species can also live among arboreal mosses (Wake 1987), presumably benefitting from the moisture and cover they provide. Its direct development precludes the need for open water.

This species has fared better than most and is listed only as vulnerable by IUCN (2010b). Nevertheless, it has not been seen since the mid 1980's, but this may be due to limited searching. Its mossy habitat can easily hide it from an undiscerning eye.

Figure 50. *Pseudoeurycea scandens* on moss-covered log where it blends well with the bark and the patchy environment. Photo by Sean Michael Rovito, with permission.

Figure 51. More muted color patterns on another *Pseudoeurycea scandens* (Tamaulipan False Brook Salamander) on bark where it blends well with the bark and lichens, permitting it to be inconspicuous among the patches of mosses as well. With no mating call and small size, these salamanders are difficult to locate and may be lurking nearby undetected. Photo by Timothy Burkhardt, with permission.

***Pseudoeurycea werleri* (False Brook Salamander, Plethodontidae)**

Pseudoeurycea werleri (Figure 52), a lower elevation salamander, lives in the rainforest and cloud forest from 900-1500 m asl on Sierra de los Tuxtlas, Veracruz, Mexico, where it is endangered due to its small distribution and declining habitat (Flores-Villela & Martínez-Salazar 2009; IUCN 2010b). Its home is in the arboreal mosses, where its direct development permits it to survive without pools of water.

Wake (1987) stated that bromeliads and moss mats in mid-elevation wet and rain forests provide "ideal"

microhabitats for insectivorous, direct developing amphibians. This suggests that we may be overlooking such secretive species as this one.

Figure 52. This *Pseudoeurycea werleri* came very close to being dinner, with its entire tail being disarticulated in an attack. Photo by Sean Michael Rovito, with permission.

***Lineatriton* (placed in *Pseudoeurycea* by Frost 2011) (Plethodontidae)**

This genus is combined into *Pseudoeurycea* by Frost (2011). In its narrow *Lineatriton* sense, it is a relatively rare Mexican genus with three described species. The systematics of these species is uncertain and they may actually represent more or fewer species. It uses moss mats to some degree (Wake 1987) and is secretive, nearly always under cover in the rainforest floor (Brodie *et al.* 2002 for *L. orchimelas*). When predators approach, it propels itself by coiling and uncoiling its body rapidly.

Pseudoeurycea lineola (Veracruz Worm Salamander; Figure 53) lives only at 800-1250 m asl in a small area of oak-pine forest in the Sierra Madre Oriental of Veracruz, Mexico (Frost 2011). It lives under stones, logs, and debris, possibly including mosses, and in subterranean hideouts. Its need for moisture suggests that mosses might be a suitable habitat. This species is endangered due to its small, fragmented distribution and continuing loss of habitat (IUCN 2010b). None of its known locations is protected by law.

Figure 53. *Pseudoeurycea lineola*. Photo by Sean Michael Rovito, with permission.

Pseudoeurycea orchileucos (Sierra de Juárez Worm Salamander) lives around Yetla and Vista Hermosa at 800-1390 m asl on the humid northern slope of the Sierra de Juárez, Oaxaca, Mexico (Frost 2011). In these cloud forests it can live below ground (**fossorial**), making it difficult to locate. It does not survive in disturbed habitats, probably due to its need for moisture (IUCN 2010b). Its development is direct, so pools of water are not needed. Hence, mosses might be used to keep its body moist. The species is endangered due to its small population size and limited distribution; logging contributes to its loss of habitat (IUCN 2010b). None of its habitats is on protected land.

Pseudoeurycea orchimelas (San Martín Worm Salamander) lives at 100-1300 m asl in the Sierra de Los Tuxtlas and adjacent Sierra de Santa Marta, Veracruz, Mexico (IUCN 2010b). It is fossorial (lives below ground) in leaf litter. Its direct development does not necessitate open water. Its relationship to bryophytic habitats is unclear. Wake (1987) considered the genus to make some use of bryophytes, but there is no specific mention for this species. This species likewise is endangered because of its small population, limited distribution, and habitat destruction, despite being abundant within its distribution (IUCN 2010b). Unlike the other two species of the former *Lineatriton*, it is protected where it occurs in the Reserva de la Biosfera Los Tuxtlas.

***Thorius* (Mexican Pigmy Salamanders, Plethodontidae)**

***Thorius dubitus* (Acultzingo Pigmy Salamander, Plethodontidae)**

Thorius (Figure 54) represents the smallest of the tailed amphibians (Hanken 1983), with some members less than 2 cm, including the tail (Wikipedia 2010). The genus occurs in the pine-oak cloud forest on high mountain crests of west-central Veracruz and adjacent Puebla, Mexico at 2475-2800 m asl (Frost 2011). *Thorius dubitus* occurred under mosses (Wake 1987) and other plants and occurred at slightly higher elevations than the other salamander species of the area (Hanken 1983).

Figure 54. *Thorius arboreus*, a relative of *T. dubitus*, and possible a moss dweller. Photo by Sean Michael Rovito, with permission.

Old-growth Temperate Habitats

Old growth forests offer a variety of microhabitats not available in younger secondary forests. Dense growths of bryophytes there ameliorate the temperature, providing safe sites that help to cool by evaporation as well as provide dense shade from the dangers of the sun. These same bryophytes likewise provide a haven of moisture when bare soil and branches become dry (Figure 28). Hence, they are able to harbor an array of interesting miniature communities about which we really know very little.

***Aneides aeneus* (Green Salamander, Plethodontidae)**

Aneides aeneus (Figure 55-Figure 57), also known as Web-footed Salamander, Bronzy Salamander, or Bronzed Salamander, lives in the Appalachian region from southern Ohio, southern Indiana, and southwestern Pennsylvania to western South Carolina, Tennessee, northern Georgia, northern Alabama, and northeastern Mississippi, USA (Frost 2011). It eats a diet that can easily be found among, under, or on top of mosses. In Bat Cave, North Carolina, USA, Rubin (1969) found that one individual had eaten 53% ants, 32% spiders, 13% shed salamander skin, and 2% unidentified insect larvae. But when Lee and Norden (1973) examined gut contents of 25 individuals from Coopers Rock, West Virginia, USA (at the northern limit of their range), they found some interesting organic matter – leaf fragments, humus, mosses, and hemlock needles, as well as sand grains.

Figure 55. *Aneides aeneus* adult in crevice in its mossy habitat. Photo by Bill Peterman, with permission.

Canterbury (1991) found that juveniles remained with their mother for about a month. They climbed up the rock faces from their birth crevices toward moss-covered ledges. Cryptic coloration of mottled green and dark colors would render these youngsters almost invisible (Figure 56). Adults live in crevices in boulders and retreat deep into the crevice to hibernate for the winter (Figure 57) (Gordon 1952).

Figure 56. *Aneides aeneus* juvenile in its mossy habitat. Photo by Bill Peterman, with permission.

Figure 57. *Aneides aeneus* adults with eggs in crevice in its mossy habitat, North Carolina, USA. Photo by Bill Peterman, with permission.

***Aneides vagrans* (Wandering Salamander, Plethodontidae)**

Aneides vagrans (Figure 58) lives in coastal northern California, USA, from northwestern Sonoma County to Smith River near Crescent City, and has been introduced and is widespread on Vancouver Island, British Columbia, Canada (Frost 2011). Nevertheless, its populations are decreasing and its IUCN status is near threatened (IUCN 2010b).

Although the ground-dwelling **Wandering Salamander, *Aneides vagrans*** (Plethodontidae) (Figure 58) lives under bark of fallen trees, arboreal members living on large coast redwoods (*Sequoia sempervirens*; Figure 67) may inhabit mosses as well (Spickler *et al.* 2006). Like most of the arboreal salamanders, the species is lungless and the young are hatched fully formed, *i.e.*, they do not form larvae first. Hence, they require high moisture and high oxygen levels. Sillett (1995) found this species among the branches of the moss *Antitrichia curtispindula* (Figure 59-Figure 61) at 30 m above ground. However, the moss study was not designed to be quantitative, and the more quantitative study on mats of the epiphytic fern *Polypodium scolopendri* suggests that *A. vagrans* spends much time among the fern mats, occupying tunnels and cavities left by dead roots and rhizomes (Spickler *et al.* 2006). (I have to guess that these tunnels may actually be in mosses.) Nevertheless, the moist habitat and production of photosynthetic oxygen provided by mosses suggest that mosses should be suitable habitats for these salamanders as well. In any event, the salamanders are at least indirectly dependent on the bryophytes.

Polypodium scolopendri requires either bryophytes or litter to provide the moist substrate needed for their gametophytes to establish (Lovelace 2003).

***Batrachoseps wrighti*, formerly *B. wrightorum*
(Oregon Slender Salamander, Plethodontidae)**

Batrachoseps wrighti (Plethodontidae; Figure 62-Figure 63) [85-120 mm total length (Bury 2011)] is also known as the Western Four-toed Salamander. It is endemic to the northwestern USA, where it occurs from the Columbia River Gorge of northwestern Oregon, USA, southward along the slopes of the Cascade Mountains in Oregon, from sea level to about 1430 m asl (Kirk 1991; Kirk & Forbes 1991; Frost 2011). It lives in temperate zone forests of moist Douglas fir (*Pseudotsuga menziesii*), maple (*Acer*), and red cedar (*Juniperus*) (Bury 2011) and is considered vulnerable on the IUCN Red List due to continuing habitat loss (IUCN 2010b).

Figure 62. *Batrachoseps wrighti* on a bed of mosses. Photo © Gary Nafis at CaliforniaHerps.com, with permission.

The specific habitats of these salamanders include decayed logs and stumps, especially in older decay classes (Bury 2011). However, they have also been found under moss-covered bark in termite channels in decaying logs (Storm 1953) and under large rocks that are moss covered (Bury 2011). It is possible that they require the mosses when they venture out for food, using the mosses to

maintain their moisture. On the other hand, as far as we know, they seem to spend their time in burrows underground or deep within large logs except in early spring just after snowmelt.

They develop without a larval stage, emerging from eggs as froglets (Lannoo 2005), an adaptation to terrestrial living.

Figure 63. *Batrachoseps attenuatus* on moss. Photo by Brian Gratwicke, through Creative Commons.

***Rhyacotriton cascadae* (Cascade Torrent Salamander, Rhyacotritonidae)**

The Cascade Torrent Salamander (*Rhyacotriton cascadae*; Figure 64-Figure 65), also known as Cascade Salamander and Cascades Torrent Salamander, lives in torrents (AmphibiaWeb 2009a) on the western slope of the Cascade Mountains from just north of Mount St. Helens, Washington, south to northeastern Lane County, Oregon, USA (Frost 2011). Although it seems to occur where there are lots of mosses, documentation of its actual use of the moss as a place of shelter or laying eggs is lacking. There is only one published record of its nest, which was under cobble in a quiet area of a small stream (MacCracken 2004). Since this genus is apparently the least desiccation-tolerant genus of salamanders (Ray 1958), it is likely that the salamanders migrate to mosses during times of diminished flow.

Figure 64. Cascade Torrent Salamander, *Rhyacotriton cascadae*. Photo by John Clare, through Creative Commons.

Figure 65. Ventral side of the Cascade Torrent Salamander, *Rhyacotriton cascadae*. Photo by Henk Wallays, through Creative Commons.

***Rhyacotriton olympicus* (Olympic Torrent Salamander, Rhyacotritonidae)**

The Olympic Torrent Salamander (*Rhyacotriton olympicus*; Figure 66), also known as Mountain Salamander, Olympic Salamander, Olympic Mountain Salamander, and Northern Olympic Salamander, is another inhabitant restricted to old-growth forests of northern California and southwestern Oregon (Anderson 1968; Welsh 1990). The Olympic Torrent Salamander (*Rhyacotriton olympicus*), like *Plethodon elongatus*, rarely occurs in open water and likewise seems to require the moisture of mosses, rocks, and organic matter (Welsh 1990) (Figure 67-Figure 68).

Figure 66. *Rhyacotriton olympicus*, the Olympic Torrent Salamander. Photo by Michael Graziano, with permission.

As we have seen in other taxa, *R. olympicus* (Figure 66) often occurs under moss-covered stones in both larval and adult stages, particularly in seepage areas (Stebbins 1955). Stebbins found that the stream was mostly hidden by the moss-covered rocks. Slater (1933) noted that collectors generally hunt for them only during the day. On his night trips he noted that they were on stones and moss a

meter or so away from the water (Figure 68). He suggested that they made these excursions onto the mosses in search of food. The mossy habitat would help to conserve their moisture during these wanderings.

***Rhyacotriton variegatus* (Southern Torrent Salamander, Rhyacotritonidae)**

The Southern Torrent Salamander (Figure 69-Figure 70) is also known as the Southern Olympic Salamander and the California Mountain Salamander. As its name implies, it has a more southerly distribution in the coast ranges from southern Mendocino County, California, north to the Little

Nestucca River and the Grande Ronde Valley in Polk, Tillamook, and Yamhill counties, Oregon and the western slope of the Cascade Mountains near Steamboat, Oregon, USA (Frost 2011).

Figure 69. *Rhyacotriton variegatus* on a bed of mixed mosses. Photo by Henk Wallays, through Creative Commons.

Figure 70. *Rhyacotriton variegatus* creeping across a moss. Photo by William Flaxington, with permission.

Welsh and Lind (1996) conducted an extensive survey of *Rhyacotriton variegatus* (Figure 69-Figure 70) in northwestern California to identify those attributes most important to its location. They determined that it has a rather narrowly defined niche that is encompassed by cold, clear headwaters to low-order streams that have loose, coarse substrata (little sedimentation), in humid forests with large conifers affording more than 80% canopy closure and abundant ground-layer moss. That defines old-growth, undisturbed forest. Their preference for shallow, cold, percolating water with cover of moss and rocks is supported by observations of Anderson (1968), Nussbaum & Tait (1977), Nussbaum *et al.* 1983, Stebbins (1985), Bury (1988), Bury & Corn (1988), Corn & Bury (1989), Welsh (1990), Bury *et al.* (1991), Good & Wake (1992), and Leonard *et al.* (1993). Large conifers, moss, and high canopy closure indicated sites with this species, whereas those with grass and stumps lacked the species (Welsh & Lind 1996). As reported by Bingham and Sawyer (1991), significantly greater moss abundance occurs in old-growth compared with young forests in northwestern California. The moss appears to be important in maintaining moisture in this salamander, but so far there seems to be no direct evidence they live there.

Asia – One Plethodontid!

I was nearly finished with this chapter when I suddenly realized that the salamander chapter had a strong western hemisphere bias. A little checking revealed that the eastern hemisphere does not have many species of these little 4-footed creatures, but I was certain at least some might make use of mosses. Google didn't get me very far, so I appealed to bryonettors for help.

Karsenia koreana (Korean Crevice Salamander, Plethodontidae)

Known in Korea as the Moss Salamander (Figure 71) (Hiromi Matsui, pers. comm. 25 March 2011), or Ikkee dorongyong (Wake 2005), *Karsenia koreana* is a disjunct curiosity. But what is so special about this salamander? It is the first and only plethodontid salamander found in Asia (Min *et al.* 2005)! The world plethodontid specialist David Wake is quoted as saying, "I've discovered and named nearly 50 species of salamanders – more than 10 percent of the total in the world. I've discovered new genera in Guatemala and Costa Rica. But this tops everything I've ever found by a long ways. For me, this is the most stunning discovery in the field of herpetology during my lifetime. It's so utterly unexpected, so completely unexpected." (Sanders 2005).

Figure 71. *Karsenia koreana*, the only known plethodontid in Asia. Photo by Todd Pierson, with permission.

Figure 72. *Karsenia koreana* in a mossy habitat in Asia. Photo by Todd Pierson, with permission.

But that is not the only remarkable circumstance. It was not described until 2005 (Min *et al.* 2005) when a high school teacher from Illinois, Stephen J. Karsen, was on a field trip with his Korean students looking for salamanders in the same sorts of places (Figure 72) he might find them in Illinois (Wake 2005). But in South Korea, this was not considered as a likely habitat because the terrestrial plethodontid species so common in North America were totally unknown and thought to be absent here. Discovered at 210 m asl (Min *et al.* 2005) and endemic to the middle portion of the Korean Peninsula, South Korea, the species is now known from 16 locations in three provinces of South Korea (Wake 2005). With this many locations, it is listed as a species of least concern on IUCN Red List (IUCN 2010b).

This was not, however, the first find of the species. It had been collected 34 years earlier by a Japanese-Korean collecting team but never described as a species (Nishikawa 2009).

Karsenia koreana (Figure 71) was both a new species and a new genus in the family Plethodontidae, representing a considerable disjunction from this predominantly western hemisphere family, and raising questions about its venture to Asia 100 million years ago (Sanders 2005). It averages 42 mm snout to vent length and only superficially resembles the North American *Plethodon* (Wake 2005). It occurs in rock slides and on damp, mossy slopes, causing the Koreans to call it the moss salamander. Its habitat is young forests of hardwoods and pines, 15-50 years old, in limestone areas. Its resting habitat seems to be under small rocks and slices of limestone in areas with fine-grained soil. Since it requires moisture, bryophytes are likely to play a role in maintaining its hydration.

Europe – One Plethodontid Genus

Speleomantes supramontis (Supramonte Cave Salamander, Plethodontidae)

The Plethodontidae in Eurasia are limited to *Karsenia koreana* in Korea and *Speleomantes*, a genus of six limestone cave dwellers (Marc P. Hayes, pers. comm. 26 March 2011). Of these six, it appears that *S. supramontis* (Figure 73) from east Sardinia (around the Gulf of Orosei, Italy, from 100-1360 m asl) is the only one frequently associated with bryophytes. In the Mediterranean oak forests it occurs under mosses on rocks near streams (Nöllert & Nöllert 1992). Not surprisingly, a species such as this with a limited habitat and distribution is endangered (IUCN 2010b).

Figure 73. *Speleomantes supramontis* (Supramonte Cave Salamander) on a rock ledge. Photo by Franco Andreone, through Wikimedia Commons.

Peatlands and Wetlands

Peatlands would seem to provide an ideal habitat for many kinds of amphibians. They have open areas where the amphibians can bask, they have open water for tadpoles and larvae, and they provide moist mosses that keep the amphibians hydrated (Figure 74). This combination also makes them ideal sites for nesting for some species. But there is a caveat – acidity!

Stan A. Orchard of BulfrogControl.com Inc. (pers. comm. 27 March 2011) gave me this summation of his observations: "I have routinely found amphibians (toads, frogs, semi-aquatic salamanders, newts) in and around *Sphagnum* bogs, but they tend to be found in and around open water pools (Figure 74) that are used for spawning, larval stage development, and over-wintering. Amphibian associations with *Sphagnum* (Figure 21) bogs seem to me to be co-incidental and the result of a need by both for damp conditions. However, Plethodontid salamanders, for example, that require damp, shady conditions but reproduce on land are not so likely to be found in a peat bog as on a damp shaded forest floor. Conversely, amphibian species that are found in bogs tend to have migrated in specifically to escape summer dehydration, to forage, and to utilize permanent or seasonal pools for reproduction. *Sphagnum* patches do not seem to be attractive sites for over-wintering for semi-terrestrial species because they are too water soaked in the winter and subject to water table fluctuations, as opposed to damp but drained upland habitats. It is also possible that peat bogs may be uncomfortably acidic for some species."

Figure 74. Developing peatland, seen from upland at Lawrence Lake, Michigan, USA. Photo by Janice Glime.

Despite the acidity, some salamanders are able to tolerate *Sphagnum* habitats. Most of these have been discussed in the subchapter on Ground-dwelling Anurans, including results of various experiments on acidity. In peatlands of Maine, USA, twelve species of amphibians appeared in traps (Stockwell & Hunter 1989). Of the 2179 amphibians captured, only 4.5% were salamanders. Nevertheless, four species were present: *Ambystoma laterale* (Blue-spotted Salamander; Figure 75), *Desmognathus fuscus* (Northern Dusky Salamander; Figure 76), *Eurycea bislineata* (Northern Two-lined Salamander; Figure 77), and *Notophthalmus viridescens* (Eastern Newt - Salamandridae; Figure 106).

Figure 75. *Ambystoma laterale* (Blue-spotted Salamander), a peatland salamander that occurs in eastern USA and Canada (Frost 2011). Photo by Henk Wallays, through Creative Commons.

In addition to the salamanders just mentioned, at least occasional *Sphagnum* (Figure 21) dwellers include some members of the genera *Bolitoglossa*, *Eurycea*, *Hemidactylium*, *Lissotriton*, *Pseudotriton*, *Stereochilus*, and *Triturus*. Some *Ambystoma* species in *Sphagnum* waters seem to suffer lower developmental rates and reduced activity, but survive; some, however, suffer death in the acid water (see chapter on Ground-dwelling Anurans). The relationship of some *Eurycea* species to wetlands with *Sphagnum* are discussed here, and later those of the Salamandridae.

Figure 76. Northern Dusky Salamander, *Desmognathus fuscus*. Photo by Janice Glime.

Figure 77. The Northern Two-lined Salamander, *Eurycea bislineata*. Photo by Henk Wallays, through Creative Commons.

Eurycea wilderae (Blue Ridge Two-lined Salamander, Plethodontidae)

The Blue Ridge Two-lined Salamander lives in the Southern Appalachian Mountains, USA. In the Tullula Wetlands, North Carolina, USA, one can find *Eurycea wilderae* (Blue Ridge Two-lined Salamander, Figure 78-Figure 81) and *E. guttolineata* (Three-lined Salamander; Figure 82-Figure 83) among the *Sphagnum* (Amphibians: Tullula Wetlands 2009). Although it would seem that *Sphagnum* would provide a safe site for eggs, both lay their eggs in the water, presumably because they have aquatic larvae. Instead, their preferred habitat for egg laying appears to be streams and stream banks (AmphibiaWeb 2010).

Figure 78. *Eurycea wilderae* on a moss mat. Photo by Todd Pierson, with permission.

Figure 83. *Eurycea guttolineata* on a bed of mosses. Photo by Matthew Niemiller, with permission.

Figure 81. *Eurycea wilderae*. Photo by John D. Willson, with permission.

***Eurycea guttolineata* (Three-lined Salamander, Plethodontidae)**

Eurycea guttolineata (Figure 82-Figure 83) is also known as Holbrook's Triton and Southern Long-tailed Salamander. It lives in the southeastern USA where it is found in the Mississippi Embayment from eastern Louisiana to extreme western Kentucky and western Tennessee, throughout most of Mississippi and Alabama, the panhandle of Florida and northward through Georgia, South Carolina, North Carolina, to the eastern half of Virginia (Frost 2011).

In the Tulula Wetlands, North Carolina, USA, it lives among the *Sphagnum* (Figure 74) (Amphibians: Tulula Wetlands). Nevertheless, it lays its eggs in the water, presumably because the larvae are aquatic, preferring streams and stream banks (AmphibiaWeb 2010). This very long-tailed *Eurycea guttolineata* is common in swampy areas and along the margins of sluggish streams in Georgia, USA (Salamanders of Georgia and South Carolina 2010).

Figure 82. *Eurycea guttolineata* at the edge of a stream. Photo by Michael Graziano, with permission.

Streams and Springs

***Eurycea bislineata* (Northern Two-lined Salamander, Plethodontidae)**

Eurycea bislineata (Figure 84-Figure 85) lives in eastern North America from the St. Lawrence River in Canada and northeastern Ohio, USA, to northern Virginia, USA. It is widespread and known enough to have ten additional English names (Frost 2011). This species frequently uses mosses for nests and shelter. Eggs may be laid on rocks and logs, but Bahret (1996) found clutches of eggs, fully exposed, on the uppermost leaves of an aquatic moss, *Sphagnum trinitense* (Figure 86-Figure 88). Jobson (1940) found larvae and adults in patches of moss in a swift stream. Richmond (1945) found a nest with 42 eggs among underwater roots under a clump of mosses and other plants. When he turned the mosses back and left them undisturbed for an hour, he returned to find that the salamander had returned to its nest.

Figure 87. Emergent *Sphagnum trinitense*. Photo by Jan Janssens, with permission.

Figure 88. Close view of submerged *Sphagnum trinitense* in South Carolina, USA. Photo by Blanka Shaw, with permission.

***Eurycea lucifuga* (Cave Salamander, Plethodontidae)**

The Cave Salamander (Figure 89) is also known as the Spotted Tailed Triton, Hoosier Salamander, and Spotted-tail Salamander. It appears to be limited to limestone

areas near and in limestone caves at higher elevations of the Appalachian Mountains from eastern Tennessee northward almost to Maryland, USA, and in the Ozark uplift of northeastern Oklahoma, southeastern Kansas, northern Arkansas and central and southern Missouri, southern Illinois, southern Indiana and southwestern Ohio through Kentucky and Tennessee to northeastern Mississippi, northern Alabama, and northwestern Georgia (Frost 2011). This species is common in large springs in Oklahoma, hiding in wet mosses and other vegetation (Bragg 1955).

Figure 89. *Eurycea lucifuga*. Photo by Danté Fenolio, with permission.

***Eurycea multiplicata* (Many-ribbed Salamander, Plethodontidae)**

Also known as the **Many-ribbed Triton**, the species *Eurycea multiplicata* (Figure 90) occurs in the Ouachita Mountains of west-central Arkansas and southeastern Oklahoma, USA (Frost 2011). Its apparent avoidance of acidic conditions was exemplified by Bragg (1955) when he placed them in an aquarium with peat moss (*Sphagnum*) at one end. The entire aquarium, including the sand, was moistened, but after two days of drying, the salamanders had not collected in the peat moss as expected, but rather were curled up on the dry limestone from their native habitat. After several more days they died from desiccation. A limestone rock-dwelling moss may have been a more appropriate choice, but the *Sphagnum* avoidance suggests that it has properties that keep these salamanders away from it, possibly its acidity due to its cation exchange ability.

Figure 90. *Eurycea multiplicata*, a *Sphagnum* avoider. Photo by Michael Graziano, with permission.

The natural habitat of this species is cave springs, cave runs, and cold streams (IUCN 2010b). Despite its apparent aversion to peat mosses in the experiments of Bragg (1955), some mosses do seem to play a role in its life. Dundee (1947) reported that during winter these salamanders remain active, taking cover under rocks, logs, and mosses near streams. It is only during extreme cold that they actually go into **torpor** (state of inactivity), and this may occur under mosses.

***Eurycea tynerensis*, formerly *Eurycea griseogaster* (Oklahoma Salamander, Plethodontidae)**

Eurycea tynerensis (Figure 91) (formerly *Eurycea griseogaster*), was once considered part of *E. multiplicata*. This species likewise occurs on the Ozark Plateau of southwestern Missouri, extreme southeastern Kansas, northern Arkansas, and northeastern Oklahoma, USA, where it lives in streams, springs, and seeps. Dundee (1947) found the species under rocks, logs, and clumps of moss at the edges of streams.

Figure 91. *Eurycea tynerensis* (Oklahoma Salamander) on a liverwort, *Conocephalum* sp. Photo by Michael Graziano, with permission.

Proteidae

This is a small family of salamanders with only one known representative that makes use of bryophytes.

***Necturus punctatus* (Dwarf Waterdog, Proteidae)**

Necturus punctatus (Figure 92) ranges along the coastal plain from southeastern Virginia to central Georgia, USA. This species is unusual in retaining its gills as an adult. Its typical habitats are slow-moving muddy or sandy streams, deep irrigation ditches, cypress swamps, stream-fed rice fields, and mill ponds (IUCN 2010b).

Neill (1948) found as many as twelve individuals of this species hibernating in decaying hardwood logs, under bark, or in beetle tunnels, but also in insect burrows under thick moss on sunny slopes in Richmond County, Georgia, USA.

Figure 92. *Necturus punctatus* among mosses in water. Photo by Todd Pierson, with permission.

Salamandridae

The **Salamandridae** are the newts, a naming choice that will always be a mystery, or at least a point of consternation, for me. But a newt is really just a salamander that differs enough from members of the large **Plethodontidae** family to be distinguished by its own family. One major difference is the life cycle of newts. They have three stages rather than two. Their **larval** stage is aquatic. They then metamorphose into juveniles that are terrestrial, known as the **eft** stage. Finally, as **adults**, they return to the water, but can at times venture onto land, often including peatlands. In their adult stage, a number of them are sold as aquarium pets, but they need a way to get above water occasionally.

Newts are more common than other salamanders in Eurasia, and they often live in mossy habitats or make use of them at times during their wanderings (Marc P. Hayes, pers. comm. 26 March 2011). The newt family **Salamandridae** occurs in Africa in the Mediterranean fringe (Stan A. Orchard, pers. comm. 27 March 2011). Asia has an endemic newt family, the Hynobiidae, mostly known from Japan.

Klaus Weddeling (Bryonet 26 March 2011) informed me that all the European species of salamanders use mosses for shelter during hibernation and during dry periods. Young adults use the wet mosses and soil as shelter for 2-3 years while they mature. But that doesn't mean you are likely to find one. Des Callaghan (Bryonet 26 March 2011) reported that there are only three species of salamanders in Britain, all of them newts in the **Salamandridae**. Although these might traverse bryophytes, they are not particularly associated with them.

***Calotriton asper*, formerly *Euproctus asper* (Pyrenean Brook Salamander, Salamandridae)**

In the French Pyrenees, Michael Lüth and fellow bryologists found the endemic *Calotriton asper* (Figure 93-Figure 94) among mosses close to a waterfall (Figure 94; Bryonet 26 March 2011). Its distribution is the Pyrenees Mountains of France, Spain, and Andorra at 175-3000 m asl. This species is also known as Pyrenean Mountain Newt, Pyrenean Mountain Salamander, Pyrenees Mountain Newt, Pyrenees Mountain Salamander, Pyrenean Salamander, and Pyrenean Newt.

