) to be a specialist on bryophytes; they furthermore build their cases from *Fontinalis* (Figure 62) (Malicky 1994). As adults they typically crawl, not fly, among the **riparian** (streambank) vegetation.

Figure 15. *Chaetopterygopsis maclachlani* adult, a species whose larvae live among *Fontinalis* and eat mosses as 65% of their diet. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Chaetopterygopsis machlachlani is widespread in the Pyrenees to Baikal, specializing in *Fontinalis* and other streambed mosses (Báilint *et al.* 2011).

In the mid-Appalachian Mountain, USA, streams, the **Limnephilidae** are poorly represented among bryophytes (Glime 1968). Furthermore, those few that are present differ from any of the species I found in the literature as moss dwellers. Two species of *Pycnopsyche* [*P. luculenta*, *P. cf. scabripennis* (Figure 16)] were the most common, appearing in clumps of *Fontinalis* (Figure 62) (Glime 1968). This restriction is most likely due to the large size of the **Limnephilidae** larvae, especially when their bulky case is considered. They would have real difficulty moving about in *Hygroamblystegium fluviatile* (Figure 4-Figure 5) or *Platyhypnidium riparioides* (Figure 13).

Figure 16. *Pycnopsyche scabripennis* larva, a *Fontinalis* dweller. Photo by Tom Murray, through Creative Commons.

In an experimental study on *Limnephilus rhombicus* (Figure 17), Higler (1975) was able to keep the larvae alive on a diet of *Fontinalis antipyretica* (Figure 11) with dead birch and oak leaves. However, it appears that its natural diet is mostly living plants (Slack 1936), dead leaves (Slack 1936; Lepneva 1966) and sometimes Naididae (aquatic segmented worms). It is not typically a moss dweller, so the moss diet was most likely unnatural. But Slack (1936) did find that it ate *Fontinalis* in the field. On the other hand, when *Potamophylax rotundipennis* (Figure 18-Figure 19) was provided choices of birch, oak, and beech leaves and *Fontinalis antipyretica*, it avoided the moss and beech leaves.

Figure 17. *Limnephilus rhombicus* larva, showing yet a third very different case, one using snail shells. Photo by Dragiša Savić, with permission.

Figure 18. *Potamophylax* larva and case. *Potamophylax rotundipennis* rejects *Fontinalis antipyretica* as a food choice. Photo by Michael Wiesner <www.waldzeit.ch>, with permission.

Although most of the *Limnephilidae* make large cases with large components of twigs and leaf fragments, some use bryophytes. *Limnephilus externus* (Figure 20-Figure 21) larvae are known to use the moss *Leptodictyum riparium* (Figure 22) to construct their barrel-shaped cases (Pritchard & Berté 1987). In experiments, this species was able to use wheat flakes, but not alder leaves, to make its case. In the same experiment, *Nemotaulius hostilis* (Figure 23) used alder, willow, and burreed but did not use wheat flakes or mosses. These same two insects are shredders that consume tracheophyte detritus, but the proportion of mosses in the diet increases as the larvae become older.

Figure 19. *Potamophylax* adult. Photo through Creative Commons.

Figure 20. Two *Limnephilus externus* larvae with the second grabbing the rear of the first. The two cases appear to be made of bits of grass and this camouflage most likely fools their predators because it confused my non-biologist reviewer! Photo by Wendy Brown <www.gunnisoninsects.org>, with permission.

Figure 21. *Limnephilus externus* larva. Photo by Wendy Brown <www.gunnisoninsects.org>, with permission.

Limnephilus peltus (Figure 24) doesn't spend much time among mosses as a larva, but when it is time to pupate, it burrows into mosses along fen streams where it spends its pupal life (Erman 1984). Unfortunately, if the stream dries out, the pupa is likely to die.

Figure 22. *Leptodictyum riparium*, home of larvae of *Limnephilus externus*. Photo by Jan-Peter Frahm, with permission.

Figure 24. *Limnephilus* sp. larva, a genus that sometimes pupates in mosses of fens. Photo by Jason Neuswanger, with permission.

The habitat of larvae of the high altitude *Drusus discolor* (Figure 25) in the Pyrénées consisted of filamentous algae and the moss *Bryum* (Figure 26) (Décamps 1968). This caddisfly is one of the two most abundant caddisflies among mosses (Décamps 1967). In the River Rajcianka in Slovakia, *Drusus annulatus* (Figure 27) occurs not only among submerged bryophytes but also moving about among the wet bryophytes that emerge above the water level (Krnó 1990).

Figure 25. *Drusus discolor* adult, a species that lives among the moss *Bryum* in the Pyrénées. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Frenesia difficilis (Figure 28) lays its eggs out of the water, sometimes on mosses that overhang the water (Flint 1956). In this terrestrial location the eggs may freeze in winter. In the Massachusetts, USA, fish hatchery, Flint found no other relationship with mosses during the life cycle.

Figure 28. *Fresnia difficilis* male, a species that sometimes lays its eggs on mosses that overhang the water. Photo by Tom Murray, through Creative Commons.

The Arctic caddisfly *Sphagnophylax meiops* lives in Arctic pools in the tundra in the Northwest Territories of Canada (Wiggins & Winchester 1984) where the larvae take advantage of the surface water in the pool (Winchester *et al.* 1993). When the water recedes the larvae move to the organic materials accumulated above the permafrost to feed, grow, and metamorphose into pupae and adults. This caddisfly is flightless and has long bristles on its short wings.

Most **Trichoptera** spend their larval life in the water, but in the genus *Enoicyla* (**Limnephilidae**; Figure 29), the larvae are terrestrial and the adult female has only vestigial wings, limiting her travel and agility. Males, however, are capable fliers. Larvae may live far from water among the mosses around tree roots (Watson & Dallwitz 2003). Green (2012) noted at least 50 of these larvae climbing up logs, with several browsing a black slime mold. One can observe many larvae together on the surface of mosses and liverworts growing on a stream bank following rain.

Enoicyla pusilla (Figure 29) uses fine sand grains and other vegetable matter to make cases where it lives among the mosses (Watson & Dallwitz 2003). The larvae of *Enoicyla*, despite being terrestrial, require 100% humidity (Green 2012). But when they become saturated, they climb upwards to dry, then drop back down when they need to get wet again (at 7% relative humidity). Their respiration is through the cuticle; they lack gills.

Figure 29. *Enoicyla pusilla* larvae, a terrestrial species that requires 100% humidity – a condition often found among mosses. Photo by Ernest van Asseldonk, through Creative Commons.

In his arguments to support that the **Trichoptera** (with hairs on wings) and **Lepidoptera** (with scales on wings) were closely related, Crampton (1920) used the common ability to use mosses in the caddisfly *Enoicyla* (**Limnephilidae**; Figure 29) and the larvae of moths in **Micropterygidae**.

The caddisflies living in peatlands are typically generalist taxa with wide habitat requirements (Flannagan & Macdonald 1987). But a few are **tyrphobionts** (living only in peat bogs and mires). The larvae of *Phanocelia canadensis* (Figure 30-Figure 31) are elusive. The second report of the larvae by Colburn and Clapp in 2006 was from kettle hole wetlands in Massachusetts, USA. Colburn and Clapp attribute the limited reports of larvae of this species to its limited habitat requirements. It lives in *Sphagnum* (Figure 10) habitats with low pH and makes its case from *Sphagnum* (Figure 30) [The picture below (Figure 31) indicates other mosses are used as well.] Larvae remain closely associated with the moss during development. They become dormant in summer, remaining in unsealed cases that are firmly attached to the moss. In autumn they seal the ends of the case and develop into pupae. Even fossil records support their preference for *Sphagnum* (Figure 10) bogs. The larva was originally described from floating *Sphagnum* at the edge of acidic ponds in a spruce-*Sphagnum* bog in New Brunswick, Canada (Fairchild & Wiggins 1989). It appears that adult habitats are much broader, perhaps misleading its collectors (Colburn & Clapp 2006).

Leberfinger and Bohman (2010) gave larvae of *Limnephilus bipunctatus* (Figure 32) choices of food that included grasses, mosses, algae, and leaves. The larvae preferred leaves of the shrubby cinquefoil. Although they ate little of the mosses, grass was the least preferred food.

Figure 32. *Limnephilus bipunctatus* larva in case, a species that includes mosses in its diet. Photo by James K. Lindsey, with permission.

Philocasca is not a genus one often reads about in moss habitats. Nevertheless, mosses appear to be suitable sites for pupation. In describing the new species *Philocasca rivularis* (see Figure 33) Wiggins and Anderson (1968) state that pupae attach to the undersides of moss clumps along stream banks. Mutch and Pritchard (1984) found that instar V larvae of *P. alba* (Figure 34) in a Rocky Mountain stream had mostly moss (*Hygrohypnum luridum* – Figure 35) in the gut in spring and summer, but had leaf fragments in the gut in autumn. Furthermore, when fed detritus supplemented with moss these larvae grew significantly better than when fed detritus alone, suggesting that the moss was an important nutrient source.

Figure 37. *Onocosmoecus unicolor* adult. Photo by Bob Newell, with permission.

Chyranda centralis (Figure 38) is a caddisfly of small spring streams among leaf accumulations. Its food includes leaves, bark, and may even include mosses (National Park Service 2014).

Figure 38 *Chyranda* larva of small spring streams; it may sometimes eat mosses. Photo from California Department of Fish and Wildlife, through public domain.

Mosses provide vertical zonation possibilities for the caddisflies. Krno (1990) addressed these vertical zones in the River Rajcianka in Slovakia. There, the limnephilids *Allogamus auricollis* (Figure 39-Figure 40) (a shredder), *A. uncatus*, and *Drusus annulatus* (Figure 41) occurred among the submerged mosses, but above water only *Allogamus auricollis* and *Drusus annulatus* occurred among emergent wet mosses. On the other hand *Parachiona picicornis* (Figure 42) was only found above water among the wet mosses.

Figure 39. *Allogamus auricollis* larva, a species that traverses among mosses both below and above the water surface. The larva is seen here breaking the surface tension. Photo through Creative Commons.

Lepidostomatidae – Bizarre Caddisflies

This family is widespread in the Northern Hemisphere, extending southward to Panama, New Guinea, and the Afrotropical region (Holzenthal *et al.* 2010a). Hilsenhoff (1975), in reporting on Wisconsin, USA, **Lepidostomatidae**, considered the larvae of this family to inhabit a wide range of clean streams. The larvae live among rocks, debris, and mosses on rocks and eat mostly detritus (BugGuide 2005). In North America the larvae inhabit springs, streams, and large slow-moving rivers where they eat detritus. They build a log cabin style of case from stem and leaf pieces or sand grains.

I did find *Lepidostoma americana* in clumps of *Hygroamblystegium fluviatile* (Figure 4-Figure 5) in the Appalachian Mountain streams (Glime 1968). Some older cases of *Lepidostoma* sp. contained fragments of the liverwort *Scapania undulata* (Figure 74) in them near the opening. *Lepidostoma hirtum* (Figure 44-Figure 45) is common among mosses at both Ballysmuttan and Straffan in the UK (Frost 1942). Its diet consists of algae, mosses, and tracheophytes (Rousseau *et al.* (1921). The moss not only provides a suitable location to find its food, but provides it protection from trout and other fish that are its predators.

Figure 44. *Lepidostoma hirtum* larva, an inhabitant of bryophytes that also eats them. Photo by Urmas Kruus, with permission.

Figure 45. *Lepidostoma hirtum* larva head. Photo by Urmas Kruus, with permission.

Crunoecia irrorata (Figure 46) prefers moss cushions and fallen leaves (Köcherfliegen 2015). In UK streams, this species had mosses in the gut (Percival & Whitehead 1929).

Oeconesidae

This is a small family from Tasmania (1 species) and New Zealand (Holzenthal *et al.* 2007), but of a relatively large size (adults 30-38 mm) (Oeconesidae 2013). Larvae live in small, forested streams, make cases from plant and

rock material, and feed on plant debris (Holzenthal *et al.* 2007).

Figure 46. *Crunoecia irrorata* larva, a moss consumer. Photo by Niels Sloth, with permission.

In New Zealand, both *Oeconesus maori* (see Figure 47) and *Zelandopsycha ingens* (Figure 48) occasionally ingest bryophytes (Suren 1988). Suren and Winterbourn (1991) determined that of the 14 taxa that had bryophyte fragments in their guts, only *Zelandopsycha ingens* and *Oeconesus similis* consumed them regularly.

Figure 47. *Oeconesus* larva, a bryophyte dweller and bryophyte consumer in New Zealand. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Figure 48. *Zelandopsycha* larva and case, a bryophyte dweller and regular bryophyte consumer. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Uenoidae

This family lives mostly in cool, fast-flowing headwaters and is distributed in North America, southern Europe, and eastern Asia (Holzenthal *et al.* 2007). Their cases may be constructed either of coarse pebbles, as in *Neophylax* (Figure 53-Figure 55), or of fine sand, flattened, and shaped like the shell of a limpet, as in *Thremma* (Figure 49). Larvae eat diatoms and fine particulate matter that they scrape from rocks. These larvae are among the smaller caddisflies, being up to 15 mm (Wiggins 2004), although for moss dwellers they would be in the medium to large category.

Figure 49. *Thremma gallicum* larva showing limpet type of case. Photo from Guillaume Doucet, with permission.

Thremma sp. (Figure 49) in the trout streams of Yellowstone National Park, USA, occurs among mosses and the alga *Cladophora* in strong rapids (Muttkowski & Smith 1929). Each of these caddisflies collected from the mosses had mosses in the gut, averaging 70% of the contents. The alga *Epithemia* (Figure 50), most likely living among the mosses, comprised the remaining 30%. Brown (2007) found significant numbers of *Neothremma alicia* (Figure 51-Figure 52) in small, mossy streams in the headwaters of the East River, Colorado, USA.

Figure 50. *Epithemia*, a diatom genus that is a common food source for the caddisfly *Thremma*. Photo by Kristian Peters, with permission.

Figure 52. *Neothremma alicia* larva outside its case. Photo from Biodiversity Institute of Ontario, through Creative Commons.

In the Appalachian Mountain stream bryophytes, the **Uenoidae** were represented by a completely different genus from the ones I found in publications, the only one being *Neophylax* (Figure 53-Figure 55), a genus that sometimes reached large numbers among the **Trichoptera**, but usually was absent (Glime 1968). Nevertheless, three species were represented: *N. concinnus* (Figure 53), *N. consimilis* (Figure 54), *N. oligius* (Figure 55). These were usually in the mat-forming bryophytes, a location permitted by their smaller size.

Phryganeioidea

Brachycentridae – Humpless Casemaker Caddisflies

The **Brachycentridae** are a Northern Hemisphere family (Holzenthal *et al.* 2010b). They eat algae and plankton (Neuswanger 2015b), but some also ingest bryophytes (Muttkowski & Smith 1929). These caddisflies build cases that resemble log cabins or cylinders made of tiny plant fragments (Holzenthal *et al.* 2010b), including bryophytes in some genera (Glime 1968). Often they are found among mosses (Bouchard 2004). When they emerge, they do so on the surface, which sometimes subjects them to 3-7 m of drifting (Neuswanger 2015b). Females may dive to lay eggs or land with spread wings on the surface to accomplish the task.

Brachycentrus

Larvae of *Brachycentrus* (Figure 56-Figure 59) species actually attach to the mosses (Armitage 1961; Glime 1968). *Brachycentrus* was one of only two genera of caddisflies that Muttkowski and Smith (1929) found among mosses in the trout streams of Yellowstone National Park, USA. Needham and Christenson (1927) reported *Brachycentrus* from mosses in streams of northern Utah, USA. In Europe, Krno (1990) found *Brachycentrus montanus* (Figure 56) among mosses in the River Rajcianka, Slovakia. In the Appalachian Mountains, *B. cf. numerosus* (Figure 56) occurred in clumps of the moss *Hygroamblystegium fluviatile* (Figure 4-Figure 5) (Glime 1968).

Figure 58. *Brachycentrus americanus* larva, a moss consumer. Photo by Donald S. Chandler, with permission.

Figure 59. *Brachycentrus occidentalis* larvae, a moss consumer species. Photo by Arlen Thomason, with permission.

Gallepp (1977) found that two species of *Brachycentrus* were more responsive to temperature and food availability than to the flow rate. Although case-building decreased with increasing temperature over the range of 4-17°C, *B. occidentalis* (Figure 59) grew faster as the temperature increased in the range of 4-27°C.

Micrasema

The larvae of the grazer genus *Micrasema* (Figure 60) (Gallepp 1977) are common among mosses (Glime 1968, 1994; Tada & Satake 1994). In the mid-Appalachian Mountain streams I was able to distinguish three different morphotypes (species?) among the bryophytes (Glime 1968). In fact, this genus seems to be almost restricted to that habitat (Hilsenhoff 1975). Tada and Satake (1994) found a species in this genus to be the most abundant insect taxon on mats of *Platyhypnidium riparioides* (Figure 13) in a cool mountain stream in central Japan. Among the bryophyte mats its density exceeded 100,000 individuals per square meter in November, an abundance that was 2.8-16.3 times as high as that on the bare rock bottom. At least one species of *Micrasema* (Figure 60) constructs a "log cabin" out of moss stems and leaves (Glime 1968).

Figure 60. *Micrasema charonis* larva, a common moss-dweller that often makes its case from mosses. Photo by Bob Henricks, with permission.

Chapman and Demory (1963) found that in two streams in Oregon, USA, this genus occurred only among mosses and liverworts where there was little detritus. They graze on periphytic algae during the first instar, but in later instars they are likely to be herbivore-chewers (shredders) on mosses and other small photosynthetic material (Chapman & Demory 1963; Aquatic Insects). In fact, Chapman and Demory (1963) found that *Platyhypnidium*

riparioides (Figure 13) was the most frequent food, but both mosses and liverworts were eaten. Diatoms were also present in the gut, but they might have been eaten inadvertently along with the bryophytes. And in the Pyrénées *Micrasema morosum* behaves as a shredder and eats mosses (and periphyton) as well (Décamps & Lafont 1974).

In the Pyrénées Décamps (1968) found that *Micrasema morosum* was abundant in the mosses *Cratoneuron commutatum* (Figure 61) and *Bryum* (Figure 26) and was the most abundant bryophyte-inhabiting caddisfly. At one station *M. morosum* comprised 56% of the Trichoptera fauna among mosses and at another it comprised 87.8% (Décamps 1967). *Micrasema vestitum* was abundant in *Fontinalis squamosa* (Figure 62) and in one location it comprised 69% of the Trichoptera fauna among the mosses.

Figure 62. *Fontinalis squamosa*, home to several species of *Micrasema* larvae. Photo by David T. Holyoak, with permission.

Décamps and Lafont (1974) demonstrated the change in moss substrate for *Micrasema morosum* as altitude changes in the Pyrénées. At 1940 m asl the dominant bryophytes were *Brachythecium rivulare* (Figure 63), *Cratoneuron commutatum* (Figure 61), and *Hygrohypnum molle* (Figure 64). At 1590 m asl dominance shifted to *Fontinalis squamosa* (Figure 62), *Fissidens polyphyllus* (Figure 65), and *Platyhypnidium riparioides* (Figure 13). At 1360 m asl *Fissidens grandifrons* (Figure 66) appeared and *Platyhypnidium riparioides* (Figure 13) remained in the stream flora. At

550 m asl the dominant mosses were *Brachythecium rivulare*, *Fissidens grandifrons*, *Platyhypnidium riparioides*, and *Chiloscyphus polyanthos* (Figure 67), with a change in the *Micrasema* species to *M. morosum*, *M. longulum*, *M. moestum*, *M. difficile*, and *M. minimum*. At the lowest location of 430 m, asl *Brachythecium rivulare*, *Cinclidotus fontinaloides* (Figure 68), *Fontinalis antipyretica* (Figure 11), *Platyhypnidium riparioides*, and *Cratoneuron filicinum* (Figure 69) with *Micrasema morosum* once again the predominant species. The food of these *Micrasema* species consisted of fragments of mosses and periphytic algae, with some food unidentifiable.

In Japan, *Micrasema uenoi* (Figure 70) feeds on the leaves of *Platyhypnidium riparioides* (Figure 13) and the first instar larvae make their cases of its leaves (Kato 1995). The first two instars live in greater numbers among mosses than on cobble, but by third to fifth instars the numbers are about equal. When artificial mosses (glass wool) and cleaned mosses were introduced, these larvae reached normal densities in 15-30 days. Surprisingly, the density on the glass wool was 2-3 times that among the mosses, but it subsequently decreased quickly. Gut contents of those third to fifth instars on bryophytes was 80% moss; those on the glass wool contained litter and detritus instead. The larvae move about a lot between the pebbles and the mosses. Eggs were apparently absent on the mosses, suggesting that the hatchlings move there.

Figure 70. *Micrasema uenoi* adult, a species whose larvae feed on leaves of *Platyhypnidium riparioides* in Japan. Photo by Takao Nozaki, with permission.

D. N. Bennett (pers. comm. 6 August 2013, 12 August 2014) observed *Micrasema wataga* (Figure 71-Figure 72) larvae eating moss (possibly *Hygrohypnum montanum*) leaves (Figure 71) in the Blue Ridge Mountains of Virginia, USA. They made their cases of the same moss, starting with a tiny cone of minute sand grains. The mosses closest to this cone part, hence the oldest, were no longer green, but those near the opening were still green. This can be a possible source of dispersal of fragments that break away from the unfinished cases. But a later observation showed that the mosses in the case actually sprouted there (Figure 72)! This case was apparently occupied by a pupa, ceasing the activity that could break off these sprouts before they attained sufficient size to exist on their own.

Adicrophleps hitchcockii

This interesting larva makes its case from bryophytes. It was relatively common among *Hygroamblystegium fluviatile* (Figure 4-Figure 5) in Appalachian Mountain streams (Glime 1968). It appeared to have used costae from this moss in the construction of its cases.

D. N. Bennett likewise collected larvae of the somewhat rare *Adicrophleps hitchcockii* (Figure 1, Figure 73) in several cold, rapid streams (1-10 m wide) from the aquatic leafy liverwort *Scapania* (Figure 74) growing in riffle areas (Henricks 2013; D. N. Bennett, pers. comm. September 2014). But the case is not made of liverworts, but rather it displays mosses. Wiggins (1977) described these as "4-sided, tapered, and constructed of pieces of moss arranged transversely; trailing ends frequently left attached to the moss pieces give the case a furry appearance."

Phryganeidae – Giant Casemakers

This family with relatively large larvae lives mostly in lakes and rivers (Neuswanger 2015a). The pupae crawl from their watery location to shore to emerge. Females run across the water surface to lay their eggs. The larvae are most common among aquatic plants in ponds and marshes, but some occur in streams and others in temporary pools and deep in lakes (Holzenthal *et al.* 2007). Larvae are typically either predators or herbivores.

This family is not common among the bryophytes. But, *Yphria californica* (Figure 75), a species restricted to the west coast states of USA, lays its eggs (Figure 76) underwater among mosses that dangle over the stream in the Sierra Nevada, North America (Erman 1984). To do that, the adult must swim underwater.

Figure 75. *Yphria californica* adult, a USA west coast species that lays its eggs among mosses. Biodiversity Institute of Ontario, through Creative Commons.

Figure 76. *Trichoptera* eggs, often laid on bryophytes. Photo by Bob Armstrong, with permission.

The larvae of *Eubasilissa regina* (Figure 77) in Japan begin their construction days by making cases of liverworts, but as they develop they change to terrestrial leaf litter and move their abode from the liverworts to pools (Ito 1988).

Figure 77. *Eubasilissa regina* adult, a large Japanese caddisfly for which the larvae begin their case construction using liverworts. Photo through Creative Commons.

Oligostomis ocelligera (Figure 78) lives in moist places such as under mosses where it is protected (Redell *et al.* 2009). It usually occupies positions with a mean distance of 6.1 cm below the surface.

Figure 78. *Oligostomis ocelligera* larva, a species that lives under mosses. Photo by Tom Murray, through Creative Commons.

Hagenella clathrata is a rare caddisfly in Europe, inhabiting the disappearing bog habitat (Buczyńska *et al.* 2012). In particular, the species often occurs in bog pools that occur only in rapidly disappearing floating bogs, hence being dependent on the particular habitat created by *Sphagnum* (Figure 10) (Kleef *et al.* 2012).

Sericostomatoidea

Beraeidae

This family is scattered about the globe, being concentrated in the western **Palearctic Region** (Eurasia from western Europe to the Bering Sea), but also occurs in Tanzania, Japan, and eastern North America (Hamilton 1985; Holzenthal *et al.* 2007). Adults have forewings that are only 4-6 mm long (Watson & Dallwitz 2003). Larvae live in springs, seeps, and small streams where they utilize a variety of substrates, including bryophytes (Hamilton 1985; Holzenthal *et al.* 2007). They eat plant and fungal material, but there seem to be no records of eating bryophytes.

Beraea maura (Figure 79) represents this family in the River Rajcianka, Slovakia, where it inhabits the submerged bryophytes (Krno 1990). Unlike several members of the **Limnephilidae** and **Rhyacophilidae**, this species is not found above the water level in the wet mosses there. In the Pyrénées, Décamps (1968) found larvae of this family among mosses, but this family had a wide range of habitats in addition to the mosses.

Figure 79. *Beraea maura* adult, a species that lives among submerged bryophytes as larvae. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Conoesucidae

Among the unfamiliar **Trichoptera** names (to those of us in the northern hemisphere), the **Conoesucidae** (Figure 80) is another of bryophyte-dwelling families from down under (Winterbourn & Gregson 1981). The family is endemic to Australia, New Zealand, and Tasmania (Johanson *et al.* 2009). Among the bryophyte dwellers is *Confluens hamiltoni*, an endemic on the North Island, New Zealand, where it is associated with mosses, liverworts, and algae in rapid-flow streams (Winterbourn & Gregson 1981). On the South Island, this species is replaced by *C. olingoides*, occupying conditions like those of *C. hamiltoni*.

Figure 80. *Pycnocentroides aureolus* adult, member of a family (**Conoesucidae**) with bryophyte dwellers in the Australian region. Photo by Maurice, through Creative Commons.

Helicophidae

This family of 6-14 mm length (Helicophidae 2015b) is mostly known from Australia, New Zealand, and New Caledonia, but also from southern South America and scattered locations in North America (Helicophidae 2015a). The larvae live in slow streams and are mostly detritivores (Helicophidae 2015b).

Trichoptera are not as common in New Zealand as in other parts of the planet, but the **Helicophidae** are represented there, sometimes associated with mosses (Winterbourn & Gregson 1981). *Zelolessica cheira* (Figure 81) occurs among *Fissidens rigidulus* (Figure 82) in the torrential waters near the middle of stream channels in the Southern Alps (Cowie & Winterbourn 1979). *Zelolessica cheira* is usually associated with mosses and liverworts in rapid streams with a stable, rocky substrate (Winterbourn & Gregson 1981; Eward *et al.* 1994). The cases are curved, comprised variously of sand grains, liverworts, and mosses.

Figure 82. *Fissidens rigidulus*, home for *Zelolessica cheira* in torrential New Zealand waters. Photo by Bill & Nancy Malcolm, with permission.

Alloecentrella (Figure 83) is known from China, Australia, New Zealand, and the Antarctic. In New Zealand, *Alloecentrella magnicornis* and an unnamed species occur among mosses and liverworts in rocky streams where they build their cases using bryophytes (Eward *et al.* 1994).

Figure 83. *Alloecentrella* sp. larva, a species that covers its case with mosses and liverworts. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Sericostomatidae – Bushtailed Caddisflies

These caddisflies are of moderate size, with wings 8–15 mm long (Watson & Dallwitz 2011). This family is cosmopolitan except for the Australian region (Sericostomatidae 2015). Nevertheless, many of the genera are endemic to small areas of their continents. At least some larval members of the family move little. For example, more than 120,000 larvae of *Gumaga nigricula* (Figure 84–Figure 85) were released in pools of a California mountain stream and 87–93% of them remained within 4 m of the pools (Jackson *et al.* 1999). In this clever experiment, the larvae were provided with bright gold or magenta sand grains to complete their cases so that they could easily be tracked.

Figure 84. *Gumaga* sp. larva, a relatively immobile caddisfly. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Figure 85. *Gumaga nigricula* adult, a relatively immobile caddisfly in the larval stage. Photo from Biodiversity Institute of Ontario, through Creative Commons.

The **Sericostomatidae** live in both streams and lakes and mostly feed on leaf litter (Family Sericostomatidae 2015). They build slightly to strongly curved tubular cases from sand grains or just silk. Because of their interesting designs and strength, the Tupi-Guarani Indians in Brazil used the cases of *Grumicha* as adornment.

Some of the moss dwellers are quite rare. Stern and Stern (1969) found the larvae of *Sericostoma* sp. (Figure 86) only among algae and mosses in a Tennessee, USA, springbrook.

Sericostoma pedemontanum (Figure 86), a caddisfly of fast-running streams, refused *Fontinalis antipyretica* (Figure 11) when provided a diet of birch, beech, and oak leaves with it (Higler 1975). Birch was the preferred food.

SUBORDER SPICIPALPIA

Glossosomatoidea

Glossosomatidae – Tortoise or Saddle-case Makers

This worldwide family makes its larval cases from pebbles in the shape of a turtle shell (Glossosomatidae 2014). It is probably this structure that forces them to build a new case in each new instar, rather than adding to the old one as most caddisfly families do. These small to medium-sized larvae usually occur in cool mountain streams where they scrape algae from the rocks as their food. The female adults lay their eggs in gelatinous masses under rocks at the water surface or on floating objects, probably including mosses. The gelatinous material protects the eggs from desiccation.

From Ceylon, Schmid (1958) reported *Agapetus rawana* (see Figure 87-Figure 90) from large, mossy rocks in the torrent. In the Appalachian Mountains, *Glossosoma* (Figure 91) larvae and pupae were often present among the bryophytes (Glime 1968).

Hydroptiloidea

Hydroptilidae – Microcaddisflies, Purse-case Caddisflies

This is a worldwide family, less than 5 mm long, that builds flattened cases often resembling an eyeglass case (Hydroptilidae 2015). The members of the family solve the problem of locating food by depositing their eggs near a suitable food source (Leader 1970). They typically feed on algae by sucking out the cell contents or by feeding on diatoms.

In the Appalachian Mountain streams where I worked, this tiny caddisfly is usually not very common, but Percival and Whitehead (1929) found them more commonly among mosses on stones than on other substrates in the UK. Hughes (1966) found them to be more abundant in open areas than in shaded ones, a factor that usually contrasts with bryophyte preferences. Percival and Whitehead (1929) found that the hydroptilids from mosses feed on algae and diatoms. The larvae of this family have mouthparts that are able to pierce and suck, enabling them to suck the contents from filamentous algae or to scoop up diatoms (Nielsen 1948).

It is perhaps telling that at least in Denmark, the genera *Agraylea* (Figure 92), *Hydroptila* (Figure 93), *Oxyethira* (Figure 94-Figure 95), and *Orthotrichia* (Figure 96) are very common in eutrophic lakes (Nielsen 1948). This suggests that in streams we should look for the bryophyte dwellers deep within the mat where there is reduced flow. But even in the lakes these genera occupy vegetation near the surface. *Agraylea* and *Orthotrichia* occur in slowly flowing water, and this is where mosses can add possible niches. *Orthotrichia* often becomes coated in detritus and will pass one of its hind legs down the dorsal side of its abdomen to clean the tracheal gills there.

Figure 92. *Agraylea sexmaculata* larva, a genus that lives among bryophytes in slowly flowing water. Photo by Massimo Del Guasta, with permission.

Figure 96. *Orthotrichia* sp larva and case, a species that lives among mosses in lakes. Photo by Urmas Kruus, with permission.

Hydroptila (Figure 93) can build a case of detrital matter and sand grains in about four hours (Nielsen 1948). To increase the size of the case, the larva splits it open along the ventral edge, adding sand grains to the edge. The completed case, as in most members of the family, looks like a case for eye glasses (Figure 93) – the one with an

open end – which is where the head protrudes in the caddisfly version. Some cases are built with algal filaments, especially in *Agraylea* (Figure 92), and I have observed cases made almost entirely of diatoms. In both *Hydroptila* and *Agraylea* the outer coating of sand or algae will wear off as the larva nears maturity, leaving only the smooth inner wall made of silk spun by the larva as it cements the case together. *Orthotrichia* (Figure 96) and *Ithytrichia* (Figure 97) species use only silk in the construction of their cases. These genera feed by sucking the contents out of algal cells.

Figure 97. *Ithytrichia lamellaris* larva & case, a genus that uses only silk in its case. Photo by Urmas Kruus, with permission.

When these four genera (*Agraylea*, *Hydroptila*, *Orthotrichia*, *Ithytrichia*) emerge, they split the pupal case, then move about until they find a protruding object to climb up and out of the water (Nielsen 1948). Once out they can flit about on the water surface and in the air.

The moss-dwelling genus *Oxyethira* (Figure 94-Figure 95), including more than one species, comprised 44.5% of the Trichoptera fauna at the acid site in Frost's (1942) moss fauna study of the River Liffey, Ireland. It was absent at the alkaline site. *Oxyethira frici* lives in the angle between the leaf and the stem of the moss and pupates among the mosses, a behavior that is uncommon among caddisflies. By contrast, *Ithytrichia lamellaris* (Figure 97), a species almost restricted to mosses, was common at the alkaline site and absent from the acid site. It likewise lives in the angle between the leaf and the stem of the moss and pupates among the mosses. Both of these genera were present, but rarely, among the bryophytes of Appalachian Mountain mostly acid streams, USA (Glime 1968). They were more common on *Fontinalis*, where larvae of *Oxyethira* and *Hydroptila* sometimes decorated the branches of *Fontinalis dalecarlica* (Figure 98).

From Ceylon, Schmid (1958) reported *Chrysotrichia hapitigola*, and *Hydroptila kirilawela* from large, mossy rocks in the torrent.

Figure 98. *Fontinalis dalecarlica*, home to many insects. Photo by J. C. Schou, with permission.

Woodall and Wallace (1972) found *Ochrotrichia* sp (Figure 99) on moss-covered granite outcrops in the Appalachian, USA, streams that they studied. They considered the moss-covered rock outcrops to be the central factor influencing the distribution of this species in the area. In my own studies of the mid-Appalachian Mountain streams, this genus was not present, but I did occasionally find *Mayatrichia*, *Neotrichia*, and *Stactobiella* in addition to the more common ones discussed above under this family (Glime 1968).

Figure 99. *Ochrotrichia eliaga* larva and case, a genus found on moss-covered granite outcrops in Appalachian streams. Photo by Trevor Bringloe, Biodiversity Institute of Ontario, through Creative Commons.

In a Tennessee, USA, springbrook, *Ochrotrichia unio* (see Figure 100) live among algae and mosses as larvae, then move to bare rocks to pupate (Stern & Stern 1969). In Great Britain, the larvae of this species feed on diatoms and other algae (Percival & Whitehead 1929).

Figure 100. *Ochrotrichia* larva, a genus in which some larvae live among mosses, then migrate to bare rocks to pupate. Photo from California Department of Wildlife, through public domain.

Ptilocolepus

Ptilocolepus granulatus is **crenophilic** (describing organism preferring spring environments but may also occupy similar habitats), living in montane to subalpine regions of central Europe (Waringer & Graf 2002). Wesenberg-Lund (1943) reported that *Ptilocolepus granulatus* lives in moss cushions and makes its case from moss fragments. Similarly, González *et al.* (2000) reported that *P. extensus*, an endemic on the Iberian Peninsula and a close relative, uses leaf pieces of several moss and liverwort species to make its final instar case. Unlike most of the **Hydroptilidae**, this case is flattened dorsiventrally, but still has the typical elongate-oval shape.

In the Pyrénées, Thienemann (1950) and Décamps (1968) found *Ptilocolepus granulatus* among mosses and liverworts. These bryophytes also formed a significant portion of their food as well as construction material for their cases. Ito (1998) reported that this genus lives among, eats, and builds its cases from the leafy liverworts *Chiloscyphus polyanthos* (Figure 67) and *Scapania undulata* (Figure 74). Depisch (1999) and Ito and Higler (1993) all found that the species commonly lives among and feeds on the liverwort *Scapania undulata*. In Belgium *Ptilocolepus granulatus* uses *Jungermannia riparia* for food, but surprisingly, it also sometimes builds its case from the moss *Fontinalis* (Figure 11) (Ito & Higler 1993). Thus it is not surprising that Dittmar (1955) found it associated with *Fontinalis*. Ito and Higler found that it does not seem to feed on the moss, but later Ito (1998) states that it is the only species in the subfamily **Ptilocolepinae** that is able to feed on *Fontinalis* (and other mosses), attributing this ability to its large mandibles.

Palaeagapetus

Microcaddisflies such as *Hydroptila* (Figure 93) often attach their tiny homes to the moss leaves and stems, but *Palaeagapetus* in the same family constructs its home strictly out of leafy liverworts (Flint 1962; Glime 1978; Ito & Hattori 1986; Ito 1991), even when these are growing

side by side with mosses such as *Fontinalis* (Figure 11). The species of liverwort depends on availability, with cases of *Palaeagapetus celsus* from the eastern USA known from *Scapania nemorea* (Flint 1962; Glime 1978) (Figure 101), *S. undulata* (Glime 1978) (Figure 74), *Plagiochila porelloides* (Glime 1978) (Figure 102), *Frullania* sp. (Glime 1978) (Figure 103). In those I observed, the pieces of liverwort were cut into nearly circular pieces and cemented together along their margins, forming a case typical of many hydroptilids – the shape of an eyeglass case. Ito and Vshivkova (1999) described the pieces of liverworts comprising the cases of *Palaeagapetus finisorientis* from the Russian Far East similarly as being roughly rounded fragments.

Figure 101. *Scapania nemorea*, one of the species used for making cases of *Palaeagapetus celsus*. Photo by Bernd Haynold, through Creative Commons.

Figure 103. *Frullania eboraensis*, a terrestrial epiphytic species that may fall into the water and be used in the case of *Palaeagapetus celsus*. Photo by Bob Klips, with permission.

Not only do members of this genus use liverworts in the construction of their cases, but the liverworts are also a primary food source (Botosaneanu & Levanidova 1987). In his review of four species of *Palaeagapetus*, Ito (1998) found that all of them used the liverworts *Chiloscyphus polyanthos* (Figure 67) and *Scapania undulata* (Figure 74) for food, housing, and case construction. It appears that all known members of the genus have this same strong dependence on leafy liverworts, including those in the eastern part of the former Soviet Union (Botosaneanu & Levanidova 1987), Japan (Ito & Hattori 1986; Ito 1988, 1991), and North America (Flint 1962; Glime 1978). In the western USA, *Palaeagapetus nearcticus* uses *Scapania uliginosa* for its case and food (Ito *et al.* 2014). The larvae pierce the cells and consume the liverwort one cell at a time. Ito and Vshivkova (1999) found that in the *Palaeagapetus* species they observed, the early instars fed on the contents of the liverwort cells, whereas the final instar cut off the leaves and apparently ingested them, reminiscent of human babies who also shift from sucking to chewing. Ito (1991) found that *Palaeagapetus rotundatus* feeds on the leaves of leafy liverworts *Chiloscyphus polyanthos* and *Scapania undulata* (Figure 74), but will not feed on the moss *Platyhypnidium riparioides* (Figure 13).

Ito (1988) followed the life history of *Palaeagapetus ovatus* in a spring stream in Japan. He found that the density changed with season, reaching the highest in winter and being low in summer. Living with it was a predatory Trichoptera, *Eubasilissa regina* (Phryganeidae; Figure 77), that preyed upon it among the liverworts.

We know more about this genus and its liverwort relationship through the description of a new species, *Palaeagapetus ovatus*, in Japan (Ito & Hattori 1986). This liverwort dweller fed exclusively on the leaves of the leafy liverwort *Chiloscyphus polyanthos* (Figure 67). Its fifth and final instar made the typical oval case from the leaves of this liverwort. And the females, within two days of emergence, laid 50-85 eggs on the leaves of this liverwort. The eggs do not form a mass and at 10.5-12°C they hatch in 21-23 days. *Palaeagapetus nearcticus* also deposits its orange eggs on liverwort leaves (Ito *et al.* 2014).

More recently, Woods (2002) was surprised to find the thallose liverwort *Riccardia chamedryfolia* (Figure 104) moving in a slow, jerky motion on the sandy bottom of a pool in Wales. Investigation revealed that two matching pieces of the thallus had been cemented together by a caddisfly larva that was using it for a home (case). The larva was not identified but could have been a member of Hydroptilidae.

Scelotrichia

My email makes Christmas come all year-round. One of these nice surprises came when Andi Cairns sent me pictures of a caddisfly that was a bryological surprise. This new species, actually in a genus new to Australia, was *Scelotrichia willcairnsi* (Figure 105) living among the mosses in a waterfall (Figure 106). It was feeding on *Rhynchostegium brevinerve* (Figure 107), a new species previously thought to be *Platyhypnidium muelleri* and renamed by Huttunen and Ignatov (2010), in north-eastern Queensland, Australia. This microcosm was full of surprises!

Figure 104. *Riccardia chamedryfolia*, a liverwort that some caddisflies use to make a case. Photo by Kristian Peters, with permission.

Figure 105. The caddisfly *Scelotrichia willcairnsi* (Hydroptilidae) with a case made of pieces of the moss *Rhynchostegium brevinerve*. Note the way pieces fit together as parallel rings. Photo courtesy of Andi Cairns.

Figure 106. *Rhynchostegium brevinerve* in Fishery Falls, Australia, home to *Scelotrichia willcairnsi*. Photo courtesy of Andi Cairns.

Figure 107. *Rhynchosetegium brevinerve*, home to the caddisfly *Scelotrichia willcairnsi*. Photo courtesy of Andi Cairns.

The *Scelotrichia willcairnsi* larva had a case (Figure 105) it had built by cementing moss leaf fragments together (Figure 108) – the same species of moss it was eating (Cairns & Wells 2008). It remained in this case to pupate, cementing it to the moss stems (Figure 109). When making a case, the larvae cut the leaves longitudinally, in parallel with the long axis of the leaf and its cells, giving them long pieces (Figure 108). Cairns and Wells described these: "neatly, the fragments fitted together, almost in rings." Ohkawa and Ito (2002) had already distinguished the types of cuts for leaves and for food in *Scelotrichia ishiharai*. This microcaddis uses the moss *Rhynchosetegium* sp. (Figure 107-Figure 109) for food (Figure 110-Figure 111) and case building (Figure 105-Figure 109), likewise using different orientations for the two kinds of cuts.

When Cairns and Wells (2008) examined the gut contents, they discovered that these tiny caddisfly engineers cut the pieces of moss very differently for food than they did for cases. For food, they cut the leaves perpendicular to the long axis and across the cells (Figure 110-Figure 111). Such a cut would give the gut enzymes more access to the contents of the cells.

Figure 110. Pieces of the moss *Rhynchosetegium brevinerve* from the gut of the caddisfly *Scelotrichia willcairnsi* (Hydroptilidae). Photo courtesy of Andi Cairns.

Figure 111. Pieces of the moss *Rhynchosetegium brevinerve* from the gut of *Scelotrichia willcairnsi*. The moss fragments are stained with Toluidine blue to make cell walls more evident. Note that cell contents appear to be gone in nearly all fragments, suggesting digestion. Photo courtesy of Andi Cairns.

Elsewhere, in Papua New Guinea, *Scelotrichia* was similarly collected from mosses in the strong currents at the crest of a short waterfall (Wells 1990). They likewise made their cases of the moss leaves and later attached their pupal cases to the stems of the same species of moss. Wells found adults of two other species of *Scelotrichia* near waterfalls or soaked mosses. As in *S. willcairnsi* (Figure 105), the caddisfly larvae from Papua New Guinea had cut slivers of the moss down the long axis of the leaf, making the cells parallel to the length of the fragment. These differed from the pieces cut by *Paleagapetus* and *Ptilocolepus*, which were cut from leafy liverworts and glued together to resemble a patchwork quilt (Ito 1998; Ito & Higler 1993). It appears that cutting behavior can determine the type of bryophyte that is suitable for making the case.

Rhyacophiloidea

Rhyacophilidae – Free-living Caddisflies

This is a Northern Hemisphere family from the temperate parts of North America, Europe, and Asia, extending into India and the tropical areas of southeastern Asia (Kjer 2010). The larvae are 9-16 mm long and are green or brown, blending easily with the bryophytes (Bumble.org 2013). Don't be misled by the pink color they assume in preservative.

Larvae of this family do not build cases (Figure 112), so they do not attach themselves to the substrate by gluing their cases like some caddisflies do. Their life cycle is one year, with two generations overlapping. The larvae prefer rapid, cold streams where they are able to stay themselves in the current by clinging to mosses or debris (Hilsenhoff 1975). Most are carnivorous, but a few are herbivorous. And some can live above the water level among wet emergent mosses: *Rhyacophila nubila* (Figure 113), *R. polonica*, and *R. tristis*, whereas in the same River Rajcianka, Slavakia, these three species plus *R. obliterate* (Figure 117), *R. philopotamoides*, and *R. vulgaris* occur among the mosses under water (Krnó 1990).

Figure 112. The free-living caddisfly, *Rhyacophila*, is a common member of the stream moss community. Its color is typically green, and it has large hooks that permit it to cling to mosses and other substrata to avoid being washed away by the fast-flowing water it inhabits. Its lack of a case permits it to traverse the internal chambers of the moss without getting caught by the branches. Photo by Janice Glime.

Figure 113. *Rhyacophila nubila* larva, a species that can live among mosses above or below the water surface. Photo by Niels Sloth, with permission.

In my studies of Appalachian Mountain stream mosses in Maryland and Pennsylvania, USA, the genus *Rhyacophila* was among the most common and constant of the caddisfly larvae among the bryophytes. Décamps (1967, 1968) found *Rhyacophila laevis* to be abundant among mosses in the Pyrénées. In a cool mountain stream of central Japan, Tada and Satake (1994) found that *R. towadensis* was significantly more abundant among the moss *Platyhypnidium riparioides* (Figure 13) than in bare rock areas.

Many members of *Rhyacophilidae* most likely benefit both from the protection afforded by the bryophytes, but also from the resident fauna that serves as food, especially the numerous *Chironomidae*. In their study of four small Appalachian, USA, streams, Woodall and Wallace (1972) found larvae of *Rhyacophila torva* (Figure 124) (see also Roback 1975), *R. nigrita* (Figure 114), *R. carolina* (Figure 121), *R. minor* (Figure 115) (see also Glime 1968), *R. glaberrima* (Figure 116), and *R. fuscula* (Figure 122-Figure 123) among mats of mosses on rock outcrops. They fed on the *Chironomidae* larvae (Ross 1944) that shared the bryophyte habitat. In one of my collections from the mid-Appalachian Mountains I caught *R. carolina* in the act – it was preserved with a chironomid larva in its mouth. Although *R. minor* in a wooded Ontario, Canada, stream is typically carnivorous, early instars feed on plant material (Singh *et al.* 1984). This strategy works well until they gain the size and skill to be predators.

Food

Most *Rhyacophila* species are carnivores that do not make cases, but the *Verrula* group eat photosynthetic organisms with their **hypognathous** heads (oriented downwards), feeding on algae, diatoms, and particularly bryophytes (Smith 1968; Thut 1969). Cummins (1973) likewise reported that *R. verrula* in western North America is a herbivore and especially eats aquatic mosses (Slack 1936; Gerson 1982; Smith 1968). In his study of diets of the *Rhyacophila* species in constructed streams in western USA, Thut (1969) found that *R. verrula* feeds predominantly on aquatic mosses. This effect is intensified in winter when several mosses are dominant and diatoms are abundant. Interestingly, diatoms become more important in the fourth and fifth instars than they are in earlier instars.

In a Tennessee cold springbrook, *Rhyacophila lobifera* larvae fed among the moss and algae, eating smaller caddisfly larvae, midge larvae, naiads of mayflies and stoneflies, detritus, and diatoms (Stern & Stern 1969). Slack (1936) also reported that one out of nine *Rhyacophila dorsalis* (Figure 118) had leaves of *Fontinalis antipyretica* (Figure 11) in the gut, but that it is primarily carnivorous. Nevertheless, one specimen contained only diatoms in the gut and the one with *Fontinalis* had only plant material. In a study in the English Lake District, Elliott (2005) found that early instars ate primarily diatoms (mostly *Achnanthes* spp., Figure 119), with bryophyte fragments also present in nearly all gut samples, but the bryophytes appeared to be undigested, displaying their chlorophyll. These bryophytes may have been eaten to obtain adhering diatoms. Both second and third instars would disappear into the bryophyte clumps to search for prey, but they returned to the surface of those clumps to consume their finds. Fourth and fifth instars fed only at night and used an ambush strategy to capture prey, which includes *Baetis* and *Gammarus*.

Figure 118. *Rhyacophila dorsalis* larva, a carnivorous species that sometimes has leaves of *Fontinalis antipyretica* in its gut. Photo by Walter Pfliegler, with permission.

Larvae of most of the predominantly carnivorous *Rhyacophila dorsalis* (Figure 118) occur among bryophytes [leafy liverwort *Scapania* sp. (Figure 74) and mosses *Platyhypnidium riparioides* (Figure 13) and *Fontinalis antipyretica* (Figure 11)] (Slack 1936). For less active prey they use a searching strategy (**Chironomidae**, **Simuliidae**). The percentage of larvae with bryophytes in the gut was much smaller than that of prey. It appears that this species changes its diet as it grows, but it may also be

an opportunist regarding its diet. But if one considers that both the diatoms and bryophytes still had chlorophyll in their cells, it appears that even the first and second instar larvae may have been carnivores, eating these photosynthetic organisms by chance while attempting to capture prey. Instead, the first and second instar larvae eat copepods, rotifers, and tardigrades, common bryophyte inhabitants, but these require special preservation techniques in order to recognize them in gut samples. Instead of a shift from apparent herbivore to carnivore, Elliott (2005) demonstrated a shift in size of prey.

Figure 119. *Achnanthes longipes*. Photo by Victor Chepurinov, through non-commercial license.

The caddis larvae of *Rhyacophila dorsalis* (Figure 118) begin their early instars by feeding equally day and night, but by the 4th to 5th instar they shift to feeding almost totally at night (Elliott 2005). They can feed on other insects inhabiting their moss habitat, such as **Ephemeroptera** (mayflies), **Simuliidae** (blackflies), and **Chironomidae** (midges). As they grow older, instars 4 and 5, they adopt an ambush strategy at dusk and dawn, catching such active prey as the mayfly *Baetis* and the scud *Gammarus*. During the night they used a searching strategy to capture the more sedentary prey, for example **Chironomidae** (midges) and **Simuliidae** (blackflies).

Thut (1969) suggested that the high proportion of moss fragments in the diets of the herbivorous *Rhyacophila* was at least in part the result of seasonal changes in the available primary producers in streams. Bryophytes are available in winter when most of the algae are dormant in a resting stage.

Substrate Preference

Rhyacophila species typically make their larval homes under rocks or among mosses (Bouchard 2004). They are able to use their claws (Figure 120) to anchor themselves or cling to the mosses, but also use them as they creep along in the stony stream bed (Badcock 1949). Percival and Whitehead (1929) found that *Rhyacophila dorsalis* (Figure 118) preferred thick mosses and *Potamogeton* on stones. Elliott (2005) found some larvae found under large stones, but most were among bryophytes growing on the upper surfaces of large stones [*Scapania* (Figure 74), *Platyhypnidium riparioides* (Figure 13), *Fontinalis antipyretica* (Figure 11)].

Figure 120. *Rhyacophila fuscula* larva showing anal hooks that cling to its substrate. Photo by Jason Neuswanger, with permission.

In the Great Smoky Mountains National Park, *R. montana* lives in the films of water that flow over vertical rock faces, crevices, or among wet mosses (Parker *et al.* 2007). *Rhyacophila evoluta* and *R. intermedia* are characteristic of mosses in torrents in the Pyrénées (Décamps 1967). *Rhyacophila evoluta* has the ability to go into a cold-induced diapause at any stage in its development. This permits it to complete its development in one, two, or three years, depending on the temperatures.

Some species seem to prefer liverworts and some to prefer mosses for their homes (locations, not cases). In the mid-Appalachian Mountain streams I found *Rhyacophila* cf. *carolina* (Figure 121) primarily among liverworts (*Scapania undulata*; Figure 74), whereas *R. fuscula* (Figure 120, Figure 122-Figure 123) predominated in *Fontinalis dalecarlica* (Figure 98) and *R. torva* (Figure 124) in *Hygroamblystegium fluviatile* (Figure 4-Figure 5) and *Platyhypnidium riparioides* (Figure 13). *Rhyacophila invaria* (Figure 125) occurred frequently among clumps of the moss *Platyhypnidium riparioides* (36% frequency) but was absent among *Hygroamblystegium fluviatile* clumps despite the frequent intermingling of these two mosses. It reached its greatest numbers in *Scapania undulata*.

Unknown Caddisfly Cases

One caddisfly larva included moss leaves, liverwort leaves, and even hornwort thallus, all in one case (Chris Cargill, pers. comm. 30 March 2016). And all these pieces were still alive! (Figure 126-Figure 129).

Figure 126. *Megaceros flagellaris* fragments used in caddisfly case. Photo courtesy of Andi Cairns.

Figure 127. *Megaceros flagellaris* fragments used in caddisfly case. Photo courtesy of Andi Cairns.

Figure 128. *Megaceros flagellaris* fragments used in caddisfly case. Photo courtesy of Andi Cairns.

Figure 129. *Megaceros flagellaris* fragment used in caddisfly case. Photo courtesy of Andi Cairns.

Chris Cargill told me she later found discarded cases made of thalli from liverworts or hornworts and new thalli had started to grow from the case (Figure 130). I think we have just added a new means of bryophyte dispersal!

Helicophidae

Andi Cairns brings me many interesting interactions of animals with bryophytes. This one is a member of the **Helicophidae** (Figure 131Figure 132) that has made a case from *Solenostoma* sp. (Figure 133) leaves where it lives in a stream in Australia.

Figure 131. **Helicophidae** sp with *Solenostoma* sp case, Cloudy Ck, Australia. Photo courtesy of Andi Cairns.

Summary

The **Limnephilidae** are mostly large and therefore are usually absent from the smaller mosses. However, sometimes several may occur within a clump of *Fontinalis*.

The **Brachycentridae** are common among bryophytes. Some (*Micrasema*, *Adicrophleps hitchcockii*) use mosses in their cases and some also eat them.

The genera *Palaeagapetus* and *Scelotrichia*, both in the **Hydroptilidae**, use bryophytes (exclusively?) for food and case construction, the former using leafy liverworts and the latter using mosses. In the same family, *Ptilocolepus* uses both mosses and liverworts for food and in case construction.

The family **Rhyacophilidae** is a free-living caddisfly and is mostly carnivorous. However, some of the bryophyte dwellers eat bryophytes, whereas others use them as a place to capture prey.

Other families that can be found among bryophytes less commonly include **Odontoceridae**, **Goeridae**, **Limnephilidae**, **Lepidostomatidae**, **Oeconesidae** (especially in New Zealand), **Uenoidae**, **Phryganeidae**, **Beraeidae**, **Conoesucidae**, **Helicophidae**, **Sericostomatidae**, and **Glossosomatidae**. Among these, the **Limnephilidae** and **Phryganeidae** have mostly large larvae that are unable to move about in most of the bryophytes but that can live among the large branches of *Fontinalis* species. Unlike the **Coleoptera**, this order is poorly represented in bogs and fens, but they are common in streams and less so in lakes.

Acknowledgments

As a graduate student I relied heavily on the expertise of Oliver Flint, Glenn Wiggins, Tom Waters, and Ken Cummins for both encouragement and identification help in my novice years. Thank you so much to D. N. Bennett for making a special trip to photograph live *Micrasema wataga* eating and showing the mosses sprouting on the case, just for this chapter! She also made additional trips to the field to determine the identity of the moss. David Tempelman helped me to obtain some of the images and permission for use and provided me with references on *Ptilocolepus*. Eileen Dumire proofread the chapter and helped me improve the clarity and readability.

CHAPTER 11-13a

AQUATIC INSECTS: HOLOMETABOLA – DIPTERA, SUBORDER NEMATOCERA

Figure 1. *Triogma trisulcata* among mosses. This species makes its home among wet mosses of bogs and swamps and is effectively a moss mimic. Photo by J. C. Schou, with permission.

DIPTERA – FLIES

Gerson (1969) suggested that the ancestral fly groups originated among mosses where it is always damp. Because the systematics of the fly groups are still poorly understood, I have divided the treatments into the two suborders, **Nematocera** and **Brachycera**. From there they are alphabetical within superfamilies, but the superfamilies are not delineated by name.

Diptera adults are distinguished by having only two wings, as reflected in the name of **Diptera** (*di* = 2; *pteron* = wing). In place of the second pair of wings the flies have a pair of **halteres** (Figure 2), thoracic projections that resemble lollipops, one on each side of the thorax. In the larval stage, they are distinguished by having only fleshy **prolegs** (Figure 9) or no legs. They lack the chitinized, jointed thoracic legs found in most larval insects (Johannsen 1969).

Figure 2. **Tipulidae** showing two wings and halteres. Photo by Pinza, through Creative Commons.

Gerson (1982) reported a number of bryophyte-dwelling **Diptera** of medical and veterinary importance because they bite. Among these are the sand flies [**Psychodidae** (see Chapter 13b; Quate 1955)], mosquitoes [**Culicidae** (see Chapter 13b; Fantham & Porter 1945)], black flies [**Simuliidae** (Figure 3); Snow *et al.* 1958)], biting midges [**Ceratopogonidae** (Figure 84-Figure 88; Séguy 1950)], and horse flies [**Tabanidae** (Figure 4; Teskey 1969)]. All of these are discussed in this chapter except **Tabanidae**. I found it only occasionally among bryophytes in Appalachian Mountain, USA, streams; the other studies I reviewed did not mention it.

Figure 3. **Simuliidae** larvae in the rapid flow of a stream. Photo by Janice Glime.

Figure 4. *Chrysops divaricatus* (**Tabanidae**) adult, an adult pest (horse fly) whose larvae sometimes live among the bryophytes. Photo by Kallema, through Creative Commons.

In streams, bryophytes are often important contributors to biodiversity. Flow rates are important in determining the type of **Diptera** able to live there. The abundance of **Chironomidae** (see Chapter 13b) is negatively correlated with flow rate as it approaches clumps of mosses (*Fontinalis antipyretica*; Figure 5), whereas the abundance of the smallest **Simuliidae** (Figure 3) is positively correlated (Linhart *et al.* 2002a). In the Plitvice Lakes National Park in the Dinaric karst region of Croatia, Čmrlec (2013) found that the Diptera families were least abundant in silt and that mosses were the preferred substrate. These correlations with speed and silt do not prevent both groups of species from living in the same bryophyte clump – the slow-water silt lovers live near the bottom while the fast-water silt avoiders live near the surface of the bryophyte clump.

Figure 5. *Fontinalis antipyretica*, home for numerous aquatic insects and suitable for larger ones. Photo from Projecto Musgo, through Creative Commons.