Figure 93. *Calotriton asper* that has been living among mosses in the Pyrenees. Photo by Michael Lüth, with permission.

Figure 94. Habitats of *Calotriton asper* in the French Pyrenees. Photos by Michael Lüth, with permission.

As a cave dweller, this species faces food deprivation for extended periods up to a year. Issartel *et al.* (2010) attempted to follow the physiological responses to 42 days of fasting, followed by 10 days of refeeding in a subterranean and an epigeal population of *Calotriton asper*. The control subterranean population exhibited hypometabolism together with higher glycogen (+ 25% in liver and muscles) and triglyceride stores (+ 50% in muscles), suggesting it was ready to fast. While fasting, the subterranean cave individuals had a 20% decrease in VO_2 (liters of oxygen used per minute) while epigeal individuals showed little change. Furthermore, the underground population maintained a higher energetic reserve. It appears that the cave population is genetically better adapted to fasting, inducing a decrease in metabolism and greater capacity to accumulate energy reserves. But

one must ask if this is, rather than a genetic change, one that has been induced by the prior experiences in the cave. In either case, those organisms with this ability to retain reserves are the ones who will be more likely to survive to breed.

This advantage is almost ensured by the limited dispersion of individuals. Montori *et al.* (2008) demonstrated that the mean distance this species migrated in a year was less than 50 m. There did not seem to be any seasonal migration. Suitable habitats that favored abundance relate to the number of refugia: woody debris, stones, and fissures, places where the salamander can hide and remain hydrated. Larval abundance is correlated with streambed structure. With the limited movement in this species, suitable adult and larval habitats must be in close proximity.

***Chioglossa lusitanica* (Golden-striped Salamander, Salamandridae)**

***Chioglossa lusitanica* (**

Figure 95-Figure 96) is known from northwestern Spain (Iberian Peninsula) and the northern-central part of Portugal (Frost 2011) where it occurs in forested streams (IUCN 2010b) and uses mosses as a refuge (Goux 1957; Marc P. Hayes, pers. comm. 26 March 2011; Iñigo Martínez-Solano, pers. comm. 30 March 2011).

Its limited distribution, pollution, and loss of habitat contribute to its listing as vulnerable (IUCN 2010b).

Figure 95. The **Golden-striped Salamander, *Chioglossa lusitanica***. Photo by Andreas and Christel Nöllert, with permission.

Figure 96. Close view of the **Golden-striped Salamander, *Chioglossa lusitanica***. Photo by Andreas and Christel Nöllert, with permission.

***Euproctus platycephalus* (Sardinian Mountain Newt, Salamandridae)**

In Sardinia, Italy, there seems to be a salamander species that makes use of mosses. Michael Lüth (Bryonet 26 March 2011) informed me of *Euproctus platycephalus* (Figure 97); a group of bryologists disturbed one in wet mosses, *Thamnobryum alopecurum* (Figure 98). In the hot, dry summer of the Mediterranean (Figure 99), mosses provide a place to aestivate.

Figure 97. *Euproctus platycephalus* photographed on the leafy liverwort *Porella platyphylla*, but it was under a moss when it was disturbed. Photo by Michael Lüth, with permission.

Figure 98. *Thamnobryum alopecurum*, home to a population of *Euproctus platycephalus*. Photo by Michael Lüth, with permission.

The **Sardinian Mountain Salamander** is also known as Sardinian Newt, Pyrenean Brook Salamander, Sardinia Mountain Salamander, Sardinian Brook Salamander, and Flat-headed Salamander. It is endemic to the mountains of Sardinia, Italy, at 50-1800 m asl (Frost 2011). This rare species is red-listed as endangered (IUCN 2010b). It is threatened by treatment of water bodies with DDT in the 1950's in the battle against malaria, introduction of trout that may eat the larval and possibly adult salamanders or compete with them for food, and reduction of water levels due to increasing pressures from human activities including tourism and agriculture (Boehme *et al.* 1999).

Figure 99. Habitat of *Euproctus platycephalus* in Sardinia, Italy. Photo by Michael Lüth, with permission.

This salamander spends its larval stage in primarily calm, but also running water (Meijden 1999). The terrestrial phase is always near water, under stones, but also in root zones of bushes and trees and under mosses. The size is 120-140 mm for males and 100-130 for females, total length. This is the opposite of many species of salamanders where the female is the larger gender.

Eggs are only 3 mm in diameter, achieving 4-5 mm with the gelatinous envelope (Meijden 1999). The female lays them over a 3-5.6 month period and development averages 37.6 days at 15°C, or 12.7 days at 14.5°C. Larval development can take 376-453 days at 15°C, exposing the small larvae to predation for a dangerously long time. Even at 20.5°C, development takes 184-260 days.

***Lissotriton boscai* (Bosca's Newt)**

This species (Figure 100) is endemic in the western Iberian Peninsula, excluding southwestern Portugal, and southernmost Spain from sea level to 1800 m asl (Frost 2011). Its habitats include peat moss, running water, and deep, still waters, but it prefers small, shallow ponds with aquatic plants (AmphibiaWeb 2000). In its terrestrial phase, it lives near ponds and hides in humid, shady places under roots, stones, mosses, and trees.

Figure 100. *Lissotriton boscai*, a peatmoss dweller in the Iberian Peninsula. Image through public domain.

***Lissotriton helveticus*, formerly *Triturus helveticus* (Palmate Newt, Salamandridae)**

This species (Figure 101) occurs in western Europe, including Great Britain (Wikipedia 2011e). Smaller than most newts, males reach only 8.5 cm and females 9.5 cm. It has a wide range of habitats, including terrestrial forests, pastures, and agricultural land, as well as aquatic ponds, lakes, canals, and marshes. It is more tolerant of lower pH levels than most amphibians, permitting it to range into more habitats. In the moorlands it can occupy acid pools, and it occurs in peatlands, so Marc P. Hayes (pers. comm. 26 March 2011) suggested that it might make some use of mosses. It is likely that this mostly aquatic species uses the mosses to maintain hydration when it ventures onto land.

Figure 101. Water form of a male **Palmate Newt**, *Lissotriton helveticus*. Photo by H. Krisp, through Creative Commons.

***Lissotriton montandoni*, formerly *Triturus montandoni* (Carpathian Newt, Salamandridae)**

This newt, also known as Montadon's Newt (Figure 102), lives in the Carpathian and Tatra Mountains of Europe, where it makes use of streams (Frost 2011), but also forest habitats rich in mosses (Marc P. Hayes, pers. comm. 26 March 2011). Like *L. helveticus*, it tolerates acid more than most other amphibians, permitting it to occupy a wider range of habitats.

Figure 102. *Lissotriton montandoni*, a moss dweller in European forests. Photo by Maciej Pabijan, through Creative Commons.

***Lissotriton vulgaris*, formerly *Triturus vulgaris* (Smooth Newt, Salamandridae)**

The **Smooth Newt** (Figure 103) has pages of Latin synonyms and a good share of English names. It occurs in Europe in the British Isles and western France west through

southern Norway and southern Finland to the Urals and south to the northern Balkans, northwestern Turkey, and Kazakhstan (Frost 2011). Forests are critical to its existence, but it can occur in meadows and shrub land where forests existed previously, and even occurs in gardens, parks, and fields (AmphibiaWeb 2009d). In the steppe zone it is present in wooded river valleys. In Northern Ireland, this species is legally protected, but it is listed as a species of least concern worldwide (IUCN 2010b).

Figure 103. *Lissotriton vulgaris*, the **Smooth Newt**. Photo by Andreas & Christel Nöllert, with permission.

Newts are not common among mosses, with adults needing a place to swim, but peatlands with open water seem suitable for some. In Ireland, the Smooth Newt (*Lissotriton vulgaris*; Figure 103) prefers the moist habitat of peatlands (Peatlands 2009). After courtship and mating, the female gathers the sperm packets and lays her eggs on aquatic plant leaves that she rolls around the sticky eggs, thus necessitating peatlands that have open water.

This species is rapidly disappearing. Kinne (2006) attempted to determine factors that would improve its habitat and foster greater survival. He determined that the terrestrial phase would hide, especially in the daytime, under mosses, as well as rotting wood, roots of trees and bushes, log piles, and earth holes. When this species was maintained in a terrarium, it chose mosses for its overwintering habitat. There seems to be no documentation of its overwintering activities among mosses in nature.

***Notophthalmus viridescens* (Eastern Newt, Salamandridae)**

This species of newt (Figure 104-Figure 106) is widespread in the eastern USA and into the Midwest (Hunsinger & Lannoo 2011). Its life cycle is unusual, taking it to a variety of habitats. The eggs (Figure 104) are laid in streams, where the larvae develop. Juveniles migrate to land where they may spend 2-7 years in the red eft stage (Figure 105). As mature adults (Figure 106), they are amphibious, spending most of their time in water, but also traversing the land.

Figure 104. Eggs of *Notophthalmus viridescens*. Photo by Tom Murray, with permission.

Figure 105. Terrestrial red eft stage of the **Eastern Newt**, *Notophthalmus viridescens*, displaying warning coloration and Muellerian mimicry that announce its toxic skin. Photo by Janice Glime.

Figure 106. Aquatic adult stage of **Eastern Newt**, *Notophthalmus viridescens*. Photo by Janice Glime.

The eft and adults both make use of mosses for cover, as well as a variety of other cover types (leaves, branches, logs, rocks, grass) (Roe & Grayson 2008). The bright orange coloration of the red eft contrasts sharply against the green bryophytes, but acts as a warning coloration to ward off predators who could have a bad experience with the toxins in the skin (Brodie 1968). The brightly colored efts are more than 10X as toxic as the adults. Only 0.005 cc of eft back skin killed white mice in 10 minutes.

***Salamandra salamandra* (European Fire Salamander, Salamandridae)**

European Fire Salamanders occur in central and southern Europe, from the Iberian Peninsula to Iran and North Germany to North Africa (Kuzmin 1999), mostly at altitudes of 400-1000 m asl (Wikipedia: Fire Salamander 2011). In the Balkans and Spain, they can be at even higher altitudes. Of these, *Salamandra salamandra* (Figure 107-Figure 109) is the best known species, living in deciduous forests in hilly areas. Its abundance classifies it as a species of least concern (IUCN 2010b). Although its primary habitat is among fallen leaves, it also lives on mossy tree trunks (Wikipedia 2011d).

Figure 107. *Salamandra salamandra* on a mossy rock. Photo by Marek Szczepanek, through Wikimedia Commons.

Figure 108. *Salamandra salamandra* on a wet day in the Harz National Park in central Germany. This colorful salamander is hiding in a minicave made by tree roots. The mosses are *Schistostega pennata* and *Atrichum undulatum*. Photo by Katja Reichel, with permission.

This species gets its English name of fire not from its yellow spots, but from its behavior (Wikimedia: Fire Salamander 2011). Adults often hide in crevices in logs. When the logs are used as fire wood, the heat drives them from their hiding places and a number of them may appear "from the flames." Hence, they have earned the name of Fire Salamander.

As Klaus Weddelling pointed out on Bryonet (26 March 2011), the adults of *Salamandra* species are completely terrestrial, using terrestrial habitats even for spawning, having no need for spawning waters any more. Eggs are developed internally and larvae are deposited into the water as they "hatch" (Manenti *et al.* 2009; Wikipedia: Fire Salamander 2011). Adult life spans are known up to 50 years.

You might ask why this salamander has such a bright black and yellow coloration, thus advertising its presence (Figure 109). This is one of the **warning color** combinations, also seen in a number of species of bees, butterflies, and snakes. And yes, this is a poisonous species. But many salamanders are poisonous when consumed. This one is, however, one of the most, perhaps the most, poisonous (Mebs & Pogoda 2005). Its poison glands are concentrated around its head and are usually associated with the colored spots. When disturbed, it assumes a defensive posture and actually sprays, at high velocity ($>3 \text{ m s}^{-1}$), defensive alkaloid poisons and **salamandrin** (Brodie & Smatresk 1990; Oracle Thinkquest 2000). **Salamandrin** is a strong alkaloid neurotoxin that usually causes convulsions (Oracle Thinkquest 2000; Wikipedia: Fire Salamander 2011), hypertension, and hyperventilation in all vertebrates (Wikipedia: Fire Salamander 2011). However, it is only dangerous if swallowed, thus not dangerous to humans, but washing one's hands after handling it is highly advisable (Oracle Thinkquest 2000). The secretions probably do double duty in protecting against bacteria and fungi (Wikipedia: Fire Salamander 2011).

Figure 109. *Salamandra salamandra* on a bed of mosses, in plain view, advertising its warning coloration of black and yellow. Photo by Iocopo Buttini, through Creative Commons.

***Triturus cristatus* (Great Crested Newt, Salamandridae)**

This species (Figure 110), with at least ten English names, occurs in northern and middle Europe to the Alps, westward to middle and eastern France, and eastward to central Russia (Frost 2011). This species is diminishing, despite considerable protection of its habitats in many countries in Europe.

Figure 110. The **Great Crested Newt**, *Triturus cristatus*. Photo by Milan Koříněk, with permission.

Müllner (2001) found a distinct preference for forested sites over grassland, attributing this to increased structural diversity that offered better shelter and higher humidity. In the highland and transitional peatlands of Poland, *Triturus cristatus* (Figure 111) inhabits the peatlands. In their land phase, the newts hide in the daytime, using stones, mosses, dead or rotting wood, tree roots, shrubs, log piles, and holes to hide in or under (Kinne 2006). In Europe this **Great Crested Newt** (*Triturus cristatus*; Figure 110-Figure 111) uses mossy habitats from June until March (Klaus Weddeling, Bryonet 26 March 2011). In winter, the adult newts move to land where they hide in mosses and moist grasses (Kinne 2006).

During breeding season, peat mosses may again become important, but in the water. Dag Dolmen (pers. comm. through Karen Thinggaard 4 April 2011) of NTNU The Museum, Trondheim, Norway, advised me that both *Triturus cristatus* (Figure 110-Figure 111) and *Lissotriton vulgaris* (Figure 103) often attach eggs to *Sphagnum* (Figure 21) in the ponds where they breed.

This species seems to be rapidly disappearing, largely due to disappearance of its habitat (UK Biodiversity Action Plan 1995). This newt was fairly common in Europe and has been protected by law in England and elsewhere in Europe (HCT 2009), including prohibition of habitat destruction. Nevertheless, both its terrestrial habitat and ponds needed for its young are disappearing rapidly (AmphibiaWeb 2009b). Protected peatlands may be its last holdout.

Global warming is also likely to impact this species by changing the sex ratio (Wallace & Wallace 2000). At temperatures of 18-24°C the sex ratio is generally 1:1. At higher temperatures, the population develops more males than females, whereas at lower temperatures than 18°C, the number of females increases significantly. Thus, at higher temperatures one might expect a lower reproductive rate due to the smaller number of females.

Figure 111. The **Great Crested Newt**, *Triturus cristatus*. Photo from Wikimedia Commons.

This newt seems to be one of the species that utilizes the moist mosses during migrations. Stein (1938) observed "great numbers" near Sunderland, Massachusetts, USA, during their migration toward a pond. Many were on the moist mossy bank. As they climbed out of the stream, they travelled along the projecting mosses toward the top of a waterfall. Stein was able to collect over 1000 individuals without exhausting the population. At the very end of their journey the newts had to ascend a dam with a perpendicular wall. It seems that the mosses permitted them to maintain a foothold against the force of the water.

Importance of the Bryophyte Amphibian Community

The bryophytes not only support large amphibians and reptiles like green frogs and rattlesnakes, but more importantly, they provide critical habitat for a number of smaller amphibians and reptiles. Araujo (1999), working in Portugal, concluded that these small amphibians and reptiles may be better indicators of biodiversity than the larger, more conspicuous species. That suggestion is even more applicable in the tropics among the arboreal bryophyte fauna.

Salamanders may play a much greater role in the ecosystem than most of us realize (Conniff 2014). Conniff considers them to be at least one of the top predators in North American forests. In many locations, they have a high abundance and eat a lot. He reports that an average salamander eats 20 ants, 2 flies or beetle larvae, 1 adult beetle, and half a springtail in a single day. But this is an ecosystem, and nothing acts alone. Their food consists almost entirely of shredding invertebrates – those organisms that shred and eat the leaf litter. And when these shredders eat, they release carbon from the leaves, carbon that comprises 47.5% of the litter. When the shredders are eaten by the salamanders, less carbon is released to the atmosphere.

To assess the importance of salamanders in the carbon cycle, Dr. Hartwell H. Welsh Jr., a herpetologist at the United States Forest Service research station in Arcata, California, and Dr. Michael L. Best, currently at the College of the Redwoods in Eureka, California, built enclosures that permitted free access to invertebrates but kept salamanders out of half of them (Conniff 2014). The results – fly and beetle larvae and adult beetles and springtails declined significantly when in enclosures with salamanders. Welsh and Best calculated that the density of salamanders in their study would account for 179 pounds (81.2 kg) of carbon per forest acre being stored in the soil instead of contributing to atmospheric gases that affect global climate.

The small size and lack of lungs in most salamanders translates to a small caloric need. This permits them to eat really small invertebrates that provide insufficient calories for birds and mammals. Bryophytes contribute part of the habitat where many of these salamanders reside.

Summary

Bryophyte-dwelling terrestrial salamanders, particularly arboreal ones, are typically slender with short legs, presumably making movement within the moss mat easier. Terrestrial life cycle adaptations are essential. Egg construction requires tradeoffs among need for gas exchange, need for mechanical support, same-species sperm attraction, other species sperm avoidance, heat conservation or cooling, predator defense, moisture retention, UV light protection, prevention of polyspermy, and protection from bacteria and fungi. Terrestrial eggs are turgid compared to aquatic eggs, usually have a tough outer layer, and may have pigments. Parental care

of eggs helps to minimize bacteria and fungi. Eggs may hatch into tadpoles, but many hatch directly into young salamanders, skipping the larval stage.

Many undescribed species of tiny salamanders most likely lurk among the mosses in the tropical forests. Those that are known are limited in distribution and are threatened by habitat loss. In Costa Rica, the moss salamander *Nototriton* and the climbing salamander *Bolitoglossa* can be found in such habitats, and in Mexico *Cryptotriton* occupies bryophytes in the cloud forest. These three genera are tiny and seem to be moss specialists, with large eggs, long development times, and no larval stages. In Guatemala, the similarly adapted *Dendrotriton cuchumatanus* may occupy moss mats. *Oedipina* species, a Central American group, may live on the ground or be arboreal, using bryophytes for moisture and cover.

In the temperate zones, old growth forests are likely to have more developed bryophyte communities than younger forests. Bryophyte growths are often well developed in old growth, and small amphibians can find refuge from desiccation and predation and in some cases use them as an oxygen source. In old-growth forests of northern California and southwestern Oregon, moss dwellers include species of *Batrachoseps*, *Rhyacotriton*, and *Plethodon*. The wandering salamander *Aneides vagrans* seems to be dependent on mosses among the coast redwoods. *Aneides vagrans* salamanders benefit from the photosynthetic oxygen produced by the bryophytes, while remaining moist among their masses. They also use tunnels made by rhizomes and roots of the fern *Polypodium scolopendri*, which seems to depend on the bryophytes to develop its gametophytes successfully.

Asia has only one Plethodontid species; Europe has one genus, of which only *Speleomantes supramontis* has known bryophyte associations.

North American streams and springs can have species of *Eurycea* among the bryophytes, especially on streambanks.

Peatlands support salamanders and newts, including *Eurycea* species (lined salamanders), *Necturus punctatus* (Dwarf Waterdog), *Lissotriton vulgaris* (Smooth Newts), *Triturus cristatus* (Great Crested Newt), *Notophthalmus viridescens* (Eastern Newt), *Ambystoma laterale* (Blue-spotted Salamander), and *Desmognathus fuscus* (Northern Dusky Salamander).

The bryophyte amphibian fauna, especially the small species, are good indicators of biodiversity.

Acknowledgments

Most importantly, I thank herpetologists Edmund (Butch) Brodie for reading the salamander subchapters and offering his scientific comment and editorial advice. Herpetologists have been extremely helpful in answering my questions and providing images. David Wake helped me sort out the truth from a reference that overstated the role of poisons in salamanders, among other helpful comments. Sean Michael Rovito was helpful in providing

images and anecdotal information about Guatemalan salamanders. Twan Leenders has been kind enough to provide me with original images. Eduardo Boza provided me with images and helped me to find literature on the tropical moss salamanders. Many Bryonettters helped me gain certainty of the identification of *Monoclea* in the picture of *Oedipina gracilis*: Jeff Duckett, Rob Gradstein, David Long, Denilson F. Peralta, Tamás Pócs, Matt Renner, Noris Salazar Allen, Steve Timme. Bryonettters: Özcan Şimşek provided me with a wonderful article on *Triturus*. Wynne Miles steered me toward the story of *Aneides vagrans* in the sequoias. Bill Boelema provided me with the article by Coniff on the importance of salamanders in the carbon cycle. Thank you to Hiroaki Matsui for alerting me to the wonderful story of *Karsenia koreana*. Michael Lüth alerted me to the genus *Euproctus*. Others are credited under the images. I appreciate all the kind individuals who have placed images in the Public Domain.

Bryophyte-dwelling Salamander Checklist

bryophyte use

species	distribution	habitat	mossy habitats under or in mosses	nests	aestivation	hibernation	foraging	source
Hynobiidae								
<i>Hynobius tokyoensis</i> Tokyo Salamander	Japan	forest floor	x					Kusano & Miyashita 1984
<i>Salamandrella keyserlingii</i> Siberian Salamander	northern Asia	wet forest of taiga	x		x	x		Potapov 1993; Hasumi <i>et al.</i> 2009
Ambystomatidae								
<i>Ambystoma laterale</i> Blue-spotted Salamander	western N. Amer.	deciduous & mixed forest	x					LeClere 2011
<i>Ambystoma maculatum</i> Spotted Salamander	eastern N. Amer.	peatlands	x					Amphibians: Tulula Wetlands
<i>Ambystoma jeffersonianum</i> Jefferson Salamander	central E. N. Amer.	forest floor & wetlands	x					Freda & Dunson 1986
Plethodontidae								
<i>Plethodon teyahalee</i> Southern Appalachian Salamander	high elev S. Appalachians	decid. forest & peatlands	x					Amphibians: Tulula Wetlands
<i>Plethodon serratus</i> S. Red-backed Salamander	SE USA	forest floor		x				Aaradema 1999
<i>Plethodon nettingi</i> Cheat Mountain Salamander	Cheat Mtn, WV, USA	red spruce forest floor	x	x		?		Pauley 1985
<i>Plethodon cinereus</i> E. Red-backed Salamander	NE USA, SE Canada	peatlands, forest floor	x	x				Hughes <i>et al.</i> unpubl.
<i>Plethodon dorsalis</i> Northern Zigzag Salamander	lower midwest USA	rocky slopes		x				Ferguson 1961
<i>Plethodon welleri</i> Weller's Salamander	mtns of TN to VA, USA	conifer logs		x				Organ 1960
<i>Plethodon elongatus</i> Del Norte Salamander	SW OR to NW CA	old growth forest	x					Welsh & Lind 1995
<i>Plethodon idahoensis</i> Coeur d'Alene Salamander	northern Rocky Mtns	seeps, springs, waterfalls		x				Wilson 1990; Dumas 1957
<i>Plethodon vandykei</i> Van Dyke's Salamander	Washington, USA	coniferous forest floor		x				Slater 1933
<i>Plethodon larselli</i> Larch Mountain Salamander	Columbia R Gorge USA	talus slopes		x				Burns 1962
<i>Plethodon glutinosus</i> Northern Slimy Salamander	eastern USA	bottomland		x				VA Dept Game Inland Fish 2011
<i>Plethodon richmondi</i> Southern Ravine Salamander	eastern USA	ravines, hillsides, mesic forest		x				VA Dept Game Inland Fish 2011
<i>Plethodon metcalfei</i> Southern Gray-cheeked Salamander	S Blue Ridge Mtns USA	forest floor	x					Organ 1958
<i>Plethodon jordani</i> Red-cheeked Salamander	Great Smoky Mtns	spruce-fir forest	x	x				King 1939
<i>Plethodon stormi</i> Siskiyou Mountains Salamander	S Oregon, N California	talus		x				Gary Nafis 28 April 2011

CHAPTER 15

REPTILES

Figure 1. A hatchling Spotted Turtle, *Clemmys guttata*, traversing mosses near its wetland home. Photo courtesy of Steve Soldan, Woodlot Alternatives.

Vertebrates

A chipmunk scampers across a log. A bird builds a nest in the tree above. A toad awakens from its winter nap. A bear gathers grubs to fill its empty gut. These and many more animals have interacted in secret ways with the bryophytes of the forest, dispersing them, using them for nesting and bedding, escaping the cruel crystals of ice by hiding beneath them, eating the tiny invertebrates among them. Reptiles are no exception, using them for nesting sites and hibernacula. So many animals use the mosses in so many untold ways. And surely many more secrets remain to be discovered.

With reptiles I must face a capitalization dilemma. Whereas only proper nouns in plant names are generally capitalized, reptiles, like birds, have official English names that are capitalized. Hence, I shall be inconsistent and capitalize these names, although it bothers me, and I will not capitalize those of plants.

Order Testudines – Turtles

The moist environs of the *Sphagnum* peatlands (Figure 2) make ideal habitats for aquatic turtles like the

Spotted Turtle *Clemmys guttata* (Figure 1; Wright 1919; Folkerts & Skorepa 1967) and the Painted Turtle *Chrysemys picta* (Krawchuk & Brooks 1998; Rydin & Jeglum 2006) and their eggs (Figure 3).

Figure 2. Virus raised bogs, Estonia. Photo by Lysy, through Creative Commons.

***Clemmys guttata* (Spotted Turtle, Emydidae)**

Clemmys guttata (Figure 1) is globally endangered (IUCN 2011). In New York, USA, *Clemmys guttata* is rare in *Sphagnum* peatlands (Figure 2), particularly those suitable for cranberries. But in Pennsylvania, USA, it has been known to congregate on the peatlands in May and June (Netting 1936). In the Georgian Bay, Ontario, Canada these animals hibernate in the *Sphagnum* swamps from September until April (Litzgus & Brooks 2000). Litzgus *et al.* (1999) found that the turtles actually have two types of hibernation niches in Georgian Bay: *Sphagnum* hummocks with cave-like spaces created by tree roots (Figure 4) and rock caverns at the shores of the swamps (Figure 5), both requiring *Sphagnum* peatlands. The stable temperature of the hummocks protects the turtles from freezing, permitting them to maintain a body temperature of 0.3-3.9°C at the northern limits of their range, despite air temperatures that reach -35°C.

Figure 3. Eggs of the Painted Turtle, *Chrysemys picta*, exposed from their underground home. Photo by John White, with permission.

Figure 4. Spotted Turtle, *Clemmys guttata* in air pocket beneath moss hummock, with body submersed and head above water. Redrawn from Litzgus *et al.* 1999.

Clemmys guttata (Figure 1, Figure 6-Figure 7), a shallow-water turtle, prefers a soft bottom substrate with both submerged and emergent vegetation. Therefore, boggy ponds, fens, and *Sphagnum* (Figure 2) seepages provide suitable habitats. In the spring the turtles travel to seasonal pools, then search for suitable nesting sites (Milam & Melvin 2001). Babcock (1938) reported finding nests among damp logs and moss. Nesting sites include *Sphagnum*, among others (Hunter *et al.* 1992; Ernst *et al.* 1994). Dick Andrus (pers. comm.) found "a bunch of little ones buried in a *Sphagnum* hummock (Figure 13) once on Long Island." In summer, the turtles frequently wander onto land between their wetlands, where they may aestivate for weeks at a time (Figure 6) (Ernst *et al.* 1994; Harding 1997, 2002). They seldom wander very far; turtles in a Massachusetts, USA, study travelled an average maximum distance of 265 m from their winter hibernacula, although some travelled as far as 1025 m (Milam & Melvin 2001).

Figure 5. Relationship of hibernating Spotted Turtle, *Clemmys guttata*, in an air pocket under the safety of a rock. Redrawn from Litzgus *et al.* 1999.

Milam and Melvin (2001) demonstrated that even though these turtles do not wander far from their winter hibernacula in the peatlands, they wander farther than the buffer protected by the Massachusetts' Wetlands Protection Act. The act provides buffers of 30 and 60 m in uplands around the wetlands, but in this study, females nested 75 – 312 m from the wetlands and aestivated at distances up to 412 m. To maintain turtle populations, larger surrounding areas will need to be preserved along with the wetlands.

But not all Spotted Turtles spend their lives in association with peatlands. In Georgian Bay, Ontario, Canada, one island population of Spotted Turtles placed their nests in shallow soil of exposed Precambrian Shield rock outcrops (Litzgus & Brooks 1998). Although there were patches of lichens and mosses among the rocks, it is doubtful that these were large enough to provide habitat for the turtle. On the other hand, the low-lying *Sphagnum* interspersed among the rocks may have been essential for

maintaining hydration and could provide a suitable nesting site. The authors speculated that the rocks provided the warmth needed for incubation. Milam and Melvin (2001) found that the dominant ground cover in the habitat of spotted turtles in their Massachusetts, USA, study was *Sphagnum* spp, although they only mentioned three (out of 19) hibernacula in abundant *Sphagnum*, in an area of shrub wetlands where there was a slow current of shallow water.

Figure 7. *Clemmys guttata* sunning on a rock. Photo by S. Duranceau, through Wikimedia Commons.