Bryophytes accumulate coarse (CPOM), fine (FPOM), and ultrafine (UPOM) particulate organic matter that serves as a food source for their inhabitants (Habdija *et al.* 2004). These conditions favor small forms of oligochaetes, **Diptera**, and **Coleoptera** that comprise 64-99% of the **macrophyte** (plant – especially aquatic – large enough to be seen without a lens) individuals. Collector gatherers dominate in spring and summer, collector-filterers in autumn, and scrapers in winter.

In a cool mountain stream in central Japan, five of the six taxa of Diptera identified (mostly at the level of family or subfamily) were significantly more abundant in clumps of the moss *Platyhypnidium riparioides* (Figure 6) than in areas of bare stones (Kato 1992). These included **Limoniidae** (*Antocha* spp.; Figure 7), **Simuliidae** (Figure 3), and **Chironomidae** [Figure 8; **Tanypodinae**, **Diamesinae**, *Orthocladius* spp.].

Figure 6. Emergent but wet *Platyhypnidium riparioides* in Europe, a common home for **Diptera**. Photo by Michael Lüth, with permission.

Figure 7. *Antocha*, a larva that inhabits the moss *Platyhypnidium riparioides* (Figure 6) in cool mountain streams in Japan. Photo by Bob Henricks, with permission.

In Alaska, **Diptera** dominate by an even larger proportion than in streams of temperate North America (Oswood 1989). The **Chironomidae** (Figure 8) exhibit a significant increase from south to north, whereas most other taxa (excluding **Nemouridae**) decrease.

Figure 8. **Chironomidae** larva, a common bryophyte-dwelling family whose numbers increase from south to north. Photo by Jason Neuswanger, with permission.

The **Diptera** have a variety of adaptations to their aquatic domicile of choice. For example, Bass and Cooling (1983) reported that **Muscidae** (**Brachycera**), **Ichneumonidae** (**Hymenoptera**), and **Simuliidae** (Figure 3) were associated with mosses below a reservoir in southern England. Both the larvae and pupae had posterior projections to anchor them to the mosses. Amos (1999) describes the role of the brook moss *Fontinalis* (Figure 5) in providing a safe habitat in the torrent, and this moss likes cold water (Glime 1987) where few tracheophytes persist. Here one can find many small invertebrates, but it seems still to be a challenge to stay put. The mountain midge larva (**Deuterophlebiidae**, Figure 9) survives the torrent by the use of strong suction to hold the rock. The suction cups of *Deuterophlebia* (Figure 9) are of little use among bryophytes, but are fantastic for adhering to "bare" rocks. Respiratory adaptations are numerous and will be discussed for the various families.

The floating community includes only a few species of bryophytes, notably *Ricciocarpus natans* (Figure 10) and *Riccia fluitans* (Figure 11). In some cases, the **Diptera** associated with the thallose floating liverwort *Ricciocarpus natans* are the same ones found among floating tracheophytes such as *Spirodela*, *Lemna minor* (Figure 10), and *Wolffia* (Scotland 1934).

Figure 11. *Riccia fluitans* with pearly (oxygen bubbles produced by the plants), a floating community that provides cover and oxygen for aquatic insects. Photo by Christian Fischer, through Creative Commons.

Despite the number of families of **Diptera** among the bryophytes, and the presence of such mixed terrestrial/aquatic families as the **Tipulidae** (Figure 46-

Figure 73, Figure 75, Figure 77-Figure 76), it is interesting that this order is poorly represented among the wet emergent mosses in the River Rajcianska in Slovakia (Krno 1990). Only the **Psychodidae** (see Chapter 13b) were able to take advantage of the safety of the emergent bryophytes there. On the other hand, fauna of the submerged mosses were represented by not only the **Psychodidae**, but also the **Ceratopogonidae** (Figure 84-Figure 88) and **Simuliidae** (Figure 3). Conspicuously absent in these **eutrophic** (referring to lake or other body of water rich in nutrients and thus supporting dense plant/algal populations) waters were the **Tipulidae** and **Chironomidae** (Figure 8).

Occasionally, or perhaps frequently, the insects do something beneficial for the bryophytes they visit. In a study to determine the role of adult **Diptera** in dispersing algae and **Protozoa**, Revill *et al.* (1967) found that in addition to 21 species of viable algae and 5 of **Protozoa**, the washings from the four species of **Diptera** produced viable moss spores/protonemata as well. These transporting insects included *Tipula triplex* (**Tipulidae**; Figure 12), *Bittacomorpha clavipes* (**Ptychopteridae**, Figure 13), *Chaoborus punctipennis* (**Chaoboridae**, Figure 14-Figure 15), and *Chironomus* (**Chironomidae**; Figure 16).

Suborder Nematocera

The name **Nematocera** means "thread horns" and refers to the long, threadlike antennae. These are elongated flies with thin, segmented antennae. The larvae are mostly aquatic and the family includes crane flies, gnats, midges, mosquitoes, and blackflies.

Nymphomyiidae

This is a family of tiny (2 mm) flies in the northern parts of the Northern Hemisphere, especially eastern North America and eastern and central Asia (Nymphomyiidae 2013). The adults are **neotenic** (retaining larval or immature characters in adulthood), with straplike wings having **poor venation** (few wing veins). They live in running waters, where they often are found on moss-covered rocks, and **pupation** (development process between larva and adult) usually occurs in the same place (Courtney 1994). Adults have aborted mouth parts and live only a short time, some dying while still in the copulatory (mating) position.

Nymphomyia is the only genus currently listed in this family (Myers *et al.* 2014). It lives among aquatic mosses in small, rapid streams (Courtney 1994; Courtney *et al.* 1996). Not only larvae, but also often pupae and adults of *Nymphomyia*, live on rocky substrates covered with aquatic mosses such as *Platyhypnidium riparioides* (Figure 6), *Fontinalis* (Figure 5), and *Hygroamblystegium* (Figure 91) (Cutten & Kevan 1970; Adler *et al.* 1985).

Cylindrotomidae – Long-bodied Craneflies

The family **Cylindrotomidae** is often separated from the **Tipulidae** (Figure 46-Figure 73, Figure 75, Figure 77-Figure 76), which I have chosen to do to make it easy to discuss its unique characters relative to bryophytes. These are of moderate size (11-16 mm) and yellowish to pale brownish as adults (Cylindrotominae 2014). Most larvae live among mosses – terrestrial, semiaquatic, and aquatic mosses (Cylindrotominae 2014), and feed on mosses and **tracheophytes** (plants with lignified vascular tissue) (Gelhaus *et al.* 2007). The family occurs mostly in the Holarctic and Oriental Regions, but there are scattered records in southern South America, New Guinea, and Australia.

The aquatic insects don't seem to have the elaborate camouflage known in some terrestrial insects, but some still do an excellent job at blending. The **Cylindrotomidae** in particular are bryophyte dwellers and are world-class mimics of that habitat – bryocamouflage!

The larvae of *Triogma trisulcata* (Figure 1, Figure 17) are known for their mimicry in a *Sphagnum* (Figure 69) habitat, but they also occur in streams where the larvae attach to *Fontinalis antipyretica* (Figure 5) (Gerson 1969). The leaflike appendages most likely are equally useful in that habitat as camouflage.

Figure 17. *Triogma trisulcata* larva posterior showing flanges that make it almost invisible among *Sphagnum*. Photo by Walter Pfliegler, with permission.

Triogma trisulcata (Figure 17) larvae are inhabitants of semiaquatic mosses, especially in stagnant water in bogs (Brinkmann 1997). In contrast to the tracheal gill respiration of *Phalacrocer replicata* (Figure 18), another bryophyte dweller in this family, the larvae lie on the leaves of the moss in a position that places the **spiracular disk** (apparatus that contains the breathing openings called spiracles) at the level of the water surface. Like *P. replicata*, these larvae have appendages that match the color and mimic the morphology of the surrounding mosses. These have been variously interpreted as mimetic camouflage to protect them against enemies and as respiratory organs. It seems reasonable that both interpretations may be correct. The pupae remain in these same positions until a short time before the adults emerge (**ecdysis**). Just before ecdysis, they search for drier mosses. Eggs are laid singly on mosses just below the surface by females dipping the tip of the abdomen into the water to touch the leaves. The eggs are attached by an adhesive.

Figure 18. *Phalacrocer replicata* larva, an effective moss mimic that develops among mosses. Photo through Wikimedia Commons.

Phalacrocer replicata (Figure 18) lives among *Sphagnum* (Figure 69), *Fontinalis antipyretica* (Figure 5), and *Warnstorfia fluitans* (Figure 19) (Brinkmann 1997). Larvae in this species find tufts of mosses, then attach themselves to the leaves and stalks by affixing the anterior part of the body using the **mandibles** (crushing organs in an arthropod's mouthparts) to grab onto the edge of a leaf. They then crawl by crooking the body and securing the dorsal hooks. They have backward-pointing appendages that presumably help prevent them from being swept away by the current. At this stage they have functional spiracles that they do not use. Instead, the long, filiform appendages along the body function as tracheal gills, supplemented by **cutaneous** (referring to outer cuticle of insect body) gas exchange. But when it is time for pupation, the larvae move to the water surface to expose their **spiracles** (external openings through which insects breathe) to the atmospheric air. To maintain this contact with surface air, the pupae hang beneath the surface film, using their

respiratory horns, and cling to the stems of mosses or other plants with the appendages on the last of the abdominal segments, positioning their bodies horizontally.

Figure 19. *Warnstorfia fluitans*, one of the homes of larvae of *Phalacrocer replicata*. Photo by Michael Lüth, with permission.

Clymo and Hayward (1982) reported that *Phalacrocer replicata* feeds on *Sphagnum* (Figure 69). Miall and Shelford (1897) found that *P. replicata* (Figure 18) larvae eat *Warnstorfia exannulata* (Figure 20). They described pupae that attach to the moss leaves by dorsal appendages on posterior segments. The females lay about 60 eggs in **axils** (upper angle between leaf stalk or branch and stem from which it grows) of the moss leaves.

Figure 20. *Warnstorfia exannulata*, food for *Phalacrocer replicata* (Figure 18). Photo by Michael Lüth, with permission.

Byers (1961) reported that the larvae of *Liogma* (Figure 21) use bryophytes for their larval habitats. Larvae of the genera *Liogma* and *Triogma* (Figure 17) have a green color with markings that make them look like leafy mosses (Gerson 1969). These two genera live among and eat the mosses *Rhytidiadelphus squarrosus* (Figure 22) and *Hypnum cupressiforme* (Figure 23). Larvae of *Triogma trisulcata* (Figure 17) inhabit the brook moss *Fontinalis antipyretica* (Figure 5) in mountain streams (Alexander 1920). These larvae have appendages that resemble leaves on a branch, and the color is typically green and black.

Limoniidae – Limoniid Craneflies

The **Limoniidae** (Figure 24) family is an offshoot of the **Tipulidae** and thus many of the taxa discussed here were originally reported as members of **Tipulidae**. They are a worldwide family, mostly aquatic, and of moderate size (Limoniidae 2015). Their feeding groups vary considerably, including **phytophagous** (eating plants), **saprophagous** (eating dead organisms), **mycetophagous** (eating fungi), and **carnivorous** (eating animals) species.

Figure 24. **Limoniidae** adults mating, a family with larvae that often live among mosses, some consuming them. Photo by Anki Engström at <www.krypinaturen.se>, with permission.

From Cape Town, South Africa, we have a report of the **Limoniidae** occupying mosses in the stream of an isolated mountain (Harrison & Barnard 1972). The genus *Geranomyia* **rostrata** (see Figure 25) lives among algae, wet mosses, and thallose liverworts in the eastern part of North and South America (Rogers 1927; Johannsen 1969). These larvae are greenish and **translucent** (allowing light but not clear images to pass through), slow movers, and herbivores on algae and moss (Johannsen 1969). *Geranomyia* **sexocellata** (see Figure 25) larvae live in a gelatinous tube made with minute sand grains and attached to mosses in waterways that are only trickles.

By contrast, *Dicranomyia* **capicola** (syn. of *Limonia* **capicola**?; see Figure 26) larvae live among mosses at the edge of a rapidly flowing streamlet (Harrison & Barnard 1972) and larvae of *Limonia* sp. and *Ormosia* sp. (Figure 28) live among bryophytes in Appalachian Mountain streams (Glime 1968). Harrison and Barnard (1972) also found *Elephantomyia* **aurantiaca** (see Figure 29) larvae among the damp mosses and liverworts.

Several researchers have reported *Limonia* species from bryophytes (Byers 1961; Hilsenhoff 1975; Suren 1991). Suren (1991) found that *Limonia* **hudsoni** (see Figure 27) apparently required more from the bryophytes than just a substrate. It failed to colonize the artificial bryophytes in his New Zealand stream studies. Instead, Suren and Winterbourn (1991) reported that it actually commonly consumes bryophytes. Apparently artificial ones couldn't fill the bill.

Figure 29. *Elephantomyia westwoodii* adult female; larvae live among damp mosses and liverworts. Photo by Robert Lord Zimlich, through Creative Commons.

An important use of bryophytes can be that of providing a place for them to emerge. *Rhipidia maculata* emerges from the stream bed and also from thin moss layers on exposed rocks (Needham 1908; Johannsen 1969).

In my studies of Appalachian Mountain stream moss communities, both *Hexatoma* cf. *longicornis* and *H.* cf. *spinosa* occurred among the leafy liverworts *Scapania undulata* (Figure 30) (Glime 1968). *Hexatoma* (Figure 31- Figure 32) is known to ingest mosses (Percival & Whitehead 1929), so perhaps it is looking for food.

Figure 31. *Hexatoma* larva; some members of this genus eat mosses. Photo by Jason Neuswanger, with permission.

Figure 32. *Hexatoma (Eriocera) gravelyi* male adult. Photo by Muhabbet Kemal, with permission.

Limnophila occurs among bryophytes in several locations (Alexander 1919; Hilsenhoff 1975). In the Appalachian Mountain streams several species occur among the bryophytes, including *L.* cf. *macrocera* (Glime 1968). *Limnophila allenii* (see Figure 33) lays its eggs

among mosses (Alexander 1919). Lauga and Thomas (1978) found that **Limoniidae** in France were more likely to be found among bryophytes when it was time for pupation and molting. The same relationship was seen for members of **Athericidae** and **Rhagionidae** (**Brachycera**).

Figure 33. *Limnophila* larva, member of a genus known to lay eggs in mosses. Photo by Tom Murray, through Creative Commons.

Erioptera (Figure 34), *Pseudolimnophila* (Figure 35), and *Pilaria* (Figure 36) in Wisconsin, USA, use mosses among their larval substrata (Hilsenhoff 1975). Byers (1961) reported that the larvae of *Erioptera* and *Gonomyia* (Figure 37) use bryophytes as larval habitats. In the Appalachian Mountain streams (USA), one can find the genus *Antocha* (Figure 7) (Glime 1968), a genus found in similar habitats in Japan.

Blanket bogs have their own fauna, some of which is unique. Larvae that live in these habitats in Dartmoor, UK, include *Molophilus occultus* (Figure 38) whose larvae seem to require areas of bare, wet peat where they live in litter and among mosses (Boyce 2011). But this genus can also be found among bryophytes in Appalachian Mountain, USA, streams (Glime 1968). *Phylidorea squalens* (Figure 39) larvae in the Dartmoor blanket bogs live in the bog pools.

Figure 39. *Phylidorea squalens* adult male, a species whose larvae live in bog pools. Photo by James K. Lindsey, with permission.

Pediciidae – Hairy-eyed Craneflies

The **Pediciidae** occur in the temperate zones of both hemispheres (Kits 2005b). These are medium to large (20-35 mm) flies (Pediciidae 2014) that resemble craneflies.

Pedicia (Figure 40) (now placed in **Pediciidae**) is one of the craneflies found among mosses as larvae (Figure 41) in some streams in the Appalachian Mountains, USA (Glime 1968). Hilsenhoff (1975) reported the genus in Wisconsin, USA, where it includes mosses among its substrata.

Figure 41. *Pedicia albivitta* larva, member of a genus of moss dwellers. Photo by Jason Neuswanger, with permission.

Tipulidae – Craneflies

This is a worldwide family that occupies a wide range of habitats as larvae, from water to mosses to dry logs (Hofsvang 1997). As adults they live only a few days and

may not eat. That's right, they are not giant mosquitoes and won't bite you! But they do look like giant mosquitoes, with long legs and bodies 7-35 mm long (Tipulidae 2014), but narrow. Unlike the **Limoniidae**, the **Tipulidae** (Figure 42) are mostly terrestrial. Their larval food choices include algae, microflora, and both living and decomposing plant matter, including wood.

Figure 42. The crane fly *Tipula* occurs frequently among leaf litter that it helps to shred by eating it, but it can also occur among submerged and moist moss clones where its ecological role is unknown. Photo by Janice Glime.

The **Tipulidae** accomplish most of their respiration by using a posterior respiratory apparatus (Figure 43-Figure 44) (Pritchard 1983). They have a single pair of spiracles located there. The spiracles can't be closed, but there are tiny hairs on the walls of the spiracle opening that reduces water loss. There also seems to be cuticular respiration.

Figure 43. Larva of *Tipula* showing respiratory apparatus at right. Photo from Beentree, through Creative Commons.

Figure 44. Respiratory apparatus with spiracles of *Tipula* sp. Photo from Beentree, through Creative Commons.

Egg-laying (Figure 45) of tipulids on bryophytes has been known for a long time. For example, Alexander (1919) reported that *Tipula nobilis* laid her eggs in moss. Females already have mature eggs when they emerge from the pupa and after copulation they deposit them on wet soil or algae, or drop them (Tipulidae 2014). These eggs are usually black and may have a thin thread that could help to attach them in the water.

Figure 45. Crane fly laying eggs in submerged mosses. Photo by Janice Glime.

Tipulidae adults look like giant mosquitoes because of their long legs (Figure 46). In some regions they are known as daddy-long-legs for the same reason, but these are not to be confused with the 8-legged daddy-long-legs that are arachnids. Many **Tipulidae** live among aquatic leaf litter and mosses as larvae. Likewise, most of them pupate in soil near water, in mosses, or in litter (Byers 1978, 1996; Erman 1984).

Figure 46. *Tipula* adult. Photo by Micka 972, through Creative Commons in <Omnilexica.com>.

Larvae of crane flies are highly susceptible to desiccation (Pritchard 1983) and bryophytes seem to be an important habitat for maintaining moisture in bog species and terrestrial species. *Tipula montana* burrows into mosses when it is disturbed (Smith *et al.* 2001). *Dolichopeza* (Figure 77) species select their moss habitat for its suitability for making burrows (Byers 1961). The crane fly larvae seem to prefer compact mosses rather than loose ones in the same species (Todd 1993).

Tipula ignobilis occurs throughout the year among mosses on boulders in a Tennessee, USA, springbrook

(Stern & Stern 1969). Slightly farther north in the Appalachian Mountains, I found what appeared to be seven different species of *Tipula* among bryophytes in the 28 streams I studied, including *Tipula collaris* (Figure 47) (Glime 1968). At Barrow, Alaska, USA, *Tipula carinifrons* (Figure 48) is common in the dry moss hummocks (MacLean 1980).

Figure 48. *Tipula carinifrons* adult male, a common species in dry moss hummocks of Alaska. Photo by Ashley Bradford, through Creative Commons.

Byers (1961) listed bryophytes as the larval habitat of many *Tipula* species. The genus *Tipula* is typically a consumer of leaf litter. But mosses can be a major part of the diet in some species. Dangles (2002) found that in the four study streams of Vosges Mountains in northeastern France bryophytes comprised 96% of the diet of *Tipula* (*Savtshenka*) (Figure 49).

Figure 49. *Tipula* (*Savtshenkia*) adult, a genus in which the larvae can eat considerable amounts of bryophytes. Photo by James K. Lindsey, with permission.

Tipulidae larvae commonly feed on mosses (Coulson 1962; Freeman 1967; MacLean 1980; Richardson 1981; Todd 1993), and these mosses often form a significant portion of the diet (Coulson 1962). Larvae of *Tipula signata* (Figure 50) feed on aquatic mosses (Hemmingsen 1965).

Figure 50. *Tipula signata* adult male, a species whose larvae eat aquatic mosses. Photo by James K. Lindsey, with permission.

Tipula montana is a bog dweller and is surrounded by bryophytes as a larva. Smith *et al.* (2001) experimented with food preference in larvae of this species. The research team gave the larvae trials with five individual species of mosses, then with two-species pairs, to determine their growth responses and preferences. Larvae grew on diets of each of the five species of mosses [*Racomitrium lanuginosum* (Figure 51), *Dicranum fuscescens* (Figure 52), *Sphagnum girgensohnii* (Figure 53), *Pleurozium schreberi* (Figure 54), and *Polytrichum commune* (Figure 55)], but there was a wide range in which mean weights differed by a factor of two. The highest development rate, by far, was for larvae fed *Pleurozium schreberi*, with nearly 50% reaching the fourth instar, whereas fewer than 5% of those fed on the other moss species reached that stage (Figure 56). *Pleurozium schreberi* also was the best moss for promoting growth, with weight gain double that of larvae fed on *Sphagnum girgensohnii* (Figure 57). Nevertheless, there was little difference among the survivorships of the larvae fed on each on the five mosses (Figure 58). But the larvae preferred *Racomitrium*

lanuginosum to the other mosses and often avoided *Pleurozium schreberi* when given a choice (*Sphagnum girgensohnii* was the least preferred). This avoidance of *Pleurozium schreberi* is likely because of the high phenolic content (compounds that taste bad, including tannic acid) of *P. schreberi* (Liao 1993; Glime 2006; Hribljan 2009; see chapter 10-3 on Isopoda in this volume).

Smith *et al.* (2001) issued a note of caution: The fecal indications of moss herbivory did not match the observational data. They suggested this may have been due to behavior differences between the larvae and the observers. The observers noted feeding behavior between 8:30 hours and 19:30 hours, but the larvae may have been feeding actively above ground at night, with daylight causing them to avoid the greater exposure on the sedge *Carex bigelowii*. This could explain the estimated lower percentage of *Carex bigelowii* in the observed diet in the field when using observations, and accounting for the higher percentage of *Dicranum fuscescens* (Figure 52) in the observations when compared to the ratio in the feces. Ratios of other mosses were similar using both methods. In the field, when *Carex bigelowii* was readily available, it was the clear choice compared to the mosses. The researchers also concluded that the bryophytes may be more important as a refuge than as a food source in nature. As pointed out by the researchers, experiments in which

development and growth on the sedge compared to those of the mosses would be instructive. It may be that the best growth is on a combination of these, with reduced growth or development resulting when no mosses are eaten. On the other hand, avoidance of predators may force the larvae to remain among the mosses and to eat them in the daytime. Several birds are primary predators on these larvae (Galbraith *et al.* 1993; Nethersole-Thompson 1966).

Tipula subnodicornis (Figure 59) feeds on liverworts in British moorland blanket bogs and consumes large quantities of *Sphagnum* (Figure 53, Figure 69) leaves (Coulson 1962; MacLean 1980). MacLean estimates that more than 25% of the energy consumption may be derived from the living plants of *Sphagnum*.

Figure 59. *Tipula subnodicornis* adult, a crane fly whose larvae feed on liverworts in British blanket bogs but seem to have little preference in experiments with moss species. Photo by James K. Lindsey, with permission.

In the genus *Tipula*, later instars ingest only slightly more vegetable matter as they grow to larger and larger instars. Rather, the early and late instars ingest similar-sized particles. In feeding experiments, Todd (1993) found that *Tipula confusa* (Figure 60) preferred woodland moss species, whereas *T. subnodicornis* (Figure 59) showed no preference between woodland and moorland mosses. *Tipula confusa* had a hierarchical preference among the 10 moss species offered, whereas *T. subnodicornis* showed much less hierarchy in food choices. Brindle (1960) noted that *T. subnodicornis* (Figure 59) typically associates with wet species such as those of *Sphagnum* (Figure 69) and *Hypnum* (Figure 23) in moorlands. Among 11 species Todd (1993) studied, 8 were moss consumers, with 7 of these in the same subgenus *Savtshenkia* (*Tipula rufina* (Figure 61), *T. confusa*, *T. pagana* (Figure 62), *T. staegeri*, *T. limbata* (Figure 63), *T. alpium* (Figure 64), and *T. subnodicornis*). Brindle (1960) had earlier observed that all the moss feeders known to him had four pairs of short anal papillae, whereas in wetter environments these papillae were longer. The eighth, *T. montana* is in the subgenus *Vestiplex*. In Great Britain, approximately one-fourth of the 59 (Freeman 1967) members of *Tipula* feed on mosses. Even the invasive species *Campylopus introflexus* (Figure 65) is *Tipula* food in the recently

burned *Calluna* heath. *Tipula montana* in the upland moors feeds exclusively on mosses.

Figure 60. *Tipula confusa* adult; larvae eat mosses, preferring woodland species. Photo by Malcolm Storey, through Creative Commons <www.discoverlife.org>.

Figure 65. *Campylopus introflexus*, an invasive species that has become a food source for *Tipula* larvae in the *Calluna* heath. Photo by Michael Lüth, with permission.

The insect **feces** (excrement; waste material discharged from gut) reveal a great deal about the use of mosses as food (Todd 1993). The particle size remains the same in the feces as it was in the cut ingested portion (Pritchard 1983). Interior cells of the pieces are significantly less damaged (Todd 1993). Instead, digestion appears to be limited to the broken cells on the edges, with little or no damage caused by passage through the gut. This inability to obtain nutrients from the interior cells accounts for the consistency in small-sized particles from early to late instars. The particle sizes are significantly smaller for *Tipula rufina* (Figure 61), *T. lateralis* (Figure 66), and *T. subnodicornis* (Figure 59); *T. paludosa* (Figure 67) and *T. oleracea* (Figure 68) ingest significantly larger particles than any other species. These differences are at least partly explained by mandible size. *Tipula paludosa* has significantly larger mandibles and *T. rufina* has significantly smaller ones than any other species. In short, those species feeding on grass are generally larger and have longer mandibles than those species feeding on mosses.

Figure 66. *Tipula lateralis* adult, a species whose larvae ingest small particle sizes. Photo by James K. Lindsey, with permission.

Figure 68. *Tipula oleracea*, a bryophyte consumer that ingests large particles. Photo by Malcolm Storey, through Creative Commons <www.discoverlife.org>.

Tipula has both terrestrial and aquatic members. Some of these in both habitats consume bryophytes. But *Tipula subnodicornis* (Figure 59) prefers the cottongrass *Eriophorum vaginatum* to the terrestrial moss *Campylopus paradoxus* and bog moss *Sphagnum papillosum* (Figure 69) (Todd 1993). However, in early winter (10 December to 9 January) the preference changes significantly from cottongrass to *Sphagnum papillosum*. It is interesting, however, that during the growing season there is a mix of *Eriophorum vaginatum* with *S. papillosum* where the larvae spend the most time.

Figure 69. *Sphagnum papillosum*, a moss that becomes a preferred food in winter for *Tipula subnodicornis*. Photo by Michael Lüth, with permission.

Bisang (1996) reports a rather bizarre experience in The Bryological Times. She had several cultures of *Anthoceros agrestis* (Figure 70) and *Phaeoceros carolinianus* (Figure 71), both hornworts. Using the same techniques as she had used previously, she cultured these in jars, keeping two in Switzerland and taking one to Sweden. To her surprise, one of the cultures in Switzerland and the one taken to Sweden virtually disappeared from the jar. They had not dried and sabotage seemed absurd. Careful examination revealed larvae 1.5 cm long with a breathing apparatus at the posterior end. The cultures were supporting a healthy colony of larvae of *Tipula* (Figure 42), craneflies. The hornworts seemed to be a preferred

food, as *Bryum* (Figure 72) sp. and several seedlings were untouched.

Figure 70. *Anthoceros agrestis*, food source for *Tipula* larvae. Photo by Jan-Peter Frahm, with permission.

Figure 71. *Phaeoceros carolinianus*, food source for *Tipula* larvae. Photo by Michael Lüth, with permission.

Figure 72. *Bryum capillare*. A species of *Bryum* was refused as food by larvae of a species of *Tipula*. Photo by Aimon Niklasson, with permission.

The members of *Tipula* are among the few documented moss consumers, although there is much more consumption than is generally recognized. Todd (1993) suggested that the presence of cell wall bioflavonoids in bryophytes might function not only to resist fungal invasion (Geiger 1990), but also to discourage insect

browsers. It is also possible that in some cases the fungi are needed to facilitate digestion, making mosses that lack them indigestible. Furthermore, lignin-like compounds in the bryophyte cell walls protect the cell wall compounds (cellulose, hemicellulose, and other kinds of polysaccharides) from **hydrolytic attack** (using a chemical reaction where something reacts with water and is changed into a new substance), preventing the consumers from using hydrolytic attack to extract cell contents, as demonstrated in *Tipula abdominalis* (Figure 75) (Martin *et al.* 1980). Nevertheless, in North America the genus *Tipula* (Figure 75) is able to hydrolyze proteins from unconditioned maple (*Acer*) leaves (Barlocher & Porter 1986).

Suitable food sources often depend on *pH* of the gut (Martin *et al.* 1980). Very high and very low *pH* levels seem to work best. But Barlocher and Porter (1986) found that the larvae of *Tipula caloptera* (Figure 73) have a gut *pH* that is somewhat alkaline. Fungal carbohydrases ingested with the leaves do not remain active in the *T. caloptera* gut, but do in the nearly neutral *pH* of the amphipod *Gammarus tigrinus* and net-spinning caddis larva *Hydropsyche betteni* (Figure 74).

Figure 73. *Tipula caloptera* adult female. Larvae of this species have an alkaline gut that may help it digest plant material. Photo by Tom Murray, through Creative Commons.

Figure 74. *Hydropsyche betteni* larva, a species with a slightly alkaline gut and ability to keep fungal enzymes alive. Photo by Donald S. Chandler, with permission.

In *Tipula abdominalis* (Figure 75) the midgut has a *pH* near 11.5 in a narrow section where there is extremely high proteolytic activity (Martin *et al.* 1980). In addition to low *pH* created by *Sphagnum* (Figure 69) and other mosses, mosses are well known for their antibiotics (McCleary *et al.* 1960; McCleary & Walkington 1966), additional factors that might interfere with gut digestion.

Figure 75. *Tipula abdominalis* larva. Larvae have a high *pH* in the midgut. Photo by Tom Murray, through Creative Commons.

Dolichopeza (Figure 77) is a genus known from mosses in various parts of the world. *Dolichopeza americana* is generally considered to be a terrestrial larva (Byers pers. comm.), but in the Appalachian Mountain streams it occurs among the leafy liverworts (*Scapania undulata*; Figure 30) in small waterfalls in March and December (Glime 1968). *Dolichopeza albipes* (see Figure 77) is a white-footed ghost crane fly whose larvae live among the mosses and liverworts of the Ghyll woodlands in Sussex, UK (Roper 2001). But this genus also chooses mosses for home in South Africa (Harrison & Barnard 1972). Members of this genus are known to lay their eggs among bryophytes, giving these larvae their start in life among the bryophytes.

Dolichopeza barnardi, *D. hirtipennis*, and *D. peringueyi* larvae live beneath and within cushions of wet mosses and liverworts at the sides of waterfalls in South Africa (Harrison & Barnard 1972). And in North America, the genus feeds on terrestrial mosses (Byers 1961). In the coastal tundra near Barrow, Alaska, *Prionocera recta* (Figure 76) is restricted to mossy depressions.

Figure 76. *Prionocera turcica* adult, relative of *P. recta* restricted to mossy depressions in the Alaskan tundra. Photo by Andre Vrigens, through Creative Commons.

Figure 77. *Dolichozepe carolus* adult. Larvae of several species in this genus live among mosses, including at the sides of waterfalls. Photo by Tom Murray, through Creative Commons.

Many of the **Tipulidae** that inhabit mosses as larvae do so among terrestrial bryophytes and will be discussed in a separate chapter on Terrestrial Insects.

Anisopodidae – Wood Gnats, Window Gnats

This family is worldwide, but bryophytes are not a usual habitat. Most are small (4-12 mm) (Anisopodidae 2014). Fungi are typical foods, but it appears that at least some feed on micro-organisms, as I have observed.

While looking for mosses one day, I found some (*Philonotis fontana*?; Figure 78) in a seepage area on a cliffside. There on one of its branches was a small larva eating away at the wet moss. But as I watched for awhile, I realized that the mosses were going into one end of the larva covered with detritus and coming out the other end clean and still bright green. I was unable to identify this single larva beyond family.

The larvae of *Sylvicola cinctus* (Figure 79) was reported from mosses in Norway (Søli 1992). Perhaps there are other members of this small family hiding among the bryophytes.

Axymyiidae

This is a small family of six known species (Axymyiidae 2014). Its limited distribution is Holarctic and Oriental (Hauser 2008). The larvae live in decomposing wood (Axymyiidae 2014).

Figure 79. *Sylvicola cinctus* male adult, a species whose larvae live among bryophytes in Norway. Photo by Walter Pfliegler, with permission.

I have seen only one record from this little-known family. *Axymyia furcata* (Figure 80) is a semi-aquatic fly in its larval stage and is typically a wood inhabitant. However, Wihlm and Courtney (2011) found that the larvae often choose logs that are covered with mosses.

Figure 80. *Axymyia furcata*, a semi-aquatic larva that lives among mosses on logs. Photo by M. J. Hatfield, through Creative Commons.

Cecidomyiidae – Gall Midges, Gall Gnats

This family is worldwide with most records in the Northern Hemisphere. They are small flies, mostly 1-5 mm (Balaban & Balaban 2004). Most of these are gall makers, with their larvae living on the gall material, but some feed on plants and some on decaying matter. Hence, as one might expect, they are predominantly terrestrial, but there are aquatic exceptions.

Although the **Cecidomyiidae** (Figure 81) are not typical bryophyte inhabitants, some do prefer mosses in torrents (Thomas 1980). *Porricondyla ramadei* was described as a new species from tufts of mosses in the turbulent waters of high Pyrénées streams. This is a poorly known fauna, and it is likely more insects may be discovered among the bryophytes there.

Figure 81. **Cecidomyiidae** larva; some members of this family live among mosses in torrents. Photo by M. J. Hatfield, through Creative Commons.

Mycetophilidae – Fungus Gnats

As the name implies, these flies live among fungi, hence making them most common in damp or sometimes wet habitats (Mycetophilidae 2014). They are worldwide, especially in forested areas (Kits 2005a). Although they are worldwide, most records are in the Northern Hemisphere (Mycetophilidae 2015). They typically feed on the fruiting bodies of the fungi (Mycetophilidae 2014). But some live among mosses and liverworts.

Fungi are often moist, so it may not be so surprising that some of these fungus gnats have found bryophytes to be suitable habitats. *Gnoriste apicalis* (Figure 82) is a semi-aquatic species. The larvae are able to live in saturated moss clumps on lake shores (Lenz 1927; Johannsen 1969). The pale green coloring may help it to be inconspicuous as it feeds on detritus. It may also make a dense but delicate white web in which it lives in such habitats, with the web offering further camouflage.

Sciaridae – Dark-winged Fungus Gnats

As you might expect of a fungus gnat, these flies prefer moist sites and eat the fruiting bodies of mushrooms and various parts of other fungi (Sciaridae 2014). They are worldwide in distribution, including such extremes as deserts, sub-Antarctic islands, and altitudes over 4000 m.

Because they live among litter and fungi, they are frequent in flower pots. They are small, up to 7 mm long.

Figure 82. *Gnoriste* sp. adult; larvae of *Gnoriste apicalis* live in saturated mosses. Photo from Biodiversity Institute of Ontario, through Creative Commons.

In Korea, Japan, China, and other parts of Asia, the shiitake mushroom business is important. To this end, studies on the pests of this delicacy are common. And sometimes we find that mosses are involved. Shin *et al.* (2012) found that one of the mushroom pests, *Bradysia difformis* (Figure 83), also occurs in moorland on peat moss.

Figure 83. *Bradysia difformis*, a shiitake mushroom pest whose larvae sometimes live on peat mosses of moorlands. Photo by David Pilling, with permission.

Ceratopogonidae – Biting Midges, No-see-ums, Sand Flies, Punkies

Their small size (<3 mm) has earned the **Ceratopogonidae** such names as no-see-ums and the adults can be quite a nuisance along lakes in June and July (Moisset 2005). Their distribution is worldwide in salt and freshwater marshes, forests, edges of ponds, and streams.

Usinger (1974) lists mosses among the usual habitats for larvae in the **Ceratopogonidae** and Krno (1990) found them to be representative of bryophyte habitats in the River Rajcianka in Slovakia. In addition to those aquatic

members, *Forcipomyia* (Figure 84) species live among damp mosses, including building nests in *Sphagnum* species (Figure 69) (Oldroyd 1964). The larvae in this family are elongate, wider in the middle, and most of them lack legs (Usinger 1974).

Figure 84. *Forcipomyia* sp larvae – inhabitants of damp mosses. Photo by Tom Murray, through Creative Commons.

In Germany, *Kolenohalea calcarata* occurs among mosses in a spring and *Serromyia femorata* (Figure 85) occurs among damp mosses (Strenzke 1950).

Figure 85. *Serromyia femorata* adult, a damp moss dweller. Photo by James K. Lindsey, with permission.

In the Atlantic Forest of the coastal area of South America, *Ceratopogonidae* were second in dominance during the rainy season among mosses in a first-order stream (Rosa *et al.* 2011). Living among the bryophytes minimizes the downstream loss in fast-moving water.

In European alpine areas, *Dasyhelea modesta* (see Figure 86-Figure 87) and *Bezzia xanthocephala* (see Figure 88) use mosses for their pupal site (Thienemann 1936). *Dasyhelea* (Figure 87) larvae likewise can spend their lives among mosses. The species known to Thienemann as *Culicoides neglectus* (*nom. dub.* – a name without valid publication) lived as pupae among mosses in small alpine waterfalls. (This name is now excluded, so I can't be sure what species he found.) Species in *Culicoides* as it is currently known are the ones that bite humans (Moisset 2005).

Figure 87. *Dasyhelea lithotelmatica* larvae, member of a genus that frequents stream bryophytes. Photo by Roger S. Key, with permission.

Figure 88. *Bezzia* larva, a frequent inhabitant of stream bryophytes. Photo from California Department of Wildlife, through public domain.

In my Appalachian Mountain, USA, streams, I found at least two species of *Bezzia* (Figure 88), two of *Dasyhelea* (Figure 86-Figure 87), and one each of *Alluaudomyia* (Figure 89) and *Atrichopogon* (Figure 90)

among the bryophytes. These were mostly among *Hygroamblystegium fluviatile* (Figure 91) – *Platyhypnidium riparioides* (Figure 6), but also occurred among *Fontinalis dalecarlica* (Figure 92) and *Scapania undulata* (Figure 30).

Summary

The **Nematocera** are primarily aquatic as larvae and a number of species and genera live among bryophytes. Adaptations to the bryophyte habitat, differing little from those needed for aquatic living, include claws and hooks to hold them in place, cutaneous breathing and/or gills, small size, often slender, and a detritus feeding habit. In return for the hospitality of the bryophyte, they may disperse bits of the plants or their spores to other suitable locations.

The dominant **Diptera** among bryophytes are **Chironomidae** and **Simuliidae**, with **Tipulidae**, **Limoniidae**, and **Ceratopogonidae** being less abundant. The **Chironomidae** can reach 1000's in a single handful of moss.

The **Cylindrotomidae** are among the few bryophyte mimics. They live among mosses in wet areas and bogs and the projections from their bodies resemble moss leaves.

In the genus *Tipula* (**Tipulidae**), a high gut *pH* may facilitate digestion of bryophytes.

Acknowledgments

George W. Byers verified my identifications of Tipulidae and Julian P. Donahue verified some of the remaining Diptera from my mid-Appalachian Mountain study.

CHAPTER 11-13b

AQUATIC INSECTS: HOLOMETABOLA – DIPTERA, SUBORDER NEMATOCERA

Figure 1. **Chironomidae** larvae, the most common and abundant family of insects among mosses. Photo by Simon Carmichael, through Creative Commons.

Suborder Nematocera, continued

Chironomidae – Midges

These small flies are 1-10 mm long and are everywhere (Cotinis 2004)! Only some areas of the desert seem to lack them. They are the flies that seem to follow you as clouds (swarms). The larvae are mostly aquatic and use filter feeding.

If you haven't met the **Chironomidae**, you haven't looked at the bases of aquatic moss leaves. Hynes (1961) considered the **Chironomidae** (Figure 1) to be the "key industry" organisms among mosses. Such a concept is supported by their role as food for fish. Johannsen (1969) contended that in some locales they may constitute almost the entire diet of brook trout (*Salvelinus fontinalis*). But

the mosses provide excellent hiding places for these larvae, so the bryophytes may be a detriment rather than a source of fish food.

Thienemann (1936) reported many **Chironomidae** from mosses in the alpine areas of Europe. These occurred in springs, waterfalls, bogs, and streams. The **Chironomidae** are by far the most numerous organisms in most stream bryophyte habitats (Arnold & Macan 1969; Gerson 1982; Maurer & Brusven 1983; Brusven *et al.* 1990; Glime 1994; Chantha *et al.* 2000; Linhart *et al.* 2002a), typically comprising more than 50% of the insects living there (Brusven *et al.* 1990). Needham and Christenson (1927) reported *Chironomus* (Figure 1) and

Tanytarsus (Figure 2) from moss-covered boulders in streams of northern Utah, USA. Frost (1942) found that among submerged mosses she studied in Ireland, about five-sixths of the almost 600,000 organisms in those streams were **Chironomidae**. Lindegaard *et al.* (1975) found that more than 40% of the invertebrates living among the moss *Cratoneuron* (Figure 3) were **Chironomidae**.

Figure 3. *Cratoneuron commutatum* var *falcatum* in Europe, a habitat where many **Chironomidae** live among the mosses. Photo by Michael Lüth, with permission.

Chironomidae (Figure 1) can reach 100,000 in a collection of *Cratoneuron* (Figure 3) (Gerson 1969). Frost (1942) found that in an acid stream the **Chironomidae** comprised 84% of the moss fauna; in the alkaline stream they comprised 83%. Haefner and Wallace (1981) found that this family had mean annual densities of 23,000 m² among the thick mosses of rockface habitats in a southern Appalachian, USA, stream. Brusven *et al.* (1990) reported that moss clumps had insect communities in which 50% of the organisms were **Chironomidae**. These did not seem to contribute to increased daytime drift.

Boerger *et al.* (1982) found that densities of **Chironomidae** (Figure 1) on mosses in a brown-water stream of Alberta, Canada, were high (978) compared to a

range of 32-466 on tracheophytes, sponge colonies, and algae. But diversity was only 3 species on mosses, compared to 13 for sediment, 2 for *Sparganium*, and 1 for the other tracheophytes, algae, wood, and none for sponges and leaf litter.

Nolte (1991) found that the **Chironomidae** (Figure 1) in the mosses of a small upland stream in central Germany were small, with 98% being <5 mm. There were more than 65 species in 26 genera! The greatest diversity was near the source and the species changed downward in the stream. The fully submersed mosses had approximately five times as many larvae as those that were semi-submersed. The highest density reached 830 larvae per 10 square cm. Nolte found that the location of the moss in the stream had the greatest effect on the diversity, but the biomass and abundance were most influenced by the constancy of flow and factors such as temperature and detritus deposition that related to flow.

In most locations, species of bryophyte doesn't seem to matter much. In the Appalachian Mountain streams of eastern USA, they were abundant in all three dominant species: *Fontinalis dalecarlica* (Figure 4), *Hygroamblystegium fluviatile* (Figure 5) – *Platyhypnidium riparioides* (Figure 6), and *Scapania undulata* (Figure 7).

Emergence

Some **Chironomidae** (Figure 1) use the mosses for emergence. Adults of *Microtendipes pedellus* (Figure 8) emerged from both mossy and muddy substrates in a Quebec highland stream (Harper & Cloutier 1979). The researchers suggested that some typically lentic (non-moving water) chironomid species were able to live in the protection of mosses in streams. The huge numbers found there and in other habitats result in clouds of adults during emergence time (Figure 9).

Figure 8. *Microtendipes pedellus* adult, a midge that often uses mosses for emergence. Photo through Wikimedia Commons.

Figure 9. **Chironomidae** adult swarm. Photo by Robert Janke, with permission.

Unger (1974) reared *Boreochlus* sp. (Figure 10) from mosses in a bog near Washington, D.C., USA. Becker and Wagner (2004) compared the emergence of **Chironomidae** (Figure 1) from sand and moss-covered rocks in a stream in Germany. They recorded 99 species from the sand traps and 85 from the traps over the moss-covered stones! The **Tanytarsini** (Figure 2) dominated in the traps on the moss-covered stones, whereas the **Prodiamesinae** and **Chironomini** predominated in traps above sand. They suggested that the smaller number of species above the moss-covered rocks may have been due to escapes from the nets on the irregular surfaces with lower flow rates trapping more pupae over the sand.

Figure 10. *Boreochlus sinuaticornis* larva, member of a genus that lives among bryophytes in bogs. Photo by Pete Cranston, with permission.

In Appalachian Mountain, USA, streams, the **Chironomidae** make thin cases for their pupae between the upper and lower leaves of the leafy liverwort *Scapania undulata* (Figure 7) (Glime 1968). One larva even crawled into an empty case of the caddisfly *Paleagapetus celsus* to pupate, a case made from *Scapania undulata*. The leaves of this liverwort also provide a location where one can find larvae and eggs of the midges.

Seasons

The **Chironomidae** (Figure 1) are present year-round, but the taxa change. For example, among bryophytes in an Atlantic Forest stream (biome along the Atlantic coast of Brazil from Rio Grande do Norte in the north to Rio Grande do Sul in the south), Rosa *et al.* (2011) found that **Chironomidae** were dominant in both periods of study (3 months each of dry season and rainy season). In the dry season, the **Naididae** (annelid worms) were second in number.

Pseudodiamesa branickii (Figure 11) demonstrates the variability in life cycles of some **Chironomidae**. This species produces three generations in one year in a German stream, but the generation time varies based on photoperiod effects on eggs and larvae (Nolte & Hoffmann 1992). In this stream there are two strains, one that is **bivoltine** (producing two broods per season) and one that is **trivoltine** (producing three broods per season).

Figure 11. *Pseudodiamesa branickii* larva, a species with at least two strains that differ in the length of the life cycle. Photo by Erik Bostrom, NTNU Museum of Natural History and Archaeology, through Creative Commons.

Temperature differences can cause differences in emergence times. For example, in the high Arctic, **Chironomidae** (Figure 1) from deeper water emerge as much as three weeks later than those in warmer shallow water (Danks & Oliver 1972). Among the 112 species of **Chironomidae** in a muskeg stream in Alberta, Canada, emergence extends over 140 days. In New South Wales, emergence (Figure 12) is governed by flooding, with *Chironomus tepperi* (Figure 13) emerging first and *Procladius paludicola* (see Figure 14) emerging as the former declines (Stevens 1994).

Figure 14. *Procladius lugens* adult. *Procladius paludicola* is a later emerger than *Chironomus tepperi*, thus separating their niches. Photo by James K. Lindsey, with permission.

Differences in emergence times can maintain the isolating mechanism that keeps species distinct, as in two sibling species of **Chironomus** (Figure 15) in Arctic ponds (Butler 1982). Although the two species are morphologically indistinct as larvae, they maintain strict, but different, emergence times, despite 7-year developmental periods.

Cold-water Species

Cold temperatures seem to favor some of the **Chironomidae** (Figure 1). Welch (1976) found that *Orthocladius* (Figure 16), *Pseudodiamesa arctica* (see Figure 11), *Paracladius quadrinodosus* (see Figure 17), and *Micropsectra*(?) sp. (Figure 18) occur primarily in the rocky and moss zones. They are able to withstand temperatures down to 0°C, which is important for their life cycle of 2-3 years. The genus *Diamesa* (Figure 19-Figure 20) is common among mosses of European glacier-fed streams where the temperature is constantly less than 2°C (Lods-Crozet *et al.* 2001). Elgmork and Sæther (1970) found it among mosses in creeks and springs in the Colorado Rocky Mountains, USA. It is able to overwinter under the snow (Anderson *et al.* 2013).

Macropelopia notata (Figure 21) and *M. adauca* are cold-water species that are **crenobionts** (living in springs) (Fittkau 1962). They prefer mosses in soft water. *Macropelopia notata* occurs in **rheo-hygropetric** springs (flowing film of water on rocks in springs) and **helocrenes** (springs originating from marshes or bogs) with abundant mosses (Lencioni *et al.* 2011). In the Danish spring

Ravnskilde, Lindegaard *et al.* (1975) found large numbers of *Macropelopia notata* in the moss carpets. These carpets exhibit both vertical and horizontal zonation patterns that do not seem to be influenced by the fauna of the neighboring stone. Rather, horizontal distribution seems to result from differences in current velocity and detritus capture.

Figure 21. *Macropelopia notata* adult, a species whose larvae live among mosses in springs. Photo by James K. Lindsey, with permission.

In the Antarctic, mosses often play a role in protecting invertebrates from the harsh and changeable environment. The **Chironomidae** (Figure 1) are no exception, living among bryophytes in a first-order stream of the Atlantic Forest (Tilbrook 1967; Rosa *et al.* 2013). The mosses are able to provide protection from the rushing waters during periods of higher rainfall, and the high retention of food particles support both species richness and density during the high rainfall periods.

Parochlus steinenii (Figure 22) is a chironomid of lakes in the central plateau of the Byers Peninsula, Antarctica (Rico & Quesada 2013). It lives among the mosses on the bottoms of lakes and streams. The second of the two chironomids in that part of Antarctica is *Belgica antarctica* (Figure 23) that lives in streams that run through moss beds. Both species feed on a variety of foods associated with the biofilm and microbial material among the mosses.

Overwintering

Some **Chironomidae** larvae become encased in ice in winter, yet survive, an ability that is rare among the insects (Moore & Lee 1991). Although this seems only to be known where they can live in sediments of pools and ponds, it is possible that they likewise do this among sediments collected by bryophytes. Irons *et al.* (1993) found that **Chironomidae** (Figure 1) in Alaska, USA, are able to overwinter in a frozen habitat.

Frost (1942) found that the chironomid larvae in her River Liffey, Ireland, survey reached their peak in winter in the moss samples.

Current Velocity

Many of the **Chironomidae** (Figure 1) live in areas of high water velocity, but are protected from it by the bryophytes. They are able to nestle at leaf bases where they benefit not only through protection from the current, but also from the collection of detritus there. Oliver and Bode (1985) described a new species of *Cardiocladius* (Figure 24) that resembles *Cardiocladius albiplumus* among bryophytes where the current velocities are 20-100 cm s⁻¹.

Figure 24. *Cardiocladius* adult, a genus that has larvae that sometimes live among bryophytes. Photo by M. J. Hatfield, through Creative Commons.

Diversity

The **Chironomidae** do not lack species diversity among bryophytes (see Table 1). In a mountain river in the Western Tatra Mountains, Ertlova (1984) found 56 species. The most varied species composition occurred among mosses on large stones. The dominant species was *Orthocladius rivicola* (Figure 25).

Figure 25. *Orthocladius rivicola* larva, a moss inhabitant. Photo from Stroud Water Research Center, through Creative Commons.

The **Chironomidae** is a large family and its species are difficult to identify. Few people attempt the identification of larvae (Figure 1). Most ecologists simply indicate **Chironomidae**. This results from the difficulty of finding distinguishing characters between related species and the need to rear them before a name can be applied and the larva described. For example, *Krenosmittia* (Figure 26) larvae are known in Europe from springs and moss-filled seeps (Ferrington 1984). The habitat of North American larvae is unknown, although adults are known, but the habitat is likely to be similar, or they might occur in the **hyporheic** zone (area or ecosystem beneath bed of river or stream, saturated with water and supporting invertebrate fauna) of streams. Creating a list of bryophyte taxa is further complicated by changing views of the classification. For many of the taxa in Table 1 I was unable to verify the name or find the name currently in use.

A few brave souls have done the tedious work to provide species lists of **Chironomidae**. In their study of the Colorado Rocky Mountain, USA, streams, Elgmork and

Sæther (1970) identified a number of **Chironomidae** (Figure 1) species among mosses. These included *Pseudokiefferiella parva* (Figure 27) in creeks and springs, and occasionally *Orthocladius* (Figure 16). Among the mosses of high mountain brooks they found *Metriocnemus* (Figure 28), *Parakiefferiella*, and *Rheocricotopus effusus* (see Figure 29). *Paraphaenocladius* (Figure 30), a primarily terrestrial genus, can also occur in bogs and among mosses of mountain creeks, particularly cold springs. They found species of *Nanocladius* (Figure 31) in their streams, but did not mention mosses; *Nanocladius bicolor* lives among mosses in high mountain creeks in Europe (Thienemann 1954; Freeman 1956). Likewise, *Thienemannia* cf. *gracilis* (see Figure 32), present in their study, is known among mosses in mountain creeks (Thienemann 1954; Brundin 1956a, b) and among perennial mosses in a river in Romania (Gardenfors 2001). Frost (1942) was also among the brave who identified the **Chironomidae** among the mosses in the River Liffey, Ireland. Including both an acid and an alkaline area, she found 24 genera, many different from those of Elgmork and Sæther (1970) in the Rocky Mountain, USA, streams, as seen in Table 1.

Suren (1993) considered that the dominance of **Chironomidae** (Figure 1) among New Zealand mosses may reflect the absence in New Zealand of some of the important moss families of **Ephemeroptera**, **Plecoptera**, and **Trichoptera** in other parts of the world.

Bryophyte Preferences?

Like the **Chironomidae** (Figure 1), the mosses are difficult for non-bryologists to identify and few studies actually name both the mosses and the **Chironomidae** associated with them. In the pristine streams of the Russian Karelia, Vuori *et al.* (1999) found that algae-eating **Chironomidae** larvae dominated the insect fauna in stable lake outlets where mosses formed abundant vegetation. The mosses were predominantly *Fontinalis* (Figure 4) and *Hygrohypnum* (Figure 56). *Cricotopus* sp. (Figure 38) and *Thienemannimyia* sp. (Figure 57) were the dominant **Chironomidae**.

Figure 56. *Hygrohypnum ochraceum*, home of **Chironomidae**. Photo by Michael Lüth, with permission.

Figure 57. *Thienemannimyia* larva posterior, a moss dweller. Photo by Pete Cranston, with permission.

In their study of an Arctic stream (Alaska, USA), Lee and Hershey (2000) found that **Chironomidae** increased in density when the mosses (*Hygrohypnum*, Figure 56) increased to dense growths. They suggested that it was the increase in habitat complexity that caused the increase in the **Chironomidae**.

In New Zealand, the **Chironomidae** (Figure 1) were most abundant in *Fissidens rigidulus* (Figure 58) in the midstream torrential water, whereas other taxa dominated in mosses of the spray zones (Cowie & Winterbourn 1979).

What's for Dinner?

Aside from nematodes and rotifers, the **Chironomidae** were the dominant fauna in beds of *Fontinalis antipyretica* (Figure 59) in the Czech Republic, making them the most abundant insect group (Linhart *et al.* 2000, 2002a,c). Those among mosses had a positive density correlation with organic particles of 30-100 μm . Some **Chironomidae** larvae build tubes to trap detritus (Figure 60). In one rip-rapped channel (used to stabilize the stream banks) in the Czech Republic, Linhart *et al.* (2002b) found the fine particulate matter trapped by the moss provided a food source for the moss dwellers. Unlike those in many mossy habitats, the **Chironomidae** comprised only 4.08% of the fauna, outnumbered by rotifers and nematodes. They concluded that the rip-rap rocks, covered with mosses, increased both stability and diversity of the streams.

Figure 60. These tubes of **Chironomidae** are often present among mosses. The larvae live near the bottom of the moss clump and trap detritus in the net or use the moss as a trap, using the detrital matter for food. Photo by Janice Glime.

Smirnov (1961) concluded that no abundant insects fed on mosses in bogs, but *Psectrocladius psilopterus* (Figure 61) – a chironomid larva, ate the *Sphagnum* (Figure 62). There is some evidence that bryophytes may serve insects as emergency foods or provide an important part of the diet, albeit in small proportions.

Figure 61. *Psectrocladius sordidellus* emerging female adult. Larvae of *Psectrocladius psilopterus* eat *Sphagnum*. Photo by James K. Lindsey, with permission.

Figure 62. *Sphagnum capillifolium*, member of a genus that is eaten by *Psectrocladius psilopterus* in bogs. Photo by Blanka Shaw, with permission.

Although **Chironomidae** (Figure 1) feed predominately on the detritus among the mosses, they consume mosses as well (Kalachova *et al.* 2011). This consumption may actually be moss components of the detritus. Using acetylenic acids as biomarkers from the moss *Fontinalis antipyretica* (Figure 59), Kalachova *et al.* (2011) demonstrated this chemical group in the **Chironomidae**, especially in winter when other food sources, especially zoobenthos and biofilms, become scarce.

Parasite Protection?

Mosses might offer an advantage unknown in most habitats. They protect their guests from parasitic mites. In Luxembourg, two species of *Chaetocladius* (Figure 63) were free of water mite parasites (Stur *et al.* 2005). Stur *et al.* suggested that the semiterrestrial lifestyle of these insects among the mosses made them less available to the

mite larvae. On the other hand, moss dwellers like *Tvetenia calvescens* and *T. bavarica* (see Figure 64-Figure 65) did have mite parasites in the springs where they lived. Of the **Chironomidae** species examined, those free of mites lived in bryophyte habitats where the numerous generalist parasitic mites *Sperchon thienemanni* (see Figure 66) and *Atractides fonticolus* were not likely to occur.

Refuge in Bryophytes

Not only do the bryophytes provide a refuge among their leaves, but some Chironomidae use bryophytes to make a case and others **pupate** (Figure 67) among the leaves (Suren 1988). But Humphries and Frost (1937) found few pupae of **Chironomidae** (Figure 1) among the mosses in the River Liffey in any season, despite the huge numbers of larvae. Rather, most pupae are free-living in the open water (Armitage *et al.* 1995).

Figure 67. **Chironomidae** pupa, a rare find among bryophytes. Photo by Jason Neuswanger, with permission.

Tube Makers

It is not unusual for **Chironomidae** larvae to make tubes. However, *Eukiefferiella endobryonia* (Figure 68) is unusual (Imada 2020). It lives in streams among the leaves of *Fontinalis dalecarlica* (Figure 69) and *Fontinalis novae-angliae* (Figure 70) and feeds on the leaves (Figure 71). It makes its "tubes" (more like a case) for pupation by

binding together a case from the leaves of *Fontinalis* (Figure 72), a truly aquatic moss. The third instar larva may use feces of mature larvae to build its case (Figure 73), but the fourth instar larva uses *Fontinalis* spp. leaves exclusively and it remains attached to the apical shoot of the moss (Figure 74-Figure 75). The larvae pupate in this moss case. Debris and other materials are deposited at one end of the case as the larva changes into a pupa (Figure 76-Figure 77). There are few other chironomids that make tubes exclusively of plant materials.

Culicidae – Mosquitoes

Although most mosquitoes are small, they can range 3-15 mm long (Bartlett 2004a). They are distributed worldwide and the larvae live almost anywhere there is quiet water. These larvae are able to feed on algae, Protozoa, and organic debris that is filtered from the water. Only a few are predaceous.