***Chrysemys picta* (Painted Turtle, Emydidae)**

Although the Painted Turtle (*Chrysemys picta*; Figure 8-Figure 10) is common in ponds, lakes, marshes, and other forms of slow-moving water with a muddy bottom, it can also be found in fens and bogs (Rydin & Jeglum 2006) – habitats where bryophytes predominate. It has an interesting courtship in which the male uses his long claws, palms facing outward, to stroke the female on the cheeks and neck (Wikipedia 2011b). Females lay the eggs in several events in sandy soil exposed to the sun, preferably with open water within 200 m. The nest is shallow (5-11 cm deep), but doesn't need to protect the next generation over the winter. Instead, the eggs hatch in 72-80 days and the independent young dig their way out.

Figure 10. *Chrysemys picta* on its back, revealing the decorated plastron. Photo © Gary Nafis, with permission.

Winter is a dangerous season for the young turtles. Although they tolerate freezing down to -6°C (Churchill & Storey 1992), contact with soil causes ice crystals to penetrate their integument when the soil is just below freezing (Packard *et al.* 2000). At temperatures below -2.5°C , apparently these hatchlings increase their ability to tolerate cold as the winter continues, extending an initial survival of 3 days at -2.5°C to survival for 11 days at that temperature (Churchill & Storey 1992). It appears that ingestion of nesting soil raises their temperature of crystallization by increasing their ice-nucleating activity and hence decreases their survival at winter temperatures in the field (Costanzo *et al.* 2003). This effect can last for a month and can account for greater survival of laboratory-

reared turtles that are deprived of these soil-derived ice-nucleating proteins.

The muddy pond or lake bottom provides a place for the adult turtles to hibernate during the winter, using the calcium and magnesium in their bones and shell to buffer the lactic acid produced by their anaerobic respiration (Storey & Storey 1990; Storey 1996; Jackson 2002). At the same time 40-45% of the lactic acid is stored into the bone and shell and remains there until the turtle ceases hibernation and once again obtains fresh oxygen. Along with a severe depression in metabolism, this mechanism, known only from turtles, permits the turtle to remain in anoxic hibernation for months at a time.

Like snakes, the turtles must bask in the sun to gain enough heat to digest their food (Wikipedia 2009). On the other hand, too much heat will kill them within minutes.

***Glyptemys* (formerly *Clemmys*) *muhlenbergii* (Bog Turtle, Emydidae)**

The Bog Turtle, *Glyptemys* (= *Clemmys*) *muhlenbergii* (Figure 11), inhabits many of the same locations as the spotted turtle, so it is not surprising that hybrids exist (Ernst 1983). As the name implies, the Bog Turtle, also known as the cranberry turtle, lives largely in *Sphagnum* peatlands (Ashley 1948; Barton & Price 1955). (The term bog must be interpreted liberally because it is relatively recently that North Americans began using the narrower European definition of bog; previously, almost anything with *Sphagnum* was considered a bog.) The moist peat is most likely important in keeping the turtles hydrated. *Clemmys* (= *Glyptemys*) *muhlenbergii* (Figure 11) is the smallest of the turtles in North America (NRCS 2006). It has been diminishing in numbers due to over-collection and destruction of habitat. As early as 1918 Wright considered it to be disappearing due to destruction of peatlands. The northern population lives in the eastern United States from Massachusetts to Maryland; the southern population lives in southwestern Virginia, south to northern Georgia.

Their small size permits them to traverse peatlands through tunnels that at times afford them protection from predators – and human collectors. This secretive behavior makes them to be more rare than they really are. In a study of several *Sphagnum* peatlands in Pennsylvania and New Jersey, USA, Ernst *et al.* (1989) found that some Bog Turtle tunnels appeared to have been made by meadow voles (*Microtus pennsylvanicus*; Figure 12) and widened for use by the turtle. In fact, few of the tunnels appeared to be strictly the results of the labor of the turtles.

All things considered, one might think of these turtles as lazy inhabitants of peatlands. Carter *et al.* (2000) used threadpooling to determine their movements and found that 75% of their movements remained within 20 m. Only 2% of the movements took them more than 100 m. Hence, they seldom moved between wetlands, underscoring the importance of individual wetlands and the unlikelihood that restored wetlands will be easily recolonized by these turtles.

It appears that despite its common name of Bog Turtle, *Glyptemys muhlenbergii* (Figure 11) does not require peatlands. In Maryland, USA, turtles from two locations lived in wetlands dominated by low grasses and sedges in one area and by cattle and sheep pasture in the other

(Morrow *et al.* 2001). Almost no *Sphagnum* (Figure 13) peat was present.

Figure 13. *Sphagnum magellanicum* hummock, a moist location for bog herps. Photo by James K. Lindsey, with permission.

Nevertheless, Bog Turtles do use *Sphagnum* (Figure 13) for basking and as a nesting site where eggs incubate for 42-56 days (NRCS 2006). Mating occurs in spring and nesting occurs from May to July (Smith 2006). These nests

generally are close to the hibernacula. Barton and Price (1955) describe a nest among *Sphagnum* (Figure 13) extending about 12 cm above the water surface with hatchlings emerging. Apparently the female had buried herself in the moss, deposited the eggs, and crawled out, allowing the mosses to close over behind her, camouflaging the eggs.

Although the turtles prefer to feed on slugs, worms, spiders, and insects, they will also eat mosses (NRCS 2006; Smith 2006). However, one must ask if this is an accidental consumption in an attempt to eat invertebrates.

***Glyptemys* (formerly *Clemmys*) *insculpta* (Wood Turtle, Emydidae)**

The Wood Turtle, *Glyptemys* (= *Clemmys*) *insculpta* (Figure 14-Figure 15) seems to prefer open areas and cornfields to hemlock swamp with mosses (Kaufmann 1992). In a study in central Pennsylvania, only one turtle chose the hemlock forest that had a thick carpet of *Sphagnum*. Was she the outcast, or did she have the sole privilege of staying in this damper habitat?

Figure 14. Wood Turtle, *Glyptemys* (= *Clemmys*) *insculpta*. Photo by USGS, licensed as public domain.

Figure 15. *Glyptemys insculpta* among vegetation. Photo by Steve Silluzio, with permission.

***Emydoidea blandingii* (Blanding's Turtle, Emydidae)**

In Nova Scotia, juveniles of Blanding's Turtle (*Emydoidea blandingii*; Figure 16) selected habitats with *Sphagnum* (Figure 13), sweet gale (*Myrica gale*), and leatherleaf (*Chamaedaphne calyculata*) (McMaster &

Herman 2000). Butler and Graham (1995) found that hatchlings often sought refuge under *Sphagnum* in dry vernal pools. After a literature and field study, the U. S. Fish and Wildlife Service (2007) concluded that the best place to release hatchlings might be in beds of *Sphagnum*.

Figure 16. Blanding's Turtle, *Emydoidea blandingii*. Photo by Phil Myers, through Creative Commons.

Power *et al.* (1994) provided a plausible explanation for the choice of sphagnum habitats, among others. In their study of the Kejimikujik National Park in Nova Scotia, Canada, they found that they could predict the occurrences of this turtle by the color of the water. Within the park, the turtles would seek out highly colored bodies of water, typically small streams and lakes draining peatlands. In addition to data from 1572 captures (60 turtles), three turtles that left one body of water migrated through more lightly colored waters to settle in another location that was highly colored. Graham (1992) made similar observations on the preference for highly colored water in Maine, USA. These highly colored waters typically drain peatlands that provided the source of the coloration. Kerekes and Freedman (1989) indicated that these colored areas were high in secondary productivity, especially aquatic invertebrates, that would serve as a food source for the turtles. It is the same colored organic material coming from the peatlands that provides the food for this greater invertebrate productivity.

I have to wonder if the colored water of vernal pools in peatlands might offer another advantage. Packard *et al.* (2000) found that these turtles do not overwinter in the nests where they were born. They can survive to -6°C, but that when they are in contact with frozen soil their integument is penetrated by ice crystals at temperatures barely below 0°C. The freezing is fatal at temperatures below -2.5°C. Since dark-colored water should absorb more heat than clear water, perhaps these colored ponds are a mechanism to keep them warm.

***Chelydra serpentina* (Snapping Turtle, Chelydridae)**

A snapping turtle is not one that would come to mind as a moss eater. Those powerful jaws that one must avoid when trying to capture this large freshwater turtle don't suggest a diet of bryophytes. But Ralph Pope provided me with a picture that may represent snapping turtle feeding on *Sphagnum capillifolium* (Figure 17) – or was it those beetles we can see? The wide swath suggests to me it was eaten by something larger than a beetle.

Figure 17. *Sphagnum capillifolium* with middle portion eaten, lacking its capitula. This may have been done by the snapping turtle that was found nearby (dead!), or was it the two beetles on the right side of the picture? Photo by Ralph Pope, with permission.

Marine Turtles

At the risk of perpetuating a myth, I found an interesting reference to marine turtles that fed on mosses! Fritts (1981) reported that Dampier (1906) had found that the marine turtles on the Galapagos Islands and adjacent areas were "rank, fat, and fed on moss." Fritts considered it likely that these were Olive Ridley Turtles, based on their size and habits, but he also stated that Dampier had mentioned loggerhead turtles (*Caretta caretta*?, Cheloniidae; Figure 18) fed on moss and were rank. I doubt that the moss made them rank, and I have to wonder if it was true moss or another mosslike plant, like Spanish moss (a bromeliad) that also grows there.

Figure 18. *Caretta caretta* (Loggerhead Sea Turtle) swimming in a marine habitat. Photo by Ukanda, through Wikimedia Commons.

Testudo (Spur-thighed Tortoise, Testudinidae)

Serhat Ursavaş wrote to me that he saw a turtle [*Testudo (graeca) iberica*, Spur-thighed Tortoise or Greek tortoise; Figure 19] in the Kirzil Mountain National Park near Beyşehir Lake, Turkey (1234 m asl). The overstory vegetation was *Pinus nigra* subsp. *pallasiana*, *Salix alba*, and *Populus tremula*. The turtle was eating a mixture of moss (*Calliergonella cuspidata*; Figure 20) and grass on very wet, muddy soil. When approached, it stopped eating.

This species is widespread in the Mediterranean, where it survives relatively dry conditions (Highfield 1992). It is a relatively large tortoise, with females reaching up to 30

cm. Typical food plants include vetches (*Vicia*), dandelions (*Taraxacum*), mallows (*Malva*), and numerous species of the legume family (Fabaceae).

Figure 20. *Calliergonella cuspidata* in a wetland where the Spur-thighed Tortoise can eat it. Photo by Michael Lüth, with permission.

Dispersers

The Snapping Turtle (*Chelydra serpentina*, Chelydridae; Figure 21-Figure 23) is not thought of as a moss dweller and spends much of its time in the water. But it has a different relationship with bryophytes. It contributes to dispersal, at least for *Riccia rhenana* (Figure 22), dragging fragments from one place to another (McGregor 1961). Apical segments of these liverworts can survive two months of desiccation and five weeks embedded in ice, despite the death of older parts. My own experience with dispersal involved a Box Turtle (*Terrapene carolina*, Emydidae). My *Conocephalum conicum* (Figure 24) spread in my garden room when I had a Box Turtle, but not at any other time.

Figure 22. *Riccia rhenana*, a species that is dispersed by the Snapping Turtle (*Chelydra serpentina*). Photo by Štěpán Koval, with permission.

Winter

Winter presents particular challenges for reptiles. Species in higher altitudes generally have better freezing survival than those of lower elevations (Storey 2006). Adults also are more freeze tolerant than juveniles. Live bearers have better long-term freezing survival than do egg bearers. And juveniles that hibernate in bogs go to greater depths than do adults. Thus, mosses help in the survival of at least some reptiles by providing insulation that keeps temperatures warmer than air temperatures in winter.

Order Squamata – Lizards

Lizards bring images of rocks, fence posts, and other dry habitats. But some include mosses as important habitat characteristics. Block and Morrison (1998) reported that *Sceloporus* (Figure 25) lizards in dry California oak woodlands were positively associated with mosses. Other lizards make rather unique uses of mosses.

Figure 25. *Sceloporus magister* in its typical rocky habitat where its disruptive coloration resembles rocks and lichens. Photo by Kalderi, through Wikimedia Commons.

Adaptations

Lizards are predominately terrestrial. There is one marine species and a few aquatic ones, including the Jesus Lizard (*Basiliscus plumifrons*), a basilisk lizard. Hence, adaptations to the bryophyte habitat do not necessarily differ from those of lizards in general – they are terrestrial adaptations.

Among the more common bryophyte-associated lizards are some members of the genus *Anolis*. Whenever considering terrestrial adaptations, the life cycle is often a major factor, and *Anolis* seems to exemplify an extreme adaptation to its somewhat hazardous terrestrial life. Instead of the multiple-egg clutch size typical of other lizards, it has a clutch size of one! (Andrews & Rand 1974). This small number is, however, compensated by laying an egg at intervals of 1-2 weeks. This staggered and frequent production of eggs has several advantages: the female is able to produce larger eggs without a great increase in weight (light weight is important for escaping); the eggs each experience different weather conditions so that it is more likely that at least some will survive. With a generation time of only 4 months, this is a high reproductive potential.

The protection of the eggs is of paramount importance to reproductive success. Andrews and Sexton (1981) examined the water relations of eggs for *Anolis auratus* and *Anolis limifrons* (a bryophyte dweller; Figure 26). They found that rate of water loss from the egg surface had a linear relationship with egg mass in both species. *Anolis auratus* lost water more slowly, a factor related to its thicker calcium carbonate eggshell. These differences permitted *A. auratus* to live in the drier grasslands, whereas *A. limifrons* was confined to wetter habitats, i.e. the rainforest.

Figure 26. *Anolis limifrons* on a bed of mosses and liverworts. Photo by Peter Janzen, with permission.

The arboreal habitat poses its own hazards, *i.e.*, climbing and potentially falling. Adhesive toe pads facilitate climbing (Andrews & Rand 1974), but come at a price. Toe pad size increases by the square of the length. Body weight, on the other hand, increases by the cube of length. Hence, larger animals put more burden on the toe pads, causing a selection for smaller animals in arboreal habitats. Since many bryophytic habitats are arboreal, these adaptations can coincide with bryophyte dwellers.

Andrews and Rand (1974) suggest that this relationship of toe pad size to body weight and a foraging habit likewise put a limit on the egg weight at a given time. But another selection pressure on clutch size is the climate itself. In temperate and seasonal habitats of the tropics, clutch size is larger than in more moderated tropical climates. Hence, in those habitats with short-term fluctuations in rainfall, opportunistic reproducers are more likely to be successful. This strategy is likewise a safer approach in this habitat that likewise typically has high predation.

Predation can be an important factor in the strategy of a forager. The movement that permits these animals to chase or look for prey also makes them more conspicuous to their own predators. Anoles not only provide food for adult birds, but in Costa Rica birds such as the Bare-necked Umbrella Birds are known to capture the anole *Anolis capito* (syn.=*Norops capito*; Figure 27) from moss-covered tree trunks and feed them to their young (Losos 2011). These birds can detect the lizard from 10 m. Losos reports seeing a bird swipe a lizard from 2-3 m in front of him when the lizard had been invisible to him until the catch.

Figure 27. *Anolis capito* (= *Norops capito*), a cloud forest anole from Nicaragua. Photo by Josiah Townsend, with permission.

Both unpredictable weather conditions and opportunistic reproduction favor **r-selected life strategies** (high growth rate and many offspring with low probability of survival to adulthood, beneficial in less crowded niches and unpredictable habitats). Anoles exhibit the small body size, early maturity, short generation time, and high fecundity of an **r-strategist**. Arboreal anoles, in particular, are **iteroparous** (having multiple reproductive events), another r strategy.

Vitt and Congdon (1978) expanded on these ideas. They suggested that the "sit and wait" **ambush predators** were able to sustain a high clutch mass, whereas predator escape and foraging selected for small clutch size/mass. The anoles are foragers. They escape the problems of high egg mass by having only one egg at a time.

Even the **dewlap** (Figure 28, Figure 29), that often brightly colored flap of skin under the head that anoles (and others) flash to announce their aggressive defense of territory and attract females (Williams & Rand 1977), can relate to habitat/climate. Seasonally dry climates force reproduction into a short window of time annually. In these conditions, rapid choice of a mate is important, and males are selected for brightly colored, relatively large dewlaps (Fitch & Hillis 1984). In such seasonal environments, the males are typically larger than the females. In tropical rainforests and cloud forests, on the other hand, the breeding season is prolonged or even year-round, and dewlaps tend to be relatively small. In this case, some are brightly colored and others dull brown, tan, or white. Williams and Rand (1977) found that where populations of numerous species contact or overlap, the dewlap colors and patterns are sufficiently different to aid recognition. But Nicholson *et al.* (2007), in studying species of *Anolis*, failed to demonstrate any link between dewlap color and size with similar habitat specialization. They furthermore were unable to show that greater variation in dewlap morphology exists among sympatric (overlapping distribution) species, and suggested that the role of the dewlap in sexual selection still needs to be tested.

Figure 28. Brown Anole (*Anolis sagrei*) displaying its dewlap. Photo through Wikimedia Commons.

Anolis (Anole, Polychrotidae)

The tropical cloud forests hide numerous species of lizards (Wilson & McCranie 1982, 2004; McCranie *et al.* 1993b), but finding specific relationships with bryophytes is a story of a needle in a haystack. Among these genera is the well-known genus *Anolis* (Figure 31).

This genus is best known for its use as a pet and laboratory organism, especially the Green Anole, also known as the American Chameleon, *Anolis carolinensis* (Figure 29), that is able to change color in response to temperature. This arboreal lizard parachutes to the ground when disturbed (Oliver 1951). *Anolis carolinensis* sometimes lays its eggs (Figure 30) among mosses (Greenberg & Noble (1944). In this case, the female uses her forelegs to part the branches, but the snout does most of the digging. Some individuals deposit their eggs deep in *Sphagnum* (Figure 13).

Figure 29. *Anolis carolinensis*, a species that sometimes uses mosses for nesting sites and oviposition. Note the red dewlap. Photo by Jeff Heard, through Creative Commons.

Figure 30. *Anolis carolinensis* and egg. Note the soil on the snout that was used to dig the hole for the egg. Photo by J. Cody Parmer, from <www.discoverlife.org>.

The adult *Anolis limifrons* (Figure 26) seems to prefer grass for its habitat, whereas the related *A. humilis* (syn.=*Norops humilis*; Figure 31) prefers leaf litter (Talbot 1977). But for laying eggs, *Anolis limifrons* (Figure 26) may use mats of moss at the base of bromeliads, as well as leaf litter or clumps of decaying vegetation in tree crotches 1-2 m above ground.

The cloud forest is home to a number of anole species (e.g. Wilson & McCranie 1982; McCranie *et al.* 1993a; Townsend & Wilson 2009). In the cloud forests of Honduras, there are 27 known species of lizards (Wilson & McCranie 2004). Since the cloud forest is also home to many bryophytes, the anoles must necessarily interact with the bryophytes daily in many of the niches. For example, the anole *Anolis morazani* in Figure 32 is running across

bryophytes on a branch. It is likely that bryophytes provide a means of moistening the ventral surface, as shown for salamanders, and can provide a collection substrate for drops of moisture collected from clouds, providing a suitable drinking location for the anoles and other arboreal lizards.

Figure 31. *Anolis humilis* (= *Norops humilis*). Photo by John D. Willson, with permission.

Figure 32. *Anolis morazani*, a cloud forest anole from Honduras. Photo by Josiah Townsend, with permission.

The montane ecotype of the Dominican Anole (*Anolis oculatus montanus*; Figure 33) lives in high elevation rainforests of central Dominica (Wikipedia 2012). This ecotype form lives on moss-covered tree trunks and has a deep green color to match. Occasional splotches and spots form a disruptive pattern, more closely resembling the non-uniform pattern of these bryophytes.

Figure 33. *Anolis oculatus montanus*, showing the green coloration with disruptive spots for this bryophyte-dwelling anole. Photo by Hans Hillewaert, through Creative Commons.

***Brookesia vadoni* (Mossy Pygmy Leaf Chameleon, Chamaeleonidae)**

This lizard doesn't cultivate bryophytes. It resembles them! A native of Madagascar, the rare Mossy Pygmy Leaf Chameleon looks like it has mosses and lichens growing on its back, enabling it to blend in with similar surroundings (Brygoo & Domergue (1968). Most members of this plant-mimic genus are slow-moving and hide under litter. ***Brookesia vadoni*** (Figure 34-Figure 35) lives in the northeastern part of Madagascar where more than 330 days have rain, and mosses and lichens abound.

Figure 34. The Mossy Pygmy Leaf Chameleon (*Brookesia vadoni*) exhibiting green patches that blend with these mosses and lichens. Photos from Flickr, through Creative Commons license.

Figure 35. The Mossy Pygmy Leaf Chameleon (*Brookesia vadoni*) exhibiting tubercles that give it the disruptive look that blends with mosses. Photos from Flickr, through Creative Commons license.

***Rhampholeon spectrum* (Spectral Pygmy Chameleon, Chamaeleonidae)**

Rhampholeon spectrum (Figure 36) develops growths of liverworts on its body (Böhme & Fischer 2000). But this lizard does not restrict this to a head dress (Figure 36-Figure 37). Rather, it can have its entire body covered in liverworts! It is interesting that the only cryptogams inhabiting it are liverworts, and not mosses or lichens, but these liverworts are all in the family **Lejeuneaceae**, the family that is so common among the epiphyllous bryophytes.

These dwarf chameleons were collected in the montane cloud forest of Mt. Nlonako, Cameroon, at approximately 1200 m asl (Figure 38). Böhme and Fischer write that the "strikingly greenish coloration is not caused by a pigment, but by the overgrowth of otherwise epiphyllous liverworts." In all, they could identify four different species of liverworts, and claimed the first reported case of more than one species on the same individual.

Figure 36. This *Rhampholeon spectrum* appears to have liverworts on the eye socket, and there are enough to color the head green. Photo by Wolfgang Böhme, with permission.

Figure 37. These liverworts appear dangerously close to the eye of this *Rhampholeon spectrum*. Photo by Wolfgang Böhme, with permission.

Figure 38. Cloud forest in Cameroon where *Rhampholeon spectrum* was collected, adorned with leafy liverworts. Photo by Wolfgang Böhme, with permission.

Figure 39. Green, liverwort-covered male and interested "naked" female Spectral Pygmy Lizard (*Rhampholeon spectrum*) in Cameroon. Photo by Wolfgang Böhme, with permission.

Cololejeunea jovetastiana (formerly *Aphanolejeunea jovetastiana*; see Figure 41) and *Colura digitalis* (see Figure 42) had the greatest abundance on the lizards, whereas Böhme and Fischer found only a few plants of *Cololejeunea* sp. and only two samples of *Lejeunea* (Figure 45-Figure 46). In addition to liverwort camouflage (Figure 40), this lizard is able to change color in the range

of dull shades of tan to gray (Wikipedia 2011c). The rough surface created by the scales gives sufficient topography for lodging of the spores and establishment of the liverworts (Figure 43).

Figure 40. This Spectral Pygmy Chameleon (*Rhampholeon spectrum*) seems to be in early stages of liverwort colonization, but it appears that soon they may impair its vision. Photo by Wolfgang Böhme, with permission.

Figure 41. *Cololejeunea minutissima*. *Cololejeunea jovetastiana* is a common member of the liverwort flora on the lizard *Rhampholeon spectrum*. Photo by David T. Holyoak, with permission.

Figure 42. *Colura calyptrifolia*. *Colura digitalis* is one of the two most abundant species of liverworts on *Rhampholeon spectrum*. Photo by David T. Holyoak, with permission.

Not only does the green covering of liverworts help to camouflage the lizard, but the researchers observed that one male so-adorned aroused the sexual interest of a nearby female! (Figure 39; translated from Böhme & Fischer by Rob Gradstein, pers. comm. 14 November 2011). Such a benefit must surely be considered a symbiosis.

Figure 43. Close view of scales of *Rhampholeon spectrum* with several species of leafy liverworts attached. Photo by Wolfgang Böhme, with permission.

***Corytophanes cristatus* (Helmeted Iguana, Chorytophanidae)**

There is another lizard that reverses the relationship of habitat and inhabitant. It's hard to imagine walking around with a garden growing on your head. But for the Helmeted Iguana *Corytophanes cristatus* (Figure 44) in the lowland rainforest of the Chiapas, southern Mexico, not only algae, but also the leafy liverwort *Lejeunea obtusangula* (Figure 45-Figure 46), grow from their heads (Figure 47) (Gradstein & Equihua 1995).

Figure 44. The Helmeted Iguana/Basilisk, *Corytophanes cristatus*. Note the scoop-shaped head where bryophytes are able to grow. Photo © John Sullivan, Ribbit Photography, with permission.

Figure 45. The leafy liverwort *Lejeunea obtusangula*. This liverwort has been identified from the head of the Helmeted Iguana, *Corytophanes cristatus*. Photo by Elena Reiner-Drehwald, with permission.

The liverwort in this story grew among a mat of algae comprised of four species in the Chlorophyta and Cyanobacteria. These included the common genera *Cladophora*, *Rhizoclonium*, and *Trentepohlia*. Together they resulted in a tear-drop shape of green on the head of the lizard. A picture by Twan Leenders from Costa Rica indicates that more than one species of liverwort can grow there as well (Figure 48).

Figure 46. Ventral view of *Lejeunea* such as that cultured on the head of the Helmeted Iguana. Members of this family are common as epiphyllous liverworts in the tropics. Photo by Michael Lüth, with permission.

The head seems to be especially adapted for green colonizers. The algae and liverworts reside in a depression in the head (the crest) that creates a catchment area where it could remain moist enough to support the growth of these photosynthetic organisms (Gradstein & Equihua 1995). The liverwort, *Lejeunea* (Figure 46), is a common epiphyte in the Neotropical rainforest, including living epiphyllous on tracheophyte leaves. Sporophytes of the liverwort were common in the forest and most likely represented its means of colonizing the lizard.

But what is the real function of this depression on the head? Although no one seems to have witnessed the act directly, it is likely that the head serves as a shovel to excavate a nest (Leenders 2002). Many lizards are known

to use their heads to excavate nests; their legs are weak and of little use for heavy digging (Twan Leenders, pers. comm. 20 February 2009). And, the one observation indicating nesting behavior was of a female with mud on her head standing over a hole in the ground that held two eggs. Since spores and fragments collect in the soil sporebank as they rain from the tree branches, the digging may also be at least one means of accomplishing the head gardening.

Figure 47. Head of the Helmeted Iguana *Corytophanes cristatus* showing the leafy liverwort *Lejeunea obtusangula* growing in the crest. Photo by Clementina Equihua, with permission.

Figure 48. Head of Crested Basilisk/Helmeted Iguana, *Corytophanes cristatus*, or possibly a different species, in the Rara Avis Rainforest Preserve, Costa Rica, showing at least two different leafy liverworts. Rob Gradstein (pers. comm. 14 November 2011) has suggested these liverworts may be *Symbiezium transversale* and *Lejeunea flava* (Figure 49), two species that are locally common, but not typically as epiphylls. Photo by Twan Leenders, with permission.

Figure 49. *Lejeunea flava*, a tiny liverwort that might colonize the head of *Corytophanes cristatus*. Photo by Jia-dong Yang, through Creative Commons.

One would assume that colonization of liverworts on the lizard's head would be challenging because the lizard most likely sheds its skin several times annually. Thus it's not surprising that the bryophytes are epiphyllous species of *Lejeunea* (Figure 45-Figure 46) that are already adapted to a transient habitat. The rainforest is moist and the lizard is able to move quickly if needed, but it spends many hours without moving (Figure 50) (Twan Leenders pers. comm. 31 January 2009), earning it the nickname of Old Man Lizard. Further supporting its name, its long life provides a combination that makes such colonization possible. It would be interesting to see what happens to the crown garden when the skin is shed. Perhaps fragments from the disposable garden are able to colonize the new crest immediately. The lizard may gain a camouflage advantage as it hangs out on trees with patches of epiphytes on the bark (Figure 51).

Figure 50. *Corytophanes cristatus*, looking a bit like its bryophyte habitat. Photo © 2007 Petrovan Silviu, with online permission for academic use.

Figure 51. Helmeted Iguana, *Corytophanes cristatus*, on a trunk covered with leafy liverworts. A crown of liverworts would have made it less conspicuous. Photo by John D. Willson, with permission.

Sasa and Monrós (2000) reported that both *Corytophanes cristatus* (Figure 47-Figure 51) and *C. hernandezii* (Figure 52) had remains of bryophytes in the guts of several individuals. It is possible these were consumed while targetting invertebrate food.

Figure 52. *Corytophanes hernandezii*, a species that occasionally eats mosses. Photo through Creative Commons.

***Ceratophora karu* (Agamidae)**

The name *Ceratophora* literally means horn-bearer, referring to the horn at the tip of the snout on the males. This genus is endemic to Sri Lanka (Bahir & Surasinghe 2005). *Ceratophora karu* (Figure 53) is rare and critically endangered, living in a 10 km² area at 900-1070 m asl in tropical moist montane forest. All the endangered agamid species in Sri Lanka are forest-dwellers. The genus *Ceratophora* is considered a geographical relict (de Silva 2006). In 2011, researchers Janzen & Bopage were unable to locate *Ceratophora karu* near its known Morningside Estate location. The lack of protection for this species forebodes its likely extinction.

Figure 53. *Ceratophora karu*, an endemic of Sri Lanka with mosses growing on its back and head. Photo by Friedrich Wilhelm Henkel, with permission.