Bryophytes are not typical habitats for the mosquitoes. Nevertheless, Elgmork and Sæther (1970) found that *Aedes excrucians* (Figure 78; a woodland mosquito that bites humans) occurred in bog pools and occasionally among *Sphagnum* mosses (Figure 79).

Simuliidae – Blackflies

These are small flies, 1-5.5 mm (Kits 2005). They are best known for their nasty bite that leaves the wound bleeding due to an injection of an anticoagulant, although most species get their blood meal from birds. Although they are more abundant at higher latitudes, their distribution is worldwide in rapid, cold water. They are filter feeders and must therefore live on the surface of the substrate.

In the right habitat, blackfly larvae occur in large numbers (Figure 80). Blackfly larvae require fast flowing water where they can get sufficient oxygen and trap their food with their large head fans. Carlson (1967) suggested that at depths within 10 cm of the surface, the bryophytes offer a preferred habitat for the **Simuliidae**. In suitable sites, they can be quite dense; e.g., one blade of grass 1 cm wide and 15 cm long can hold 300-800 *Simulium vittatum* (Figure 81) larvae (Anderson & Dicke 1960).

Figure 80. **Simuliidae** larvae on rock, showing how dense they can be. Photo by Janice Glime.

Figure 81. *Simulium vittatum tribulatum* complex larva, an abundant species on some bryophytes. Photo by D. S. Chandler <www.discoverlife.org>, through Creative Commons.

They are adapted to such sites by a circle of hooks on the abdominal posterior and on the prolegs, facilitating their anchorage (Arnold & Macan 1969). They furthermore produce silken threads that serve as anchors and that they use to cover the surfaces of stones to make a small mat to anchor themselves (Arnold & Macan 1969; Tarshis & Neil 1970). When water flow is stopped in a stream, larvae form both single silken threads and cables. The latter, supporting the greatest numbers of blackflies, reveal 25-50 threads with the larvae attached in concentric rings around the threads and cables (Tarshis & Neil 1970). The threads can be more than 1 m long and facilitate regaining the original position when falling from it or travelling to a new one (Rubtsov 1962). Tarshis and Neil (1970) observed a spectacular display of threads ranging 1-8 m long!

Many blackflies overwinter in the egg stage (e.g. *Simulium venustum* (Figure 82), *S. vittatum* (Figure 81)), but others hatch as early as December. Hatching of the eggs is apparently dependent on temperature, as noted in this family in Wisconsin, USA (Anderson & Dicke 1960). Larval development takes several weeks, 4-5 at temperatures of ~15-20°C, but the pupal stage is brief, lasting only 5-7 days. Wolfe and Peterson (1959) reported a unique use of stems of dead mosses to form the stalk on the pupal cocoon of *Ectemnia invenusta* (Figure 83). Depending on the local species, late summer and autumn often lack blackflies in bryophyte collections; at this time

some species are either in egg or adult stages (Anderson & Dicke 1960).

Figure 83. *Ectemnia invenusta* larva, a blackfly that uses dead mosses to form its pupal stalk. Photo by Tom Murray, through Creative Commons.

Needham and Christenson (1927) reported **Simuliidae** from mosses in streams in northern Utah. In the Plitvice Lakes National Park in the Dinaric **karst** (landscape underlain by limestone eroded by dissolution, producing ridges, towers, fissures, sinkholes, *etc.*) region of Croatia, the **Simuliidae** showed a statistically significant preference for moss on **tufa** [porous limestone formed from calcium carbonate (CaCO_3) deposited by springs *etc.*] and pebbles (Čmrlec 2013). This family is known from every continent but Antarctica (Clifford 2014).

In their experiments on the effects of phosphorus on Arctic streams, Lee and Hershey (2000) found that the moss *Hygrohypnum* (Figure 56) increased, forming dense growths. As one might expect, this changed the structure of the insect communities. Whereas some may have benefitted from an increase in periphyton abundance as a food source, the **Simuliidae** were apparently not affected by these changes. Since these larvae live at the surface and collect food from the passing water, the increased habitat complexity of the mosses did not change the available habitat for them.

In a Polish river, blackflies were in greater numbers on the tracheophyte *Potamogeton* than on the brook moss *Fontinalis* (Figure 59) (Niesiołowski 1980). Niesiołowski attributed this to the differences in leaf size and position that permitted the blackflies to live both at the water surface and on any of the lower leaves of *Potamogeton*. Blackflies are restricted to the surface region of the substrate where they can use their head fans to filter algae from the passing water, and in mosses this prevents them from living in the interior of the moss clumps.

Crosskey (1990) describes larvae in this family, stating that they use mosses as larval food as well as a substrate. As adults they use the mosses for mating.

The blackflies do not seem to be able to sort the food flowing by them. Anderson and Dicke (1960) found that all the food available in the flowing water was also present in the gut. In addition to these, the guts contained the diatoms *Rhoicosphenia* spp. (Figure 84) and *Cocconeis* spp. (Figure 85). The latter is a common diatom adhering to moss leaves (*pers. obs.*).

Figure 85. *Cocconeis placentula*, a diatom that embeds itself in the surface of bryophyte leaves and also serves as food for blackflies in streams. Photo by Ralf Wagner at <<http://www.dr-ralf-wagner.de/>> (Mikroskopie).

Simulium

These larvae can be quite dense on their substrate. For example, *Simulium pictipes* is common in the eastern USA where larvae attach to bedrock of swift-flowing streams, especially below waterfalls (Kurtak 1974) where the water is well oxygenated. These larvae congregate, forming dense patches with as many as 50 individuals per cm². Members of this species, and most blackflies, overwinter as larvae and are among the most abundant insects in winter. Reisen and Prins (1972) found that *Simulium* increased in the drift as the temperature increased. This genus has a low tolerance for temperatures above 16°C.

Butcher *et al.* (1937) suggested that *Simulium equinum* (Figure 86) apparently does not occur among mosses because it was absent in the River Tees above Croft. But Frost (1942) found it among mosses in the River Liffey, Ireland, in alkaline waters, along with *S. ornatum* (Figure 87). In acid waters of the same river she found *S. venustum* (Figure 82) and *S. latipes* (Figure 88) on bryophytes. Pentelow (1935) likewise found *S. equinum* in alkaline waters. But in a different river he found *S. ornatum*, likewise in alkaline water.

Figure 88. *Simulium latipes* adult, a blackfly of mosses in acid waters. Photo by James K. Lindsey, with permission.

Simulium cataractarum (Figure 89), as its name implies, lives in waterfalls. It seems to play it safe, living primarily on the wet mosses on the rock wall beside the main waterfall Schroeder 1988).

Figure 89. *Simulium cataractarum* devouring an *Ephydriidae* larva. Photo by Simon Pollard, Department of Biological Sciences, University of Alberta, Canada.

In studying blackflies in Utah, USA, Peterson (1956) found that *Simuliidae* avoid algae-covered rocks and sticks. Rather, the dominant *Simulium* species occur primarily on rocks that are covered with mosses and the alga *Vaucheria*. Peterson found that these larvae would scrape algae and other food items from the surrounding substrate. But when only slimy algal films cover the rock, they are unable to attach. In his study of New York, USA, blackflies, Jamnback and Stone (1955) found several bryological associates. *Simulium fibrinflatum* (Figure 90) occurred on mosses at several locations, but also occurred on twigs and other types of vegetation.

Figure 90. *Simulium fibrinflatum* larva, a moss-dweller in streams in New York, USA. Photo by Donald S. Chandler, with permission.

In the Appalachian Mountain streams this family is common among the bryophytes, repeating many of the species reported by other studies in North America and Europe. These include *Simulium* cf. *gouldingi*, *S. impar*, *S. parnassum*, *S. tuberosum* (Figure 91), *S. venustum*-*S. verecundum* complex (Figure 82), and *S. vittatum* (Figure 81). The most widespread of these is *S. tuberosum*, appearing among all the common bryophytes: *Fontinalis dalecarlica* (Figure 4), *Hygroamblystegium fluviatile* (Figure 5) – *Platyhypnidium riparioides* (Figure 6), and *Scapania undulata* (Figure 7).

Figure 91. *Simulium tuberosum*, the most common blackfly on mosses and liverworts in Appalachian Mountain, USA, streams. Photo by Tom Murray, through Creative Commons.

The **Simuliidae** require a relatively rapid flow rate. For *Simulium ornatum* (Figure 87) this is a rate of at least 20 cm/sec in order to filter enough food items from the water using their head fans (Figure 92) (Harrod 1965). For *Simulium*, these head fans catch algal cells, especially diatoms, but also trap fragments of mosses and leaves [Puri 1925; Percival & Whitehead 1929 (*S. reptans*); Jones 1949, 1950]. Fredeen (1960, 1964) fed several members of *Simulium* [*S. venustum* (Figure 82), *S. verecundum* (Figure 82), *S. vittatum* (Figure 81), *S. arcticum*] on three species of bacteria as food and concluded that bacteria form an important food base for these blackflies in some streams. In these experiments, *Simulium arcticum* did not develop past the last larval instar, but all the others reached the adult stage. *Simulium venustum*, *S. verecundum*, and *S. vittatum* are widespread and commonly abundant species (O'Kane 1926; Anderson & Dicke 1960); bryophytes are not a unique habitat for them.

Hynes (1970) noted that members of the genus *Simulium* are able to coexist due to developmental timing. *Simulium reptans* and *S. variegatum* exemplify such timing differences with large larvae of one coexisting with small larvae of the other. In this way they don't compete for the same food sizes.

Peterson (1956) observed the emergence of *Simulium vittatum* (Figure 81). These newly emerged adults took flight almost immediately when they broke through the surface tension of the water, but they soon alighted to dry their wings. Others [*S. vittatum*, *S. decorum* (Figure 93- Figure 94)] crawled out of the water onto various substrata to dry their wings before their first flight.

Figure 92. **Simuliidae** larva head showing head fans that are used to trap food. Photo by Bob Henricks, with permission.

Figure 93. *Simulium decorum* larvae, blackflies that crawl out of the water to dry their wings before flight. Photo by Whitney Cranshaw, through Creative Commons.

Figure 94. *Simulium decorum* pupa with thin cocoon. Photo by Whitney Cranshaw, through Creative Commons.

As one might expect for a fly whose larvae live on mosses, the adults use them for egg-laying sites (Baba &

Takaoka 1989). *Simulium japonicum* and *S. rufibasis* both laid eggs on bryophytes on a water-splashed boulder. These were laid individually in the upper 5 cm of water.

Females seem to have some difficulty in laying their eggs where there is sufficient oxygen because these locations have high water velocity. Peterson (1956) observed several that dived into the water and reappeared 70 cm downstream. Several were washed downstream. Some of these flies seem to have two options – dropping eggs into the water while in flight and letting them settle to the bottom or climbing/diving into the water and depositing the eggs on a substrate. Surely these flies fare better when they choose bryophytes for their egg-laying.

Figure 95. Blackfly (*Simuliidae*) larvae attach by tiny posterior hooks in fast current. Their heads with head fans point downstream and trap small particles of detritus, bacteria, algae, and even mosses for food. Photo by Janice Glime.

Figure 96. These blackfly larvae (*Simuliidae*) are just as common on these mosses as they often are on rocks in fast water. Larvae of the blackflies, *Simuliidae*, can use leaves of *Fontinalis* (Figure 59) in place of the usual net-like cocoon used to house the pupa. Photo by Janice Glime.

Prosimulium

Prosimulium was a common genus among the bryophytes in my Appalachian Mountain stream study. Krno (1990) likewise found it among bryophytes in the River Rajcianka in Slovakia.

Prosimulium fontanum lives in forest and bog-fed streams (Davies & Syme 1958) where *Sphagnum* (Figure 62) influences the pH in the latter and may be an important

determinant of habitat suitability. This species commonly pupates in *Fontinalis* (Figure 59). Its cocoon is the least developed of all the *Prosimulium* species in three Ontario, Canada, streams.

It appears that this genus builds its cocoons based on flow rate and abrasive potential (Davies & Syme 1958). *Prosimulium fuscum* (Figure 97) lives in the fastest, most abrasive water of the three species studied and builds the strongest cocoon. The second in line is that of *P. mixtum* (Figure 98), an inhabitant of slower streams, that builds a somewhat weaker cocoon. Of these three, *P. fontanum* makes the weakest cocoon.

Figure 97. *Prosimulium fuscum*, a species that lives on bryophytes in very fast water. Photo by Donald S. Chandler, with permission.

Figure 98. *Prosimulium mixtum* larva lives on bryophytes in slower streams than those of *Prosimulium fuscum*. Photo by Donald S. Chandler, with permission.

The genus *Prosimulium* was common among bryophytes in Appalachian Mountain, USA, streams (Glime 1968). The most common was *Prosimulium hirtipes* (Figure 99-Figure 100, appearing among all the common mosses: *Fontinalis dalecarlica* (Figure 4), *Hygroamblystegium fluviatile* (Figure 5) – *Platyhypnidium riparioides* (Figure 6), and *Scapania undulata* (Figure 7). Others included *P. magnum* (mostly on *Hygroamblystegium fluviatile*), *P. mixtum* (Figure 98), and *P. rhizophorum*.

Figure 99. *Prosimulium hirtipes* among leafy liverworts. Photos by Janice Glime.

Figure 100. *Prosimulium hirtipes* is a common blackfly on stream mosses. Photos by Janice Glime.

Prosimulium hirtipes (Figure 99-Figure 100) avoids rocks with algal layers in a Utah, USA, stream, instead occupying those with mosses or the filamentous alga *Vaucheria*. In the mid-Appalachian Mountain streams, this species reaches its greatest abundance on the leafy liverwort *Scapania undulata* (Figure 7) (Glime 1968). In May one could find numerous pupae attached to the curled tips of the liverwort on both upper and lower surfaces. In June it was *Simulium tuberosum* that pupated there. This is a highly seasonal family, disappearing from June until the eggs hatch again in the cold water of late autumn (Davies *et al.* 1962).

Although some insects empty the gut rapidly, *Prosimulium hirtipes* (Figure 99-Figure 100) requires more than a week to empty its gut at 49-50°C (Davies 1949). Peterson (1956) found that at a lower temperature (4.4-10°C) it likewise takes more than a week for them to empty the gut. They can fill their guts in 20-26 hours (Davies 1949). This may permit them to digest intransigent materials that drift into their head fans.

Prosimulium hirtipes (Figure 99-Figure 100), *P. tomosvaryi*, and *P. subrufipes* use moist terrestrial mosses, mostly *Brachythecium rivulare* (Figure 101), for egg deposition, laying them about 20 cm above the streams (Davies 1949). Unlike those of many of the *Simuliidae*, the eggs are deposited in batches, sometimes quite large ones with as many as 56×10^6 eggs. These eggs cannot survive complete desiccation, hence the need for mosses. Many eggs hatch in response to the diminishing temperatures and rainfall that saturates the mosses. But

others actually stay in the mosses and hatch in spring. The first instar larvae lack the distinctive head fans needed for filter feeding. Instead, the first instar feeds as a scraper in a stage that lasts 5-11 days at 10°C.

Figure 101. *Brachythecium rivulare* at the edge of a stream where some species of blackflies lay eggs. Photo by Janice Glime.

Prosimulium kiotoense in a stream on Kyushu Island, Japan, likewise oviposits among mosses on riverbank rock surfaces (Baba & Takaoka 1991). Although the eggs are laid singly, so many females select the same site that the eggs soon form large, irregular masses. These blackflies select dense bryophyte cover 0-15 cm above the water instead of depositing eggs in the water. Eggs are laid in late April when the air temperature rises to approximately 15°C. It appears that this above water position is sufficient to keep the eggs moist while they develop, permitting the larvae to take advantage of the June rainy season (and perhaps warmer temperatures for development).

Cnephia/Metacnephia

I found larvae of *Cnephia mutata* (Figure 102) among mosses in my Appalachian stream study, but they were not as abundant as *Prosimulium* (Figure 97-Figure 100) or *Simulium* (Figure 86-Figure 95) (Glime 1968). Other aquatic bryophyte habitat studies I have found do not mention them.

Figure 102. *Cnephia* adult; larvae of *C. mutata* occasionally occur among mosses in mid-Appalachian, USA, streams. Photo by Sam Houston, with permission.

Meissner *et al.* (2009) conducted a fascinating experiment that explains the interesting relationship of the blackfly larvae of *Metacnephia pallipes* with the predator caddisfly *Rhyacophila nubila* (Figure 103) in Europe. In the absence of the predator, these blackflies show no preference between rocks and mosses. *Rhyacophila nubila* prefers stones only when the flow is slow. But, when *R. nubila* is present, the blackflies prefer mosses – the preferred habitat of the caddisfly! This seeming lapse in judgment by the blackflies must be examined in 3-d. The *M. pallipes* occupies the tips of branches, placing them at the surface of the moss clump, whereas *R. nubila* occupies the bases where they are protected from the rapid flow. When they attack the blackflies, the latter typically let go and enter the drift. If they are fast enough, they escape predation. They fully colonize artificial bryophytes (Finnturf) in only one day. The caddisflies are most successful in prey capture at intermediate velocities. For the blackflies to be safe from predation, they require velocities of 100 cm sec⁻¹. The blackflies are a preferred food because they have high fat reserves (Wotton 1982; Crosskey 1990) and in this case seem to be the only food (Meissner *et al.* 2009).

Stegopterna

Pupae of the *Stegopterna mutata* complex (Figure 104-Figure 105) are often concealed among mosses in streams in Pennsylvania, USA (Adler & Kim 1986). Moving to mosses to pupate makes it easier for the adult to break through the surface tension to emerge.

Figure 104. *Stegopterna*, a genus that often moves to mosses to pupate. Photo courtesy of the State Hygienic Laboratory, University of Iowa, with permission.

Figure 105. *Stegopterna mutata-diplomutata* complex, with larvae that move to mosses to emerge from streams in Pennsylvania, USA. Photo by Donald S. Chandler, with permission.

In Slovakia, in the River Rajcianka, Krno (1990) found the genus *Odagnia*, a genus I have not found elsewhere in preparing for this chapter.

Thaumaleidae – Trickle Midges

These are little fellows, 2-4.5 mm long (Carr 2013). They live mostly in the temperate areas of both hemispheres where their larval habitats are predominantly in vertical, thin water films alongside waterfalls and torrents where they are able to graze on diatoms.

Curran (1927) described *Thaumalea* adults (Figure 106) as occurring along streams, particularly those bordered by mosses. In the Appalachian Mountains, USA, I occasionally found larvae of this genus (Figure 107) among the stream mosses (Glime 1968). They may be more abundant among bryophytes elsewhere – typical stream sampling methods are likely to miss them in this habitat.

Figure 107. *Thaumalea* larva, an occasional bryophyte dweller. Photo by J. C. Schou, with permission.

Psychodidae – Moth Flies and Sand Flies

Larvae of this species are 3-10 mm long, but adults are smaller (1.5-4 mm) (Bartlett 2004b). They are worldwide,

but they are most common in the tropics. The larvae live mostly in organic sludge where they feed on algae, fungi, and bacteria, but a few wander into clean water where bryophytes may provide a habitat.

Unger (1974) included mosses of quiet or slow-moving streams and splash areas among the typical habitats for members of this family in California, USA.

In Britain, the moss *Leptodictyum riparium* (Figure 108) has gotten the reputation of being a nuisance moss because of the **Psychodidae** and **Chironomidae** (Kelly & Huntley 1987). These insects breed in the organic and other particulate matter trapped by this moss in the brewery channels, causing swarms of insects.

Figure 108. *Leptodictyum riparium*, a stream and lake moss that is home for such nuisance **Diptera** as **Psychodidae** and **Chironomidae**. Photo by Michael Lüth, with permission.

Thorup (1963) found *Pericoma blandula* (Figure 109), a detritus feeder, living among mosses in a Danish springs. Satchell (1949) reported breeding of *Pericoma* among damp mosses. It, like other moss dwellers, has only one generation per year (**univoltine**) (Thorup 1963). The temperature among the mosses in the springs has almost no annual variation. Omelkova and Ježek (2012) likewise found this widespread European species among mosses in the Czech Republic in both shaded and unshaded habitats.

Figure 109. *Pericoma blandula* adult female; larvae live among mosses. Photo by Walter Pfliegler, with permission.

Pericoma fallax is a moss dweller that occurs in Europe and western Siberia where it is common in both shaded and unshaded habitats of ponds, swampy meadows, bottomlands of brooks, and reservoirs. In the streams of the Appalachian Mountains, USA, its larvae are fairly frequent among *Hygroamblystegium fluviatile* (Figure 5) and *Platyhypnidium riparioides* (Figure 6) colonies but not among those of the leafy liverwort *Scapania undulata* (Figure 7) or the large moss *Fontinalis dalecarlica* (Figure 4) (Glime 1968).

Both larvae and pupae of *Pericoma* (Figure 110) live in damp sites at the banks of streams in the UK, with mosses being a common habitat, sometimes with several species in a small (several meters) area (Satchell 1949; Roper 2001). *Pericoma albitarsis* lives among mosses in streams and among wet mosses near waterfalls (Johannsen 1969). In a Tennessee, USA, springbrook, this species lives among mosses and algae (Stern & Stern 1969; Stern & Stern 1969). The larvae of this genus are substrate feeders that eat the path in front of them (Vaillant 1959). They are able to do this even on a moss substrate. Vaillant found larvae of *Pericoma marginalis* and *Telmatoscopus* sp. (Figure 111) on a dripping rock cliff among mosses where diatoms were abundant. Egglshaw (1969) reported a species of *Pericoma* as being restricted to moss. In the southern Appalachian Mountains, Haefner and Wallace (1981) found that densities of *Pericoma* were five times as high in moss-covered outcrops compared to non-moss areas of a first-order stream.

Figure 111. *Telmatoscopus* (*Clogmia*) larva. Some members live on dripping cliffs among mosses. Photo by Ashley Bradford, through Creative Commons.

In the Ghyll woodlands of Sussex, UK, several other members of this family are moss dwellers (Roper 2001). These include *Bazarella neglecta* larvae among mosses around mill races and waterfalls. *Bazarella subneglecta* is an uncommon Eurasian species from hygropetric (water on a vertical surface) ones with moss cushions, spring areas, and brooks (Omelkova & Ježek 2012). Ježek *et al.* (2012) reported *Peripsychoda fusca* from Czech Republic and Slovakia wetland habitats that have moss cushions and leaf packs.

Larvae of the moth fly *Sycorax silacea* (see Figure 112) live on wet stones and mosses near cascades, springs, and "trickles" (Jung 1958; Andersen 1992). Omelkova and Ježek (2012) reported this species from European spring areas and from mosses in running water habitats and their "neighborhoods." The ornate larvae in this genus are protected from would-be predators by mimicking mosses (Roper 2001).

Figure 112. **Psychodidae** larva, a family that occurs among bryophytes in small numbers. Photo by Erin Hayes-Pontius, through Creative Commons.

Jungiella longicornis is widely distributed in Europe and western Siberia, living in both unshaded and shaded stream banks among moss cushions, as well as in ponds and forest seepages (Omelkova & Ježek 2012). *Satchelliella crisp*i inhabits decaying organic matter in Europe, typically in leaf packs or moss cushions near springs and streams. *Satchelliella pilularia* is widespread in Europe, but is nevertheless relatively rare; its larvae live among mosses in running water of springs and streams from lowlands to mountains.

Ulomyia fuliginosa (Figure 113) is among the most common of European **Psychodidae** (Omelkova & Ježek 2012). It lives among mosses in running water where it associates with detritus and in springs, streambanks, marshes, swampy meadows, and forest pools.

Figure 113. *Ulomyia fuliginosa* adult, a species whose larvae live among mosses in running water. Photo by James K. Lindsey, with permission.

Berdeniella (Figure 114) larvae are also known to live among mosses (Troiano 1981) and are particularly abundant in alpine streams (Withers 2005). Wagner *et al.* (2011) contend that this genus lives exclusively among partly or totally inundated mosses at the shoreline of cold mountain streams in Central Europe, based on their study of the Breitenbach. In these habitats they found *B. illiesi*, *B. manicata*, and *B. unispinosa*.

Summary

The two most common dipteran bryophyte dwellers are the **Chironomidae** and **Simuliidae**. The **Chironomidae** in particular can have many species within a single stream. **Chironomidae** have a wide range of habitats and temperatures and are tolerant of low oxygen and slow flow. **Simuliidae**, on the other hand, require cold temperatures and rapid flow with high oxygen content. **Chironomidae** eat mostly detritus that they can scavenge from that trapped by the bryophytes or available in the sediments, whereas the **Simuliidae** filter the detritus and microalgae from the water using their head fans.

Both families can overwinter among the bryophytes as larvae and emerge in spring or early summer. Both use the bryophytes for emergence, but the **Simuliidae** commonly pupate there whereas the **Chironomidae** are more common in open water as pupae.

Bryophytes can serve as a refuge from predators for both families. And in some cases, it appears that the bryophytes may protect the **Chironomidae** larvae from parasites, although the mechanism is unclear.

Other **Nematocera** of families of much less importance include the **Culicidae** (quiet water), **Thaumaleidae** (beside waterfalls), and **Psychodidae** (quiet or slow-moving water).

Acknowledgments

Douglas M. Davies verified the Simuliidae and Julian P. Donahue verified some of the remaining Diptera from my mid-Appalachian Mountain study. Eileen Dumire helped me pull the numerous **Chironomidae** from the bryophytes. She proofread the chapter and offered suggestions to make it clearer.

CHAPTER 11-14

AQUATIC INSECTS: HOLOMETABOLA – DIPTERA, SUBORDER BRACHYCERA

Figure 1. *Limnophora* sp. larva (**lower**) and pupa (**upper**) (**Muscidae**), occasional bryophyte inhabitants. Photo by Stephen Moore, Landcare Research, NZ, with permission.

DIPTERA – FLIES

Suborder Brachycera

This suborder is less aquatic than the **Nematocera**. Furthermore, few of its members use aquatic bryophytes. Nevertheless, it is a convenient way to break up the chapter into shorter segments.

Athericidae/Rhagionidae – Watersnipe Flies

The larvae of these flies occur in pristine streams with the adults nearby (Kits 2005). They include predaceous members that eat other invertebrates, including caddisflies, and saprophagous members on wooden debris (Athericidae 2014). The larvae are distinguished by **crochets** on their abdominal prolegs (Figure 2), permitting them to live in rapid montane streams and torrents without being washed away.

Figure 2. *Atherix ibis* larva showing crochets in two rows in each proleg. Photo by Urmas Kruus, with permission.

This family is not well represented among bryophytes. *Atherix ibis* (Figure 3) includes bryophytes among its substrates in streams (Neveu 1976). The larvae eat small invertebrates (McLeod 2005), most likely finding the bryophytes to serve as an adequate dinner table. In Carpathian streams, this species is positively correlated with stream order and warmer water temperatures (Bulánková & Duricková 2009). Its eggs are laid on overhanging leaves and hatched larvae slide into the water; the larvae are henceforth very sensitive to desiccation. They are, however, quite tolerant of human activity and pollution.

Figure 3. *Atherix ibis* larva, a stream-dweller that can be found among bryophytes. Photo by Niels Sloth, with permission.

In the acid streams in the Appalachian Mountains, USA, *Atherix variegata* occurred in all of the common moss habitats [*Fontinalis dalecarlica* (Figure 4), *Hygroamblystegium fluviatile* (Figure 5), *Platyhypnidium riparioides* (Figure 6), and *Scapania undulata* (Figure 7)] (Glime 1968).

Figure 7. *Scapania undulata*, home to *Atherix variegata* in Appalachian Mountain streams. Photo by Michael Lüth, with permission.

In the Plitvice Lakes National Park in the Dinaric karst region of Croatia, the *Athericidae* preferred moss on tufa ($P < 0.05$, $n = 12$) (Čmrlec *et al.* 2013). These flies pupate on mosses, and that substrate is the preferred substrate for emergence of the adults (Thomas 1997; Čmrlec *et al.* 2013).

Spaniidae/Rhagionidae

This family, well known from records in amber, exhibits only scattered records throughout the world today (Arillo *et al.* 2009). Roper (2001) reported the bryophyte dweller *Spania nigra* (Figure 8), a snipe fly, from ghyll (deep ravine) woodlands in Sussex, UK (Roper 2001).

Dolichopodidae – Long-legged Flies

These are small (1-9 mm) flies with a worldwide distribution (Dolichopodidae 2015). The larvae are predominantly terrestrial, but there are also many semi-aquatic taxa that live in or near water margins. Some can even walk on the water surface. Larvae are typically predatory, although a few live in the stems of reeds and other monocots near water.

Figure 8. *Spania nigra* adult, a species with a larval bryophyte dweller in Sussex. Photo by Marko Mutanen through Creative Commons.

This family does not seem to be reported as a moss dweller, but it does occasionally live among mosses in the Appalachian Mountain, USA, streams (Glime 1968). I was able to identify *Hydrophorus* larvae (Figure 9-Figure 10) in these collections. But it is also possible that they fell in or got swept in by flooding.

Figure 9. *Hydrophorus oceanus* larvae, member of a genus that sometimes occurs among stream bryophytes. Photo by Hans Hillewaert, through Creative Commons.

Empididae – Dance Flies

These are small flies with a worldwide distribution and that can be aquatic, but can also live in semiaquatic habitats, in dung, in bird nests, among roots, and associated with fungi (Cresswell 2004). Larvae mostly feed on decaying matter, but also can be predatory.

Figure 10. *Hydrophorus praecox* adult, member of a genus that can be found among Appalachian Mountain stream bryophytes. Photo by James K. Lindsey, with permission.