Thanks to Wolfgang Böhme and Friedrich Wilhelm Henkel, we are able to document here the occurrence of

mosses growing on the back of at least one of these rare *Ceratophora karu* (Figure 53).

***Zootoca* (formerly *Lacerta*) *vivipara* (Viviparous Lizard, Lacertidae)**

Lizards are generally found in dry habitats where their scales help them to avoid desiccation. The common *Zootoca* (= *Lacerta*) *vivipara* (Viviparous Lizard; Figure 54-Figure 55) may be the only lizard to frequent peatlands in northern Europe, where it reproduces (H. Strijbosch in Desrochers & van Duinen 2006). It is one of a number of reptiles that have live birth instead of depositing eggs. In highland areas, this lizard is able to increase its ability to resist ice formation during its hibernation, which it spends under 2-4 cm of peatmoss or grass litter (Grenot *et al.* 2007). A contributing factor is that it can increase its blood glucose levels about 4-fold from September to March, followed by a rapid decline when it exits hibernation. The mosses act as insulation that reduces daytime temperatures and keeps nighttime temperatures warmer.

Zootoca vivipara (Figure 54-Figure 55) is most typical in raised bogs that transition into pine or pine-birch forests (Ėeirāns 2004). These areas are characterized by wet *Sphagnum* (Figure 2).

Figure 54. The Viviparous Lizard, *Zootoca* (formerly *Lacerta*) *vivipara*. Photo by Marek Szczpanek, from Wikipedia Commons.

The Viviparous Lizard, as its name implies, gives birth to live young. The courtship is a rather strange one in which the male grabs the female's head in his mouth (Peatlands 2009). Following copulation, the female must stay warm for the next three months, basking in the sun, so that the eggs can develop properly. In Northern Ireland they are legally protected not only from direct harm or capture, but also from disturbance.

Figure 55. The Viviparous Lizard, *Zootoca* (= *Lacerta*) *vivipara*. Photo by Marek Szczpanek, from Wikipedia Commons.

***Plestiodon* (formerly *Eumeces*) *anthracinus* (Coal Skink, Scincidae)**

The Coal Skink, *Plestiodon* (formerly *Eumeces*) *anthracinus* (Figure 56), can be found on the edge of swamps (Wright 1919), but it is more common among boulders on limestone cliffs, under ledges, sandstone slabs, and under rocks (Virginia Department of Game and Inland Fisheries 2009). It is rarely seen and has an interesting habit when pursued – it jumps into a shallow stream and hides under rocks or debris (ZipCode Zoo 2008). Females defend their eggs, which are usually placed under rocks or logs on land. The young can be recognized by their blue tails (Virginia Department of Game and Inland Fisheries 2009). In Tennessee it is considered very rare or imperiled (Atlas of Reptiles in Tennessee 2008). But information on its dependence on or use of bryophytes is lacking, aside from its occurrence on the edge of a swamp. The ability of bryophytes to ameliorate temperature and maintain moisture suggests that there are most likely many more reptiles that make use of bryophytes, but we have very little information on their use of this habitat.

Figure 56. Coal Skink, *Plestiodon* (formerly *Eumeces*) *anthracinus*. Photo through Creative Commons.

***Lobulia* (Scincidae)**

The genus *Lobulia* in the family Scincidae has several species that utilize mosses in the high altitude areas of New Guinea (Greer *et al.* 2005), where it is endemic. *Lobulia subalpina* is common in shrubby-grassy clearings of forests with dense moss cover, but may not actually use the mosses. *Lobulia alpina*, on the other hand, is common on fallen, decaying logs of tree ferns (*Cyathea* spp.) that are covered with mosses, their primary habitat. *Lobulia stellaris* sometimes occurs in mossy clumps. Greer *et al.* found one active at around 0900 hrs at the base of a moss mound. *Lobulia* species use mossy-grassy clumps in the alpine grassland for sunning themselves. The landscape is dotted with large mounds about 1 m high and 1-2 m in diameter, providing ideal sunning locations. They not only give good sun exposure, but serve as shelter sites. Nevertheless, none of the *Lobulia* were found in the dense moss forest.

***Cnemaspis spinicollis* (Geckonidae)**

Cnemaspis spinicollis (Figure 57) from Cameroon is poorly known, recorded only from the Takamanda Forest Reserve in the southwest province of Cameroon (LeBreton 2003). Its home is large rainforest trees that are covered with layers of mosses, stems of vines, and exfoliating bark.

Figure 57. *Cnemaspis* sp. *Cnemaspis spinicollis* lives among mosses on the rainforest trees of Cameroon. Photo by L. Shyamal through Creative Commons.

***Uroplatus sikorae* – Mossy Leaf-tailed Gecko**

Ourá means tail and *platys* means flat, referring to the flattened tail of the genus *Uroplatus* (Wikipedia 2015). It ranges 15-20 cm from its nose to the base of its tail as an adult. The Mossy Leaf-tailed Gecko is an endemic lizard in Madagascar, occurring in both primary and secondary forests.

Uroplatus sikorae (Figure 58) can change its skin color to match its surroundings and even has dermal flaps to break up its smooth appearance when at rest (Wikipedia 2015). But more to our interests, it looks like it has bryophytes growing on its scales, enough so that I thought from the picture that they were real bryophytes. It rests head down on tree trunks during the day, blending well with its surroundings. *Uroplatus sikorae* is a nocturnal tree dweller where it feeds on insects. These geckos die very quickly if the humidity is too low, requiring a range of 60-100% (Dunlop 2016).

Figure 58. *Uroplatus sikorae* (leaf-tailed gecko) in Madagascar, with bryophytes on scales. Photo by Paul Bertner, with permission.

Order Squamata – Snakes

Like the lizards, the mention of snakes does not bring bryophytes to mind, but of course some make use of mosses in their habitat. The mosses can help provide moisture and may be suitable hiding places for smaller species.

Diadophis punctatus punctatus (Ringneck Snake, Colubridae)

If one imagines snakes among mosses, it is small ones like *Diadophis punctatus* (Figure 59-Figure 60) that come to mind. This primarily nocturnal species is known from insect burrows under thick mosses of sunny slopes, although it might be more common in the soft tissues of decaying logs, under bark, or in beetle (*Passalus cornutus*) tunnels (Neill 1948).

Figure 59. *Diadophis punctatus* on a bed of the moss *Plagiomnium* sp. Photo by John White, with permission.

This nocturnal species is a native North American, occurring from southeastern Canada to Mexico. Although they are slightly venomous, they are no danger to humans. Their greater resource against predation seems to be their ability to roll up and expose the underside of the tail, displaying a bright red warning coloration (Figure 60).

Figure 60. *Diadophis punctatus* showing the warning coloration of the underbelly. Photo by William Flaxington.

In northern and western areas these snakes are typically located in open woodlands near rocky hillsides or in wetter environments that have good cover, including coarse woody debris (Stebbins 2003). But southern

populations live primarily in arid habitats within riparian and wet environments (Dundee & Miller 1968).

Pseustes poecilonotus (Dos Cocorite, Colubridae)

Pseustes poecilonotus (Figure 61) lives in Amazonian South America (Boos 2001) where it is a species of IUCN least concern (Lee *et al.* 2007). It is known from sea level to 1200 m asl. This diurnal snake lives in humid lowland forest and savannas. It feeds on frogs, lizards, birds, and small mammals. These are all available in its arboreal habitat where it also encounters bryophytes. It is too large to live under bryophytes or hide in them, but they could provide moisture or egg-laying sites.

Figure 61. *Pseustes poecilonotus* on tree trunk in Tortuguero, Costa Rica. Photo by John D Willson.

Sibon longifrenis (Stejneger's Snail Sucker, Colubridae)

Sibon longifrenis (Figure 62) is an egg-layer that lives in Costa Rica, Honduras, Nicaragua, and Panama (McCranie 2007; Lewis 2009; Hosek 2011). Kofron (1990) considered this and several other *Sibon* species to be synonyms of *S. dimidiata*, but later Savage and McDiarmid (1992) provided convincing argument that this species is distinct. *Sibon longifrenis* is a nocturnal moss mimic, with patches of white, green, and brown in a disruptive pattern that makes it blend well in its arboreal tropical habitat. Its diet consists of snails, slugs, and amphibian eggs, all of which can be found among the epiphytic bryophytes. Other members of the genus in Costa Rica have similar green coloration (Solórzano 2001).

Figure 62. *Sibon longifrenis* in a tropical tree among mosses and liverworts where it is almost invisible. Photo by Josiah Townsend.

Ryan and Lips (2004) found that the most common food for the related species *Sibon argus* (Figure 63) is slugs, but some eat eggs of anurans, gaining the species the common name of goo-eater. The researchers found a snake of this species in Panama with its head hidden in a moss clump. When the snake was pulled out, it was swallowing eggs of *Espadarana prosoblepon*. At night this species moves along branches, flicking its tongue at moss clumps and undersides of leaves, apparently searching for eggs.

Figure 63. *Sibon argus*, a species that eats amphibian eggs in moss clumps. Photo by Twan Leenders, with permission.

***Virginia valeriae* (Smooth Earth Snake, Colubridae)**

Virginia valeriae (Figure 64) is not a snake one would probably associate with bryophytes, but Tobias Landberg found an unlikely connection. This is a snake that lives in the soil and leaf litter where it eats earthworms and soft-bodied arthropods. But just by chance, Landberg found this species dispersing moss spores!

Figure 64. Smooth Earth Snake, *Virginia valeriae*, sunning itself on a moss. Photo by Tony Gerard through Creative Commons.

Figure 65. Smooth Earth Snake, *Virginia valeriae*, wending its way among moss capsules. Photo by Tobias Landberg.

Figure 66. Smooth Earth Snake, *Virginia valeriae*, showing moss spores that have collected on its head. Photo by Tobias Landberg.

***Natrix natrix* (Grass Snake, Colubridae)**

Natrix natrix (Figure 67) in Eastern Europe is frequent on poor *Sphagnum* and *Carex* peat in drained pine forests (Èeirâns 2004). They also occur around flooded peat mines in raised bogs, but they avoid pre-drained forest types and active raised bogs.

Figure 67. *Natrix natrix*, a *Sphagnum* inhabitant. Photo by Fafner, through Creative Commons.

***Sistrurus catenatus catenatus* (Eastern Massasauga Rattlesnake, Viperidae)**

Some moss inhabitants you would rather not meet. Such is most likely the case for the Eastern Massasauga Rattlesnake, *Sistrurus catenatus catenatus* (Figure 68). It inhabits low-lying areas including peatlands, where it uses temperature sense organs on its head to locate small prey such as mice, voles, and shrews (Johnson 1992, 1995). When winter approaches, these snakes seek places where the temperature does not drop below freezing, and at least in New York, USA, the raised hummocks of *Sphagnum* often provide a suitable place (Johnson & Breisch 1993, 2000; Johnson *et al.* 2000; Department of Environmental Conservation 2010). These hummocks typically overlie branching roots that provide spaces for the snakes.

Figure 68. The poisonous Eastern Massasauga Rattlesnake, *Sistrurus catenatus catenatus*. Photo by John White.

***Vipera berus* (European Viper, Viperidae)**

The common European Viper (*Vipera berus*; Figure 69-Figure 70) may easily be encountered in peatlands, where the presence of juveniles indicates that reproduction in the peatland is successful (H. Strijbosch in Desrochers & van Duinen 2006). Its bite can be dangerous or fatal to the very young and very old, but generally it is not fatal, the poison being mild.

Figure 69. The common European Viper (*Vipera berus*) amid the *Sphagnum* and cranberries. Photo by Twan Leenders, with permission.

Figure 70. The European Viper (*Vipera berus*) in a bed of *Sphagnum*. Photo from Wikipedia Commons.

North of the Arctic Circle in Sweden, *Vipera berus* (Figure 69-Figure 70) lives between 300 and 450 m asl (Andersson 2003). Its chosen hibernation sites are always within 1 km of peat bogs and marshlands where they fed on voles during their active season of mid-June to mid-August.

***Bothriechis schlegelii* (Eyelash Viper, Viperidae)**

The Eyelash Viper (Figure 71) derives its name from the superciliary scales above the eyes, believed to disrupt the contrast between the smooth body and its surroundings, making it less conspicuous to would-be predators and to its own prey (Wikipedia 2011a). This somewhat small (75 cm) species is characterized by a rainbow of color variants, some of which mimic the lichen and bryophyte encrusted bark of its arboreal habitat.

Figure 71. *Bothriechis schlegelii* (Eyelash Viper), demonstrating its color pattern that blends with bark, lichens, and bryophytes, where it waits quietly for its food. Note the upturned scales above the eyes. Photo by Josiah Townsend, through Creative Commons.

The Eyelash Viper is a pit viper, and thus is poisonous, sensing its prey through heat-sensitive glands between the eyes and nostrils. It lives in dense foliage of the mesic forests of Southern Mexico, south to Colombia and Venezuela at elevations from sea level to 2640 m asl (Wikipedia 2011a). The bryophyte collector must beware –

this venomous snake lies quietly in wait, an **ambush predator**. It is inconspicuous on branches, sometimes among mosses or tangled among vines, until it detects its prey. It is nocturnal and preys on other arboreal animals such as lizards, frogs, small rodents, and birds. As a likely adaptation to their arboreal habit, they are **ovoviviparous**, giving annual birth to 10-12 live young.

Visitors

The common Eastern Garter Snake (*Thamnophis sirtalis*; Figure 72-Figure 73) (Stockwell & Hunter 1989) and Green Snake (*Opheodrys vernalis*; Figure 74-Figure 75) also appear in peatlands (Rocheffort in Desrochers & van Duinen 2006), but they are widespread elsewhere.

Figure 72. Eastern Garter Snake, *Thamnophis sirtalis*. Photo by Janice Glime.

Figure 73. *Thamnophis sirtalis tetrataenia* flicking its tongue. Photo by Brian Gratwicke, through Creative Commons.

Figure 74. Green Snake, *Opheodrys vernalis*, sunning on a rock near a patch of mosses. Photo © Gary Nafis, with permission.

Figure 75. Green Snakes, *Opheodrys vernalis*, hatching from eggs. Photo by John White, with permission.

The rough green snake (*Opheodrys aestivus*) lives in dense brush of lakeshores, streambanks, upland ravines, and forest edges, where they obtain their water by sucking droplets of dew from leaves (Goldsmith 1984). Bryophytes can provide droplets as well, especially early in the morning. Goldsmith observed this species two different times sucking water from piles of damp *Sphagnum* in its terrarium. Clark (1949) observed 5 eggs of the species in mosses beside a decaying log in Louisiana, USA. Nevertheless, it may be more of a visitor to bryophytes.

Figure 76. *Opheodrys aestivus*, a species that obtains water from mosses. Photo by James Harding, through Creative Commons.

Order Crocodylia – Crocodiles (Family Crocodylidae)

In the Philippines, *Sphagnum* is used for nesting material in crocodile farms for incubating eggs (Tan 2003). At crocodile breeding stations, wild-collected eggs are cushioned or layered in *Sphagnum* for incubation. But information on natural uses of mosses by crocodylians is lacking.

Reptiles in Captivity

Bryophytes are popular in terraria, albeit difficult to keep healthy. Even reptiles seem to benefit from bryophytes in their captive homes (Brough & Rearick 2011; Foster & Smith Inc 2012), and use of bryophytes in live sample containers is a common practice for collectors (LeBreton *et al.* 2011).

At Reptile and Supply Co Inc (2010), New Zealand *Sphagnum* is recommended as the best *Sphagnum* for reptiles due to its water-holding capacity. They also sell sheet moss (US\$13.99 per 6.75" circle) and cushion moss (US\$9.99 per sq ft) for lizard terrariums.

Kaplan (1997) recommends *Sphagnum* as a suitable substrate for reptiles, but admonishes that it can cause fungal infections to those who handle it. She recommends that it be dried thoroughly periodically and baked at 121°C for one hour to kill and fungal growth that may be occurring. The moss provides moisture and maintains air humidity.

One possible caution is that the lizard might eat the moss. One pet owner wrote to Just Answer.Reptile (2012) with concern that her Leopard Gecko had passed bits of "Fluker's" moss in her feces and had stopped eating. [It appears that Fluker's is a trade name and includes true moss and Spanish moss (a bromeliad)]. It is not clear that the moss played any role in the loss of appetite because the lizard had just shed and was also provided night temperatures that were too cool. The advice from Just Answer.Reptile was to provide moist towels instead of moss for the "moist pot." I would think a fine mesh or cloth over the moss might be a good alternative. On the other hand, the primary concern was that the moss might cause an obstruction, but X-ray indicated that did not seem to be the case.

Summary

Peatlands are especially important for some of the reptiles, particularly turtles. *Chrysemys guttata* (Spotted Turtle) uses *Sphagnum* swamps for hibernation, being protected from freezing by the insulation. Later it uses *Sphagnum* and other mosses for nesting. *Glyptemys muhlenbergii* (Bog Turtle) lives primarily in peatlands, apparently using the mosses to maintain their hydration. They travel within the peatlands in small rodent tunnels. The *Sphagnum* is used for nesting. Turtles such as the Snapping Turtle may help in dispersal of bryophytes.

Sistrurus catenatus (Massasauga Rattlesnake) and *Vipera berus* (European Common Viper) live in low-lying areas such as peatlands and often hibernate in raised hummocks where the temperature is buffered. *Thamnophis sirtalis* (Eastern Garter Snake) and *Opheodrys vernalis* (Green Snake) also can live in peatlands.

In Europe, the Viviparous Lizard (*Zootoca vivipara*) frequents peatlands, hibernating under the moss. Coal Skinks (*Plestiodon anthracinus*) can occur on the edge of swamps.

The Helmeted Iguana (*Corytophanes cristatus*) can have leafy liverworts growing on the crest of its head, possibly providing camouflage, whereas species of *Brookesia* have color patterns that resemble bryophytes. Species of the arboreal snake genus *Sibon* also blend with the bryophytic epiphytes in their habitat.

Many reptilian caretakers use *Sphagnum* in the cages, and even crocodile eggs can be reared in *Sphagnum*.

Several snakes use bryophytes, some for sites of finding food, others to rehydrate, and some to modulate their temperature.

The only connection between bryophytes and crocodiles seems to be for breeders who use mosses for rearing the eggs.

Acknowledgments

Herpetologists have been very kind in providing me with image permission, as cited with each picture. I thank Bill Boelema for helping me find literature on turtles and for making suggestions and editorial comments on the chapter. Twan Leenders has been very helpful in providing original pictures and information on the Crested Basilisk. Steve Soldan provided me with interesting discussions, pictures, and papers on *Clemmys guttata*. Bryonettors Elena Reiner-Drehwald and Clementina Equihua responded to my call for photographs. I thank all the kind individuals who provided images in the Public Domain, requiring no permission. Ryan Burrows introduced me to *Brookesia vadoni*.

Thank you to all the Bryonettors who went out of their way to help me get the chameleon paper and to Rob Gradstein who first alerted me to it. Thank you to John Steel for sending me the Böhme and Fischer paper that gave the story about *Rhampholeon spectrum* and for all the others who tried to help me acquire it. Many of you went to friends for help. And thank you for Wolfgang Böhme who not only sent me the color images of *Rhampholeon spectrum*, but also alerted me to *Ceratophora karu* and obtained a picture of it from Friedrich Wilhelm Henkel. Ulmar Grafe kindly offered to translate for me.

CHAPTER 16-1

BIRDS AND BRYOPHYTES INTERSECT

Figure 1. *Lepidocolaptes affinis*, Spot-crowned Woodcreeper, a bird that specializes on foraging among bryophytes and lichens, especially epiphytes such as these. Photo by Larry Thompson, through DiscoverLife <www.discoverlife.org>.

Where Birds and Bryophytes Intersect

Bryophytes, including epiphytes (Figure 1), form an important source of food and habitat for many birds in the tropical rainforests (Gradstein *et al.* 1996). Nadkarni (1994) considered that the epiphytes contributed to the diversity of birds by adding to the resources available, providing more opportunities for resource specialization, and spread the available resources in the canopy throughout the year. These included retention of nutrients in the canopy, providing habitat for invertebrates, and providing a foraging substrate in the canopy (Nadkarni *et al.* 2004).

There is a positive relationship between bryophytes, vascular plants, and breeding birds in marginal habitats bordering agricultural areas (Wuczyński *et al.* 2014). A study in Lower Silesia, Poland, revealed 47 species of birds and 90 of bryophytes in 70 of these marginal habitats. These numbers were topped by 414 species of tracheophytes. The number of species of bryophytes was

positively correlated with the number of species of breeding pairs of birds. These relationships suggest that bryophytes are good biodiversity indicators and can be used as a surrogate taxon for overall species richness. But do the birds use the bryophytes in some way, or do both simply like the same habitats? Bryophyte species richness was significantly correlated with the number of trees and shrubs, explaining 49% of the variability.

Birds have the potential to play a major role in bryophyte use and dispersal (Takaki 1957). It only took me a short time to realize how destructive my finches were to the mosses in my garden room due to their continuous nest-building activities.

Some interactions with mosses may not even involve use of the mosses. Davis (1981) reports that Skuas on Signy Island in the maritime Antarctic were disruptive to the moss community because of their activities there. Once the Skuas have pulled up the mosses, the wind will transport them elsewhere.

Bryophytes also provide microclimate buffers, offering thermal protection (Wolf 2009). This not only provides an ameliorated "climate" for birds' feet, but also affects their food organisms living under and in the bryophyte mat.

Unfortunately, observer location introduces bias into the sampling (Wolf 2009). Ground-level birds were more difficult to observe. The presence of bryophytes, lichens, and *Cyanobacteria* increases the roughness of the canopy. This microtopography provides important ecological functions that include nesting and foraging. In the Pacific Northwest states of Oregon and Washington, 100 bird species breed in the coniferous forests, using bryophytes, lichens, or mistletoe among construction materials in their nests. In North America, nearly 40% of the 262 bird species use either lichens or bryophytes in their nests. In the coniferous forests of Oregon and Washington, 65% use lichens or bryophytes, and 45 species use both. Wolf argues for the maintenance of old-growth forests to support these relationships.

Even the Northern Spotted Owl (*Strix occidentalis caurina*; Figure 2) depends on bryophyte and lichen epiphytes because this owl eats the northern flying squirrel (*Glaucomys sabrinus*; Figure 3), a species that depends on lichens and mosses extensively for both food and nesting materials (FEMAT 1993).

Modified from Kuc 1996.

Watch Towers and Sentinels

If you search for information on birds and watch towers, you are likely to find many articles on dangers of tall buildings, towers, and windmills to birds in flight. But in the tundra, where topography can be somewhat monotonous due to lack of trees and vertical structure, some birds use watch towers that they construct or that occur naturally in the landscape (Figure 4; Kuc 1996). And some of these birds use mosses as watch towers (Figure 5- Figure 6). This is known on Insla Grande de Tierra del Fuego, but mounds of mosses are likely used elsewhere as well.

Spending time on these towers detracts from the time spent foraging and thus is a tradeoff (Metcalf & Furness 1984; Wickler 1985). The importance depends in part on how conspicuous the bird is and on the hunting tactics of the predators (Lendrem 1983a, b). The cost of this vigilance is reduced when it is shared with other birds, including those of other species (Metcalf 1984; Sullivan 1984).

Hollén *et al.* (2008) demonstrated that in the Pied Babbler (*Turdoides bicolor*; Figure 7) the foragers gain more weight when these sentinels are in cooperative calling groups.

Bathing

But bath mats? Appressed bryophytes on branches and limbs of trees provide bathing opportunities in the canopy, escaping the predators on the forest floor. One adult male Pacific Wren (*Troglodytes pacificus*; Figure 8) was using the mat of *Dicranum* spp. (Figure 9) 1.5 m above ground for his private bath, dipping into the creek beneath repeatedly, then rubbing his head and plumage into the moss to preen his feathers. But the moss was also wet,

saturated by heavy fog in the morning. Winter Wrens (*Troglodytes troglodytes*; Figure 10) in Europe (now considered a separate species from those in North America) also bathe in dew-covered vegetation (Armstrong 1955). In Amazonia, the Conures (Figure 11), a kind of parrot in the subfamily *Arinae*, bathe communally in wet moss mats 23 m above the forest floor (Brightsmith 1999). Even the pelican may use mosses as a bathmat (Figure 12).

Thirsty Birds

Sometimes the mosses are the best source of a drink of water. In the Sandwich Isles of Hawaii, the Hawaii Mamo (*Drepanis pacifica*; Figure 13) obtains water from the epiphytic mosses, using rapid darts of the tongue on the wet mosses (Perkins 1903). The stomach contained no insects, so that could not explain the behavior.

Figure 13. *Drepanis pacifica*, Hawaii Mamo, a bird that obtains water from epiphytic mosses. Photo by Hiart, through Creative Commons.

Fertilizer Effects of Birds on Bryophytes

Owls have yet another effect on bryophytes. Owl perches in Alaska provide a unique habitat for a few not-so-unique mosses: *Bryum argenteum* (Figure 14), *Dicranum elongatum* (Figure 15), *Orthotrichum speciosum* (Figure 16), and *Syntrichia ruralis* (Figure 17) (Steere 1976).

Figure 14. *Bryum argenteum* with capsules, a moss that can live on owl perches in Alaska. Photo by Ivanov, with permission.

Figure 15. *Dicranum elongatum*, a moss that can grow on owl perches in Alaska. Photo by Michael Lüth, with permission.

Figure 17. *Syntrichia ruralis*, a species that can grow on owl perches in Alaska. Photo by David Holyoak, with permission.

Similarly, in Svalbard the "manuring" causes production of moss carpets that have a thin active layer (Vanderpuye *et al.* 2002). Beneath that is an accumulation of thick peat with no standing water. These manure deposits from the seabirds provides needed nutrients in this low-nutrient habitat.

Aplodon wormskioldii (Splachnaceae; Figure 18), includes owl pellets (Figure 19) among its substrates

(Koponen 1990). Owl pellets are not guano, but rather are the regurgitated mass of indigestible materials.

In the more temperate UK, Ken Adams (20 February 2014) reports on a *Metzgeria violacea* (Figure 20) on the side of a *Crataegus* bough. This location was so dense in a blackthorn bower that he supposed it could only have been introduced on a bird's foot. Air movement in the valley was too restricted to imagine that it had arrived that way. Recalling that *Ulota phyllantha* (Figure 21) supposedly prefers the nitrogen-rich bird droppings, he mused that this could be a similar situation. Or are these bryophytes simply tolerant of the droppings. It could also be that gemmae are simply deposited on branches where the birds perch. We know little of these relationships in the temperate zone.

Guano

Some birds favor certain mosses by large quantities of **guano** (accumulation of feces). Some seabirds tend to choose certain cliffs for roosting and defecating. The resulting **guano** (Figure 23) is high in some nutrients and provides the ideal substrate for its own unique flora. Among these plants are a number of **ornithocophilous** bryophytes – those that grow on bird dung. The most common of these include *Ceratodon purpureus* (Figure 22), *Eurhynchium praelongum* (Figure 24), and *Mnium hornum* (Figure 25), all species with a wide ecological amplitude (Watson 1964).

Figure 25. *Mnium hornum*, a species that is able to grow on and may benefit from bird dung. Photo by Des Callahan, with permission.

On Svalbard, near the Arctic Circle, Kuc (1996) reported an interesting relationship between the bryophytes and the Parasitic Jaeger (*Stercorarius parasiticus*; Figure 26). In the Nornsund Area, the moss *Syntrichia ruralis* (Figure 17) forms dense, high tufts in rings immediately

adjacent to the nests. Likewise, the moss *Drepanocladus exannulatus* (Figure 27), another dominant species, surrounded the nests, but in some areas this species was significantly degraded by the activities of the Parasitic Jaeger. In the dry tundra, the terrain was dominated by the moss *Racomitrium lanuginosum* (Figure 28-Figure 29), a moss that was heavily fertilized by guano from the Parasitic Jaeger.

Figure 29. *Racomitrium lanuginosum*, a common species that lives in the tundra where the Arctic Jaeger provides it with a heavy fertilization by guano. Photo by Juan Larrain, with permission.

Megaphorura arctica (Figure 30), an Arctic springtail, feeds on a variety of bryophyte species (Hodkinson *et al.* 1994). These springtails form dense aggregates under bird cliffs, presumably benefitting from the guano, perhaps indirectly through the bryophytes. The bryophytes include *Sanionia uncinata* (Figure 31), *Polytrichastrum alpinum* (Figure 32), and *Racomitrium lanuginosum* (Figure 29).

The most fascinating association of bryophytes with bird droppings is that of some members of *Splachnaceae*. The moss *Tayloria dubyi* (Figure 33) seems to live exclusively on bird dung in the subAntarctic Magallanes ecoregion (Jofre *et al.* 2011). In fact, it may be restricted to the dung of the Upland Goose, *Chloephaga picta* (Figure 34).

But not all guano benefits are restricted to polar regions. In western North Carolina, USA, it is not the seabirds bringing oceanic nutrients to the cliffs, but rather nitrogen sources originate in the highly productive forests and are transferred to nutrient-poor terrestrial cliffs by birds (Langevin 2015). Among these, in particular, are common Ravens (*Corvus corax*; Figure 35) and Peregrine Falcons (*Falco peregrinus*; Figure 36). These birds frequently nest on cliffs in the southern Appalachian Mountains, excreting N-rich guano that increases the nitrogen below the nesting sites. Langevin showed that the ammonia levels were significantly higher below the nest sites. Likewise, there was a significant difference in vegetation, with particular lichens known to prefer high N being more common there. Beneficial effects of these forest N sources on bryophytes remain to be documented.

But guano does not always favor the mosses. In the polar Mac. Robertson Land, guano has reached toxic levels, making the coastal slopes barren of mosses and lichens (Bergstrom & Seppelt 1990). This is largely due to Antarctic Petrels (*Thalassoica antarctica*; Figure 37) that breed along these slopes, with a mean nest density of 0.82 m^{-1} (Alonso *et al.* 1987)! But the area also serves as breeding grounds for Southern Fulmars (*Fulmarus glacialis*; Figure 38) and Adélie Penguins (*Pygoscelis adeliae*; Figure 39).

Penguins

Penguins deserve special note because of their extensive role in N transfer from rich oceanic sources to land in the Antarctic. Cocks *et al.* (1998) reported a range of 13.1-25.9% of the Antarctic N to be from seabird guano, with similar results in other studies (Erskine *et al.* 1998; Bokhorst *et al.* 2007a, b; Lee *et al.* 2009). Wasley *et al.* (2012) interpreted this input to be from ancient penguin rookeries (Figure 39) that have been abandoned for thousands of years (Emslie & Woehler 2005). Bryophytes have elevated $\delta^{15}\text{N}$ signatures ($>15\%$), indicating their use of animal-derived N through repeated trophic transfer by microbial activity since the original deposition.

Figure 39. *Pygoscelis adeliae*, Adélie Penguin on Antarctica, illustrating the large number of birds that can create guano. Photo by Murray Foubister, with permission

In the case of the Adélie Penguin (*Pygoscelis adeliae*; Figure 39), dung left 3000-8000 years ago remains, at least partly frozen in ice (Gill 2012). Mosses are able to derive nutrients from these deposits, giving them much needed resources that are so scarce in the sand and gravel substrate of Antarctica.

Penguin rookeries on King George Island in the maritime Antarctic are an important source of nutrients and have a strong influence on the vegetation patterns and diversity (Smykla *et al.* 2007). The nutrient input, as guano, creates a zonation pattern. The first zone includes those areas under the immediate influence of fresh guano and trampling, supporting little or no vegetation. The second zone is adjacent to the first and is covered with nitrogen-loving green algae and sometimes Cyanobacteria. The third zone is dominated by Antarctic hair-grass. The fourth zone is dominated by mosses. The fifth and last zone under the rookery influence is dominated by lichens.

Peatland Habitats

Brewer (1967) pointed out that studies on bog vegetation were much more numerous than those on the animal populations. To help remedy this situation, he studied the breeding bird populations on two peatlands in lower Michigan. In the years 1961-1966 he noted 24 species of breeding birds in Portage Bog. These included the Song Sparrow (*Melospiza melodia*; Figure 40), Field Sparrow (*Spizella pusilla*; Figure 41), Yellowthroat (*Geothlypis trichas*; Figure 42), Yellow Warbler (*Setophaga petechia*; Figure 43), Nashville Warbler (*Leiostyris ruficapilla*; Figure 44), Eastern Towhee

(*Pipilo erythrophthalmus*; Figure 45), Brown-headed Cowbird (*Molothrus ater*; Figure 46), Catbird (*Dumetella carolinensis*; Figure 47), American Goldfinch (*Carduelis tristis*; Figure 48), Traill's Flycatcher (*Empidonax traillii*; Figure 49), Black-capped Chickadee (*Poecile atricapillus*; Figure 50), Mourning Dove (*Zenaida macroura*; Figure 51), Cedar Waxwing (*Bombycilla cedrorum*; Figure 52), Yellow-shafted Flicker (*Colaptes auratus*; Figure 53), Cardinal (*Cardinalis cardinalis*; Figure 54), Brown Thrasher (*Toxostoma rufum*; Figure 55), Ruby-throated Hummingbird (*Archilochus colubris*; Figure 56), Mallard (*Anas platyrhynchos*; Figure 57), Marsh Hawk (*Circus cyaneus*), Eastern Bluebird (*Sialia sialis*; Figure 58), Tree Swallow (*Tachycineta bicolor*; Figure 59), Robin (*Turdus migratorius*; Figure 60), Whip-poor-will (*Caprimulgus vociferus*; Figure 61), and Veery (*Catharus fuscescens*; Figure 62). Among these, the Mallards were the only species for which the researchers located a nest, and the nest occurred in three of the six years. About 425 pairs were located there per hectare. Brown-headed Cowbirds were the most dense and Song Sparrows were the most abundant, the latter having an average of 138 territorial males per hectare. Others with a density of more than 24 per hectare were Yellowthroats, Field Sparrows, Eastern Towhees, and, perhaps, Brown-headed Cowbirds.

In bogs studied by Brewer (1967), as the high thicket gave way to low thicket, some of the bird species changed, including the arrival of the Nashville Warbler (*Leiothlypis ruficapilla*; Figure 44) in 1965. The trees in the bog were not suitable for cavity-nesting birds during the study. Among these birds, Field Sparrows (*Spizella pusilla*; Figure 41) preferred open bog and Song Sparrows

(*Melospiza melodia*; Figure 40) preferred thickets, as did the Towhee (*Pipilo erythrophthalmus*; Figure 45), Yellowthroat (*Geothlypis trichas*; Figure 42), and Catbird (*Dumetella carolinensis*; Figure 47). The number of species in the open bog was about 13, whereas in the thicket it was about 21. When examining peatlands on a larger scale, Niemi and Hanowski (1992) found 110 species of birds that frequented Minnesota peatlands.

Brewer (1967) concluded that most of the birds came to the bog only for feeding. For example, Robins (*Turdus migratorius*; Figure 60) nested in the deciduous areas but came to the bog for feeding. This was especially true when berries were ripe, with both juveniles and adults coming to feed. Based on these habitat relationships, it is not surprising that most of the species in this bog were forest edge species. Brewer also considered it likely that some of the visitors, like the Meadowlark (*Sturnella magna*; Figure 63), mistook the open bog for an open field.

Figure 63. *Sturnella magna*, Eastern Meadowlark, a bird that may occasionally mistake an open bog or fen for an open field. Photo by Jim F. Bleak, through Creative Commons.

Brewer (1967) only observed birds in the Sugarloaf Bog for two years. This site had 26 breeding bird species during that time, with the average per year of about 20 species. The density was high, with about 675 males per hectare. The **Black-capped Chickadee** (*Poecile atricapillus*; Figure 50) was the most abundant, with about 100 males per hectare (compared to 10 at Portage Bog).

Only nine species were common to both locations (Brewer 1967). In a larger study based on literature, Brewer found that there is little commonality among species of the open bog. Birds of the spruce forest, on the other hand, are similar to those of a cedar forest or a spruce thicket. It became clear that species of the bogs depended on the vegetation of that stand and on the vegetation of adjacent areas, as well as the geographic distribution of the species. Few birds were present in the winter, reflecting the poor winter food supply and insufficient cover.

Calmé and Desrochers (1999, 2000) and Calmé *et al.* (2002) investigated the birds in 67 southern Quebec, Canada, peatlands. They expressed concern over the loss of peatlands to urban sprawl, agriculture, forestry, and peat mining, particularly in eastern Canada (Calmé & Desrochers 2000). This loss further fragments the peatlands, making natural re-introductions more difficult.

This isolation causes the peatlands and their bird populations to behave with island dynamics. Among ten species of birds studied in detail, two rely primarily on peatlands for nesting sites. Bird species richness was primarily related to microhabitat richness and heterogeneity. The Palm Warbler (*Dendroica palmarum*; Figure 64) and Upland Sandpipers (*Bartramia longicauda*; Figure 65) depended on having larger, non-isolated peatlands.

Figure 64. *Dendroica palmarum*, Palm Warbler, a species that depends on large, non-isolated peatlands. Photo by Wolfgang Wander, through Creative Commons.

Figure 65. *Bartramia longicauda*, Upland Sandpiper, a species that depends on large, non-isolated peatlands. Photo by Johnath, through Creative Commons.

Calmé *et al.* (2002) found 17 species of birds that were significantly more frequent in peatlands than in the surrounding habitats. For some, the peatland was one of several habitats, but some were significantly more frequent in peatlands.

In studying 28 southeastern Quebec, Canada, peatlands, Desrochers *et al.* (1998) found that harvesting

effects on birds depended on the type of harvesting. Block harvesting had the least effect, presumably because it retained most of the topography and microhabitats. Vacuum harvesting, on the other hand, did alter the bird communities. Ten of the 28 species responded negatively to peatland perturbation. The Palm Warbler (*Dendroica palmarum*; Figure 64), in particular, was closely associated with the unperturbed sites.

The Palm Warbler (*Dendroica palmarum*; Figure 64) is an area-sensitive bird and in southern Québec it is restricted to peatlands (Poulin 2002). The within-site habitat configuration strongly affects the physical efficiency of this species but not necessarily functional effectiveness. While it is clear that having a number of peatlands available is important to the Palm Warbler, the biological factors they provide remain elusive.

When Lachance *et al.* (2005) investigated 16 peatlands in southern Quebec, Canada, they found 36 bird species and 154 plant species. They found that afforestation altered the vegetation structure in ways that changed the bird species composition. In particular, there were fewer mosses and shrubs, but more trees.

One reason for the diminished number of birds in disturbed peatlands is the loss of eggs and nestlings to predation. Haddad *et al.* (2000) assessed the effects of harvesting peat mosses on the survival of bog-dwelling songbirds [Palm Warbler (*Dendroica palmarum*; Figure 64), Common Yellowthroat (*Geothlypis trichas*; Figure 42), Hermit Thrush (*Catharus guttatus*; Figure 66), and several species of sparrows (*Passeridae*; Figure 40-Figure 41)]. They found greater risk of nest predation in harvested bogs.

Figure 66. *Catharus guttatus*, Hermit Thrush, a species that loses more eggs to predation in harvested bogs than in undisturbed bogs. Photo by Cephas, through Creative Commons.

Another possibility to explain loss of birds on harvested peatlands is disruption of the habitat of food organisms. **Diptera** larvae, especially the crane fly *Tipula* (Figure 67), live and pupate among the mosses in the peatland (MacLean 1980). The birds consume 35-70% of annual production of *Tipula carinifrons* and consume 50% of adults at peak emergence. The crane fly larvae feed on liverworts in these bogs (Coulson & Whittaker 1978). Paasivirta *et al.* (1988) likewise noted the importance of emerging insects for feeding birds in peatlands.

Figure 67. *Tipula*, leatherjacket larva, a genus that is eaten in great numbers by birds in bogs. Photo by Rasbak, through Creative Commons.

Effects on Bryophyte Community Structure

Birds can have considerable influence on bryophyte communities, especially in Arctic wetlands. We have already seen that guano from seabirds can provide nutrients that are otherwise limiting. And Pheasants (Figure 68) can disrupt the community while searching for food (Erkamo 1976).

Figure 68. *Phasianus colchicus*, Pheasant, a forager that can disturb bryophytes while foraging. Photo by Hugh J. Griffiths, through Creative Commons.

In the Arctic, **geese** (Figure 69) can play a role in community structure (Jasmin *et al.* 2008). Although one might expect such feeding disruption to reduce the number of species, Jasmin and coworkers found greater bryophyte species richness following 11 years of goose presence, compared to that in goose exclosures. The non-protected areas exhibited more variation in time and space than within the exclosures, promoting greater coexistence of bryophyte species at the microscale of 1 cm.

Figure 69. *Chen caerulescens*, migratory Snow Geese, foraging. Photo by Bradley Davis, through Creative Commons.

Conservation Issues

Agricultural areas might actually help bird species diversity in tropical forests (Hughes *et al.* 2002; Sekercioglu *et al.* 2007). Although we typically think of deforestation for agriculture as being detrimental to bird diversity, researchers found that most of the 144 bird species used the agricultural areas for foraging, often travelling several kilometers from their forest home (Hughes *et al.* 2002). They estimated that 46% of the native birds were using the agricultural countryside in southern Costa Rica. The authors suggest that diversity will suffer less if tall trees and edge habitats are maintained.

In an effort to understand how to protect birds with minimal effort, we have often chosen indicator species (Simberloff 1998). Unfortunately, these are not as indicative as we might hope. It is difficult to know what species should be the indicator and on just what it should indicate. Simberloff suggested instead that the species should be an "umbrella species,... one that needs such large tracts of habitat that saving it will automatically save many other species."

A flagship species is typically a charismatic large vertebrate, such as the panda or a snowy owl (Anonymous, USDA; Simberloff 1998). It is useful because it causes both public interest and sympathy (Simberloff 1998). It suffers some of the same problems – it may not be in an area that protects many other species, and it might be expensive to protect. And management of one flagship species may conflict with that of managing another. "The recognition that some ecosystems have keystone species whose activities govern the well-being of many other species suggests an approach that may unite the best features of single-species and ecosystem management. If we can identify keystone species and the mechanisms that cause them to have such wide-ranging impacts, we would almost certainly derive information on the functioning of the entire ecosystem that would be useful in its management."

Even keystone species can get complicated. As seen in a Colorado subalpine ecosystem, there may be subtle interdependencies (Daily *et al.* 1993). The Red-naped Sapsuckers (*Sphyrapicus nuchalis*; Figure 70) actually have two keystone roles. Their excavation activities to make nests in fungus-infected aspens are essential to two species of swallows, and when they drill sap wells into willows they nourish not only themselves, but also make this rich food source available to Hummingbirds (Figure 56), Orange-crowned Warblers (*Vermivora celata*; Figure 71), chipmunks (*Tamias striatus*), and other sap robbers. Thus for this community to persist, it requires the complex interactions of sapsuckers, willows, aspens, and a heartwood fungus.

As an example, the penguin (Figure 39) can be a keystone species in the maritime Antarctic (Barcikowski *et al.* 2005). We have seen above that the guano produced by the penguins can form the base for an entire community by providing an important supplement to the rare nutrients. In areas where the guano enriches the substrate with nutrients originating in the ocean, the grasses *Colobanthus quitensis* (Figure 72) and *Deschampsia antarctica* (Figure 73) predominate. Where the guano is absent, mosses such as *Polytrichum piliferum* (Figure 74) predominate.

To put this in a bryological perspective, we may find that a species is dependent on mosses in spring before herbaceous plants are available or in winter when tracheophytes cease growing. The bryophytes might depend on one or more species of birds for the bulk of their dispersal. Or the bryophytes might serve as emergency foods during years when the weather is not suitable for good productivity of other, more preferred foods. With so many possibilities, we have just begun to understand the interrelationships.

Dispersal Agents

If you have ever reared Zebra Finches (*Taeniopygia guttata*; Figure 75), you know that they are incessant nest-builders. It was impossible to keep mosses in my garden room when I had finches because these mosses were prime nest-building material. But as you would also observe, not all selected mosses made it to the nest. Pieces would fall as the birds flew, and even the nest itself would occasionally lose pieces, but fragments would especially get dropped beneath the nest as the building progressed, in some cases deliberately as the birds determined that piece to be too recalcitrant to become part of the architecture.

In addition to fragments and propagules travelling among feathers, it is also possible for bryophyte parts to

travel in the digestive system of birds (Behling *et al.* 2016). On Navarino Island, at the Cape Horn Biosphere Reserve, these researchers recovered bryophyte diaspores from fecal samples from the Upland Goose (*Chloephaga picata*; Figure 34) and the White-bellied Seedsnipe (*Attagis malouinus*). Viability remains to be established.

Figure 75. *Taeniopygia guttata*, Zebra Finch, a pet that is an incessant nest builder and uses mosses, among other things. Photo from Sky High Butterfly, through Creative Commons.

Davison (1976) describes the role of birds in the dispersal of mosses. Indeed, it was not the nest-building activities, but feeding activities that caught his attention. Where leaf litter is somewhat scarce, such as older beech woods, and mosses are abundant, foraging requires that the birds poke around among the mosses. **Blackbirds** (*Turdus merula*, Figure 76) in particular foraged among *Mnium hornum* (Figure 25) and *Polytrichastrum formosum* (Figure 77), breaking the plants and scattering them much like the Japanese do when planting a moss garden. Davison reports that within a two-month period these birds moved 34 clumps of moss from one place to another within an area of about 5 m², but also brought to the area an additional 18 pieces.

Figure 76. *Turdus merula* (Blackbird), a species that forages among *Mnium hornum* and *Polytrichastrum formosum*. Photo by Mario Modesto Mata through GNU Free Documentation.

Figure 77. *Polytrichastrum formosum*, a moss where Blackbirds forage, disturbing the moss. Photo by David T. Holyoak, with permission.

But it appears that might not be the only reason to cause **Blackbirds** (*Turdus merula*; Figure 76) to scatter bryophytes. Robin Stevenson reports (Bryonet 25 April 2010) observing a male of this same species of bird throwing clumps of mosses off a roof, alternately with mid air attacks by another Blackbird – a classic example of displacement! There was too much activity to discern if both birds were moss throwers. Apparently the two were fighting over territory or some other disagreement and the mosses were handy objects to throw from their rooftop habitat. In this case, the lucky roof mosses were *Grimmia pulvinata* (Figure 78), *Hypnum cupressiforme* (Figure 79), and *Syntrichia montana* (Figure 80). When on the ground they threw cockle shells and other things.

Figure 78. *Grimmia pulvinata*, a moss thrown about by a Blackbird during a territorial competition. Photo by Michael Lüth, with permission.

In another instance, Davison (1976) found spores of a moss on the feet of a dead Song Thrush (*Turdus philomelos*; Figure 81). Although most of the scavenging activity probably only transports moss fragments and spores for short distances, spores might occasionally be transported by feet, feathers, and beaks to considerable distances following such activity.

Figure 79. *Hypnum cupressiforme*, a species thrown about by Blackbirds in displacement activity. Photo by Jan-Peter Frahm, with permission.

Figure 80. *Syntrichia montana* (Intermediate Screw-moss), a species thrown about by Blackbirds in displacement activity. Photo by Barry Stewart, with permission.

Figure 81. *Turdus philomelos*, Song Thrush, a bird known to carry mosses on its feet. Photo by Brian Eversham, with permission

But birds are imperfect in their industrious movement of moss from natural substrate to nest. Bits fall, and hence alight in a new location. This facilitated dispersal, while

somewhat random, can be quite helpful in moving rarely fruiting mosses about. Chmielewski and Eppley (2019) found that when birds use bryophyte-covered areas for foraging and gathering nesting material, they can acquire propagules on their legs, feet, and tails. The researchers successfully germinated propagules from among the 242 propagules and 1512 spores they collected from 224 birds, comprised of bird 34 species. They found the tail feathers to be the greatest dispersal agents among bark and foliage species. Hence, birds are potential dispersal agents.

The Pintail Duck (*Anas acuta*; Figure 82) is a likely agent of dispersal of *Riccia rhenana* (Figure 83) (McGregor 1961). In this liverwort, the older parts die, but the apices survive two months of drought and five weeks submersion in ice, making it likely that they would survive transport among the feathers of the Pintail Duck.

Figure 83. *Riccia rhenana*, a species dispersed by pintail ducks. Photo by Štěpán Koval, with permission.

Lewis *et al.* (2014b) suggested that *Tetraplodon* (Figure 84) species were distributed long-distances by birds. They reasoned that the absence of wind patterns to account for their distribution in the New World and the sensitivity of the spores to extreme environmental conditions, bird dispersal, probably on feathers, was the most reasonable explanation. In support of this possibility, Lewis *et al.* (2014a) demonstrated bryophyte diaspores among the feathers of transequatorial migrant birds.

Figure 84. *Tetraplodon mnioides* with mature capsules; this species may be distributed by birds. Photo by Richard Caners, with permission.

Des Callaghan filmed a site where the White Wagtail (*Motacilla alba*; Figure 85) frequently perches on a particular branch. That branch is covered by *Splachnum vasculosum* (Figure 86-Figure 87). Does the bird simply like the soft moss and its location? Is the moss dispersed by the feathers and feet of the birds? Or might it be deposited in feces, indicating the birds ate the capsules?

In some way the petrels and other sea birds seem to be responsible for the locations of members of **Calymperaceae** in the Chathams and other areas around New Zealand. Fife and Lange (2009) suggest dispersal by birds. They consider it likely that the sea birds may have contributed to dispersal of the moss *Calymperes tenerum* (Figure 88) on the Chatham Islands and the Kermadecs to the north and east of New Zealand, respectively. Peter de Lange (pers. comm. 12 June 2017) reported that until 80-100 years ago, Tube Nose Petrels, especially *Pterodroma* spp. (Figure 92-Figure 93), were influential, but Broad-billed Prions (*Pachyptila vittata*) and shearwaters (*Puffinus griseus*; Figure 89) also were common in the areas where *Calymperes* grows now, but that these birds disappeared 80-100 years ago.

Figure 88. *Calymperes tenerum*, a species that may have been dispersed long distance by the Shearwater. Photo by Jan-Peter Frahm, with permission.

Later, de Lange (Peter de Lange, pers. comm. 12 June 2017) found *Syrrhopodon armatus* (Figure 90-Figure 91) on the smallest of the main Chatham Island, Rangatira. This island is free of predators and supports a million plus seabirds. The *S. armatus* grows on tree trunks that are used by the petrels and Broad-billed Prions (*Pachyptila vittata*) as runways. They also grow around the burrows of these birds, especially those of the Chatham Petrel (*Pterodroma axillaris*). On Rabbit Island, *Syrrhopodon*

grows around the active burrows of shearwaters (*Puffinus griseus*; Figure 89) and diving petrels.

Figure 91. *Syrrhopodon armatus* leaf, a possible propagule carried by sea birds to islands around New Zealand. Photo from Natural History Museum, London, through Creative Commons.

In addition to these islands, on the Chatham island of Rekohu and the Pitt island of Rangiuria, *Calymperes* (Figure 88) is found only in locations there the

pterodromids once had dense nesting locations, as indicated by remains of their burrows (Peter de Lange, pers. comm. 12 June 2017). At the location where de Lange first found *C. tenerum* (Figure 88) there are still seabirds, including Taiko (*Pterodroma magentae*), a critically endangered species (Fife 2009).

In New Zealand at Te Pahi, *Calymperes* (Figure 88) again is associated with *Pterodroma nigripennis* (Figure 92) and *P. gouldi* (Peter de Lange, pers. comm. 12 June 2017). And on Raoul Island, all the locations found by de Lange were also in areas frequented by the Kermadec Petrel (*Pterodroma neglecta neglecta*; Figure 93) until the rats wiped them out early in the 20th Century. As on the Chatham Islands, the birds used the trees with *Calymperes* (Figure 88) as runways.

Figure 92. *Pterodroma nigripennis*, a species that seems to be associated with *Calymperes* (Figure 88) and may disperse it. Photo by Christopher Watson, through Creative Commons.

Figure 93. *Pterodroma neglecta*, Kermadec Petrel, a species always found with *Calymperes* on Raoul Island. Photo by Lance Andrewes, through Creative Commons.

On the Poor Knights Islands, Jessica Beever has similarly collected *Syrrhopodon armatus* (Figure 90-Figure 91) associated with a heavily burrowed petrel area (Allan Fife, pers. comm. 12 June 2017).

Based on what we know about these seabird-**Calymperaceae** relationships there are three plausible explanations for the relationships. The birds may fertilize the bark with guano, thus providing nitrogen for the mosses. The birds may serve as dispersal agents. The mosses may provide foraging substrate for the birds. Felicísimo *et al.* (2008) provided evidence that the Cory's Shearwater (*Calonectris diomedea*; Figure 94) follows wind patterns that could explain dispersal patterns. Cameron *et al.* (2006) have suggested that Buller's Shearwater (*Puffinus bulleri*; Figure 95) best explains the presence of the fern *Asplenium pauperequitum* on the Chatham Islands group, a distance of 1245 km from its nearest neighbor. This bird is a New Zealand endemic species and has large breeding populations on the Poor Knights Islands where *Asplenium pauperequitum* was originally described (Allan Fife, pers. comm. 12 June 2017). In the Chathams it does not breed, but it is a regular visitor. Any and all of these explanations for the **Calymperaceae**-seabird associations may be true.

Figure 95. *Puffinus bulleri*, Buller's Shearwater, a species that might disperse mosses to islands near New Zealand. Photo by Tom Tarrant, through Creative Commons.

Chmielewski (2015) sought to support these suggestions by culturing propagules found on birds caught with mist nets. Using cotton swabs, he sampled feet, legs, and flight feathers. The spores obtained were cultured on nutrient agar. The resulting bryophyte plants were identified by PCR amplification and Sanger sequencing of the trnL region of the chloroplast genome. We shall have

to look forward to the revelation of these species when this work is published.

Dispersal of bryophytes by birds is discussed in more detail in subchapters 4-9 and 4-11 of Volume 1.

Soft Landings

Pole jumpers have sand pits or mats to protect them when they land. To me it seems reasonable that birds might choose soft landing sites as well. Birds in captivity often get a condition known as **bumblefoot** (Figure 96) (Halliwell 1975; Hawkey *et al.* 1985), but the condition can occur in wild populations, albeit much less commonly (Gentz 1996). Bumblefoot can be caused by rough perches, sandpaper on the perch, sharp corners, dirty perches, or all perches of the same size. In the wild these problems are largely absent, explaining the scarcity of bumblefoot in nature. Do wild birds select landing spots on the basis of the presence of the spongy bryophytes and lichens (Figure 97)?

Figure 97. Bird on moss perch – Is it a sentinel, or just cooling its feet on the moss? Photo by Ervin Gjata, through public domain.

Summary

Birds interact with bryophytes by foraging among them, eating them, eating capsules, getting a drink, building nests or parts of nests with them, using them as

breeding grounds, using moss hummocks as **watch towers**, throwing them in displacement behavior, bathing among them, and getting dry on them. On the other hand, the birds may help the bryophytes as dispersal agents and by providing fertilizer as guano. Or they may seriously disturb them during their foraging. Others provide so much guano that the bryophytes are intolerant of it. Soft bryophytes might also help to prevent bumblefoot in wild birds.

Acknowledgments

Thank you to Brian Dykstra for sending me the wonderful thesis on birds and epiphytes by Adrian Wolf, as well as other references and personal observations. David Dumond shared the references he got from Bryonet. Thank you to Allan Fife for helping me get the details on the Shearwater dispersal story. Bernard Goffinet has been supportive in sending me copies of new literature on various bird interactions. Thank you to Janet Marr for a critical reading of the manuscript.

CHAPTER 16-2

BIRDS AND BRYOPHYTIC FOOD SOURCES

Figure 1. *Branta bernicla hrota*, Brant, juvenile foraging; foods include bryophytes. Photo by MPF, through Creative Commons.

Many birds do depend on bryophytes for food. Some eat the leafy gametophytes, especially in the Arctic. Others use the more nutrient-rich capsules. And others, probably many more than we know, forage for macroinvertebrates among the bryophytes, especially epiphytes.

Capsules

A. J. Grout, one of the earliest of North American bryologists, observed birds pecking the capsules of *Polytrichum commune* (Figure 2), a story retold by Lewis Anderson (Bryonet 10 April 2003). To this story, Frank Cook (Bryonet 15 May 2001) contributed his own observations of White-throated Sparrows (*Zonotrichia albicollis*; Figure 3) "vigorously nipping the capsules from *Polytrichum* in a white pine (*Pinus strobus*; Figure 4) stand in Algonquin Park, Ontario.

Figure 4. *Pinus strobus* (white pine) forest, Pennsylvania. Photo by Nicholas T., through Creative Commons.

Richardson (1981) reported moss-feeding by mammals and birds in northern areas. Capsules of *Bryum* (Figure 5)

and *Polytrichum* (Figure 2) are eaten by the Norwegian Grouse chicks (*Tetrao urogallus*?; Figure 6), apparently as the main food, whereas other kinds of capsules are eaten by Scottish Red Grouse (*Lagopus lagopus scotica*; Figure 7) (Lid & Meidell 1933). The Wyoming Sage Grouse (*Centrocercus urophasianus*; Figure 8) eats small amounts of moss, Snow Buntings (*Plectrophenax nivalis*; Figure 9) eat *Bryum algovicum* capsules (Figure 10), and the Moorhen (*Gallinula chloropus*; Figure 11), Blackbird (*Turdus merula*; Figure 12), Song Thrush (*Turdus philomelos*; Figure 13), and Fieldfare (*Turdus pilaris*; Figure 14) all eat mosses. In Britain, the Blue Tits (*Cyanistes caeruleus*; Figure 15) and Marsh Tits (*Poecile palustris*; Figure 16) feed on capsules of *Dicranoweisia cirrata* (Figure 17) (Betts 1955). Catherine La Farge reported on Bryonet (15 January 2008) that high Arctic moss capsules are consumed by lemmings and Arctic hares. Thus it would not be surprising if birds also consume them when the capsules are still green.

Dan Norris (Bryonet, 22 November 1995 & 19 November 2006) reported that the Green Eastern Rosella Parrot (*Platycercus eximius*; Figure 18) in Tasmania selects the green, but mature, capsules of *Polytrichum juniperinum* (Figure 19) on clay soil banks as a primary food source. He watched the parrots for over an hour, then examined the area to find that they clipped the setae at 45° angles and left a miniature forest of setae with a litter of calyptrae that were split off, falling 5-10 mm to the right of the sporophyte. The number of barren setae suggested that harvest in this manner was widespread. Further examination on other clay banks of the island revealed that similar patterns were common in the forested mid-elevation habitats throughout the island.

Ptarmigans

In northern Europe and Alaska, the Willow Ptarmigan (*Lagopus lagopus*; Figure 20-Figure 21, Figure 23) chicks consume moss capsules of *Polytrichum* s.l. (Figure 19) and *Pohlia* (Figure 22) (Weeden 1969; Gardarsson & Moss

1970; Spidsø 1980; Martin & Hik 1992). Pullianen and Eskonen (1982) considered that moss capsules could be a source of high quality food in this Arctic environmental at a time when they were too small to handle large food items.