The **Empididae** (Figure 11) are little flies, so it is not any surprise to find them among mosses as larvae. In fact, larvae and pupae of many species occur among mosses in streams (Ivković *et al.* 2007).

Figure 11. **Empididae**, a frequent larva on bryophytes in streams. Photo by Stephen Moore, Landcare Research, NZ, with permission.

Because of their small size and the tedious process of sorting through moss samples, this family is not well known among the mosses and more species are likely to be found on close observation. Pusch and Wagner (1993) found and described the new species *Bergenstammia aurinae* in the eastern Alps where it lived among wet mosses in two small brooks with a steep elevation gradient but no glacial melt water.

In the Plitvice Lakes National Park in the Dinaric karst region of Croatia, the **Empididae** preferred moss on tufa and macrovegetation where they have shelter and food (Watson & Rose 1985; Nolte 1991; Linhart *et al.* 1998, 2002a, b, c; Ivković *et al.* 2007). Emergence was almost equal above substrates of moss on tufa, pebbles, and tufa with detritus (Ivković *et al.* 2012).

Suren (1991) experimented with artificial bryophytes in two New Zealand alpine streams. He found that whereas most insects had densities similar to that on natural bryophytes, the **Empididae** had lower densities on the artificial ones, suggesting that the bryophytes themselves have an important role for these larvae.

Fast-water Refuge

Those larvae that are truly aquatic stream-dwellers usually live among the mosses in fast water. Ivković *et al.* (2012) recorded the highest abundance of dance flies from Plitvice Lakes National Park, Croatia, in stream habitats that had moss, gravel, and particulate tufa with detritus and fast current. In Malaysia, larvae of *Hemerodromia* (Figure 12-Figure 13) live at least 10 cm beneath the water surface in the **hyporheic** zone (Grootaert 2004). They are sensitive to light and disappear from streams when the forest is gone. Light plays an important role in their mating – a behavior that earns them the name of dancing flies. Unlike many Diptera that rely on gills or spiracles, the aquatic larvae of *Hemerodromia* exchange oxygen directly from the water, whereas many other members of the family use spiracles positioned to be in direct contact with the air. Larvae are predacious and often feed on their cohabitants such as blackflies or **Chironomidae** (Vaillant 1951, 1967; Vaillant & Gagneur 1998; Grootaert 2004). The adults are small (3-5 mm) are mostly yellow or black and prefer boulders covered with moss or a splash zone where moisture loss is not a problem (Grootaert 2004). In Europe, *H. praecatoria* (syn. of *Chelifera praecatoria*?) live among mosses in nearly stagnant water (Bischoff 1924b; Johannsen 1969). In Belgium this species occurs in pools of *Sphagnum* bogs (DipteraInfo 2014). This same genus occurred among *Fontinalis dalecarlica* (Figure 4) in Appalachian Mountain, USA, streams (Glime 1968). The species resembled *H. rogatoris* and *H. seguyi*.

Figure 12. *Hemerodromia* larva, a frequent bryophyte inhabitant. Photo courtesy of the State Hygienic Laboratory, University of Iowa, with permission.

Bischoff (1924a) reported that the genus *Clinocera* occurred (Figure 14-Figure 15) among mosses in swift streams. In Malaysia, the larvae, like those of *Hemerodromia*, live at least 10 cm below the water surface in the hyporheic zone and exchange oxygen directly through the cuticle (Grootaert 2004). Sinclair (2000) described a new species, *Clinocera gressitti* (Figure 14), from mosses on submerged stones in New Zealand. Adrian Plant (pers. comm. 27 August 2014) observed that members of this genus often pupate (Figure 15) among the mosses.

Figure 13. *Hemerodromia superstitiosa* female adult, member of a genus with moss-dwelling larvae. Photo by Seth Burgess, through Creative Commons.

Figure 14. *Clinocera* larva, an inhabitant of mosses in swift streams. Photo from <www.dfg.ca.gov>, through public domain.

Figure 15. *Clinocera nigra* pupal exuvia. Photo by Adrian Plant, with permission.

In a springbrook in the Southern Alps of New Zealand, Cowie and Winterbourn (1979) found three zones of bryophytes. In the torrential waters near the middle of the channel, **Empididae** (Figure 11) were among the most abundant species living among *Fissidens rigidulus* (Figure 16). Not surprisingly, these were accompanied by several abundant species of **Chironomidae** (see Chapter 11-13b).

Figure 16. *Fissidens rigidulus*, home for **Empididae** in torrents. Photo by Bill and Nancy Malcolm, with permission.

In a German stream, larvae of *Wiedemannia bohemani* (see Figure 17) were abundant in the middle reach, with many occurring in partly submerged mosses on stones, both at and below the water level (Wagner & Gathmann 1996). Vaillant (1967) likewise found both larvae and pupae of *Wiedemannia* in streams and rivers of France, with adults remaining nearby on stones that were partially submerged. The larvae feast on the **Chironomidae** that are so abundant among mosses.

Figure 17. *Wiedemannia bistigma* emerging on stones. Photo by Adrian Plant, with permission.

Harper (1980) found that *Hemerodromia* (Figure 12-Figure 13), *Neoplasta* (Figure 18-Figure 19), and *Roederiodes* (Figure 20) in the Laurentian watershed, Quebec, Canada, typically inhabit the mainstream and the larger tributaries. These species usually prefer fast water with a substrate of moss and rubble.

Figure 18. *Neoplasta* larva, a bryophyte inhabitant. Photo from <dfg.ca.gov>, through public domain.

Figure 19. *Neoplasta* adult, a genus with larval bryophyte inhabitants. Photo by Adrian Plant, with permission.

Figure 20. *Roederiodes recurvatus* adult, a genus whose larvae are associated with mosses in fast water in the Laurentian watershed of Canada. Photo from Biodiversity Institute of Ontario, through Creative Commons.

Hemerodromia (Figure 12-Figure 13) larvae occur primarily in lotic habitats and among mosses on stream

cobble (Merritt & Cummins 1996), but also live in mosses at or just above the water level (Brammer *et al.* 2009). Larvae of *Hemerodromia* consume blackfly larvae that are living on the mosses (Vaillant 1953). Some of these **Empididae**, especially *Hemerodromia*, larvae have an interesting habitat choice, living in cases and nets of other insects. Larvae of the *Hemerodromia empiformis* complex have been found inside the tubes of the midge *Rheotanytarsus* (Figure 21-Figure 22) in southern California, USA. The last instar larvae and pupae of *H. brevifrons* have been found inside cocoons of **Simuliidae** (Figure 23) in a stream in Los Angeles County, California, USA. Pupae of a South American *Neoplasta* (Figure 18) can occur inside cocoons of caddisflies (Brammer *et al.* 2009). Thus their habitation of mosses may be indirect.

Figure 21. *Rheotanytarsus exiguus* larval tubes made by the moss inhabitant larvae, but these tubes also house the larvae of *Hemerodromia empiformis*. Photo by D. N. Bennett, with permission.

Where Shall We Go for Dinner?

Some adult members of the family devour their food from invertebrates trapped by the surface film. *Wiedemannia bistigma* (Figure 24) adults climb about on floating algae for just this purpose (Laurence 1953). Like maggots on a road kill, the empidids gather in numbers on the carcass of a dead insect. This adult behavior may not be as effective for most larval bryophyte-dwellers because the bryophyte habitats are often in fast water.

Figure 24. *Wiedemannia bistigma* adult, a species whose larvae can live among stream mosses. Photo by Adrian Plant, with permission.

Empididae larvae include both predaceous and non-predaceous larvae (and adults) (Oldroyd 1964). Many species of the subfamily **Hemerodromiinae** live in streams where their predatory larvae live among mosses and on wet rocks (Gerson 1969; Roper 2001). Some members are predators on larval blackflies (Vaillant 1951, 1953; Sommerman 1962; Wirth 1983; Werner & Pont 2003).

Empididae in the Cold

The **Empididae** are particularly adept at surviving cold conditions, whereas most insects lack cold resistance (Irons *et al.* 1993). Nevertheless, they cannot survive temperatures even 1°C below zero. In Alaska many insects survive by moving away from a freezing front or living in one that will not freeze. The **Empididae**, like the **Chironomidae**, will spend the winter in a frozen habitat. The **Empididae** have a high survival rate under freezing and thawing conditions. The ice serves as insulation

against sub-zero temperatures, with flowing water remaining typically at about 0.8°C.

Oreogetonidae

The **Oreogetonidae** is a small family, a segregate from the **Empididae** (Bayless 2011). The larvae are freshwater carnivores (Cresswell 2004). The family is widespread, with a concentration in South America, but also occurring in North America, Europe (one species), Asia, Australia, and New Zealand (Oreogetonidae 2014).

The genus *Oreogeton* (Figure 25) associates with mosses, but they are sprawlers-burrowers that engulf their prey, including blackflies and caddisflies (Aquatic Insects 2008; National Park Service 2014). These prey insects may be the reasons they enter the moss realm.

Figure 25. *Oreogeton* sp. adult. Larvae in this genus are sprawler-burrowers among mosses, feeding on blackflies and caddisflies. Photo by Tom Murray, through Creative Commons.

Syrphidae – Hoverflies

These worldwide flies are mostly 10-20 mm long, but can range up to 35 mm (Bartlett 2004). Many of the terrestrial larvae live in ant nests, but some occur in bogs. The larvae are mostly predators, although the family include a wide range of food sources. Some aquatic members have a long breathing tube, earning them the name of rat-tailed maggots. *Sericomyia borealis* (Figure 26) larvae occur in pools of peat bogs (Bloomfield 1897).

Figure 26. *Sericomyia silentis* adult, member of a genus in which some larvae live in bog pools. This one, like many syrphids, is a bee mimic. Photo by Richard Bartz, through Creative Commons.

Ephydriidae – Shore-flies

The name **Ephydriidae** literally means "living on the water" (Moisset 2004). The larvae filter microorganisms, including bacteria, one-celled algae, and yeasts, but some are predators on **Chironomidae** larvae. They are small to medium in size (2.5-9 mm) and have a worldwide distribution.

This is not typically a bryophyte family. *Discocerina* (Figure 27) burrows into moss mats or lives among algae at the borders of streams, ponds, and lakes (Merritt *et al.* 1996). *Gymnoclasiopa plumosa* (see Figure 28) breeds in algae and mosses in the forest (Grünberg 1910).

Figure 27. *Discocerina obscurella* adult, a genus that burrows into moss mats at water's edge. Photo from Zoologische Staatssammlung Muenchen, through Creative Commons.

Figure 28. *Gymnoclasiopa taxoma* adult. *Gymnoclasiopa plumosa* breeds in forest mosses. Photo from USFWS, through public domain.

Sciomyzidae – Marsh Flies

The **Sciomyzidae** family (Figure 29-Figure 30) has worldwide distribution. The adults are 5-10 mm long and

live around marshes, lakes, ponds, and wooded areas, but the larvae are aquatic (Leung 2004). These larvae feed on snails, either as predators or parasites. *Poecilographa decora* is the only American species in this genus (Usinger 1974). Its pupae are known from woodland mosses.

Figure 29. *Sciomyzidae* larva indicating spiracular disc. Photo by Stephen Moore, Landcare Research, NZ.

Figure 30. *Sciomyzidae* pupa; some species pupate among mosses. Photo by Stephen Moore, Landcare Research, NZ.

Agromyzidae – Leaf-miner Flies

The *Agromyzidae* are 1-5 mm long and are leaf miners (Murray 2005). Although these are mostly miners on tracheophytes, the *Agromyzidae* are known from liverworts from scattered locations around the world in such distant locales as the West Indies, Mexico, Peru, the Juan Fernandez Islands, New Zealand, and France (Spencer 1990).

The leaf miner *Phytoliriomyza mesnili* (see Figure 31) develops successfully on the floating liverwort *Ricciocarpus natans* (Figure 32) (d'Aguilar 1945). It also occurs on *Riccia beyrichiana* (Figure 33) where the larva feeds within the thallus, then pupates there. This miner is known exclusively from liverwort and hornwort thalli.

Figure 31. *Phytoliriomyza melampyga* larva showing leaf mine trail in a tracheophyte leaf. Photo by Malcolm Storey.

Figure 33. *Riccia beyrichiana* with eggs deposited in a cavity made on the left thallus. This liverwort species serves as home for larvae of the agromyzid fly *Phytoliriomyza mesnili*. Photo by Malcolm Storey, DiscoverLife, Creative Commons.

Muscidae – House Flies and Kin

This is a worldwide family whose larvae live in dung, carrion, soil, nests, decaying vegetation, and less commonly among bryophytes in running water (Balaban & Balaban 2004). Adults range 2-14 mm in length (Muscidae 2015).

Many species of *Limnophora* (Figure 1, Figure 34- Figure 35) carry out their larval development among mosses and liverworts in running water where they are able to prey on **oligochaetes** (segmented worms such as earthworms) and small insect larvae (Glime 1968; Skidmore 1985; Roper 2001). In the Appalachian Mountain, USA, streams these occur most abundantly among clumps of *Hygrohypnum luridum* (Figure 36), especially in small waterfalls (Glime 1968). Axelrod and Vorderwinkler (1983) found that the European muscid fly *Limnophora riparia* (Figure 35) prefers mosses as a substrate; it is a good place to eat chironomid, blackfly, and other larvae (Wotton & Merritt 1988). This species typically lives among bryophytes in waterfalls, splash zones, and lake outlets. When the larvae were placed under water in enamel trays, all of them drowned within 24 hours. They burrow into any possible substrate to avoid light.

Figure 36. *Hygrohypnum luridum*, home to *Limnophora* larvae in mid-Appalachian waterfalls. Photo by Hermann Schachner, through Creative Commons.

The larvae of *Limnophora riparia* (Figure 35) hatch from the egg as a third instar larva and are immediately ready to prey upon living invertebrates (Merritt & Wotton 1988). One of their peculiar adaptations is to attach the anterior of their prey and to remove and digest the contents of the head and body, leaving the cuticle and guts behind. The life cycle is synchronized with the main prey item, larvae of the blackfly *Simulium noelleri*, and other invertebrate prey items so that there is always plenty of food for the developing larva. When the larva matures, it continues to select mosses for its site to pupate.

Badcock (1949) found that the muscid *Calliophrys* only occurs in mosses on the vertical face of a waterfall in the Welsh Dee.

Summary

The **Brachycera** are mostly terrestrial, but a few have associations with the aquatic bryophytes. Among these, the **Empididae** are probably the most common. Bryophytes seem to be important to them as they colonize bryophytes more readily than they colonize artificial bryophytes. Both larvae and pupae live among the bryophytes. And like the bryophytes, they are often in stream openings that don't freeze.

The most interesting family to a bryologist includes those few members of the leaf miners (**Agromyzidae**) that live exclusively in the tissues of thallose bryophytes – liverworts and hornworts. As such, the thalli provide both protection and food.

Some members of the **Ephydriidae** burrow into the mosses at the borders of streams and ponds. **Sciomyzidae** larvae live in the water, but the pupae occur among woodland mosses. Even some **Muscidae** complete their larval development among aquatic bryophytes. Other families with a few members living in association with aquatic or predominantly wet bryophytes are **Athericidae**, **Spaniidae**, **Dolichopodidae**, **Oreogetonidae**, **Syrphidae**, and **Sciomyzidae**.

Acknowledgments

Julian P. Donahue verified some of the Diptera from my mid-Appalachian Mountain study. D. N. Bennett informed me about her findings of larvae and provided me with images. My sister, Eileen Dumire, has provided invaluable help in proofreading and clarifying this chapter.

CHAPTER 12-1

TERRESTRIAL INSECTS: HABITAT AND ADAPTATIONS

Figure 1. This tiny moving moss on the back of an insect is among the many unknown wonders awaiting us among the bryophyte-insect interactions. Photo courtesy of Aline Horvath.

Mosses are useful to the insect tribe, countless numbers of which find homes among their branches, and roam about in their shades as in mighty forests, looking with their thousand eyes upon the wonders of their leaves, and sunning their wings of purple and of gold, and burnishing their shining armour upon the polished columns of their urns. Frances Tripp, *British Mosses*, 1888.

Bryophytes can be so unique as to be the source of as yet undescribed species (Figure 1) and even genera of insects, as will be seen in the many orders of insects discussed in the following subchapters. They harbor numerous kinds of insects as well as other arthropods (*e.g.* Takaki 1957). And they provide habitat to protect insects all over the world (Schwarz *et al.* 1993) and in all kinds of habitats (Merrifield 1994).

Bryophytes as Habitat

Bryophytes not only provide a direct habitat for insects, but they alter the soil habitat beneath them. Gerson (1969) suggested that abundance of arthropods in the Antarctic is dependent on this soil alteration. Presence of moss can moderate the soil temperature and moisture and may in some cases discourage digging by would-be predators on soil organisms.

The bryophyte habitat is subject to the climatic and microclimatic differences dictated by elevation, distance from sea, topography, and latitude, resulting in arthropod community differences (Andrew *et al.* 2003). These differences extend to such limited habitats as that of epiphyllous liverworts (Lücking & Lücking 1998). Andrew and Rodgers (1999) found that in the Tasmanian Mountains, site scale variation (2 km or less) is the major contributor to the bryophyte faunal diversity, seemingly more important than altitude.

Drozd *et al.* (2008, 2009) found that even higher taxonomic levels formed associations that indicate interactions between the presence of bryophytes and other microhabitat features. Sampling only seven bryophyte species in the Czech Republic, they obtained more than 55,000 specimens of arthropods. They show that the presence of bryophytes, the species of bryophytes, and the moisture levels are very important determinants of arthropod abundance. Nevertheless, abundance of arthropods was greater in the litter than in the moss cushions. Since many of the arthropods are searching for prey, the density of the moss cushions limits the size and requires agility to permit the arthropods to navigate to capture prey. Instead, the bryophytes serve as a refuge for prey organisms that can find their food there. These require only limited movement, making them relatively invisible to predators. This limited movement also leads to trap bias in the pitfall traps as these insects typically do not leave the safety of the bryophyte cushions. Weikel and Hayes (1999) pointed out that while the abundance of arthropods as potential food for birds may correlate positively with bryophyte cover, the bryophytes may act as hiding places, thus rendering most of them unavailable to the birds.

Drozd *et al.* (2007) found that about 25% of the insect species in forest floor communities (litter and mosses) are present only among the mosses. Moisture was the primary factor accounting for their distribution.

But, as Drozd *et al.* (2007) pointed out, our knowledge of the mosses as a food source is all but unknown. One of the means of identifying whether bryophytes are eaten is to recognize bryophyte fragments in the faeces or frass. Matthaias Nuss (pers. comm. 16 January 2008) provided me with an image of *Tortula truncata* with chewed leaves and what appeared to be frass on the plant (Figure 2). But then, how often can we identify the producer of the frass?

Figure 2. Possible insect frass on *Tortula truncata*. Matthaias Nuss of the Museum für Tierkunde / Museum of Zoology, Dresden, Germany (pers. comm. 16 January 2008) suggests that these may be sclerified head or mandible parts that have an interesting attachment to the sporophytes of these mosses. There appear to be no silk threads, ruling out moth larvae, but *Byrrhidae* (Coleoptera) or some *Mecoptera* are good candidates. Photo courtesy of Robin Stevenson.

Drozdová *et al.* (2009) considered mosses to be unique habitats that could provide safe sites against predators. To

test this hypothesis, they used living bait in a vertical gradient (surface level, moss cushions, bushes, tree trunks). The bait was living larvae of the blowfly *Calliphora vicina*, a common prey item. The locations included leaves of blueberries (*Vaccinium myrtillus*), mosses [*Polytrichastrum formosum* (Figure 3), *Polytrichum commune* (Figure 4), and *Dicranella* sp. (Figure 4)], and spruce (*Picea abies*) trunks. After 30 minutes of exposure the researchers counted the attacked and missing larvae and noted the presence of predators. The dominant predators were ants and spiders, the same as the forest floor in general (Drozdová *et al.* 2009). The predation rate inside the moss cushions was about the same as that in the litter, but the taxonomic groupings of the predators differed. Millipedes were the dominant predators in cushions of *Dicranella* sp and *Polytrichum commune*, with spiders and beetles (*Carabidae* and *Staphylinidae*) following. Centipedes also occurred on the ground in areas of moss cushions under the *Vaccinium myrtilloides*. The highest predation occurred inside the *Polytrichum* cushions, with the same rate on the terminal parts of the plants as on the tree trunks. It appears that the structure of the moss cushion – the growth form – might be an important determinant of predation risk.

Figure 4. *Polytrichum commune*. *Polytrichum* cushions can be home to numerous beetle species. Photo by A. J. Silverside, with permission.

Figure 5, *Dicranella heteromalla* with capsules, a species that is home to millipede predators. Photo by Michael Becker, through Creative Commons.

We aren't always sure why or how bryophytes contribute to the habitat needs of insects, but there is certainly evidence that they make a difference. Pavel *et al.* (2007) used pitfall traps in the Czech Republic to compare the beetles (**Coleoptera**) in forest communities with and without a moss layer. With the caveat that there is not necessarily a cause and effect relationship, an accumulation of such studies do indicate that it is worth exploring the role of the bryophytes. In this case, two traps were placed in *Polytrichum* (Figure 4) cushions and two were at least 10 m away from the nearest cushions at each of three sites. In their collections, beetles reached the highest numbers among the insects, with 56 species and the greatest abundance. Overall, they found a higher insect species richness in the moss communities, with ~25% of the insect species only occurring among the mosses. Not surprisingly, moisture was the most important environmental character affecting habitat preference, but presence of a moss layer was not significant. Only one of the species was **bryophagous** (bryophyte consuming), a member of the beetle family **Byrrhidae** (Figure 6). Especially in drier regions, the insects tended to inhabit the moss cushions, behaving as **bryobionts**.

In the Spitsbergen coastal tundra, Bengston *et al.* (1974) found 268,000 insects on the wet moss tundra, compared to 518,000 on grassland. The abundance of major insect groups were similar between the Spitsbergen tundra and high alpine areas of southern Norway.

In the Czech Republic, Božanić *et al.* (2013) used heat extraction from bryophytes to determine the effects of species of bryophytes and environmental factors on the animals present. In these samples they found 45 species of invertebrates among the 15 bryophyte species examined. Surprisingly, few were insects, all in the **Formicidae** (4

species of ants). Rather, there were 9 species of centipedes, 7 of millipedes, 4 of pseudoscorpions, 6 of isopods, 4 of harvestmen, 6 of earthworms, and 5 of spiders. *Brachythecium oedipodium* (Figure 7) had the richest assemblages of invertebrates. These numbers are probably minimal as some bryophyte dwellers do little moving and may die before escaping the heat within the bryophyte clump in the funnel and heat separation apparatus. The ones found are all able to move rather quickly, so this may explain the absence of bugs, beetles, and other insect groups. The type of substrate and height above ground proved to be the most important factors affecting the invertebrate distribution.

Figure 6. *Cytilus sericeus* (Byrrhidae) adult on mosses. Photo by S. Rae, through Creative Commons.

Figure 7. *Brachythecium oedipodium*, home to a rich assemblage of invertebrates. Photo by Michael Lüth, with permission.

At McKenzie Table Mountain Preserve in California, USA, Bettis (2008) found that the moss fauna on two species of **Grimmia** (Figure 8) were mostly tardigrades, mites, springtails, and midge larvae. Studies of bryophyte fauna commonly indicate that spiders (**Araneae**), springtails (**Collembola**), and mites (**Acari**) are the most common fauna (von der Dunk & von der Dunk 1979; Kinchin 1990). Even on Signy Island in the maritime

Antarctic, the mites and springtails predominate (Usher & Booth 1984). The upper, green moss communities differed from the lower, dead moss communities. The same species tended to occur in both layers, but the proportions differed.

Figure 8. *Grimmia pulvinata* with capsules, home to tardigrades, mites, springtails, and midge larvae in California, USA and elsewhere. Photo by Javier Martin, through Creative Commons.

Von der Dunk and von der Dunk (1979) listed the arthropods in clumps of five species of mosses in March to May, including counts (Table 1). In addition to unidentified larvae, they listed the *Collembola Sminthurinus* (Figure 9), *Xenylla* (Figure 10), and *Tomocerus* (Figure 11-Figure 12) as well as thrips.

thrips	+	+	+		+

Nutrients in the ecosystem affect the types of plants that will grow there, and bryophytes seem to have an aversion to high nutrients. Richardson *et al.* (2002) experimented with nutrients and their effects on plant communities and their insect herbivores in a Scandinavian

sub-Arctic dwarf shrub heath. After nine years of nutrient enrichment, the subordinate plant functional groups (grasses and mosses) experienced greater effects than did the dominant dwarf shrubs. The insect herbivores showed evident changes in abundance. The biomass changes in the

grasses and mosses contributed more to these insect changes in biomass and species composition than did the shrubs. One moss-eating species of **Heteroptera** in the fertilized plots dropped to as little as 6% that of the control plots. The abundance of grass specialists in **Homoptera** in fertilized plots, on the other hand, reached 400% that of controls. This study emphasized the importance of the subdominant plant species in driving the insect species composition of the habitat.

Temperature Relations

Because of their construction with lots of air spaces, bryophytes can act like a fluffy winter quilt. They are able to buffer temperatures with these trapped air spaces (Soudzilovskaia *et al.* 2013). In some instances, they may remain warmer from reradiated heat from rocks or soil. In other cases their capillary water may cool them by evaporative cooling. Differences between bryophyte species comply with physical laws and can be explained by differences in mat thickness and moisture content. There are, however, few data sets to evaluate the extent of this role in a variety of ecosystems. Some of these differences are provided in Chapter 10-1 on Temperature in Volume 1.

Of course food is a problem in winter, but some insects are able to feed on alternate food sources. *Diamesa* sp. (**Diptera: Chironomidae**; Figure 13) is a cold-tolerant insect that lives on a glacier in the Nepal Himalayas (Kohshima 1984). This flightless insect is able to walk on the surface and in small cavities beneath the glacier. The larvae feed on Cyanobacteria and other bacteria, permitting this species to spend its entire life in the glacier. And it is still active at -16°C . While this is not a bryophyte dweller, it illustrates the ability of insects to survive in cold habitats, such as those in the Arctic and Antarctic, and to subsist on foods like bacteria and Cyanobacteria that are available among the bryophytes.

Preparation for Winter

As we noted in the aquatic insect chapter, insects can avoid freezing damage in two ways (Duman *et al.* 1991). The most flexible means is to obtain freeze tolerance, permitting the insect to survive formation of ice on the outside of the body. The second mechanism is to avoid

freezing. The latter can be subdivided into physiological mechanisms that prevent the insect from freezing by altering the freezing point of the organism or preventing ice nucleation through manufacture of antifreeze proteins (Duman *et al.* 2004). The other is a behavioral adaptation that places the insect in a place where it is protected from freezing (Duman *et al.* 1991).

Bryophytes are often a winter refuge or site of hibernation for insects. The bryophyte offers insulation against the wind and cold. Under the snow, the dark color of most bryophytes absorbs heat from the light that is able to penetrate the snow. Nevertheless, bryophytes may be exposed to severe cold before the snow arrives or after it melts in spring. Hence, their inhabitants still require some sort of protection from the cold.

Storey and Storey (1992) listed two stresses that can prevent winter survival in terrestrial insects. The obvious one in many places is lack of food, but some insect larvae are able to feed on the bryophytes. Others may survive as eggs or pupae, stages in which there is no feeding. Some insects compensate for the lack of food by accumulating large lipid and carbohydrate reserves in the body fat in preparation for winter (Storey & Storey 1992). Others enter into a state of reduced metabolic rate (**quiescence**) or arrested development (**diapause**) in which they can rely on limited food reserves.

The second winter stress is tissue damage at low temperatures, especially freezing (Storey & Storey 1992). Insects have two options to survive in areas that attain sub-freezing temperatures: **freeze avoidance** and **freeze tolerance** (Bale 2002). Freeze avoidance includes life cycle adaptations that do not require the insect to be present during the cold period. For some, this is through migration. For others, it is finding warmer locations such as deep soil, in the water, or even among deep mosses. But insects also can have physiological means of freeze avoidance while existing in locations with sub-zero temperatures.

Protein ice nucleators (PINs) limit supercooling and induce freezing (Duman 2001). When the nucleating proteins are internal, a small size can help to prevent the formation of large crystals. In insects, freeze-tolerant species produce PINs in the hemolymph. These allow freezing in the hemolymph at temperatures just below freezing and inhibit freezing within the cells. In some cases, these PINs are "removed" in the winter, promoting supercooling. **Antifreeze proteins** (AFPs) prevent freezing. One beetle has AFPs in the hemolymph and gut that inhibit the ice nucleators in winter.

One theory of freeze avoidance in insects is that of **heterogeneous nucleation**. However Zachariassen *et al.* (2004) provide evidence that it is water volume that determines the nucleation temperatures in freeze-avoiding insects. The relationship between the aqueous solutions and the particular freeze avoidance displayed behaves more like that of homogeneous nucleated samples.

One of the strategies to survive winter is the ability to **supercool** (Holmstrup *et al.* 2002). This ability seems to have evolved at the same time as the ability for insects to retain body water in dry environments. But soil invertebrates are far less resistant to desiccation than the above ground insects. It is likely that bryophyte dwellers are more like the soil invertebrates but in some cases may find greater moisture among bryophytes. Soil invertebrates

dehydrate in frozen soil; only a few degrees of supercooling causes substantial water loss which continues until the vapor pressure of body fluids equals the vapor pressure of the surrounding ice. At this point, tissue ice formation is eliminated and the invertebrate can survive subzero temperatures. But the Arctic soil invertebrates do not base their winter survival on this method of supercooling. Rather, they dehydrate to equilibrate their body-fluid melting point to that of the ambient temperature. This method works even in the extreme cooling rates of the polar soils.

For those insects that are sensitive to freezing, but still exhibit cold hardiness, their survival is typically achieved through **supercooling**, with some exhibiting supercooling points to below -25°C (Zachariassen & Husby 1982). These low non-freezing temperatures are accomplished through polyols and proteinaceous thermal hysteresis antifreeze agents that reputedly prevent the growth of ice crystals down to approximately -10°C . This prevention is increased dramatically when the crystal size is diminished. This added ability to prevent crystal formation permits them to live through temperatures as low as -30°C . In such cases, the insects can survive even in exposed areas where the snow does not accumulate.

Freeze tolerance in terrestrial insects occurs primarily among the **Coleoptera** (beetles), **Lepidoptera** (moths & butterflies), **Diptera** (flies), and **Hymenoptera** (bees & ants) (Storey & Storey 1992), whereas only the **Diptera** seem to have any tolerance to freezing in the aquatic stage (Moore & Lee 1991). Freeze tolerance may require preparation or it may be present year-round.

Freeze tolerance is energetically expensive and carries risks of ice crystal damage or other physical damage. The insect furthermore must survive osmotic stresses when water and solutes are rapidly redistributed across cell membranes during freezing and thawing periods. And part of this strategy is extracellular freezing that can damage membranes, not to mention the obstruction of oxygen flow to the body.

Freeze avoidance is the less expensive strategy and permits insects to be active under the snow where the snow provides suitable insulation (Storey & Storey 1992). Insects in cold environments further avoid freezing by the presence of hairs and dark body colors (Danks 2004), the former to insulate and the latter to absorb heat on sunny days. The insects complement these physical adaptations by behavioral adaptations – being active on sunny days and going to protected locations when it is getting cold (Danks 2004, 2005). Danks (2007) discusses their responses, including dispersal, habitat selection, habitat modification, resistance to cold, dryness, and food limitation, recognition of environmental signals, diapause, modifications to developmental rate, life cycle patterns that include multiple alternatives within the species, variation in phenology and development, and tradeoffs among these.

The behavioral escape of freezing could be to burrow into the ground below the frost line, go into decomposing material that generates heat, or find some other protected location locally. But for a few insects, this escape is a migration to a warmer climate, as is well known for the Monarch butterfly.

Bryophytes may come into the picture for some of the insects that are able to eat them. Cold induces changes in

membranes and protein structure in insects due to phase changes in the molecules, changes in electrolyte concentrations and other solutes in body fluids, and changes in metabolism (Ramløv 2000). In some cases, animals switch diets prior to winter, some of which may include bryophytes (Prins 1982). This usefulness of such a behavior among insects remains unknown.

We know that bryophytes are rich in **arachidonic acids** that help to keep membranes pliable (Hansen & Rossi 1991). Insects produce little or no arachidonic acid (McPartland *et al.* 2001). Nevertheless, ladybird beetles (*Coleomegilla maculata*; Figure 14-Figure 15) have their highest proportion of arachidonic acid in the coldest part of winter (Zar 1968). Thus, a winter switch to bryophytes by some insects seems to be a reasonable hypothesis, and a potential source of arachidonic acid.

Figure 14. *Coleomegilla maculata* larva, a species with its highest concentrations of arachidonic acid in the coldest part of winter. Photo by Tom Murray, through Creative Commons.

Figure 15. *Coleomegilla maculata* adult, a species with its highest concentrations of arachidonic acid in the coldest part of winter. Photo by Tom Murray, through Creative Commons.

Whether arachidonic acids help in cold resistance for insects or not, they may help to keep membranes pliable for movement. Although Prins (1982) demonstrated a relationship with bryophytes in the diet of vertebrates, arachidonic acid, and winter survival, and we know that insects typically have quantities of the acid in their tissues (Dadd & Kleinjan 1979; Stanley-Samuelson & Dadd 1983), there does not yet seem to be research to demonstrate this relationship between arachidonic acid, winter tolerance, and insects. The closest evidence is that arachidonic acid enables the mosquito *Culex pipiens* to fly when it emerges as an adult (Dadd & Kleinjan 1979).

Arachidonic acid may not be the only chemical change in preparation for winter. Low temperatures not only affect the insects and cause different cell and membrane chemicals to initiate, the bryophytes also produce different chemicals or different concentrations when the temperatures drop. In *Rhytidiadelphus squarrosus* (Figure 16) and *Eurhynchium striatum* (Figure 17) there is a switch from 30% **arachidonic acid** (AA) and 5% **eicosapentaenoic acid** (EPA) to higher percentages of EPA, **α -linolenic acid**, and **dihomo γ -linolenic acid**, accompanied by a slight decrease in AA and **linoleic acid** (Hansen & Rossi 1991). This particular study does not support the hypothesis that AA increases in bryophytes in preparation for winter, but it is likely that the bryophytes still have higher concentrations of arachidonic acids than tracheophytes at those temperatures or any time (Herbert & Prins 1982; Hartmann *et al.* 1986; Groenewald & Van der Westhuizen 1997; Kajikawa *et al.* 2008).

Field biologists often consider winter to be a "down" season when insects are inactive, and therefore it is not a useful season for field work. But insects must find some way to survive winter and pass their genes to the next generation. Many do this as eggs or pupae. And bryophytes seem to be an ideal place for both, at least for some insects. They provide protection against easily damaged tissues of pupae when larger animals walk or climb about, they hide them from predators, they decrease the threat of desiccation, and they provide insulation. And for active insects, they may provide food directly or through other organisms that live among the bryophytes. Surely many species spend their winters there in this bryophytic safe site.

But little literature exists on the bryophyte as an overwintering home. Not only is this season less conducive to field study, but even those who do collect are faced with a daunting task of identification. Pupae and eggs must be matched with adults to avoid the danger of creating new species for what is simply a different life cycle stage. That requires rearing to maturity, a special challenge for eggs. And someone needs to have done that already if there are to be any keys or descriptions to aid identification. Hence, even those collections that are made rarely see publication due to the lengthy process of putting names to the organisms.

Most taxonomic treatments on insects give only general habitats for the insects, and often I wonder if there wasn't a moss involved, as food or shelter, but unnoticed, or at least unreported, by the collector. Treatments of forest floor insects often compare soil and litter organisms, and even those on rocks, but no mention is made of mosses, although they are often lumped with litter.

The use of bryophytes on a phenological calendar is demonstrated by The Entomologist's Calendar (Samouelle 1819). Those arthropods living on or under mosses in January were *Philosia muscorum* (Isopoda; Figure 18), *Cylindroiulus londinensis* (Diplopoda), *Cylindroiulus punctatus* (Figure 19), *Geophilus acuminatus* (Chilopoda; see Figure 20), *Siro rubens* (Opiliones; see Figure 21), *Neobisium carcinoides* (Pseudoscorpiones; Figure 22), *Cychnus caraboides* (Coleoptera; Figure 23), *Acropagus glabricollis* (name no longer in use); in February *Bryaxis haematica* (Coleoptera; species name no longer in use; see Figure 24), *Staphylinus morio* (Coleoptera; see Figure 25); in March *Gyrophynus punctulatus* (Coleoptera; Figure 26), *Chlaenius prasinus* (Figure 27), *Tachinus analis* (Coleoptera), *Tachyporus analis* (Coleoptera), *Choleva oblonga* (Coleoptera), *Catops sericeus* (Coleoptera; species name no longer in use; see Figure 28); in April *Staphylinus aenoecephalus* (Coleoptera; species name no longer in use), *Staphylinus decorus*; species name no longer in use; in May *Dasytes ater* (Coleoptera; species name no longer in use; see Figure 29); in June – November no moss records; in December *Tachyporus chrysomelinus* (Coleoptera; Figure 30). This change from winter to summer suggests that the bryophytes offer these insects something in winter, whether it is only shelter, or there is also a food source.

Water Relations

Water is often the limiting factor for terrestrial insects (Tauber *et al.* 1998; Hayward *et al.* 2004). It can account for the importance of other variables such as elevation (Lee & La Roi 1979). Tauber *et al.* (1998) suggested that moisture was important in determining insect seasonality, stimulating diapause, modulating development and reproductive rates, and providing a cue for seasonal events. Bryophyte species are also limited by moisture, thus creating different moisture regimes available to the ground-dwelling and arboreal insects (Whittaker & Niering 1975; Slack 1977; Lee & La Roi 1979; Vitt 1991; During 1992; Wolf 1994; Li & Vitt 1995; Vitt & Belland 1997).

Fragmentation and Corridors

One of the causes of declines in species is the inability to disperse due to unfavorable habitat between suitable locations. Gonzalez *et al.* (1998) found that when patches of suitable habitat were connected by habitat corridors, they provided a rescue effect. Both abundance and distribution improved when habitats were connected. For many kinds of insects, bryophytes can provide such corridors, providing moisture and shelter even when they are unsuitable as food.

Starzomski and Srivastava (2007) experimented with landscape geometry and found that reducing the size of patches had little effect on community resilience. However, habitat loss caused complete loss of connectivity between patches. In their experiments with the microarthropod community (mostly mites and springtails) of mosses (*Polytrichum* and *Bryum*) on a granitic outcrop in BC, Canada, repeated disturbance caused rapid declines in species richness and abundance, altering community structure. These two arthropod groups were highly abundant, reaching 200 or more morphospecies in areas of only 20 m².

Insect Adaptations to Bryophytes

Insects often modify their environment to make it suitable for their homes. These include excavations in soil and other substrates, construction of feeding or resting shelters, inducing plant responses such as galls, forming aggregations, building colonial nests, and using parental care (Danks 2002). These alterations can buffer temperatures, increase moisture, and avoid flooding.

Moisture needs (Danks 2004) may drive them to bryophytes, especially during summer dry spells. The excavations and shelters protect primarily against physical factors (Danks 2002). On the other hand, aggregations, colonies, and parental actions usually influence the ability to acquire resources.

Perhaps the most important characteristic of a bryophyte inhabitant is the ability to navigate within the small spaces available. This means the insects must be small, and it means their appendages must not get in the way. Hence, large insects like butterflies and moths cannot navigate as adults, and many are likewise too large as larvae to move within the mat.

Another adaptation is the ability to utilize the moss. If it is unable to use the bryophyte as a food source, it might not be worth the energy to enter the moss community.

But food is not the only reason to enter a bryophyte clump. As seen in other invertebrates, insects can seek out the moss as a safe site from the dangers of desiccation. However, they lack the ability to encyst that is beneficial to several invertebrate groups. Instead, their life cycles permit them to be inactive during the winter season, and their mobility permits them to leave when the going gets rough. Thus, pupae of insects with a **holometabolic** (having eggs, larvae, pupae, and adults) life cycle and eggs of all insects provide life cycle options to permit residency during dry or cold periods. And most likely they, like many other invertebrates, migrate vertically as moisture or temperature within the bryophyte community changes (Markkula 1981).

The bryophyte can provide camouflage. In addition to having the bryophyte create a plethora of light and dark areas with small spaces and overlying leaves and branches, the insect may itself exhibit camouflage (Lacrampe 2003), permitting it even greater protection against predators. For example, the crane fly *Triogma* (Figure 31) has a green and black pattern that makes it resemble a moss branch, sporting projections that resemble leaves (Figure 31). Species in this genus exist in both aquatic and terrestrial habitats, exhibiting a camouflage that suggests it evolved to survive in its mossy habitat (Alexander 1920).

Figure 31. This larva of the crane fly *Triogma* has green and black patterns that make it resemble the moss branches where it lives. Photo by Janice Glime.

Abundance

Invertebrates, and particularly arthropods, can be especially abundant among mosses. Peck and Moldenke (1999) found 125 morphospecies, comprising 18 orders and

5 functional groups, in their study of vine-maple (*Acer circinatum*; Figure 32) in the Willamette National Forest (Oregon, USA). The bases of shrubs exhibited the highest species richness and abundance. The composition likewise differed between the bases and tips of the shrubs. The most abundant insect was *Sminthurus* (Figure 33), a springtail (*Collembola*). Such abundance raises serious concerns about the harvest and export of mosses, especially in the first half meter above the ground.

Figure 33. *Sminthurus* sp. with spermatophore, the most abundant species among bryophytes on the vine maple. Photo by Petter Bøckman, through Creative Commons.

The high abundance of insects in some moss communities requires special extraction techniques. Andrew and Rodgers (1999) suggest using kerosene to float the insects because it attaches to the cuticle of the insects. The moss-insect community must first be preserved in 95% ethanol for two weeks. This preserved mix is shaken vigorously after topping off with kerosene. The insects settle to the bottom, then float at the interface between the ethanol and kerosene. The kerosene can be pipetted off and insects collected from the interface layer. I have not actually tried this method, but it would appear to work only on relatively small insects and things without legs to get caught. Further discussion of sampling methods appears later in this chapter.

Food Sources

Many researchers have considered bryophytes to be inedible for insects and other invertebrates (Haines & Renwick 2009). Others have commented on how rare bryophagy seems to be (Longton 1984). Even on Bryonet, people familiar with bryophytes marvelled at how little we know about bryophyte herbivory. Nevertheless, Paul Johnson reported studying several groups of insects that feed on mosses or liverworts, many of which are strict **bryophages** (organisms that feed on bryophytes). Kathy Merrifield reported finding much evidence of grazing on mosses that grow in the cracks of tree bark. Several members have provided images that evidence the bryophage damage, as will be seen in succeeding subchapters of terrestrial insect interactions. It is likely that the presence of bryophagy has been largely overlooked.

Nevertheless, some of the oddities among growth forms seem to be the result of **bryophagy** (see Ghullam & Stevenson 2013; Figure 35). Since a dense cluster of apical filaments is an oddity among members of *Zygodon rupestris* (Figure 34), those clusters (Figure 35) observed by Robin Stevenson (pers. comm. 2 June 2016) seem to be produced in response to herbivory. The herbivore is unknown. Normal gemmae (Figure 36) of this species were present along the stem, but these terminal filaments (Figure 37-Figure 38) seemed to be the result of damage to the terminal bud (pers. comm., Robin Stevenson 2 June 2016). *Fontinalis* produces similar filaments (protonemata) when the apex of the stem is removed (Figure 39). And could it be that the herbivore deposits a hormone such as that used to produce galls in tracheophytes? Stevenson suggested that the normal axillary gemmae may be dispersed by hares and deer that brush against the tree trunks where the moss lives. It is possible that these terminal filaments might likewise be dispersed and serve as propagules. Anomalies such as these should provide an interesting area for research on development and evolution.

Biologists have considered three classes of mechanisms to provide barriers to bryophagy: chemical defenses, low digestibility, and low nutrient content. But just as in tracheophytes, not all bryophytes are the same. Some are eaten while others just beside them are not, suggesting chemical defenses (Swain 1977). Haines and Renwick (2009) compared four bryophyte species by examining pre- and post-ingestive defenses by the bryophytes, all of which were mosses. Using the generalist caterpillar *Trichoplusia ni* (Figure 40-Figure 41), a generalist caterpillar, they found that mosses were consumed much less than lettuce or wheat germ. Of the four mosses tested [(*Bryum argenteum* (Figure 42), *Climacium americanum* (Figure 43), *Leucobryum glaucum* (Figure 44), and *Sphagnum warnstorffii* (Figure 45)], only *Climacium americanum* was consumed in sufficient quantity to evaluate post-ingestive responses by the caterpillars. Extracts of *Leucobryum glaucum* placed on discs showed that this moss, the least eaten, contained a deterrent. Haines and Renwick suggested that preingestive mechanisms are more important than post-ingestive mechanisms, but much more study is needed before such a generalization is well supported.

Longton (1984) reviewed the literature on the role of bryophytes and concluded that the energy content of bryophytes is generally slightly lower than that of

associated plants. Wielgolaski and Kjelson (1975) demonstrated this for Scandinavian tundra Communities. Lewis Smith and Walton (1973) demonstrated it for a sub-Antarctic island and Bliss (1962) for an alpine tundra. But is this true in warmer habitats? Gorham and Sanger (1967) found it likewise to be true in Minnesota, USA, but that is still a relatively cold climate, at least in winter.

There does seem to be an increase in caloric content with latitude (Forman 1968, 1969; Rastorfer 1976), as there is for flowering plants, with a range of 3.7-4.8 Kcal g⁻¹ for bryophytes. Longton (1984) suggests that the lower energy content in bryophytes results from lower concentrations of carbohydrates, proteins, and lipids. This was true at least for proteins and readily soluble carbohydrates in a Norwegian alpine tundra (Skre *et al.* 1975).

Lawrey (1987) challenged the notion that bryophytes had little nutritional value. Some researchers have argued that they are lower in calories than tracheophytes (Forman 1968; Pakarinen & Vitt 1974), but others consider them to fall into the same range as those of tracheophytes (Bliss 1962; Forman 1968; Pakarinen & Vitt 1974; Rastorfer 1976). Davidson *et al.* (1990) compared uneaten gametophytes to edible sporophytes and found that the ash-free caloric values did not differ, further suggesting that caloric values are not a limiting factor. On the other hand, Skre *et al.* (1975) found that both their protein and carbohydrate content is typically low in alpine bryophytes compared to tracheophytes. And levels of potassium and magnesium tend to be lower in mosses than in tracheophytes (Prins 1982).

The sugars in bryophytes are the same as in tracheophytes, although some additional ones occur. Spores are especially high in lipids and may account for consumption by ants (Plitt 1907). Pelser *et al.* (2002) even reported that some mosses [*Catharomnion ciliatum* (Figure 46), *Canalohypopterygium tamariscinum* (Figure 47)] produce oils. They considered that the oil may have an energy storage function, but rather than considering it to be a food source for invertebrates, they suggested that it could serve to repel invertebrates, fungi, or bacteria.

Figure 46. *Catharomnion ciliatum*, a species that produces oils that may be a deterrent to herbivory. Photo by Clive Shirley, Hidden Forest <www.hiddenforest.co.nz>, with permission.

Figure 47. *Canalohypopterygium tamariscinum*, a species that produces oils that may be a deterrent to herbivory. Photo by Pieter B. Pelser, with educational permission.

Sveinbörnsson and Oechel (1991) questioned the carbohydrate and lipid changes in tundra mosses as the seasons changed. Using *Polytrichum commune* (Figure 4) and *Polytrichastrum alpinum* (Figure 48), they samples three times per year. On the raised polygon rims, both lipid and carbohydrate concentrations were higher in *Polytrichum commune* than in *Polytrichastrum alpinum*. The green parts of the plants had significantly higher concentrations of lipids than did rhizomes in *Polytrichum alpinum*, but this relationship was not true in *Polytrichastrum alpinum*. Sugar concentrations were higher in green parts in both species, whereas starch concentrations were highest in the rhizomes.

Only *Polytrichum commune* demonstrated seasonal variation in starch and sugar concentrations (Sveinbörnsson & Oechel 1991). There was a significantly strong negative relationship between sugars and starches. On the other hand, there was a significant positive relationship between lipids and starch+sugar. The seasonal relationship of these two *Polytrichaceae* mosses is like that of evergreen tracheophytes.

Figure 48. *Polytrichastrum alpinum*, a polygon rim species in the Arctic. This species has high sugar content in green parts and high starch content in the rhizomes. Photo by David T. Holyoak, with permission.

Chapin *et al.* (1986) found that seasonal fluctuations in carbohydrate concentration varied between moss species in

the Alaskan tundra. Brown parts of *Aulacomnium* spp. exhibited greater seasonal differences than did species of *Polytrichum* and *Pogonatum*. Lipids increased in autumn in brown tissues of mosses and declined in summer. Surprisingly, mosses had the greatest levels of lignin-like substances when compared with tussock graminoids (grasses & sedges), deciduous shrubs, evergreen shrubs, deciduous forbs (non-graminoid herbs), and lichens; *Eriophorum* (cottongrass) and lichens had the least. The preferences of the eight generalist herbivores in the study responded to nutrient levels, preferring higher levels of

nitrogen, phosphorus, and potassium but lower levels of lipid and cellulose in the plants.

Russell (1979) found that the liverworts preferred by *Caurinus dectes* actually had a low nutrient content (Table 2), particularly for nitrogen, an important component of protein. But he pointed out that the *Caurinus* was able to extract the nutrients from the cells without having to eat and digest the cellulose that is so abundant in some bryophyte leaves, thus making the concentrations higher than that indicated in the table.

Table 2. Macronutrient concentrations (% dry weight) in the gametophytes of some bryophytes collected in *Caurinus dectes* habitat at Marys Peak, Oregon, USA. From Russell 1979.

Rather than low nutrients, it seems likely that antiherbivore compounds may contribute to the avoidance of bryophytes by herbivores (Clymo & Hayward 1982; Davidson 1988; Davidson *et al.* 1989; Liao 1993). Lawry (1987) suggests that the same compounds already known for their antibiotic activity (Madsen & Pates 1952; Pates & Madsen 1955; Ramaut 1959; McCleary *et al.* 1960; Wolters 1964a,b; McCleary & Walkington 1966; Gupta & Singh 1971; Banerjee & Sen 1979) may serve also as antiherbivore compounds. For example, phenolic compounds and other related bio-active compounds have been demonstrated multiple times (Markham & Porter 1978, 1983; Asakawa 1981, 1982, 1984, 1990; Wilschke & Rudolph 1988; Harborne 1988; Zinsmeister & Mues 1988; Davidson *et al.* 1989; Xie & Lou 2009).

Ferulic acid in shoots (but not young capsules) of *Mnium hornum* (Figure 58) may account for avoidance of the shoots; ferulic acid, one of the hydroxycinnamic acids, is considered a primitive defense against herbivores in flowering plants (Swain 1977; Fry 1983). These cell wall components would be likely to discourage organisms that chew and grind, but may have no effect on those that pierce and suck, explaining the high incidence of such invertebrates (Longton 1992). In liverworts, it seems that the oil bodies store terpenoids and lipophilic aromatic compounds that have strong antifeedant activity, as shown against the African army worm *Spodoptera exempta* (Lepidoptera; Figure 59-Figure 60) (Asakawa 1990).

Thus far there is no evidence that insects take an **offensive approach** to bryophyte herbivory (Karban & Agrawal 2002). Karban and Agrawal suggest that offensive behavior includes choices for feeding and oviposition, enzymes that make it possible to digest or assimilate certain foods, sequestration of toxins, *etc.*, morphological adaptations, symbionts, induction of plant galls, and induced plant susceptibility. Isopods seem to have such offensive tactics that enable them to eat and assimilate bryophytes (see Chapter 10-3 in this volume). However, special enzymes, bacteria, or other mechanisms permitting insects to digest and assimilate bryophytes seemingly remain to be discovered.

Both algae (Ceh *et al.* 2005) and tracheophytes have inducible antiherbivore compounds (*e.g.* Fowler & Lawton 1985; Kruidhof *et al.* 2012). The brown alga *Sargassum asperifolium* (Figure 61) and red alga *Hypnea pannosa*

(Figure 62-Figure 63) both exhibited lower grazing levels on individuals that had been grazed previously than on those with no previous grazing, suggesting that these algae produced antiherbivore compounds in response to grazing.

Figure 61. *Sargassum* sp., a brown alga that seems to have inducible antiherbivore compounds. Photo through Creative Commons.

Figure 62. *Hypnea pannosa*, a red alga that seems to have inducible antiherbivore compounds. Photo by Ria Tan, through Creative Commons.

No one has attempted to show whether these secondary compounds are ever induced in bryophytes. Karban and coworkers considered the advantages of inducible antiherbivore compounds (Karban & Baldwin 1997; Karban *et al.* 1997). Whereas most ecologists had argued that the inducible compounds saved costs, empirical data failed to support this argument (Karban *et al.* 1997). Karban and coworkers suggested that instead it was the variability that was important – "maximal levels of defense are constrained, variability will increase the effectiveness of a given level of investment in defense."

Gerson (1969, 1982) reports that some members of **Collembola**, **Diptera**, **Hemiptera**, **Hymenoptera**, **Orthoptera**, **Cryptostigmata**, and **Prostigmata** (Acarina) feed on mosses. But it is likely that the number is far greater than we suppose. Certainly **Lepidoptera** must be added to the list (Chapman 1894; Tillyard 1926). We have found that Isopods can do considerable damage to mosses, but their feeding occurs at night. A number of insects are night active, hence avoiding visibility to birds that feed on them.

Figure 63. *Hypnea pannosa*, a red alga that seems to have inducible antiherbivore compounds. Photo by Cal Photos, through Creative Commons.

Antiherbivore compounds in liverworts have been greatly elaborated by Asakawa (1981, 1982, 1984, 1990). Despite the widespread presence of these compounds, some liverworts are still eaten. For example, Robin Stevenson sent me an image of *Marchantia polymorpha* (Figure 64) with evidence of herbivory on the gemmae cups.

Figure 64. *Marchantia polymorpha* showing gemmae cups where the gemmae have apparently been eaten; the bottom of the cup is eaten through to the soil. Photo courtesy of Robin Stevenson.

A common pattern of bryophyte consumption is for the insect to strip the leaf lamina cells while avoiding the costa and border cells (Wyatt & Stoneburner 1989; Davidson *et al.* 1990). Other insects avoid the cell wall problem by using a straw-like stylet, such as those of aphids and mites, sucking out the contents without the necessity of digesting cell walls.

Loren Russell (pers. comm.) observed the locations and food habits of insects in western Oregon and Washington, USA, and researched their food habits through

published feeding observations and gut analyses. He found at least 26 species of **bryophagous** insects (those eating bryophytes). Among these, only three species were reported as associated with liverworts. To the list of liverwort consumers, he added **Tipulidae** larvae and ***Lioligus striolatus*** (a member of the bryophyte-dwelling beetle family **Byrrhidae**; Figure 65).

Figure 65. *Lioligus nitidus* adult, a bryophyte dweller and liverwort consumer. Photo by CNC-BIO Photography Group, Biodiversity Institute of Ontario, through Creative Commons.

Bryophyte herbivory may have been more extensive among early bryological evolution. As insects and other herbivores became more abundant and diverse, those that survived were more likely to be those protected by antiherbivore compounds, tough tissues, lack of nutrients, or inconspicuous locations. To shed light on early herbivory, Labandeira *et al.* (2014) examined fossil evidence from the late Middle Devonian liverwort ***Metzgeriothallus sharonae*** (Figure 66) from eastern New York state shale fragments. Using microscopic analysis, they detected an "extensive repertoire" of arthropod herbivory. This represented three functional feeding groups and nine types of damage by arthropods. They considered the oil bodies were similar to those of modern liverworts and probably provided chemical defense against the arthropod herbivory on this species. The evidence suggested that these early herbivores were significantly smaller than those of the later Palaeozoic and that they had an important role in early terrestrial ecosystems.

Figure 66. *Metzgeriothallus sharonae* fossil showing cells. This fossil species is known to have provided food for at least three feeding groups. Photo by Susan Tremblay, with permission.

It is now clear that bryophytes are eaten, but that this is not widespread among the members of the animal kingdom. Claudio Delgadillo (pers. comm. 30 March 2016) was surprised when a student discovered bryophyte tissue in a sea urchin gut. One had a liverwort and one had a moss! And most of us have probably seen capsules with holes in their sides, indicating something had been nibbling. Sometimes only the stems remain, and in the image of ***Orthotrichum affine*** (Figure 67) sent to me by Robin Stevenson. It remains a challenge to match the identity of the bryophages with their food organisms.

Bryophytes as Pesticides

Since many bryophytes have been refused in feeding trials, and many bryologists consider their secondary compounds with antifeedant properties to be important in deterring potential feeders, it should be no surprise that some enterprising bryologists and their colleagues have attempted to use these compounds in pesticides (Singh *et al.* 2015). Singh and coworkers found the enzyme thiaminase from ferns and mosses exhibited insect resistance activity. They were able to patent crude protein extracts of several ferns and mosses that caused 70-100% mortality and reduced growth in caterpillars of the Noctuidae *Spodoptera frugiperda* (fall army worm) and *Helicoverpa zea* (corn earworm), neither of which is known to eat mosses. Such pesticides may be a boon to agriculture by decreasing destruction. Since they are natural compounds, they are probably already avoided by birds. Nevertheless, their safety as a pesticide must be evaluated, particularly in regard to pollinators.

Sampling Methods

Field Collection

A common method of field collection for soil and bryophyte invertebrates is the use of **pitfall traps**. Drozd *et al.* (2009) were surprised to find that the total abundance for arthropods was higher in the litter samples than from the moss cushions. As they point out, conclusions of this sort should be evaluated carefully based on the methods. Bryophyte dwellers may seek refuge there and may be relatively immobile. They also may be species that tend to desiccate easily, hence their retreat into the more moist

bryophyte cushions. Their nighttime movements may be vertical rather than horizontal, hence never going near the pitfall traps. In the daytime they retreat into the protective cushion of bryophytes where it is harder for predators to see them and they are more protected from desiccation. This same protection in a dense moss cushion prevents rapid movement. The arthropod surface activity may be mostly that of predators in search of dinner. Those within the bryophyte clump may be species that feed on bryophytes or the collected detritus and microorganisms, hence having no need to move from the clump at all.

If these problems concern you, then the best method of collection is to sample bryophyte clumps. Andrew and Rodgerson (1999) recommend 2.5 x 2.5 cm clumps. Unfortunately, this method is destructive and should never be done with rare bryophyte species or fragile ecosystems.

One method I have not tried is to use a **sugar flotation** technique with live bryophyte cushions (see Pask & Costa 1971 below). After floating off the insects, clean the cushion well in rainwater or stream water and return it to its original position. If the clump is kept intact, it may survive. But I don't know if it will survive the sugar solution, and the effectiveness of extracting the insects without disturbing the integrity of the moss clump needs to be tested.

Extraction

Heat gradients are common methods for extracting invertebrates from soil and bryophytes. Tuf and Tvardik (2005) used a Tullgren funnel with a heat source (lamp) above the mosses in the funnel. Invertebrates are then captured in a jar of alcohol or other preservative below the funnel. This is biased against slow-moving organisms that desiccate easily.