Figure 20. *Lagopus lagopus lagopus*, Willow Ptarmigan in summer plumage. Chicks of this species consume mosses. Photo by George Lesard, through Creative Commons.

The consumption of these moss capsules by Willow Ptarmigan chicks appears to be a regular event every spring as the capsules appeared in the diet in three consecutive years (Martin & Hik 1992). It is likely that they supply needed lipids; they contain about 20% lipids, a level higher than that in the other available vegetation (Pakarinen & Vitt

1974). In two cases the large numbers of capsules consumed suggest food selection rather than accidental ingestion (Martin & Hik 1992).

Figure 22. *Pohlia nutans* with capsules. Capsules from this genus are eaten by the Willow Ptarmigan in the North. Photo by Michael Lüth, with permission.

Martin and Hik (1992) found the crops of Willow Ptarmigan chicks (*Lagopus lagopus*; Figure 23) stuffed with capsules of the moss *Distichium inclinatum* (Figure 24). The researchers suggested that the sporophytes might be easily accessible forage for these chicks. Could the capsules possibly act as grinding agents for other foods?

Grouse

Grouse (*Tetraoninae*) chicks (Figure 7) are known to eat moss capsules (Richardson 1981). In fact, the clutch size and mean egg weight are dependent on the food of the mother (Naylor & Bendell (1989). The two most preferred foods were the trailing arbutus (*Epigaea repens*; Figure 25) and capsules of *Polytrichum* (Figure 19), and their availability was important, but not the size of the hen or her scaled body weight. Egg size, on the other hand, was not related to spring diet, but was instead related to the size of the hen. Therefore, the spring diet was important in providing the nutrients required for clutch formation.

Figure 25. *Epigaea repens*, one of the two most preferred foods of grouse chicks. Photo by Fritz Flohr Reynolds, through Creative Commons.

Titmice

Titmice eat moss capsules in the temperate zone (Richardson 1981). Haftorn (1954) on five occasions observed the Crested Titmouse (*Baeolophus* sp.; Figure 26) on snow-free rocks with mosses. The birds were pulling at the tips of the moss and Haftorn surmised that they were probably eating the capsules.

Figure 26. *Baeolophus*, Crested Titmouse, a genus that grazes on the tips of mosses, perhaps to eat capsules. Photo by Dick Daniels, through Creative Commons.

Betts (1955) considered that in oak woodlands the Great Tit (*Parus major*; Figure 27) and the Blue Tit (*Cyanistes caeruleus*; Figure 15) can compete for food with the Coal Tit (*Periparus ater*; Figure 28) and the Marsh Tit (*Poecile palustris*; Figure 29). Using gizzard analyses, she determined that the Great Tit and Blue Tit had different diets, with the former feeding mostly on adult insects, especially weevils, and the Blue Tit on scale insects, small larvae, and pupae. The Coal Tit fed mostly on small, free-living insects and scales. The Marsh Tit ate mostly adult insects, scales, and a few larval forms. But in winter the diet changed. The Blue Tit consumed large numbers of capsules from the moss *Dicranoweisia cirrata* (Figure 30), ignoring the capsules of all other species. It had so many capsules in its gizzard that the gizzard was a vivid green (300-450 capsules per gizzard). One Coal Tit had consumed a few capsules and one Marsh Tit had 233 capsules in the gizzard.

Kōkako

The Kōkako/Blue-wattled Crow (*Callaeas wilsoni*; Figure 32) in New Zealand feeds on moss capsules (Jessica Beever, Bryonet 2 May 2003, based on observations by personnel from the Department of Conservation). Of 912 observations, 26 were feeding on moss capsules. When it was a good year for tracheophytes, only 3 out of 217 observations were of capsule feeding, but in a poor-fruit year, this increased to 6 out of 178 on mosses. These are probably within normal variation, but it suggests that the moss capsules may serve as an emergency food. The Kōkako forage along the branches, snipping off the capsules with the edge of the beak. Although they also feed on invertebrates from the bark and mosses, their action in obtaining the mosses by deliberate cutting is different from the pecking used to obtain insects. Eating the capsules is no accident.

The Kōkako (*Callaeas wilsoni*) make their greatest use of mosses in spring and summer (3%) when the capsules are most abundant, but they also may consume some in winter (0.75%) (Jessica Beever, Bryonet 2 May 2003, based on observations by personnel from the Department of Conservation). The actual consumption may be larger as it is more difficult to observe moss feeding than that on bright-colored fruits.

Fruit Mimicry by Capsules?

Michael Lüth (Bryonet 16 January 2008) has observed that some members of the **Splachnaceae** change their odor as they mature. *Tetraplodon mnioides* (Figure 33) has violet-colored capsules that smell like blueberries when the capsules are still closed. Once the capsules open, the odor changes to the smell of dung. A similar change occurs in *Splachnum ampullaceum* (Figure 34). When this species has immature capsules, the capsules have a strong, sweet odor like berries. But once the capsule opens it smells like dung. Could it be that in these early fruity stages the capsules are eaten by the local fauna, including birds? Patricia Geissler once expressed the idea that birds eat the capsules of *Voitia nivalis* (Figure 35) that occur among the buds of *Salix herbacea* (Figure 36), an early season food for some of the Arctic birds. If so, this is another potential dispersal mechanism. One might be able to make some interesting observations from within a duck blind, or using time-lapse photography.

Figure 36. *Salix herbacea* fruits in Austria, resembling capsules of *Voitia nivalis*. Photo by El Grafo, through Creative Commons.

While in Tasmania in December for the Australasian Bryological Workshop, Paddy Dalton and Rod Seppelt showed their fellow bryologists *Pleurophascum grandiglobum* (Figure 37), a moss of the button grass plains in SW Tasmania. Allison Downing (Bryonet 18 January 2008) was "intrigued by the capsules (Figure 37), which are extremely large, globular, cleistocarpous, and on quite long setae, and was curious about dispersal, particularly the possibility that this species might be dispersed by birds. The capsules are light green, fading to pale yellow, and to me, had much in common with the fruits of many Epacridaceae (Ericaceae) and also of *Persoonia* (Proteaceae; Figure 38) that grow in this area." Emma Pharo stated that there are a number of birds that do feed on the ground in the button grass plains (Allison Downing, Bryonet 18 January 2008). The birds might not gain any nutrition from the capsules and their contents, but mimicry is used by many plants for pollination so why not for dispersal? The New Zealand species of *Pleurophascum*, similarly, has globular fruits that become orange/red with maturity, and the color (red, orange) would make them even more attractive to birds.

Figure 37. *Pleurophascum grandiglobum* with capsules that are large and may be eaten by birds and dispersed by them. Photo by Christopher Taylor, Australian National Botanic Gardens, with online permission.

Figure 38. *Persoonia levis* fruit; *Pleurophascum grandiglobum* capsules (Figure 37) mimic these and may be eaten by some of the same bird species. Photo by John Tann, through Creative Commons.

Michael Lüth's comment about *Tayloria* (Figure 39- Figure 41) reminded Downing that three species of *Tayloria*, *T. octoblepharum* (Figure 39), *T. gunnii* (Figure 40), and *Tayloria tasmanica* (Figure 41), all with abundant and conspicuous capsules, grow in the same habitat as *Pleurophascum* (Figure 37). Perhaps they, too, are fragrant (like the fruits of some Ericaceae) in their early stages of development and dispersed by birds before they reach the 'dung'-smelling stage of their life cycle.

Bird Color Vision

To understand bird choice based on color, it is necessary to understand how birds see color. Most studies on bird responses to color have assumed that they see colors the same way as humans do (Bennett *et al.* 1994). However, this is not true. The human eye design is different from that of birds and has different spectral abilities. Birds have four types of cones in the retina, compared to our three (Finger & Burkhardt 1994). Among their differences, at least some birds are able to see UV light, and feathers of some birds reflect UV light (Bennett & Cuthill 1994).

Using gene coding for UV- or violet-absorbing opsin in the retina, Ödeen & Håstad (2003) were able to assess color sensitivities on living birds. Their color vision can be put into two classes: short-wavelength sensitivity biased toward violet and another biased toward UV. The violet sensitivity is ancient among birds, and sensitivity to UV has evolved independently in four evolutionary lines. Many members of the orders **Psittaciformes** (parrots) and **Passeriformes** (perching birds) present UV-sensitive type color vision, but within the **Passeriformes**, the **Corvidae** (Jays, Magpies, & Crows) and **Tyrannidae** (Tyrant Flycatchers) do not. At least some members of **Laridae** (Skuas, Gulls, Terns, & Skimmers – **Charadriiformes**) and **Struthionidae** (flightless birds – **Struthioniformes**) likewise have UV-sensitive vision. Birds of prey (**Accipitridae** & **Falconidae** – **Falconiformes**), on the other hand, have the violet type.

The colorations of songbirds are significantly more conspicuous to other songbirds than they are to raptors and crows in the coniferous and deciduous forests (Finger & Burkhardt 1994; Håstad *et al.* 2005). This difference permits the **Passeriformes** to advertise their colors for mating purposes while not advertising to the raptors (birds of prey) that are their predators.

In addition to their cones birds have a complex of oil droplets in their retinas that may alter the color hues they perceive and that may also alter brightness and saturation (Bennett *et al.* 1994). Bennett and coworkers caution us that color is a product of the perception of the observer.

This brings us to the question of bird choice of bryophyte capsules and leafy stalks based on color. We know that bryophytes often serve as emergency food. Consider the observation of Bennett and Théry (2007) that plants are most likely to produce conspicuous fruit colors at times when frugivorous bird abundance is low. By contrast, if seeds, or bryophyte spores, are dispersed by birds, then I would think it would be beneficial for the fruits and capsules if they were bright-colored when it is appropriate for dispersal.

But capsules are not the only parts of bryophytes that are eaten. As you will soon see, leafy parts are as well. And we know that at least some bryophytes have fluorescent cell walls. For example, the bulbils of *Pohlia* are fluorescent under UV light (Nordhorn-Richter 1984). The value of this fluorescence for dispersal by birds remains unexplored.

Leafy Plants

It is uncommon for birds to use leafy bryophytes for food, but they may do so when food is scarce (Silllett 1994; Rhoades 1995; Wolf 2009). Among the few birds that actually eat the leafy bryophytes, we know that the Red-throated Loon (*Gavia stellata*; Figure 42), Brant (*Branta bernicla*; Figure 1), White-tailed Ptarmigan (*Lagopus leucura*; Figure 43), Willow Ptarmigan (*Lagopus lagopus lagopus*; Figure 44), and Rock Ptarmigans (*Lagopus muta*; Figure 45) all eat bryophytes in the Pacific Northwest, USA (Palmer 1962; Martin & Hik 1992; Braun *et al.* 1993; Hannon *et al.* 1998).

Figure 45. *Lagopus muta*, Rock Ptarmigan in summer plumage, a species that eats leafy bryophytes. Photo by Böhlinger Friedrich, through Creative Commons.

Ducks and Food Availability

For ducks, bryophytes are not a preferred food. Ring-necked Ducks (*Aythya collaris*; Figure 46) in temporary wetlands use mostly plants, but those in more permanent wetlands choose animal foods for half their diet. The period during pre-laying and laying is an important time for females to obtain protein, and in the northern long days of Minnesota, USA, the females may feed up to 19 hours a day to obtain needed protein. However, when their usual food sources are unavailable, Ring-necked Ducks (*Aythya collaris*) may eat bryophytes (Hohman 1985). In 1980, reduced protein content in Class II juveniles seemed to be the result of a large percentage of aquatic mosses and caddisflies in cases. In that year, aquatic mosses comprised 18% of the diet, whereas in other years there were only trace amounts.

Figure 46. *Aythya collaris*, Ring-necked Duck male, a species that obtains protein from mosses. Photo by Alan Vernon, through Creative Commons.

Geese

Geese seem to have a love-hate relationship with mosses as a food source. Sometimes they are essential to the diet, but in other times and places, they are deliberately avoided. The Canada Goose (*Branta canadensis*; Figure 47) selectively consumes the riverweed *Podostemum ceratophyllum* (Figure 48) over the moss *Fontinalis novae-angliae* (Figure 49) in a riverine system, despite the dominance (89% of biomass) of moss in that system. This preference may have been due to the presence of C18 acetylenic acid, octadeca-9,12-dien-6-ynoic acid in the mosses, a compound that deters crayfish feeding.

Figure 47. *Branta canadensis*, Canada Geese and goslings. This species avoids eating the moss *Fontinalis*. Photo by Janice Glime.

Figure 49. *Fontinalis novae-angliae* protecting invertebrates from Canada Goose grazing because the geese won't eat it. Photo by John Parker, with permission.

By contrast, polar and alpine habitats seem to encourage the consumption of bryophytes, including by geese (Longton 1992). Gloutney *et al.* (2001) report that at Karrak Lake, NT, Canada Geese (*Branta canadensis*; Figure 47), Lesser Snow Geese (*Chen caerulescens caerulescens*; Figure 50) and Ross's Geese (*Chen rossii*; Figure 51) eat primarily mosses, chickweed (*Stellaria* spp.; Figure 52), and sedges (*Carex* spp.; Figure 53). In the Svalbard breeding season, mosses form a considerable part of the diet of Barnacle Geese (*Branta leucopsis*; Figure 54) (Prop *et al.* 1980).

Figure 50. *Chen caerulescens*, Lesser Snow Geese, grazing on sedges. Photo by Walter Siegmund, through Creative Commons.

Figure 51. *Chen rossii*, Ross's Goose, grazing on sedges. Photo by Andrew C., through Creative Commons.

Figure 52. *Stellaria humifusa*; members of this genus are eaten by several species of geese. Photo by Lynn J. Gillespie, through Creative Commons.

Figure 53. *Carex aquatilis* var. *minor* in water; members of this genus are eaten by several species of geese. Photo by Jeffery M. Saarela, through Creative Commons.

Figure 54. *Branta leucopsis*, Barnacle Goose, grazing. This species grazes largely on mosses in the Arctic. Photo by Arthur Chapman, through Creative Commons.

Barnacle Geese (*Branta leucopsis*; Figure 54) arrive in Spitzbergen, Scandinavia, after a long migration, but before flowering plants are available (Prop & Vulink 1992). Thus mosses are eaten heavily during pre-laying and laying periods (62% in feces) (Fox & Bergersen 2005). The young goslings also consume the mosses, and sampling revealed that 27 out of 28 samples of adult and gosling droppings contained mosses (Prop & Vulink 1992). Snow Geese (*Chen caerulescens caerulescens*; Figure 50) and Pink-footed Geese (*Anser brachyrhynchus*; Figure 55) consume mosses to a lesser extent than the Barnacle Geese. It is interesting that moss in the diet increased as the temperature increased (Fox *et al.* 2006).

Figure 55. *Anser brachyrhynchus*, Pink-footed Geese, foraging among grasses. Photo by Brian Eversham, with permission.

The Barnacle Goose (*Branta leucopsis*; Figure 54) grazes the top layer of mosses when the *Calliargon* (Figure 56) is still frozen (Prop & de Vries 1993). Along the water's edge, the geese dug for large lumps of mosses, consuming them as soon as they appeared. Fortunately, the mosses were a nearly inexhaustible food supply, but the geese seemed to prefer them when they were still anchored in ice. That made it possible for them to scrape the upper, most nutritious part with their bills without having to attempt separating them from their lower parts that were sealed in ice. Grasses began to grow when the moss beds began to thaw and within one week the young leaves appeared and were immediately consumed by the geese. During the earliest stages of this thaw, the geese fed on **forbs** (herbaceous flowering plant other than grass) and xerophytic mosses on the few snow-free patches. Then the forbs became the dominant food for about ten days. Then the moss meadows became available and the females switched to feeding on mosses, with their forbs proportion dropping to only 50%. As they became more available, graminoids gradually took on more importance in the diet of both males and females. However, at that time the proportion of mosses in the male diet was greater than that of females, both making great use of mosses in the moss meadows for food.

Figure 56. *Calliargon cordifolium*, a genus that is grazed by Barnacle Geese (*Branta leucopsis*; Figure 54) when the moss is still encased in ice. Photo by Janice Glime.

One factor in determining suitable food is retention time (Prop & Vulink 1992). Since plant cell walls are difficult to digest, and bryophytes have a higher cell wall to cell content ratio, the bryophytes are more difficult to digest than herbaceous foods. The Barnacle Goose (*Branta leucopsis*; Figure 54) increased its retention time 2-4-fold as the short days of winter increased to the continuous light of summer in their Arctic breeding area. This permitted greater digestion of their food from 37% in winter to 56% in summer and allowed them to expand their food choices to include bryophytes – often the only food available in their summer range.

Competition may force some geese to eat mosses. When Barnacle Geese (*Branta leucopsis*; Figure 54) and Pink-footed Geese (*Anser brachyrhynchus*; Figure 55) coexist during molting time, their diet of sedges and grasses shifts to include more mosses, especially in the Barnacle Goose, reaching 33% of the diet, whereas mosses only reached 17% of the Pink-footed Goose diet (Madsen & Mortensen 1987). The Pink-footed Goose seems to be able to keep the Barnacle Goose from feeding in the preferred sedge and grass food patches. Mosses are suboptimal for both nutrients and fiber content compared to sedges and grasses.

Ardea and Sage (1982; Sage & Ardea 1982) note that the Barnacle Geese (*Branta leucopsis*; Figure 54) begin eating mosses as soon as they arrive in their Arctic breeding grounds. The authors suggest that this is necessary for them to build up **arachidonic acid**, a fatty acid in cell membranes. This notion is supported by Prins (1982). Several species of geese are known to eat mosses in their Arctic breeding grounds, including the Snow Goose (*Chen caerulescens*; Figure 50), Pink-footed Goose (*Anser brachyrhynchus*; Figure 55), Barnacle Goose, and Brant Goose (*Branta bernicla*; Figure 1). Prins suggested that the arachidonic acid helped to keep the membranes pliable as they move about on the frozen Arctic ground. The Canada Goose (*Branta canadensis*; Figure 47) instead eats horsetails (*Equisetum*; Figure 57), which are likewise rich in arachidonic acid, but mosses have the highest contents known.

Figure 57. *Equisetum arvense*, a source of arachidonic acid for Canada Goose (*Branta canadensis*). Photo by MPF, through Creative Commons.

When snow melt is delayed, as it has been recently along Hudson Bay shores, a predicted outcome of global warming, as many as 100,000 Snow Geese (*Chen caerulescens caerulescens*; Figure 50) stay for weeks instead of 1-2 days as in the past. The result is devastation of salt marsh and wetland plants, and only the moss carpet seems able to grow.

In the high Andes of sub-Antarctic South America, *Attagis malouinus* (White-bellied Seedsnipe; Figure 58), *Chloephaga picta* (Upland Goose; Figure 59), and *C. poliocephala* (Ashy-headed Geese; Figure 60) frequently consume bryophytes (Russo *et al* 2020). The fragments, including both leafy stems and capsules, occurred in 84.6% of the seedsnipe (26 samples) and 90.9% of the *Chloephaga* goose fecal samples (22 samples; Figure 61). At least one of the *Chloephaga* species consumes the mosses *Polytrichum strictum* (Figure 62) and *Notoligotrichum trichodon* (Figure 63). Of 11 collected goose droppings, more than 50% contained fragments of the **Polytrichaceae**. Such consumption suggests the possibility of dispersal of this moss family in bird feces.

Blood Pheasant

The Blood Pheasant (*Ithaginis cruentus*; Phasianidae; Figure 64) is protected in China, where it lives in shrublands on high, cold plateaus. Mosses are an important part of its diet (Shi & Li 1985; Nan *et al.* 2011). Yao (1992) dissected 46 gizzards to analyze for food preferences. This revealed 32 species of mosses, comprising 22 genera and 14 families. The preferred mosses comprised 24-54% of the content, second preference comprised 11-17%, third preference 4-9%, and those occasionally eaten comprised less than 2.1%.

Figure 64. *Ithaginis cruentus*, Blood Pheasant, a species for which mosses are an important diet component. Photo from EOL China Regional Center, through Creative Commons.

Other foods of the Blood Pheasant include grasses, and both mosses and grasses are taken during prolonged feeding expeditions in which the birds bob up and down like a slow sewing machine needle at the rate of 50 pecks per minute (Nan *et al.* 2011). In 528 observations, all individuals consumed mosses. Although it was difficult to

distinguish which bryophytes were being consumed, the researchers were able to identify *Actinotuidium hookeri* (Figure 65), *Funaria hygrometrica* (Figure 66), *Hedwigia ciliata* (Figure 67), *Homomallium connexum* (see Figure 68), *Pogonatum perichaetiale* (Figure 69), and *Rhytidium rugosum* (Figure 70). It appeared that the birds preferred mosses that were soft and easily fragmented for ease of swallowing. On the other hand, some of these mosses may help to grind food in the gizzard. Grasses were also eaten in large supply, but since they were abundant, it did not appear that the mosses served as emergency food or a source of fiber. Furthermore, it did not appear that the mosses were eaten as a source of insects because the insects were in low supply. Hence, it appears that the mosses were a preferred food.

Kakapo

On Stewart Island, the third largest island of New Zealand, the Kakapo (*Strigops habroptilus*; Figure 71) "plucks" the mast of the moss *Dicranoloma* (Figure 72), the sedge *Oreobolus*, the grass *Centrolepis*, the flowering plant *Astelia*, and the Asteraceae member *Celmisia* (Best 1984). Signs on *Dicranoloma* were rare, typically represented as foliage that had been pulled from the ground.

Turkeys?

Glover and Bailey (1949) reported that turkey droppings indicated that bryophytes formed a common food source from January to April in the beech-birch-maple-hemlock forest. However, it appears that the "mosses" in this case were instead actually *Lycopodium*, referred to elsewhere in the paper as a bryophyte.

Dispersal

The birds in some cases return the "favor." The Mallard, *Anas platyrhynchos* (Figure 73) and Lapwing *Vanellus vanellus* (Figure 74) both eat bryophytes. Wilkinson *et al.* (2017) found a large fragment of the moss *Didymodon insulanus* (Figure 75) in the feces of the Mallard in Cumbria, England, and similarly in the Lapwing feces. These fragments were cultured and proved to be viable. This suggests that consumption of bryophytes by birds can in some cases be a means of dispersal. Could this be more true for species that benefit from guano deposits?

Nutritional Value of Bryophytes

These records raise the question of nutritional value of bryophytes. Why do birds eat bryophytes? Sugawa (1960) found that puppies and chickens will eat the pendent moss *Neodickladiella pendula* that is pulverized and used as a food additive. These animals seemed to suffer no ill effects. In fact, they gained more weight than the controls. Sugawa found that these mosses contained considerable Vitamin B₂. Mosses can have high contents of vitamins, especially B₂ (Sugawa 1960; Margaris & Kalaitzakis 1974).

The greatest known use of bryophytes as food for birds occurs in the Arctic tundra. In these mosses, the caloric content is ~4.5-5.0 kcal g⁻¹ (Pakarinen & Vitt 1974). The flowering plants consist of about 15% protein and 5% fats, whereas mosses have about 4% protein and 2% fats. Much of the moss biomass is bound in lignin-like compounds. Sugars in these mosses comprise ~1.5%. These sugars include mannose, melibiose, maltose, and deoxyribose in the mosses *Syntrichia princeps* (Figure 76), *Rhynchostegium* sp. (Figure 77), *Platyhypnidium riparioides* (Figure 78), and *Homalothecium* spp. (Figure 79) (Margaris & Kalaitzakis 1974).

Figure 76. *Syntrichia princeps* with capsules. Photo by Michael Lüth, with permission.

Figure 77. *Rhynchostegium alopecuroides*. Photo by Michael Lüth, with permission.

Figure 78. *Platyhypnidium riparioides* with capsules, an emergent aquatic moss. Photo by Michael Lüth, with permission.

Figure 80. *Dicranella heteromalla*, a moss with ~3700 cal g⁻¹ dry weight. Photo by Michael Lüth, with permission.

Forman (1968) examined caloric values of thirteen bryophyte species from Mt. Washington, NH, USA. Values for fresh bryophytes varied from 3747 cal g⁻¹ dry weight for *Dicranella heteromalla* (Figure 80) to 4305 cal g⁻¹ in *Thuidium delicatulum* (Figure 81). But then, spinach has only 0.23 cal g⁻¹ of fresh spinach (1 cup) (Wikipedia 2017). When species were transplanted to a high-temperature and high-humidity environment, the caloric content decreased. On the other hand, bryophyte species that originated from the coniferous and northern hardwoods forests all had higher caloric values than those from the higher alpine area or the lowland oak forest. On Mt. Washington, the bryophytes are among those plants with the lowest caloric values.

Mosses can affect the nutritional value of forbs and grasses in Arctic wetlands (Kotanen 2002). Moss presence did not prevent the rapid uptake of nitrogen by other forage species. However, most of added N nevertheless ended up in the moss layer. Hence, the mosses are able to divert N away from the tracheophyte forage plants and into long-lasting peat. This sequestering can make it more difficult for freshwater tracheophyte forage plants to recover from excessive foraging by Snow Geese (*Chen caerulescens atlantica*; see Figure 50). On the other side of the coin, the Snow Geese fertilize the moss layer in the polygon fens (Pouliot 2006).

Figure 81. *Thuidium delicatulum*, a moss with ~4300 cal g⁻¹ dry weight. Photo by Michael Lüth, with permission.

Solheim *et al.* (1996) showed that grazing geese had a significant impact on nitrogen fixation in the Arctic Svalbard. In areas with grazing there was 10X as much N fixation as in areas with no grazing. Bird droppings under cliffs likewise increased N fixation.

Atmospheric pollutants are having a large impact on the N content of bryophytes. Pitcairn *et al.* (1995) found that atmospheric N deposition caused a significant rise in tissue N of 38% in central Scotland to 63% in Cumbria during just two decades.

Crafford and Chown (1991) suggested that herbivory by curculionid beetles on bryophytes originated in response to an absence of flowering plants during glacial periods. For birds, it appears that Arctic birds that eat bryophytes likewise have occupied a feeding niche that at least during part of the year is devoid of flowering plants.

Palatability

Bryologists for a long time assumed that bryophytes were inedible. This could result from bad taste, low nutrient value, or toxic effects. But, in fact, bryophytes are eaten. To humans they may taste terrible, with Crum (1973) describing *Dicranum* (Figure 82) as having a strong, somewhat peppery taste, *Rhodobryum giganteum* (Figure 83) as having a sickening sweet taste, and most tasting like raw green beans. But are these the tastes registered by the birds? Feeding preference tests of birds with choices of leafy bryophytes and capsules seem to be lacking. Are there species preferences? Does color matter? Do they provide some essential nutrient that is more abundant in bryophytes than in other foods?

Foraging

As already discussed in earlier chapters, many invertebrates reside among the bryophytes. These include grubs, beetles, bugs, worms, mites, spiders, and other macroinvertebrates. Many of these organisms are desirable food for birds. Hence, many birds forage among bryophytes, and some are specially adapted for this bryophyte foraging behavior.

Figure 83. *Rhodobryum giganteum*, a moss with a sickening sweet taste. Photo by David Long, with permission.

Ground Foragers

The Common Blackbird (*Turdus merula*; Figure 12) forages among mosses when snow still covers part of the ground (see film by Shutterstock 2017). It is likely that other early arrivals take advantage of the moss fauna when most insects are in the egg or pupal stage, often hidden under bark or in the soil and immobile.

Arctic Foraging Effects

In the Arctic breeding grounds, mosses are typically the dominant vegetation. The thickness of the moss mats influence the temperature of the underlying soil (van der Wal *et al.* 2001). Herbivores, including birds, can reduce that mat thickness by trampling, consumption, or foraging. When Barnacle Geese (*Branta leucopsis*; Figure 54) and reindeer were excluded from areas with moss cover at Spitsbergen, the moss mat increased in thickness and the soil temperature was reduced by 0.9°C. In all sites, the soil temperature was negatively correlated with the thickness of the moss mat. This temperature change had no effect on the moss growth rate, but the Arctic meadow-grass (*Poa arctica*; Figure 84) and polar cress [*Cardamine pratensis* (= *C. nymanii*); Figure 85] experienced a 50% reduction in biomass on the chilled soils.

Figure 84. *Poa arctica*, an Arctic grass that diminishes in cover at lower temperatures. Photo by R. J. Soreng, through Creative Commons.

Figure 85. *Cardamine pratensis*, a species that has less growth at lower soil temperatures. Photo by Aiwok through Creative Commons.

Arctic foraging can have detrimental effects on the plants in this fragile ecosystem, but at times they benefit the bryophytes. The Lesser Snow Goose (*Chen caerulescens caerulescens*; Figure 50) in the Arctic coastal region can be very destructive while foraging among roots and rhizomes for grubs and other food (Jefferies 1988). At the rate of foraging exhibited, Jeffries estimated that the sedge meadow would convert to a moss carpet in about five years.

Foraging on Epiphytes

Bryophytes are often torn up by foraging birds, presumably in search of insects and other invertebrates. In

the Pacific Northwest, USA, 44% of the foraging among epiphytes was on bryophytes. These were mostly pendant bryophytes (Figure 86), followed by foliose lichens (Figure 87), then appressed bryophytes (Figure 88). In these forests, 20% of the bryophyte foraging was on the abundant moss *Isoetecium myosuroides* (Figure 86). The bark insectivorous birds were the most frequent foraging guild on the bryophyte and lichen substrates.