In mosses as dense as some *Sphagnum* (Figure 45) mats, behavioral extraction (also a heat technique) may be beneficial (Fairchild *et al.* 1987). But Fairchild and coworkers added another gradient – dissolved oxygen. Both the heat and oxygen form a vertical gradient in a column of water with the *Sphagnum* immersed at the top. Mean sorting time was reduced from >16 hr to <2 hr per sample. This method was effective for insects and other invertebrates, but was intended for aquatic invertebrates. Its usefulness for emergent bog species remains to be tested. The method takes advantage of the need for oxygen and the avoidance of warmer temperatures among the aquatic organisms.

Temperature gradients have their problems for extracting insects. Some are slow-moving or might burrow deeper into the bryophytes to avoid the heat. Others may become desiccated by the heat and no longer be able to move.

Preserved samples permit the researchers to do the extractions at their convenience. This is sometimes a necessity for extended field work. Pask and Costa (1971) recommend preserving the samples in 10% formalin, but this is highly carcinogenic and should be avoided. Using 70% ethanol (or 95% for aquatic samples) works well. A few drops of glycerine can protect the organisms if too much alcohol evaporates (pers. experience). Pask and Costa compared preserved vs unpreserved samples using extraction with a sucrose solution of 1.12 sp. gr. They found a mean recovery of 90.8% for persevered samples

compared to 83% from unpreserved samples. Furthermore, the unpreserved samples yielded much greater variability in efficiency of recovery than did the preserved samples. And some groups seemed to be easier to recover in the preserved samples (**Zygoptera**, **Hemiptera**, **Trichoptera**, and **Chironomidae**). No group was under-represented in the preserved samples.

Andrew and Rodgerson (1999) tested two common insect extraction methods: **Tullgren funnels** (e.g. Tuf & Tvardik 2005) and **sugar flotation** (Pask & Costa 1971), and compared these to a new technique using kerosene phase separation. They found that the kerosene extraction recovered significantly more invertebrate individuals than did the sugar extraction and represented similar numbers of orders.

Kerosene phase separation (Andrew & Rodgerson 1999; Andrew *et al.* 2003): Upon collection in the field (2.5 x 2.5 cm samples), the bryophyte-invertebrate samples should be placed in 95% ethanol for 2 weeks before extraction. For densely tufted bryophytes, pre-washing samples in 95% ethanol may be useful because there is more interference by the bryophytes. In the **kerosene phase separation**, the kerosene attaches to the insect cuticle to facilitate flotation:

1. First put the bryophyte-insect mix into 2 large test tubes (2 cm wide X 17 cm long).
2. Then fill the test tube 3/4 full of sample with ethanol and top it off with 1 cm of kerosene.
3. Shake this mix vigorously to fully mix the solutions.
4. After 10-15 minutes of settling, roll each tube to release trapped bubbles from the sides and bottom.
5. When the tubes are then kept upright, a distinct interface will form between the ethanol and kerosene; insects will collect onto the interface layer. Pipette off the kerosene to within 1 mm of the interface layer.
6. Then pipette off remaining kerosene plus interface.
7. Wash the sides of the tube with 95% ethanol to dislodge the kerosene stuck to the sides and repipette and collect.
8. Repeat the whole process to get remaining invertebrates (increases total number by about 16%).
9. Push the invertebrates in the kerosene layer into the ethanol, using a fine brush, to dislodge the kerosene from the cuticle.
10. Examine the interface mix in a Petri dish with a binocular microscope under a fume hood for your own safety. Collect and sort the invertebrates.

Habitats

Many practices of humans threaten the bryophytes on the planet Earth. Perhaps the greatest of these in purely terrestrial ecosystems is the management practices of forests. Management for timber threatens the forest floor bryophytes, not to mention those that live on the trees themselves. A major problem is the imposed dispersal limitation to recolonize cut forests, and the larger the cut and isolation, the greater the problem for recolonization (Fenton & Frego 2005). Islands of trees provide refugia where at least some bryophytes may survive long enough to recolonize. Temperature, total daily photosynthetically active radiation, and vapor pressure deficit were significantly different between areas with remnant canopy and those without. If bryophytes are unable to colonize or

survive, the insects that depend on them for moisture, food, and refuge from predators are vulnerable and their mortality increases, often to their local extinction.

Bogs and Wetlands

Data would suggest that bogs and wetlands have the highest populations of insects living among bryophytes. This is at least in part due to the greater biomass of mosses, a ratio of 1.6:1 in a Stordalen mire when compared to tracheophytes (Rosswall *et al.* 1975). Since they are also the habitats with the greatest cover of bryophytes, this high population of insects should probably be expected. Nevertheless, there seems to be little evidence that the bryophytes are used as food. Of nine species of *Nematocera* (midges) larvae, Smirnov (1961) found that only *Psectrocladius* from the *psilopterus* group (Figure 68-Figure 69) had eaten *Sphagnum*, and then it constituted only 16% of the food volume. Rather, algae and detritus among the bryophytes formed the main food for the herbivorous members of the group. The *Collembola* (springtails) eat the fungi that grow on decomposing *Sphagnum*. Thus, the *Sphagnum* provides the substrate needed to make the food available.

Insects in boreal peat bogs may be more distinctive. Spitzer and Danks (2006) found that these bogs have not only the generalists that seem to be common in many bogs, but also distinct **tyrphobionts** (species restricted to bogs) and **tyrphophiles** (species frequenting bogs but not restricted to them). One reason for the great diversity in some bogs is the topographic diversity of bogs, including hummocks that can become dry and hollows that are underwater, with the opportunity to migrate short distances vertically to find suitable moisture levels. Especially in boreal regions, many bogs may be hundreds and some thousands of years old, preserving relict communities that are well established. The isolation of bogs from each other has permitted them to develop unique insect communities.

Brink and Wingstrand (1949) found that the four species considered typical for bogs (Krogerus 1939, 1947) were also present in the Virihaure area of Swedish Lapland. These were the beetles (*Coleoptera*) *Agonum consimile* (*Carabidae*) and *Elaphrus lapponicus* (*Carabidae*) and the flies (*Diptera*) *Dolichopus fraterculus* (*Dolichopodidae*) and *Delia lineariventris* (*Anthomyiidae*). They also considered *Staphylinidae* beetles *Anthobium lapponicum*, *Stenus hyperboreus*, *S. umbratilis*, the *Linyphiidae* spiders *Erigone capra* and *Bathypantes setiger*. On the other hand, Agrell (1941) was unable to find any *Collembola* that were characteristic bog species.

Forests

Biomass production of bryophytes in forests can be high. In oak woodlands, Rieley *et al.* (1979) reported that bryophytes contributed 90% of the ground vegetation green biomass compared with only 60% of the annual production, providing a standing crop (green + brown) of 200-640 g m⁻² in pine forests and mires.

Garry Oak trees sport a variety of bryophytes, providing habitat for various invertebrates (pers. comm. Wynne Miles 12 January 2008). Miles found tufts of *Orthotrichum* (Figure 70) that were missing their sporophytes and only the broken setae remained. In another case, a collection of epiphytes, including *Tortula* (Figure 71), was grazed while in its collecting bag.

Figure 72. *Sphagnum teres*, a forest moss that houses a moderate number of arthropods. Photo by A. Neumann <www.biopix.org>, with online permission.

Forest ecosystems offer a diversity of habitats to insects. Because of their ability to fly as adults, the adult habitat can differ significantly from that of the larvae. The habitats of eggs and pupae – immobile stages – are typically the same as those of the larvae. But once the adult emerges, it is able to move from the food habitat of the larva to the feeding habitat of the adult, or in some cases, the adult does not feed. For many of the adults mating is the first and only priority.

In boreal forests, the bryophytes can often form 100% cover (Oechel & Van Cleve 1986). Although they are a minor part of the biomass, they perform a major portion of the primary productivity and ground cover. Hence, they also provide a major function in determining the invertebrate communities.

Drozd *et al.* (2009) used pitfall traps in a submountain and mountain forest ecosystem of the Czech Republic amid *Polytrichum commune* (Figure 4), *Polytrichastrum formosum* (Figure 3), *Sphagnum teres* (Figure 72), *Sphagnum girgensohnii* (Figure 73), *Sphagnum fallax* (Figure 74), *Bazzania trilobata* (Figure 75), *Pleurozium schreberi* (Figure 76), *Eurhynchium angustirete* (Figure 77), and *Oligotrichum hercynicum* (Figure 78). The traps followed a moisture gradient in moss cushions and in litter with no moss (controls). Drozd and coworkers suggested that the relationship with the mosses seemed to have broader implications than just that of a substrate, *i.e.*, the data indicate interaction between moss presence and other microhabitat features. The great number of insects in these forest floor habitats was indicated by the 55,000 specimens collected (66 traps, 5 locations), averaging 850 individuals per trap. Drozd and coworkers found that moss species, as well as moss presence, was important in determining both total abundance and taxon diversity (Figure 79). But moisture was important as well, perhaps contributing to moss species preference. Nevertheless, trapped arthropod abundance was greater in the litter samples.

Figure 79. Arthropods from mosses in the Podolánky area of the Czech Republic. Poco = *Polytrichum commune*, Poly = *Polytrichastrum formosum*, Sphf = *Sphagnum teres*, Sphg = *Sphagnum girgensohnii*, Sphf = *Sphagnum fallax*, Bazz = *Bazzania trilobata*, Pleu = *Pleurozium schreberi*, Eurh = *Eurhynchium angustirete*, Olig = *Oligotrichum hercynicum*, Spha = *Sphagnum* spp., Cont = litter; moisture Wet = high, Mid = middle, Dry = low. Modified from Drozd *et al.* 2009.

As Drozd and coworkers (2009) pointed out, bryophages and detritivorous arthropods "have no reason to move about," potentially causing a low capture rate in traps that require movement. But these researchers also suggested that bryophytes may serve only as shelter and a temporary place to prevent desiccation, referring to the oft held view that the bryophytes are low in nutrients. This latter assumption, however, has been contested, as you will see earlier in this chapter.

Few studies have attempted to find the uses made by the bryophyte inhabitants (Drozd *et al.* 2009). Rather, most have simply enumerated species, perhaps correlating them with other physical factors such as temperature and moisture.

One of the few studies that elaborates on the relationship between bryophyte species and the invertebrate inhabitants is that of Božanić *et al.* (2013). In this case, *Brachythecium curtum* on a decaying tree housed the greatest number of species. The layers of the forest were important, with type of substrate and height above ground proving to be the most important factors to determine the invertebrate distribution.

Figure 80. *Brachythecium curtum*, a species with a rich fauna of arthropods. Photo by Janice Glime.

Montane Tropical Rainforests

In the Atlantic Forest of Brazil, Maciel-Silva and dos Santos (2011) found a number of insects associated with the mosses *Hypopterygium tamarisci* (Figure 81) and *Lopidium concinnum* (Figure 82). These include **Lepidoptera** larvae, leafhoppers, aphids, and **Psocoptera**, as well as isopods, snails, mites, and spiders.

Figure 81. *Hypopterygium tamarisci*, home to several orders of insects. Photo by Peter Woodward, through Creative Commons.

Figure 82. *Lopidium concinnum*, a habitat for several orders of insects. Photo by Juan Larrain, through Creative Commons.

Epiphytes

A number of species of arthropods are associated with the epiphytes, including several groups of insects. Miller *et al.* (2008) compared the epiphyte arthropod fauna at three heights on red maple (*Acer rubrum*; Figure 83) trees in the Acadian forest of Maine, USA. They found that there was a close association between springtails and spiders and suggested that the spiders were there because of the abundance of springtail prey. When the bryophytes diminished following gap harvesting, the spiders and springtails did as well. One surprise was the abundance of **Diptera** associated with the epiphytes. Fifteen families of these flies were represented. Overall, the numbers of morphospecies was positively correlated with bryophyte abundance except for the springtail family **Isotomidae**. Abundance of the other springtail morphospecies were correlated with dense bryophyte cover at the bases of trees.

Figure 83. *Acer rubrum*, a species that supports arthropods living in epiphytic bryophytes. Photo by Jean-Pol Grandmont, through Creative Commons.

In the Pacific Northwest of North America, the epiphytic bryophyte mats in the subcanopy likewise house numerous insects. In collections of over 143,000 individuals, Peck and Moldenke (2011) recovered 205 morphospecies from 337 moss mats (less than 25 kg of mosses, fresh weight). These mosses were collected to determine the impact of moss harvesting on the insect community, but they also provide us with information on community structure. The faunal morphospecies composition between moss mats from the two shrubs, vine maple (*Acer circinatum*; Figure 84) and huckleberry (*Vaccinium parvifolium*; Figure 85) did not differ. Likewise, the fauna of the vine maple did not differ between the bases and branch tips of these shrubs, differing from their results in the Willamette National Forest (Peck & Moldenke 1999). Instead, the invertebrate fauna composition correlated with elevation, stand age, and vertical distance to water.

Figure 85. *Vaccinium parvifolium*, a species with moss mats that hold arthropods. Photo by Walter Siegmund, through Creative Commons.

In the tropics, canopy bryophytes may be especially important for some of the invertebrates. Pócs (1982) estimated an excess of 1000 g m⁻² of bryophytes in the elfin forests. Trees in Costa Rican montane forests build canopy soils (including bryophytes) that house mites, amphipods,

isopods, beetles, springtails, ants, and insect larvae as the dominant invertebrate groups (Nadkarni & Longino 1990). The ground fauna had a mean density of 2.6 times that of the canopy. Only ants did not fit this pattern. However, it is difficult to assess these tropical mats because the mosses are typically only a minor component. Instead, the mats are primarily leafy liverworts and filmy ferns (Yanoviak *et al.* 2007). Yanoviak and coworkers found that these insect assemblages resembled the fauna of the soil mosses and accompanying humus layer. These are dominated by mites, springtails, ants, and minute beetles (Yanoviak *et al.* 2003, 2004). Unfortunately, the fauna of mosses in the canopy may be under-sampled because the fogging method used in many studies of canopy invertebrates is ineffective for sampling the tiny insects that inhabit the canopy bryophytes (Yanoviak *et al.* 2003).

Even within a mat of epiphytic bryophytes and other plants, vertical differences exist (Yanoviak *et al.* 2004). In a Costa Rican lower montane forest, the green portion of the mat housed twice as many individuals and species per gram dry mass compared to the brown portion. Morphospecies composition was similar, but some taxa differed significantly in relative abundance. Predators were randomly distributed in the larger patch sizes (up to 50 cm²). They found that interspecific interactions were more important than the environmental variables in determining the distribution of the mat fauna in small patch size (20 cm²).

Cryptogamic Crusts

The cryptogamic crusts are those habitats in arid ecosystems that are comprised of algae, bacteria, fungi, lichens, and bryophytes. These crusts are of major importance in these ecosystems, covering as much as 70% of the soil (Brantley & Shepherd 2004).

The arthropod fauna make use of the crusts for retreats and homes. In piñon-juniper woodland in central New Mexico, the crusts differ little in major groups from bryophyte habitats in other ecosystems, with tardigrades, nematodes, springtails, small insects, mites, and spiders predominating (Brantley & Shepherd 2004). Of the 38 taxa identified in the study, 27 occurred on mixed lichen and moss patches and 29 on moss patches. Only 21 were found on pure lichen patches. Of the three types of crusts, 15 arthropod taxa occurred on all three. Not only did the mosses have the highest number of arthropod species, but they also had the greatest abundance of arthropods. In this very dry climate, the greatest arthropod richness and abundance occurred in winter.

Altitude

Altitudinal gradients are complicated. Although the temperature tends to decrease and winds increase, moisture may be greater or less, and microhabitats abound. Vegetation changes and can increase or decrease shade. UV light may come into play.

Differences between elevations may be more due to microclimate differences than to those differences caused by elevations (Andrew *et al.* 2003). For example, Andrew and coworkers found that whereas altitude had a significant effect on diversity of insects in Tasmania and New Zealand, there was no general trend present along the altitudinal gradient. Mt. Field in Tasmania had the highest invertebrate and bryophyte diversity at 750 m. But Mt.

Rufus had low bryophyte and insect diversity throughout the altitudinal gradient. In Tasmania Mt. Otira had the highest diversity of both invertebrates and bryophytes at low altitudes, whereas Mt. Kaikoura had the highest invertebrate and lowest bryophyte diversity at the highest altitude. Clearly different factors are important for the bryophytes compared to those important for the invertebrates. Andrew and coworkers stressed the importance of scale and the need to sample both broad scale and microscale community patterns.

Tundra

Bryophytes are important ground cover in the tundra. In Spitsbergen, Bengtson *et al.* (1974) found a total arthropod abundance of 268,000 individuals m⁻² on wet moss tundra, compared to 42-63,000 on lichen tundra and 518,000 on grassland. The mites and springtails comprised 96-99% of the arthropod fauna, with small numbers of spiders, flies, and **Hymenoptera**. These major groups were similar in abundance to those of the high alpine in southern Norway.

Boreus in Norway takes advantage of mosses to provide protective space. This is a safe space in which they lay their eggs (Håvar 2001). And it appears that it might be a site of copulation, an event rarely observed on the snow. The chambered air spaces most likely also provide space for this winter-active scorpionfly. Adults of *Boreus elegans* (Figure 86) and *B. californicus* (Figure 87-Figure 88) feed on *Racomitrium heterostichum* (Figure 89-Figure 90); larvae and pupae of *B. elegans* can be found under *Brachythecium* (Figure 91) and other mosses (Russell 1979).

The family **Apteropanorpidae** has a single genus, *Apteropanorpa* (Figure 92), with only four species (Wikipedia 2011). These are the Tasmanian snow scorpionflies, and they live among mosses in Tasmania and southern Australia. The adults are predators, but the larvae live among the mosses.

Figure 92. *Apteropanorpa tasmanica*, a moss dweller that is often infested with one or two species of parasitic mites. Photo by Simon Grove ©, Tasmanian Museum and Art Gallery, with permission.

The best-known species, *Apteropanorpa tasmanica* (Figure 92), is known to carry two species of parasitic mites (Seeman & Palmer, 2011). These are *Leptus agrotis* (Erythraeidae) and *Willungella rufusanus* (Microtrombidiidae).

Antarctic

In the Antarctic, bryophytes form the dominant vegetation and house the most arthropods (mites, springtails, insects) (Gerson 1969). Gerson reported that the *Polytrichum-Dicranum* (Figure 93) mats housed more arthropods than did *Pohlia* (Figure 94-Figure 95). The former was less wet and cold in the summer and its open texture made it easier for movement, especially of larger arthropods.

Figure 95. *Pohlia nutans* with capsules, a genus that is home to arthropods. Photo by Michael Lüth, with permission.

The Antarctic is dominated by small organisms. In that regard, bryophytes are an important habitat for invertebrates. Davis (1981) compared the invertebrates on two kinds of moss communities on Signy Island: a moss turf dominated by *Polytrichum alpestre* (= *P. juniperinum*; Figure 96) and *Chorisodontium aciphyllum* (Figure 97- Figure 98) and a moss carpet composed of *Warnstorfia sarmentosa* (Figure 99), *Sanionia uncinata* (Figure 100), and *Calliergidium austrostramineum* (Figure 101), with the liverwort *Cephaloziella varians* (Figure 102). The trophic structure, organic matter transfer, and production of primary producers (which included lichens and algae in addition to the bryophytes) were similar in these two community types, but the standing crops of **Collembola** (springtails; Figure 33) and **Acari** (mites) differed. These differences may have related to the differences observed in turnover of mosses and accumulation of dead organic matter.

The maritime Antarctic has a flora that is predominately bryophytic (Tilbrook 1967). The invertebrate fauna has few species with any great abundance. This area produced a number of indigenous insects: only seven species of *Collembola* (springtails) and one of *Diptera* (flies), but 20 species of mites. The dominant arthropod is *Cryptopygus antarcticus* (*Collembola*). The highest densities of insects are among the vegetation, but some occur in areas free of permanent

ice. Habitat specificity is uncommon. It is likely that the ability of bryophytes to absorb radiation and affect the microhabitat temperature, coupled with the insulation of snow, makes the bryophyte habitat a suitable habitat for the arthropods. Geothermal areas, as discussed below, further provide a bryophytic habitat that is suitable for arthropods.

Strong (1967) considered the Antarctic mosses to serve primarily as shelter and concluded that they do not provide a significant source of nourishment. Humidity seems to be the major controlling factor, with temperature playing a secondary role. Wind is an important feature that modifies temperature and humidity. The primary consumers include springtails and the midge *Belgica* (Figure 103). Adaptations to the climate seem to be primarily physiological rather than developmental or behavioral.

Figure 103. *Belgica antarctica*, a moss consumer, mating. Photo, through Creative Commons.

Usher and Booth (1984) cut five sets of 96 contiguous samples from moss turf on Signy Island in the maritime Antarctic. They found only 10 taxa of arthropods, comprised of mites and springtails. Of the six species with enough abundance to analyze, they found a vertical separation of the species, with three occurring near the surface, two in an intermediate position, and one deep in the mat, resulting in many negative correlations arthropod between species at any given depth. However, when the depths were combined, there were no negative correlations, and many positive correlations were present. Even within a species the vertical distribution differed with life cycle stage. Overall, two distinct communities were present – the green moss community (0-1.5 cm) and the dead moss community (below 3 cm). Nevertheless, the two communities were composed of the same six species, but the proportions differed.

Geothermal

Cold climates are harsh and many organisms do not have the life cycle and physiological adaptations needed to survive in them. However, one habitat provides the year-round warmth for survival of more temperate organisms that are able to arrive there. These are the geothermal areas that are in polar regions of both the Antarctic and Arctic landscapes.

Bryophytes serve as buffers in these habitats. Their own depth insulates the tips of the plants from the heat beneath, and the "steam" emanating from the vents keeps the habitat moist (Glime & Iwatsuki 1990). Lichens seem

unable to survive these hot but moist environments, but the bryophytes protect their own growing tips and survive at higher moist temperatures than those suitable for lichens.

Elmarsdottir *et al.* (2003) address the paucity of knowledge about the geothermal ecosystems. Most studies have been descriptive, with little attention to the interactions of this unique ecosystem. Soil temperatures dominate the limiting factors, with soil pH and carbon content also influencing species composition. Nevertheless, a number of bryophytes have been able to tolerate the heat or escape it by providing their own insulation through decaying lower parts. These bryophytes provide homes for invertebrates.

Historically, geothermal areas most likely served as refugia from glaciers, and once glaciers receded, these heated areas permitted recolonization of nearby non-geothermal regions. Fraser *et al.* (2014) tested this hypothesis, based on the expectation that the greatest diversity would occur closest to the geothermal areas. Using Antarctica as a test, they did indeed find the greatest diversity closest to the geothermal areas.

Convey and Lewis Smith (2006) reported that the bryophytes on South Sandwich Islands in the Antarctic had the greatest richness in geothermally influenced ground. In fact, only four of the mosses on the islands were never associated with geothermal areas; 35 moss species and 9 liverwort species were present in all. On the other hand, 8 liverwort and 50% of the mosses occurred only on heated or recently heated geothermal areas. *Campylopus introflexus* was the only bryophyte to tolerate the maximum temperatures (40–47°C) of the upper 0.5 cm of the bryophyte layer. The flora of the unheated ground is similar to that of the maritime Antarctic (Convey *et al.* 2000). The heated ground contains species common to both the maritime and sub-Antarctic areas, supporting the importance of the geothermal areas for successful colonization elsewhere.

Given the success of bryophytes in geothermal areas, it is easy to imagine that the ubiquitous insects would likewise be represented there, likewise taking advantage of the extra warmth. Even in Hawaii, geothermal areas permit ants to extend to higher elevations than would otherwise be possible (Wetterer 1998).

Boothroyd and Browne (2006) found that the invertebrate species occupying geothermal areas of New Zealand tended to be common species. Willoughby *et al.* (2015) found that the bryophytic fauna in the Waikato Region of New Zealand did not correlate with the soil temperature.

Some studies are focussing on the impact of human activity, especially for harvesting geothermal heat and power, on the flora and fauna (Miller *et al.* 1995). Human activity poses a threat to these fragile systems. Connectivity between suitable sites is important to maintain these communities and their fauna.

Pollution Effects

Bryophytes are well known for their ability to collect air pollutants, especially heavy metals. As a result, we might expect that the bryophagous insects would also have higher concentrations than those feeding on plants that are less efficient collectors (Steiner 1994).

We might also predict that these high concentrations could be lethal for some of the inhabitants. Varga (1992) tested *Plagiobryum zierii* (Figure 104) and *Saelania glaucescens* (Figure 105) from a polluted roadside in Hungary and found higher lead concentrations in them. Concomitantly, the invertebrate fauna, including insects, was lower than that found in mosses from an unpolluted control site. Furthermore, the invertebrates from the polluted mosses exhibited high concentrations of lead.

Figure 104. *Plagiobryum zierii* from Europe, a moss that accumulates lead that can then accumulate in bryophagous insects. Photo by Michael Lüth, with permission.

Figure 105. *Saelania glaucescens*, a moss that accumulates lead that can then accumulate in bryophagous insects. Photo by Michael Lüth, with permission.

Pollution can have positive or negative effects on insects. When mosses in an area polluted with heavy metals were analyzed, those from less polluted areas had more molybdenum, whereas those from the polluted areas had increased levels of cadmium and chromium (Soltes 1996). These increased Cd and Cr contents corresponded with the areas of spruce bark beetle outbreak.

Climate Change

Pollution with CO₂ is generally blamed for global climate changes. It not only means that some areas will be hotter, some will be colder, more severe storms will occur, water levels will rise, and seasons will have different periodicities, but nutrient levels will change as well.

Richardson *et al.* (2002) examined the impact of changes in nutrients and warming in a sub-Arctic heath on vegetation and insect herbivores. The bryophagous **Heteroptera** in fertilized plots was reduced to as little as 6% that of the unfertilized controls. **Homoptera** that fed on grasses became 400% more abundant. The changes in the insect community was driven primarily by the subordinate plant groups (grasses and mosses), emphasizing the importance of the mosses in this tundra habitat. Nutrients had a greater impact than the rise in temperature.

Summary

Bryophytes serve as habitat for numerous kinds of insects. They provide moisture (an important limiting factor for insects), food, shelter, refuge from predators, and a buffer against the climate. The insects that live there are limited in their adaptations, but some are wingless, have cryptic coloration, are able to eat bryophytes, and are small and flexible enough to maneuver among the bryophytes.

Those that live in northern regions often use mosses as a winter home. They may eat bryophytes to survive in winter and it is possible these bryophytes may help to adapt them to the winter cold, possibly through providing **arachidonic acids**.

Because bryophyte dwellers typically have limited mobility, their dispersal is limited. Fragmented landscapes and separated microhabitats often require corridors that connect the habitats with suitable microhabitats to permit recolonization of disturbed sites.

Although most of the bryophyte inhabitants seem to use the associated invertebrates, algae, bacteria, and fungi as food, some do eat the bryophytes and some are even liverwort specialists. Bryophytes often have secondary compounds that prevent herbivory and those insects that eat bryophytes do have preferences. Some bryophytes are so effective at deterring herbivores that they are being developed as pesticides.

Again because bryophytes have limited mobility, typical insect sampling methods are often inappropriate and biased. Using heat to cause the insects to fall into traps or using pitfall traps may miss whole taxonomic groups that fail to move away from the bryophytes. Hand sorting of bryophyte clumps is the only (nearly) unbiased method, but it is destructive and therefore limits the number of samples.

The most common bryophyte-dwelling arthropods worldwide are spiders, springtails, and mites. The typical orders of insects present include **Collembola**, **Odonata**, **Notoptera**, **Psocoptera**, **Hemiptera**, **Megaloptera**, **Neuroptera**, **Coleoptera**, **Hymenoptera**, **Trichoptera**, **Lepidoptera**, **Mecoptera**, and **Diptera**.

In bogs and wetlands, ants are common *Sphagnum* inhabitants making nests of the *Sphagnum*. **Lepidoptera** are common and depend on plants that depend on the environment created by the bryophytes. Several families of beetles, especially **Carabidae**, live among the bryophytes.

Forest bryophytes have fewer species and the bryophyte fauna there seems to be less well known. In the tropical rain forests, epiphytes provide important habitats, especially for ants and springtails. In cryptogamic crusts of the desert, bryophytes provide a refuge from the hot sun and a place where moist periods last longer, but the life cycle needs to be attuned to the short moist periods or the insects must be able to burrow deep into the soil.

At high altitudes, in the tundra, and in the Antarctic, the bryophytes are the most hospitable habitat for terrestrial insects, providing a buffer against the extreme temperatures, maintaining moisture, and harboring smaller food organisms. It is also likely that they protect against UV light. Geothermal areas in these cold regions provide a haven for species normally found in warmer habitats, and the bryophytes are usually the dominant vegetation.

Bryophytes are known accumulators of air pollutants, so insects that eat them or eat other invertebrates that eat them may be seriously affected by the accumulated heavy metals. A warming climate is likely to decrease the bryophytes in northern climates and thus affect the insect herbivores. Furthermore, increases in nutrients resulting from climate warming cause decreases in bryophagous **Heteroptera** and increases in **Homoptera** that feed on grasses.

Acknowledgments

Will Haines helped me to locate some of the literature and contributed to the discussion about winter dependence on bryophytes for food. Dietmar Quandt helped me find Matthaias Nuss, who ventured a guess at the identity of the unknown frass on the *Tortula truncata*. Thank you to Pierre Morriset for pointing me to the Nowellia Bryologica website. Robin Stevenson has offered continued support of this project and provided me with the images of *Zygodon rupestris* with terminal gemmae and an interesting discussion about it as well as other examples of herbivory.