Figure 86. *Isoetecium myosuroides*, most common epiphytic moss foraged by birds in the Pacific Northwest. Photo by Dale Vitt, with permission.

Figure 88. *Hypnum imponens* on log, an appressed bryophyte like those that are less preferred for foraging by birds in the Pacific Northwest. Photo by Janice Glime.

As an example, we know that the Blue Tit (*Cyanistes caeruleus*; Figure 15) eats larvae of *Erannis* (Lepidoptera) in winter (Betts 1955) – a moth associated with forests with lots of bryophyte cover (Kiadaliri *et al.* 2005). Females of at least some species of *Erannis* lay eggs under mosses as well as in crevices, making this a good foraging site for birds hunting larvae.

Wolf (2009) questioned the value of epiphyte foraging to birds in coniferous forests of the Pacific Northwest. Of the 735 foraging records, ~30% occurred on epiphytic substrates. The data indicated selectivity by the Chestnut-backed Chickadee (*Poecile rufescens*; Figure 89), Red-breasted Nuthatch (*Sitta canadensis*; Figure 90), Brown Creeper (*Certhia americana*; Figure 91), Hairy Woodpecker (*Picoides villosus*; Figure 92), and Gray Jay (*Perisoreus canadensis*; Figure 93). Furthermore, the position in the canopy influenced their choices. In the mid and upper crown, lichens were preferred, whereas in the lower crown the bryophytes were preferred. Weikel and Hayes (1999) suggested that the bryophyte cover may house more arthropods that serve as food, but at the same time they hide the arthropods, making them less available to these birds.

Figure 89. *Poecile rufescens*, Chestnut-backed Chickadee, a species that typically forages among epiphytic bryophytes in the Pacific Northwest, USA. Photo by Walter Siegmund, through Creative Commons.

Figure 91. *Certhia americana*, Brown Creeper, on a tree where it often forages among mosses and lichens. Photo by Walter Siegmund, through Creative Commons.

In the Pacific Northwest coniferous forests of Washington and Oregon, USA, eleven species of birds use the bryophytes for foraging (Wolf 2009). However only four bird species comprised 79% of the foraging records. These were the Pacific Winter Wren (now named *Troglodytes pacificus*; Figure 94; 33 records), Brown Creeper (*Certhia americana*; Figure 91; 13 records), Gray

Jay (*Perisoreus canadensis*; Figure 93; 14 records), and Chestnut-backed Chickadee (*Poecile rufescens*; Figure 89; 13 records). Among these, the Brown Creeper (*Certhia americana*), Hermit Thrush (*Catharus guttatus*; Figure 95), and Winter Wren used the bryophytes in more than 20% of their foraging excursions.

Figure 92. *Picoides villosus*, Hairy Woodpecker, a species that forages among epiphytic mosses. Photo by Will Pollard, through Creative Commons.

Figure 95. *Catharus guttatus*, Hermit Thrush, a species that frequently forages among bryophytes. Photo by Cephas, through Creative Commons.

The behavior differed among these birds (Wolf 2009). The Brown Creeper (*Certhia americana*; Figure 91) and Hairy Woodpecker (*Picoides villosus*; Figure 92) hung vertically or upside-down on the epiphytes as they probed, hammered, pecked, or otherwise inspected the epiphytic bryophytes, using mostly prostrate mosses (esp. *Hypnum*; Figure 96) on the bole. The arthropods that are the victims of their searches use the epiphytes for refuge, forage, rest, aestivation, and thermoregulation (Richardson & Young 1977; Rhoades 1995; Shaw 2004). The dense mats accumulate soil, providing further habitat for invertebrates (Winchester & Ring 1996). The birds contribute a selection pressure that selects for cryptic coloration and other forms of camouflage in the arthropods (Richardson & Young 1977).

Figure 96. *Hypnum cupressiforme*, a common epiphytic genus for foraging by Brown Creepers and Hairy Woodpeckers. Photo by Jan-Peter Frahm, with permission.

With the wide range of bryophytes in the Neotropics, certainly some are better sources of food items than others. The Ochraceous Wren and Common Bush-Tanager forage among the dead organic matter and bryophytes more frequently than they do among other (tracheophyte) epiphytes (Nadkarni & Matelson 1989).

In Costa Rica, The Ruddy Treerunner (*Margarornis rubiginosus*; Figure 97) is an epiphyte specialist, foraging on bryophytes (Silllett 1994). The Spot-crowned Woodcreeper (*Lepidocolaptes affinis*; Figure 98) is a Central American foraging specialist on bryophytes and

foliose lichens, but the bryophytes were used less proportionately than lichens.

Figure 98. *Lepidocolaptes affinis*, Spot-crowned Woodcreeper, foraging among mosses. Photo by Carmelo López Abad, through Creative Commons.

The Blue-capped Ifrita (*Ifrita kowaldi*; Figure 99), a poisonous bird, is restricted to the highlands of New Guinea (Figure 100), mostly above 2000 m asl (Dumbacher *et al.* 2000). They live in mossy, moist montane forests, where they behave much like the nuthatches, foraging for insects and worms among mosses, on tree trunks, and on major branches in the midstory of the forest. They are rarely seen alone, typically travelling in groups of up to six individuals.

Pendant bryophytes (Figure 101) can protect some arthropods from foragers. These arthropods are able to dwell at some distance from the branch, away from the perches of the birds (Wolf 2009). These mosses are too unstable for many kinds of birds to perch. Among the birds that were not deterred by the pendant branches, the Pacific-slope Flycatcher (*Empidonax difficilis*; Figure 102) used a sally, hover, and glean foraging behavior to capture insects on the dangling bryophytes. The Chestnut-backed Chickadee (*Poecile rufescens*; Figure 89) used short flights and hops to forage, but occasionally hovered or hung from the bryophytes to snatch an insect from the pendant portion. Furthermore, 70% of the nests of this species contained bryophytes (Dahlsten *et al.* 2002).

Peterson *et al.* (1989) sampled trunk-surface arthropods from American beech (*Fagus grandifolia*; Figure 103) and sugar maple (*Acer saccharum*; Figure 104). The arthropod resources did not differ significantly between trees. Furthermore, they were not correlated with bark texture or bryophyte cover.

Figure 103. *Fagus grandifolia* forest in winter. Photo by Dcrjsr, through Creative Commons.

Pheasants (*Phasianus colchicus*; Figure 105) do not seem to have any particular use for the mosses themselves, but the mosses seem to be in their way on the forest floor of a wetland forest (Wiegiers 1983). When they are foraging, they turn the bryophyte cover upside down in search of food. Following these events, some mosses, including *Dicranum scoparium* (Figure 106) and *Mnium hornum* (Figure 107), that were turned upside down develop into moss balls.

Figure 104. *Acer saccharum* autumn leaves and trunk. Photo by Janice Glime.

Figure 105. *Phasianus colchicus*, Pheasant, a species that often disturbs bryophytes while foraging. Photo by Gary Noon, through Creative Commons.

Rod Seppelt (Bryonet 26 February 2013) has observed Skuas (*Catharacta lonnbergi*; Figure 108) upturning upland moss polsters of *Ditrichum strictum* (see Figure 109) on subAntarctic islands, searching for earthworms. It is puzzling because there are easier food items available than these relatively small worms.

In Eugene, Oregon, USA, the Steller's Jay (*Cyanocitta stelleri*; Figure 110) tears up mosses from the oaks as it forages for arthropods that hide there (Wagner 2013). In other locations it is Crows (Figure 112) and Scrub Jays (*Aphelocoma californica*; Figure 111).

Figure 110. *Cyanocitta stelleri*, Steller's Jay, a species that forages on mosses on oaks in the Pacific Northwest, USA. Photo by Alan D. Wilson, through Creative Commons.

Figure 111. *Aphelocoma californica*, Scrub Jay, a species that tears up mosses on oak trees. Photo by Minette Layne, through Creative Commons.

Crows (*Corvus*; Figure 112) are among those birds that can be quite destructive to bryophytes. Erkamo (1976) reported that some animal had upturned mosses on flat, open rocks in Finland. These mosses were typically only a few cm across, but some were up to 10-15 cm. Since the observations are indirect, based only on the upturned mosses, it is possible that voles, pheasants, seagulls, or crows were responsible, but crows seemed most likely. Erkamo has, at other times, seen crows engaging in such activity, presumably searching for insects or worms.

Birds keep bryophytes from growing well on red wood ant (*Formica rufa* group; Figure 113) mounds due to the bird foraging activity on the ants (Heinken *et al.* 2007).

Motley and Bosanquet (2004) reported a neglected flower pot that contained *Petalophyllum ralfsii* (Figure 114). Meanwhile, the surface had been colonized by various species of moss and the thallose liverwort *Aneura*

(Figure 115). The surprise came when birds attacked the bryophytes, pulling them out and most likely taking them for nesting material. But they were selective. They avoided taking the *P. ralpsii*.

Juncos

The Dark-eyed Junco (*Junco hyemalis*; Figure 116) in the Pacific Northwest, USA, is most active in the low understory, but it may go to the upper canopy to search for prey items among the lichens (Wolf 2009). But they may also forage on *Dicranum* sp. (Figure 82, Figure 106) and *Isoetecium* (Figure 86), where Wolf observed them on a horizontal tree bole and branch of *Tsuga heterophylla* (Figure 117) at 0.7 m and 3 m respectively.

Weaver Birds

In the Udzungwa Mountains of Tanzania, the disturbed humid forest serves as home for at least 70 species of birds (Fjelds  1999). Many of the birds search for their food among the epiphytic lichens, mosses, and ferns in the mature forests. The Tasmanian Mountain Weaver, *Ploceus nicolli* (Figure 118), is a vulnerable species that occurs in the tall forest of the Eastern Arc Mountains. It is associated with locations having large cover of epiphytic mosses and lichens.

Tropical Birds

In the tropics, some birds use epiphytes as their feeding substrates. These include at one end of the spectrum those birds that choose the substrate where they prefer to feed, and at the other end the birds choose the prey item, going to the substrate if it potentially has that prey organism. In Costa Rica, Sillett (1994) studied eight species that use epiphytes among their feeding substrates. Four species were epiphyte specialists. These included two that chose bryophytes: Ruddy Treerunner (*Margarornis rubiginosus*; *Furnariidae*; Figure 97) on just bryophytes and Spot-crowned Woodcreeper (*Lepidocolaptes affinis*; *Dendrocolaptidae*; Figure 98) on bryophytes and lichens. Orians (1969) and Remsen (1985) have provided evidence of bryophyte utilization by tropical birds, but otherwise, little documentation of this tropical resource exists. In Neotropical Costa Rica, Nadkarni and Matelson (1989) report three birds that feed upon bryophyte inhabitants (Table 1). The Emerald-chinned Hummingbird (*Abeillia abeillei*; Figure 119) and Amethyst-throated Hummingbird (*Lampornis amethystinus*; Figure 120) feed upon insects associated with the mosses and other bryophytes. The Rufous-tailed Hummingbird (*Amazilia tzacatl*; Figure 121) utilizes the flowers that are anchored in the bryophytic substrate. In fact, the Ochraceous Wren (*Troglodytes ochraceus*; Figure 122) and Common Bush-Tanager (*Chlorospingus ophthalmicus*; Figure 123) foraged in mosses more frequently than expected. Avian resources nestled among the bryophyte mats include fruits, flowers, seeds, water, and invertebrates.

Table 1. Percentage (and total number) of foraging visits to epiphytes by birds that probed moss mats and dead organic matter in the Monteverde field study, 1 July to 28 August 1985. Frequent foragers had 10 or more foraging visits recorded during the study period. Infrequent foragers had less than 10 foraging visits recorded. From Nadkarni and Matelson (1989).

Frequent foraging visits (> 10 foraging visits)

White-throated Mountain-gem, <i>Lampornis castaneiventris</i>	95 (150)
Ochraceous Wren, <i>Troglodytes ochraceus</i>	89 (19)
Common Bush anager, <i>Chlorospingur ophthalmicus</i>	57 (511)
Olive-striped Flycatcher, <i>Mionectes olivaceus</i>	46 (37)
Slate-throated Redstart, <i>Myioborus miniatus</i>	45 (47)
Prong-billed Barbet, <i>Semnornis fiantzii</i>	30 (23)
Golden-browed Chlorophonia, <i>Chlorophonia callophrys</i>	33 (187)
House Wren, <i>Troglodytes aedon</i>	26 (57)
Three-striped Warbler, <i>Basileuterus tristriatus</i>	20 (10)
Mountain Robin, <i>Turdus plebejus</i>	< 10 (146)

Infrequent foragers (< 10 total foraging visits)

Spotted Barbtail, <i>Premnoplex brunnescens</i>	
---	--

In subtropical evergreen forests, Dinesen (1995, 1997) reported on Shelley's Greenbul (*Arizelocichla masukuensis*; Figure 124). These birds found most of their food among the epiphytic mosses.

Jamaican Blackbird

Another tropical bird, the Jamaican Blackbird, *Nesopsar nigerrimus* (Figure 125), lives in the moist montane of Jamaica above 515 m (Cruz 1978). Its food includes insects, and its foraging behavior among the epiphytes, dead leaves, and moss-covered tree trunks and branches seems to be part of its adaptive evolution on the island. Its shorter legs, more curved claws, and longer, narrower bill adapt it for arboreal rummaging in crevices and among bryophytes.

Summary

Both capsules and leafy portions of bryophytes are eaten by some birds. This is particularly true in polar climates where tracheophytes are scarce or absent. These birds include grouse and pheasants, as well as

song birds. Even some parrots feed on capsules of *Polytrichum*. In tundra regions, the ptarmigan and grouse chicks often depend on bryophytes, especially the high quality food of capsules. Some birds use bryophyte capsules as emergency food, and one might describe all use of bryophytes as emergency food, although in some habitats, the emergency is long-lived. This capsule feeding can be seasonal, can depend on a bad year for tracheophytes, or can be used in a habitat with low productivity.

Use of color by birds to locate food is a topic wide open for research. Several hypotheses have suggested that members of the *Splachnaceae* with their brightly colored capsules and fruity odors may get dispersed as a result of attracting birds. This may also occur for the moss *Pleurophascum*. The ability of most songbirds and some others may enable the birds to see UV reflections that we have not discovered for capsules, or to locate bulbils and other bryophyte structures.

Leafy plants may be eaten as well, including by some diving birds and ptarmigans. Blood Pheasants, in particular, seem to consume large quantities of leafy bryophytes. In other cases, antiherbivory compounds keep the birds away, protecting the invertebrates living among the bryophyte branches. On the other hand, bryophytes may provide high concentrations of some vitamins, and one study on caloric content indicates that levels in leafy bryophytes may be high. Bryophytes can compete for nutrients, especially nitrogen, making the forbs less nutritious. Some birds may use the bryophytes to obtain arachidonic acid in preparation for winter.

The high ratio of cell wall to cell contents requires a long retention time of consumed bryophytes. This can reduce the feeding rate, causing the birds to remain quiet and less conspicuous. On the other hand, it might provide the bryophytes with a means of long-distance dispersal; some bryophytes survive passage through the digestive tract.

Perhaps the greatest food contribution of the bryophytes is through foraging. Many invertebrates reside there. This can be good or bad for the birds, with some specializing on bryophyte foraging and others unable to locate the invertebrates hidden by the bryophytes. Among these, the hanging bryophytes require the greatest specialization by the bird foragers, thus providing a safe haven for many invertebrates. On the other hand, the birds disturb the bryophytes on the ground and elsewhere, providing possible dispersal.

Acknowledgments

Thank you to Brian Dykstra for sending me the wonderful thesis on birds and epiphytes by Adrian Wolf, as well as other references and personal observations. Thank you to Marcel Schrijvers-Gonlag for supplying me with the pertinent part of the Haftorn (1954) paper. David Dumond shared the references he got from Bryonet. Bernard Goffinet has kindly alerted me to new literature on the subject and sent me an advance copy of his paper on birds

eating sporophytes in the sub-Antarctic. Thank you to Janet Marr for a critical reading of the manuscript.

CHAPTER 16-3

BIRD NESTS

Figure 1. Nest with mosses, lichens, and baby birds. Photo by Kytka through public domain.

Nests

*Within a thick and spreading hawthorn bush
That overhung a molehill large and round,
I heard from morn to morn a merr thrush
Sing hymns of rapture, while I drank the
Sound with joy – and oft an unintruding quest,
I watched her secret toils from day to day;
How true she warped the moss to form her nest,
and modell'd it within with wood and clay.*

The Thrush's Nest, by Claire
(in Marshall 1908)

Nests are complex structures that often consist of structural differences within a single nest. Most bird nests occur in unique habitats and are constructed of specific materials (Heinrich 2000). The nests themselves are typically so unique that the owner/builder can be identified

by the nest. In some cases, false nests are built by the male to discourage would-be suitors from enticing the female away.

The greatest vulnerability in the life cycle is typically during the time the young birds are in the nest (Heinrich 2000). Thus the construction and location of the nest are important survival factors (Heinrich 2000; Mainwaring *et al.* 2012). Most nests are built by the females, but in some cases it is the male who builds the nest(s), using them as sex attractants (Heinrich 2000). But the female typically chooses the site.

Although many nests are built for one-time use by the builder, some nests are reused by the same bird or by other animals for other purposes (Heinrich 2000). For example, the deer mouse climbs the tree to find a bird nest, then relocates it near the ground and fills it with seeds to store for the winter.

The importance of bryophytes in the Antarctic is illustrated at Vestfold Hills, East Antarctica. There was greater species diversity of mosses and lichens in sites

adjacent to nests than away from them. Is this a **guano** (bird droppings) benefit to the bryophytes, a moisture or insulation benefit to the birds, or a combination of both? Or do the bryophytes simply like the same locations as the birds? Soil nutrients were not significantly associated with moss diversity or abundance. Rather, both species and abundance of mosses have a positive association with soil water content. So it may be that the birds prefer nesting sites that are also preferred by the mosses.

Types of Nests

Wikipedia (2017) defines nine types of nests. The most common and familiar of these is the **cup** nest that is the product of many of the passerine birds.

The **scrape** nest (Figure 2) is the simplest. It is merely a depression in the soil or vegetation, but it may benefit from the addition of materials, such as bits of vegetation, small stones, shell fragments, or feathers. Mosses may form the base of such a nest. It usually has a rim to prevent eggs from rolling away. This type of nest is the most exposed, thus offering the least protection. This nest style is used by ostriches, many kinds of ducks, most shorebirds, most terns, some falcons, pheasants, quail, partridges, bustards, and sand grouse.

Figure 2. The **scrape** nest of *Charadrius* sp., a plover. This nest is lined with shells to support the eggs when the soil or sand become muddy. Photo by Gniazdo Sieweczki RB, through Creative Commons.

The **mound** nest (Figure 3) is typically made of soil, branches, sticks, twigs, and/or leaves (Wikipedia 2017). The females lay their eggs within the mounds, and the rotting vegetable matter generates heat that helps to warm and incubate the eggs. The largest of these nests is that of the Australasian megapodes. In some cases, as in the Australian Brush Turkey (*Alectura lathami*), the gender of the hatched eggs is affected by the temperature, with more females at higher temperatures (Göth 2007). Others building mound nests include the horned coot and the flamingo (Wikipedia 2017).

Figure 3. Malleefowl **mound** nest. Photo by Glen Fergus, through Creative Commons.

The **burrow** is an underground excavation that may be created by the bird or repurposed from a previous mammalian or tortoise owner (Wikipedia 2017). These are sometimes lined with mosses and usually have a tunnel entrance to an egg chamber. The bird occupants include white-browed tits, puffins, shearwaters, some megapodes, motmots, todies, most kingfishers, the crab plover, miners, and leaftossers.

Figure 4. The Sand Martin, *Riparia riparia*, in **burrow** nest. Photo by Bruce, through Creative Commons.

The **cavity** nest (Figure 5) is built in living or dead wood, tree ferns, or some cacti (Wikipedia 2017). The **cavity** nester is more likely to use bryophytes than the above-named nest builders. These are used to line the cavity and to elevate the base to a suitable height for entering and feeding the young birds. Some of the birds excavate their own cavities (woodpeckers, trogons, some nuthatches, many barbets). But far more species (parrots, tits, bluebirds, most hornbills, some kingfishers, some owls, some ducks, some flycatchers) must find holes already large enough.

Figure 5. *Dryocopus martius* (Black Woodpecker) with its **cavity nest**. Photo by Alastair Rae, through Creative Commons.

When most people think of a bird nest, it is the **cup** nest (Figure 6) that they visualize. These nests are open from the top and smoothly hemispherical inside, with a deep depression to house the eggs (Wikipedia 2017). The materials used are mostly pliable and some species specifically use bryophytes, either in the construction, the lining, or the outermost layer – perhaps as camouflage. The nest mass often correlates with the weight/size of the adult bird it must support. The insulation quality of the nest relates to nest mass, nest wall thickness, nest depth, nest weave density and porosity, surface area, height above ground, and elevation above sea level. Among the many cup builders are the robin and the tiny hummingbird. Some are attached to the branch with saliva, and some hummingbirds use spider webs to affix the nest.

Figure 6. *Passerculus sandwichensis*, Savannah Sparrow **cup** nest. Photo by Kati Fleming, through Creative Commons.

The **saucer** or **plate** nest is somewhat similar to the cup nest, but has very little, if any, depression (Wikipedia 2017). This nest may be within the range of nest variation for a cup builder.

The **platform** nest (Figure 7) is large and flat. It is occasionally lined with mosses (Wikipedia 2017). This nest type is common among some ducks and birds of prey. This more permanent structure can be used by the same pair of birds for many years.

Figure 7. Osprey (*Pandion haliaetus*) and **platform** nest. Photo by Tibor Duliskovich, through Creative Commons.

The **pendant** nest (Figure 8) is an elongated sac that hangs from a branch (Wikipedia 2017). Pendant nest builders include Oropendolas, caciques, orioles, weavers, and sunbirds. Some of these birds construct their nests from bryophytes.

Bryophyte Advantages in Bird Nests

Use of mosses for bird nests is not uncommon. Annie Martin (Bryonet 1 June 2010) reports that as many as forty different types of birds use mosses in constructing their nests. While that may be a local number, many more examples are known worldwide. Birds have long been recognized as consumers of mosses and liverworts for nesting materials (Figure 10) (Takaki 1957, Breil & Moyle 1976 – SE USA; Takeshita 1978, Furuki & Onuma 1996 – Japan; Hribek 1985 – Europe; Abolina 1991 – Lithuania; Cao & Caihua 1991, Cao *et al.* 2010 – China), to name a few. Richardson (1981) listed 53 British birds that use mosses to some degree in their nests; Campbell and Ferguson-Lees (1972) reported 52 from that region. Jadin and Billiet (1979) described the activities of birds building nests with mosses and liverworts on Reunion Island in the Indian Ocean.

Figure 10. Cup nest made of leafy liverworts in Costa Rica. Photo courtesy of Dave Fenlon.

Birds and bryophytes can have close relationships that permit both of them to reproduce. Some birds have an incessant need to make nests, and mosses can be a favorite building material. I found it impossible to develop any kind of moss garden in my garden room when it housed 10 Zebra Finches (*Taeniopygia guttata*; Figure 11) because within days or even hours every scrap of the moss had been moved from my chosen location to the midst of the bamboo clump, where it aided in forming massive 3-story apartment nests. I ultimately had to get rid of the finches and traded them for Society Finches, birds that have a little more reverence for mosses and don't find nest building to be an essential daily activity!

Figure 11. *Taeniopygia guttata*, Zebra Finch, a bird that often uses mosses in its nests, at least when choices are limited. Photo by Peripitus, through Creative Commons.

The families of birds using mosses to some degree in their nests ranges widely. We need consider only a few examples to illustrate this. In the **Passeriformes**, Hribek (1985) found that among others in the **Paridae**, the Great Tit (*Parus major*; Figure 18-Figure 19) and the Blue Tit (*Cyanistes caeruleus*; Figure 22) use mosses in their nests, as does the Pallas Dipper (*Cinclus pallasii*; Figure 12) in the **Cinclidae** (Nishimura *et al.* 1980). In the **Apodiformes**: **Apodidae**, the Philippine Swiftlet (*Aerodramus mearnsi*; Figure 13) uses bryophytes (Tan *et al.* 1982). In the **Podicipediformes**: **Podicipedidae**, breeding populations of the Red-necked Grebe (*Podiceps grisegena*; Figure 14-Figure 15) in the Northwest Territories use *Sphagnum* (Figure 16) in addition to cattails and other emergent vegetation in nest construction (Fournier & Hines 1998). Even the huge American Bald Eagle (*Haliaeetus leucocephalus* in the **Falconiformes**: **Accipitridae**; Figure 17) in Alaska uses mosses in old-growth forests in their nests atop tall spruce trees (Holleman 1997).

With such a large number of birds using bryophytes in their nests, we must ask why? Do they provide some special attributes that make them desirable? Or are they simply easy to collect and available?

Alabrudzińska *et al.* (2003) found that the quantity and proportion of mosses in nests and the nest size can influence the success of eggs as well as of the nestlings, as seen in the Great Tits (*Parus major*; Figure 18-Figure 19). They considered that nest size and composition must satisfy contradictory pressures needed for survival. The nest must be kept moist with a relatively constant temperature. It must also protect the eggs and young from predation and limit disease and parasites.

Insulation

Bryophytes can have beneficial effects that are not provided by other nesting materials. Providing insulation may be the first use that comes to mind. Birds often use grasses, feathers, and fur to regulate the nest temperature (Bartholomew *et al.* 1976; Winkler 1993; Blem & Blem 1994; Lombardo *et al.* 1995), much as we put on a winter coat or sleep under a quilt. But bryophytes can provide insulation as well.

Several studies have indicated the importance of nest temperature. Olson *et al.* (2006) used Zebra Finches (*Taeniopygia guttata*; Figure 11) to evaluate the importance of temperature on embryo development. They found that after 12 days of incubation, periodic cooling resulted in lower embryo mass and yolk reserves compared to controls incubated at 37.5°C. When the eggs were cooled to 20°C regularly, the embryos had higher mass-specific metabolic rates and delayed development.

Peréz *et al.* (2008) experimentally heated the nests of the Tree Swallow (*Tachycineta bicolor*; Figure 20) during incubation. They found that incubating females maintained better body condition and fed nestlings at a greater rate. Their nestlings similarly had higher body mass and better

body condition. In contrast, Ardia *et al.* (2008) examined the effects of cooling on the same species. They found that cooled eggs required longer incubation periods and the nestlings had a lower immunity to bacteria. Embryos that were exposed to experimental cooling resulted in nestlings that had lower residual and absolute body mass. The cooled females made fewer feeding trips, but this seemed to have no effect on nestling immunity to bacteria.

Figure 20. *Tachycineta bicolor*, Tree Swallow, a species in which nest temperature affects health of the nestlings. Photo by John Benson, through Creative Commons.

One means by which birds can alter the temperature of a nest is by increasing its size or thickness. This mechanism is used by the Great Tit, *Parus major* (Figure 18-Figure 19) (Alabrudzińska *et al.* 2003). Clutch size (Figure 21) correlates negatively with total nest mass, but is positively correlated with the proportion of nest mass in the lining. Successful performances of eggs and nestlings are attributable to the quantity and proportion of moss in the nest structure as well as the nest size. Alabrudzińska and coworkers suggest that nest size and composition may affect moisture, temperature, protection, and/or sanitary conditions of the nest, thus supporting the hypothesis that mosses serve as more than structural materials.

Figure 21. *Parus major*, Great Tit, nest with moss and eggs in nest box. Photo by Notts Ex Miner, through Creative Commons.

Deeming *et al.* (2012) extended this study to determine what triggers affect usage of more mosses in the nests of the Blue Tits (*Cyanistes caeruleus*; Figure 22) and Great Tits (*Parus major*; Figure 18-Figure 19, Figure 21). They found that nest mass is inversely related to temperatures experienced by the female during nest construction. Nest cup mass in particular is related to the temperatures experienced by the females during the seven days prior to the beginning of egg laying. This behavior is independent of latitude (Deeming *et al.* 2012), but nests are heavier at higher latitudes (Mainwaring *et al.* 2012).

Figure 22. *Cyanistes caeruleus*, Blue Tit adult, feeding. Photo by Dave Howes, through Creative Commons.

The Sociable Weaver (*Philetairus socius*; Figure 36-Figure 37) can serve to illustrate the role nesting materials might play and give us some insight into the role mosses could play. The nest of the Sociable Weaver consists of multiple chambers, and in summer each chamber is occupied by 1-2 birds, whereas in winter there may be up to 5 birds in a chamber, with some chambers remaining empty (Bartholomew *et al.* 1976). Bartholomew and coworkers found that for the Sociable Weaver in the Kalahari Gemsbok National Park, South Africa, the nest temperatures varied only 7-8°C when the outside temperatures ranged from 16-33.5°C. This temperature is controlled largely by the number of birds in a chamber. Van Dijk *et al.* (2013) further found that nest volume had no effect on its thermoregulatory benefits. Nevertheless, the central part of the nest had the most stable conditions.

Blem and Blem (1994) suggested that the moist bryophytes could alter the nest temperature, presumably cooling it through evaporative cooling, and certainly maintaining a cool temperature longer against the hot (~43°C) body temperature of the birds, much like a runner putting a wet band around his or her head. On the other hand, I suggest that the dark-colored mosses can also absorb sunshine like a dark body and warm the nest on cool days before leaves appear on the trees.

The nest of the Prothonotary Warbler (*Protonotaria citrea*; Figure 23), a cavity nester, consists of a cup made of grasses, leaves, and rootlets placed on a thick mat of moist, green bryophytes – both mosses and liverworts (Bent 1953;

Petit 1989; Blem & Blem 1992). These bryophytes remain moist during the incubation and nestling stages (Blem & Blem 1994). It is likely that this nest composition affects the nest living conditions (Mertens 1977 a, b). The bryophyte composition of these nests ranges 74.7-80.2% of the dry mass of the nest. *Anomodon attenuatus* (Figure 24) is the most used of the five moss and two liverwort species. The other bryophytes found in nests were the mosses *Haplocladium microphyllum* (Figure 25), *Amblystegium varium* (Figure 26), *Plagiomnium cuspidatum* (Figure 27), and *Thuidium delicatulum* (Figure 28), and the liverworts *Porella platyphylla* (Figure 29) and *Frullania eboracensis* (Figure 30). The woven bryophyte nest is also able to expand as the baby birds grow, maintaining a tight fit to the tiny eggs, but expanding as the young birds grow.

Most of the evidence of the importance of bryophytes as insulators is inconclusive. Mainwaring *et al.* (2012) found that insulative properties of nest linings decreased as

the season progressed. The Blue Tit (*Cyanistes caeruleus*; Figure 22) exhibited seasonal changes in the nest composition, but the mass of mosses in the base of the nest showed no seasonal variation (Mainwaring *et al.* 2014). On the other hand, there was a seasonal decline in the mass of materials used to line the cup (Mainwaring & Hartley 2008).

Deeming and Mainwaring (2015) found that the Blue Tits (*Cyanistes caeruleus*; Figure 22), European Pied Flycatchers (*Ficedula hypoleuca*; Figure 31), and Common Redstart (*Phoenicurus phoenicurus*; Figure 32) used different nesting materials in the same types of nest boxes. Blue Tits used mostly mosses with hair, fur, and feathers (Figure 33); Flycatchers used leaves and grass (Figure 34); Redstarts used leaves, grass, moss, and lots of feathers (Figure 35). Nevertheless, all three nest types have similar insulating properties.

Humidity Control

Humidity control can be important for young birds, and nest materials can be used to buffer changes in humidity. We can use the Sociable Weaver (*Philetairus socius*; Figure 36) once more to illustrate this role, perhaps in the extreme.

Figure 36. *Philetairus socius*, Sociable Weaver, a bird that builds a huge apartment nest that regulates humidity. Photo by Charles J. Sharp, through Creative Commons.

The Sociable Weaver (*Philetairus socius*; Figure 36) builds the largest bird nest (Figure 37) on the planet (van Dijk *et al.* 2013), housing at times over 100 pairs of birds (White *et al.* 1975). The nest is usually constructed in trees, using large twigs to construct the roof (Sociable Weaver 2017). Dry grasses separate the chambers and sharp spikes of straw deter predators from traversing the entrance tunnels. Inside, soft plant material, fur, cotton, and fluff line the nesting chambers. I can't help but wonder if bryophytes would be included if they were available in its habitat.

For the Sociable Weaver, the nest materials absorb the humidity, maintaining a lower humidity than that in the outside air (Bartholomew *et al.* 1976). The Sociable Weaver (*Philetairus socius*; Figure 36) does not use bryophytes, probably due to scarcity in its dry habitat, but where the bryophytes grow and are used by birds, I would expect them to have a significant role in absorbing and retaining humidity. I have taken bryophytes from a desiccator and watched their weight rise as I tried to weigh them. Bryophytes are able to take moisture out of the atmosphere, and thus they could also absorb moisture created by the birds' bodies. On the other hand, when the atmosphere is dry, the bryophytes could absorb moisture at night and help to keep baby birds, with scant covering of feathers, from drying out during the day.

Wimberger (1984) noted that the use of fresh bryophytes raised the humidity in nest cavities. This could prevent egg desiccation and increase hatching success (see also Clark & Mason 1985). On the other hand, the Fieldfare (*Turdus pilaris*; Figure 38-Figure 40) has an open nest, using grass and mud with very little moss or lichen. Compared to other species, the Fieldfare lost water rapidly. Within 10 minutes of removal of a water source, only 54% humidity remained in the nest, whereas the Redwing (*Turdus iliacus*; Figure 41) nest had 66%, the Eurasian Blackcap (*Sylvia atricapilla*; Figure 42-Figure 44) 71%, the Pied Flycatcher (*Ficedula hypoleuca*; Figure 31, Figure

34) 73%, the Chaffinch (*Fringilla coelebs*) 80%, and the Brambling (*Fringilla montifringilla*) 81%. Thrushes (*Turdidae*) made dense nests that still contained considerable water several days later. When the water content of the mosses and lichens was increased from 30% to 60%, the water content of the nest 24 hours later rose from 27% to 41%.

Figure 43. *Sylvia atricapilla*, European Blackcap, a nest that is able to hold moisture. Photo by James K. Lindsey, with permission.

Figure 44. *Sylvia atricapilla*, Eurasian Blackcap, nest with nestlings. Photo through Creative Commons.

Fontúrbel *et al.* (2020) noted that hummingbirds benefit from moisture retention by mosses, preventing eggs from drying out (see also Breil & Moyle 1976; Blem & Blem 1994).

In a study on passerine birds, Slagsvold (1989b) found that the width of the interior of the nest cup correlated negatively with the amount of mosses and lichens used in construction. It would seem, then, that using more mosses and narrowing the interior of the nest would provide a more insulated, more moist environment, and that bryophytes can be major contributors to those effects.

Elasticity

Elasticity can be important for both insulation and humidity. Slagsvold (1989a) noticed that the Chaffinch (*Fringilla coelebs*; Figure 45-Figure 46) and Brambling (*Fringilla montifringilla*; Figure 47) construct nest cups that expand in proportion to the number of young. This would also permit the nest to expand as the nestlings grow, continuing to maintain a warm blanket effect around them.

Slagsvold (1989a) considered selection for elastic nesting materials such as mosses and lichens as important criteria. But it appears that it is the ability to absorb rainwater rapidly, then to dry slowly, that is important.

Among the passerine birds, Slagsvold surmised that narrow nest cups were especially common with small-sized birds that nest above ground. These nests are typically open and include large quantities of mosses and lichens.

Antibacterial, Antiparasitic?

There are lots of hungry predators, albeit tiny, that enjoy living on birds. These can take a toll on survival. Adults and juveniles of the Cliff Swallow (*Petrochelidon pyrrhonota*; Figure 48) occupying parasite-free (fumigated) colonies had an average of 4.4% (adults) and 62.2% (juveniles) greater daily survival than their counterparts in naturally infested colonies (Brown & Brown 2004). Several researchers (Wimberger 1984; Clark & Mason 1985) suggest that the bryophytes may serve as insecticidal and anti-pathogenic agents in the nest. Clark and Mason examined the European Starling (*Sturnus vulgaris*; Figure 49) as a likely recipient of such help because it uses the same nest for multiple years, thus increasing the chances for parasite and pathogen encounter. This species chooses fresh green material in its nest, restricting its selection to a small number of species and choosing plants with volatile compounds that are likely to inhibit arthropod hatching or bacterial growth. These plants typically possess greater concentrations of mono- and sesquiterpenes than the local flora in general.

Figure 48. *Petrochelidon pyrrhonota*, Cliff Swallow, a bird that has lots of parasites. Photo by Ingrid Taylar, through Creative Commons.

Figure 49. *Sturnus vulgaris*, European Starling, a species that re-uses its nest and incorporates plants that contain greater concentrations of mono- and sesquiterpenes than the local flora in general. Photo by Luzmaria, through Creative Commons.

Igic *et al.* (2009) found that the Song Thrush (*Turdus philomelos*; Figure 50) used cigarette butts in its nest (Figure 51). This raised the question of anti-predatory nesting materials, as shown by Strecker (1926) and Schuetz (2005) for shed snake skins and carnivore scat. But mosses and odiferous leaves may serve this function as well, protecting birds against ectoparasites (Clark & Mason 1988; Banbura *et al.* 1995; Lambrechts & Santos 2000).

Figure 50. *Turdus philomelos*, Song Thrush, a bird that may use anti-predatory nesting material. Photo by Yvan, through Creative Commons.

Figure 51. *Turdus philomelos*, Song Thrush, feeding babies in New Zealand nest. Photo from ZipCodeZoo, through Creative Commons.

Blue Tits (*Cyanistes caeruleus*; Figure 22) use odor cues to determine when to replace green plant materials (Mennerat 2008). The female Blue Tits bring fresh plants to their nests (Banbura *et al.* 1995), so there is reason to believe that these plants may be chemically endowed in a

way that helps to protect the nest. Both parents hesitated longer before entering the nest box when the experimenter added green tracheophyte material compared to addition of mosses. Banbura concluded that we cannot rule out antiparasite functions of green plant material in the Blue Tit nests, but neither can we say conclusively that they serve this purpose.

On Corsica, Mennerat *et al.* (2009a, b) found that despite adding aromatic plants to their nests, the Blue Tit (*Cyanistes caeruleus*; Figure 22) experiences just as many parasites as without them. However, their growth is improved. The researchers found that the bacterial community in the nest was significantly affected by these plants, being reduced on nestlings. This offered the further advantage that the bacteria reduced most on the chicks with the worst infestations of the blood-sucking blowfly larvae (*Protocalliphora*). On the other hand, birds in nests where aromatic plants were replaced by mosses did not experience the benefits experienced in accompaniment of the aromatic plants: chick mass gain, higher haematocrit levels, faster feather development (Mennerat *et al.* 2009b).

Shutler and Campbell (2007) added greenery to nests of the non-greenery-using Tree Swallows (*Tachycineta bicolor*; Figure 20). They found no evidence that feathers had reduced parasites, but the added green plant material did result in lower numbers of ectoparasites in the nests. Nevertheless, there was no increase in breeding success.

Dawson *et al.* (2011) investigated the use of feathers to line nests in the Tree Swallow (*Tachycineta bicolor*; Figure 20). They found that adding feathers to nests actually increased the abundance of ectoparasites in those nests, a conclusion previously noted by Lombardo *et al.* (1995). Dawson and coworkers interpreted this to mean that the feathers separated the nestlings from the parasites. This conclusion supported that of Winkler (1993) in a study that showed that removal of feathers from Tree Swallow nests caused higher mite and lice infestation on nestlings, coinciding with lower growth rates of the nestlings, compared to controls. But there is also a cost to males that spend more time to gather more feathers – they are more likely to lose their mate to another male!

Wimberger (1984) further showed that birds in **Falconiformes** that used their nests in successive years were more likely to include green foliage, including bryophytes, than those species that did not reuse their nests. This suggests that the bryophytes may have some sort of protective function.

If birds choose nesting materials based on their antibiotic properties, it would seem that they would need to detect the odors caused by the compounds that facilitate this antibiotic use. But the **Passeriformes** (the birds that more often use bryophytes in their nests) are known to have a very small relative **olfactory** (odor-sensing) bulb size (Mennerat *et al.* 2005). Thus we have assumed that these birds have poor olfactory senses.

It appears that this wisdom is misleading, at least for some passerine birds (Mennerat *et al.* 2005; Strandh *et al.* 2012). The Blue Tit (*Cyanistes caeruleus*; Figure 22) uses mosses in her nest and this species is one of the birds that is sensitive to the odor of lavender (Mennerat *et al.* 2005). If birds choose vegetation based on the odor of volatile compounds, then I am surprised that the aromatic thallose liverworts do not seem to be used in nests.

Brian Dykstra (pers. comm. 10 December 2011) asked an interesting question. Liverworts such as species of *Frullania* (Figure 30) often house rotifers in their lobules (Figure 52). Could it be that these bacteria consumers actually help the birds by reducing the abundance of pathogens?

Figure 52. *Frullania eboracensis* lobule with rotifer. Photo courtesy of Lisa Pokorski.

We know that bryophytes themselves often have antibacterial properties (e.g. Basile *et al.* 1999; Alabrundzinska *et al.* 2003; Ariyo *et al.* 2011; Bukvicki *et al.* 2012; Asakawa *et al.* 2013; Yu *et al.* 2014), but until now, no study has demonstrated conclusively that they serve this purpose in the nests of birds.

At last, Fontúrbel *et al.* (2020) have shown that "Mamma knows best." They found that the hummingbird Picaflor Rubi (*Sephanoides sephaniodes*; Figure 53-Figure 54) selects the mosses *Ancistrodes genuflexa* (in 100% of the nests; Figure 55), *Weymouthia mollis* (27%; Figure 56), and *Weymouthia cochlearifolia* (17%; Figure 57) based on samples in austral South America, but *A. genuflexa* is particularly scarce in the forest while comprising up to 97% of the moss nesting material. They identified five compounds with antibacterial properties (Figure 58) in *A. genuflexa*.

Figure 58. Antimicrobial activity of control (C) and moss extracts (E) from *Ancistrodes genuflexa*, *Weymouthia mollis*, and *Weymouthia cochlearifolia* against five common bacteria strains. Error bars represent standard error. Modified from Fontúrbel *et al.* 2020.

We know from other studies that birds may prefer materials that have antibiotic properties. Doctoral student Sarah Knutie became curious when one of Darwin's finches (Figure 59) pulled at cotton threads on the clothes line rope to use as nesting material (Pety 2020). She followed up with an experiment using cotton balls. Half of them had antibiotic solution (1% permethrin) and half had just water. These were available in wire-mesh dispensers. Of the 26 active nests examined, 85% contained cotton. Of these, 13 nests had permethrin-treated cotton and 9 had untreated cotton. Only 4 had no cotton. Of the 8 nests with at least 1 g of treated cotton, 7 had no parasites and the eighth had only 4. Hence, it appears that the birds may select materials with antibiotic properties. That could explain at least some of the selection of bryophytes for nesting material.

There is a wide array of research projects needed to understand the role of bryophytes in nests. What is their elasticity compared to other nesting materials? Do they provide antibiotic properties that reduce parasites, fungi, or bacteria? Do they serve as better insulators than other materials? Do they keep the nest at a more constant humidity than other materials? Are they easier to work with or to carry than other materials?

Cavity Nest Elevation

Bryophytes have an additional function for cavity-nesting birds. They are often used to raise the nest cup so that the baby birds can be reached easily by the parents when feeding the birds and the birds can get in and out easily (Hamao *et al.* 2016). The bryophytes can also serve to separate the nest cups from cavity walls that may remain too moist, at the same time absorbing the excess moisture (Hamao *et al.* 2016).

Selection of Nest Materials

Just how choosy are the birds about the mosses they use? Breil and Moyle (1976) found that 11 birds had used 60 different species of mosses, including aquatic species, in their nests, suggesting that preference may simply depend on availability. Pant (1989) investigated the nests of five bird species in the Kumaon Himalaya and found that the primary mosses used were pleurocarpous. He supposed that these were preferred because they were easier to shape to suit the shape of the nest. This might also account for the use of larger leafy liverworts, in addition to pleurocarpous mosses, in the nest of the Streaked Laughing Thrush (*Trochaloxyron lineatum*; Figure 60) (Pant & Tewari 1984). Furthermore, Abolina (1991) found that the large leafy liverworts *Radula complanata* (Figure 61) and *Lophocolea heterophylla* (Figure 62) were used for nesting material in Lithuania.

In their study of nests of twelve bird species, Breil and Moyle (1976) found that most birds chose the bryophytes that were most abundant locally. These included the aquatic mosses *Fontinalis* (Figure 63) and *Hygrohypnum* (Figure 64), and *Sphagnum* (Figure 16). Terrestrial mosses were mostly the pleurocarpous *Brachythecium*

(Figure 65), *Hedwigia* (Figure 66), and *Thuidium* (Figure 67), plus the epiphytic bryophytes *Frullania* (Figure 30) and *Platygyrium repens* (Figure 68).

Other birds appear to be especially choosy. In Hawaii, one bird nest (most likely of a non-native species) made its nest almost entirely from the setae and capsules of *Pyrrhobryum* (*Rhizogonium*) *spiniforme* (Figure 69-Figure 70) (Brandon Stone, Bryonet 9 April 2003).

Figure 70. *Pyrrhobryum spiniforme* with capsule and seta that are used for nests by some birds in Hawaii. Photo by Janice Glime.

In the Uluguru Mountains of Tanzania, Tamás Pócs (Bryonet 2 June 2010) observed a nest of a small bird made purely of *Orthostichella rigida* (Figure 71), a common hanging epiphyte.

Figure 71. *Orthostichella rigida* from Tasmania, a pendent moss used in bird nests there. Photo courtesy of Tamás Pócs.

In Kenya, Min Chuah Petiot (Bryonet 2 June 2010) has collected an abandoned and fallen nest made with the hanging moss *Papillaria africana* (Figure 72). This moss was still green and alive.

Figure 72. *Papillaria africana*, nesting material in Kenya. Photo by Bruno Senterre, with permission.

Gustavo Tomás and Andrew Spink (Andrew Spink, Bryonet 2 June 2010) collected moss samples from a large number of Blue Tit (*Cyanistes caeruleus*; Figure 22) and Coal Tit (*Periparus ater*; Figure 73) nests from a woodland in the eastern Netherlands. The most common species in nests was *Hypnum cupressiforme* (Figure 74-Figure 75), which is common in the area. However, other locally common mosses were less common in the nests, indicating that the birds clearly selected certain species. It is interesting that different species were used in different parts (top/bottom) of the nest.

In the Pacific Northwest of Oregon and Washington, all seven thrush species (**Turdidae**) and six hummingbird species (**Trocholidae**) use either bryophytes or lichens in their nests (Wolf 2009). All nine crows and jays (**Corvidae**) except the Black-billed Magpie (*Pica hudsonia*; Figure 76-Figure 77) use bryophytes for nesting material. These Pacific Northwest bryophytes include *Alsia* (Figure 78), *Brachythecium* (Figure 65), *Calliergon* (Figure 79), *Dendroalsia* (Figure 80), *Dicranum* (Figure 81), *Eurhynchium* (Figure 82), *Homalothecium* (Figure 83), *Hypnum* (Figure 74), *Isothecium* (Figure 84), *Pogonatum* (Figure 85), *Pohlia* (Figure 91), *Polytrichum* (Figure 86), *Porella* (Figure 88), and *Sphagnum* (Figure 87).

One commonality to surmise from these studies is that short, acrocarpous mosses are rarely used. In the first report of bryophytes in bird nests in Chin, Cao and Gao (1991) found only pleurocarps among the 18 species used. These were mostly hanging mosses in **Meteoriaceae** (Figure 71), **Pterobryaceae** (Figure 89), and **Trachypodaceae** (Figure 90). Mosses that are long, mostly pleurocarpous species or those with a **plagiotropic** (growing inclined or nearly horizontally) habit, and larger

leafy liverworts comprise almost all of the bryophytes in bird nests. (Most leafy liverworts grow horizontally.)

Figure 90. *Bryowijkia ambigua* (Trachypodaceae), in one of the three most common bryophyte families in Chinese bird nests. Photo by Li Zhang, with permission.

Even in the case of the acrocarpous moss *Pohlia nutans* (Figure 91) in a nest, it was only the sporophytes that were used (Crum 1973). Mrs. Cuthbert, of Mount Pleasant, Michigan, USA, reported that she found a bird nest lined with moss sporophytes (a hundred or so, as in Figure 92), giving a gold-colored look to the interior on a wet day (Crum 1973). Crum identified the moss as *Pohlia nutans* (Figure 91).

Who Uses Mosses in Nests?

Breil and Moyle (1976) examined a number of nests of 12 eastern USA birds, identifying 65 species of mosses used in construction. They reported that all North American passerine birds use bryophytes in their nests, emphasizing the importance of bryophytes as an ecosystem component. These 65 species of bryophytes included 5 species of leafy liverworts. Of the nests examined, only the Indigo Bunting (*Passerina cyanea*; Figure 93) nest (Figure 94) lacked bryophytes.

Wolf (2009) conducted an extensive survey of bryophyte usage by birds in the Pacific Northwest (Oregon and Washington), USA. These are listed by orders, along with other records, in the following nest subchapters.

Summary

Birds often use bryophytes in their nests. This inclusion may help to maintain a safe temperature, to maintain suitable moisture, to prevent disease and parasitism, to provide a soft lining, to camouflage the nest, to permit the nest to expand as nestlings grow, and to help hold the nest together.

The use of bryophytes in nests is much more common among the **Passeriformes** (perching birds) than among the other orders of birds. Some birds are very specific in their choices, using only one or a few species when many are in the area. Most birds choose bryophytes with a plagiotropic growth habit and avoid acrocarpous mosses. Some select sporophytes, especially setae, to serve as nest linings.

What is clear is that we know little about the advantages that bryophytes may give birds when the bryophytes are included in the nests.

Acknowledgments

Thank you to Brian Dykstra for sending me the wonderful thesis on birds and epiphytes by Adrian Wolf, as well as other references and personal observations. David Dumond shared the references he got from Bryonettters. Tamás Pócs took a number of pictures of *Orthostichella rigida* just for this project. Thank you to Janet Marr for a critical reading of the manuscript.

CHAPTER 16-4

BIRD NESTS – NON-PASSERIFORMES, PART 1

Figure 1. Bird nest among ferns, with mosses surrounding nest cup. Photo courtesy of JeriLynn Peck.

Anseriformes Screamers, Ducks, etc

Anatidae – Swans, Geese, & Ducks

Wolf (2009) found eleven species of **Anatidae** that use bryophytes in their nests in North America:

- Anser brachyrhynchus* (Pink-footed Goose; Figure 2-Figure 3)
- Anser albifrons* (Greater White-fronted Goose; Figure 4-Figure 5)
- Branta bernicla* (Brant; Figure 6-Figure 7)
- Branta canadensis* (Canada Goose; Figure 8-Figure 10)
- Cygnus columbianus* (Tundra Swan; Figure 11-Figure 12)
- Cygnus cygnus* (Whooper Swan; Figure 13)
- Aythya collaris* (Ring-necked Duck; Figure 14)
- Clangula hyemalis* (Long-tailed Duck; Figure 15-Figure 20)
- Mergus merganser* (Common Merganser; Figure 23)
- Somateria fischeri* (Spectacled Eider; Figure 24-Figure 26)
- Somateria mollissima* (Common Eider; Figure 27)

Pink-footed Goose (*Anser brachyrhynchus*)

The Pink-footed Goose (*Anser brachyrhynchus*) may use bryophytes in the nest in parts of North America. But in the Arctic they choose dry vegetation patches for their nests. Having moist bryophytes nearby is important in nest

selection sites, however. These bryophyte areas are used for foraging (Jensen *et al.* 2008; Wiesz *et al.* 2008).

Figure 14. *Aythya collaris*, Ring-necked Duck, on water, a species that uses bryophytes in their nests in North America. Photo by MDF, through Creative Commons.

Long-tailed Duck (*Clangula hyemalis*)

I suspect that bryophytes are not the normal nesting material for the Long-tailed Duck (*Clangula hyemalis*; Figure 15-Figure 16). Its nest is typically built on the ground near water, using vegetation and lined with down (Wikipedia 2016). But Susan Studlar (pers. comm. 12 July 2017) reported to me that they built large nests (Figure 17-Figure 20) of *Rhytidadelphus* cf. *loreus* (Figure 21) when that was the only material provided to them at the Sealife Center in Seward, Alaska. I suspect most birds are adaptable, using the materials that are most available to them at the time of nest building. The Horned Puffin (*Fratercula corniculata*; Figure 22), on the other hand, ignores all those mosses in the landscape and lays its eggs in a crevice among the rocks (Wikipedia 2017).

Figure 27. *Somateria mollissima*, Common Eider, colonial nesting with Canada geese. Photo by Caroline Bond, USGS, through public domain.

Snow Goose (*Chen caerulescens*)

It is not surprising to find that in the far north, where mosses are a prominent feature of the landscape, birds like the Snow Goose (*Chen caerulescens*; Figure 28) use mosses as a major component of their nests (Figure 29) (Gianetta 2000). The Greater Snow Goose (*Chen caerulescens atlanticus*; Figure 30) in Jungersen Bay, northern Baffin Island, uses three habitat types for nesting (Giroux *et al.* 1984). One of these is wet moss-covered meadows with up to 5 cm of standing water, dominated by *Carex aquatilis* var. *minor* (Figure 31), *Dupontia fisheri* (Figure 32), *Calamagrostis stricta* (Figure 33), and *Arctagrostis latifolia* (Figure 34).

Figure 28. *Chen caerulescens* (Snow Goose) grazing; this species uses mosses as a major component of their nests. Photo by Walter Siegmund, through Creative Commons.

Figure 29. *Chen caerulescens*, Snow Goose, nest with nestlings and often containing bryophytes. Photo by James K. Lindsey, with permission.

Figure 34. *Arctagrostis latifolia* subsp. *latifolia* in the Northwest Territories, common in the habitat of the Greater Snow Goose. Photo by Jeffery M. Saarela, through Creative Commons.

McCracken *et al.* (1997) found that among the Ross' Geese (*Chen rossii*; Figure 35) and Lesser Snow Geese (*Chen caerulescens caerulescens*; Figure 37), the nest size (Figure 36) differed with habitat. The smallest were among heath, then rock, then mixed, with the largest nests among

mosses. Temperature was an important factor for these Arctic breeders. Could it be that mosses tended to insulate the eggs, but at the same time prevented the warmer temperatures that could speed up development? Were the mosses too compact and tight to be good insulators? Or did the mosses indicate a cooler ground temperature?

Figure 35. *Chen rossii*, Ross's Snow Goose, a species whose nest size is largest when among mosses. Photo by Dominic Sherony, through Creative Commons.

Figure 36. *Chen rossii*, Ross' Goose, nest with mosses and eggs. Photo by James K. Lindsey, with permission.

Figure 37. *Chen caerulescens caerulescens*, Lesser Snow Goose, a species that makes larger nests among mosses than among heath vegetation. Photo by Walter Siegmund, through Creative Commons.

Phasianidae – Quail, Pheasants, etc

Wolf (2009) found five species of **Phasianidae** that use bryophytes in their nests in parts of North America:

Falcipennis canadensis (Spruce Grouse; Figure 38-Figure 39)

Lagopus lagopus (Willow Ptarmigan; Figure 40-Figure 42)

Lagopus muta (Rock Ptarmigan; Figure 43-Figure 44)

Dendragapus obscurus (Blue Grouse; Figure 45-Figure 46)

Tympanuchus phasianellus (Sharp-tailed Grouse; Figure 47-Figure 48)

Gaviiformes: Loons

Gaviidae – Loons

Wolf (2009) found three species of **Gaviidae** that use bryophytes in their nests in parts of North America:

Gavia stellata (Red-throated Loon; Figure 49)

Gavia pacifica (Pacific Loon; Figure 50)

Gavia immer (Common Loon; Figure 51-Figure 52)

Figure 49. *Gavia stellata*, Red-throated Loon on nest. Photo by Dave Menke, through public domain.

Figure 51. *Gavia immer*, Common Loon, with chick. Photo from NPS, through public domain.

Figure 52. *Gavia immer*, Common Loon, on nest. Photo by Dana Moos, through Creative Commons.

Podicipidiformes: Grebes

Podicipididae – Grebes

Red-Necked Grebe (*Podiceps grisegena*)

Breeding populations of the **Red-necked Grebe**, *Podiceps grisegena* (Figure 53), in the Northwest Territories use *Sphagnum* (Figure 107) in addition to cattails and other emergent vegetation in nest construction (Figure 54) (Fournier & Hines 1998).

Figure 53. *Podiceps grisegena*, Red-necked Grebe, with ducklings. Photo by Donna Dewhurst, through public domain.

Figure 54. *Podiceps grisegena*, Red-necked Grebe, a species that includes *Sphagnum* in their nests. Photo by Lukasz Lukasik, through Creative Commons.

Pelecaniformes: Tropicbirds, Pelicans, etc

Phalacrocoracidae – cormorants

Wolf (2009) found two species of **Phalacrocoracidae** that use bryophytes in their nests in North America:

Phalacrocorax penicillatus (Brandt's Cormorant; Figure 55)

Phalacrocorax pelagicus (Pelagic Cormorant; Figure 56-Figure 57)

Figure 55. *Phalacrocorax penicillatus*, Brandt's Cormorants, on nests. Photo by Franco Folini, through Creative Commons.

Figure 57. *Phalacrocorax pelagicus*, Pelagic Cormorant, on nest. Photo by Alan Vernon, through Creative Commons.

Falconiformes: Vultures, Hawks, & Falcons

Accipitridae – Hawks, Old World Vultures & Harriers

Despite their large size and predatory habits, Wolf (2009) found seven species of **Accipitridae** that use bryophytes in their nests in the Pacific Northwest of the USA.:

Aquila chrysaetos (Golden Eagle; Figure 58-Figure 60)

Buteo brachyurus (Short-tailed Hawk; Figure 61)

Buteo lagopus (Rough-legged Hawk; Figure 62-Figure 63)

Buteo lineatus (Red-shouldered Hawk; Figure 64-Figure 65)

Elanoides forficatus (Swallow-tailed Kite; Figure 66)

Elanus leucurus (White-tailed Kite; Figure 67-Figure 68)

Haliaeetus leucocephalus (Bald Eagle; Figure 69)

Figure 58. *Aquila chrysaetos*, Golden Eagle, a species that uses bryophytes in their nests in parts of North America. Photo by Richard Bartz, through Creative Commons.

Figure 68. *Elanus leucurus*, White-tailed Kite, on nest. Photo by Maria Teresa Jaramillo, through Creative Commons.

American Bald Eagle (*Haliaeetus leucocephalus*)

It is of some consolation to those who fear extensive loss of mosses that protected birds use mosses for their nests. Even the huge **American Bald Eagle** (*Haliaeetus leucocephalus*; Figure 69) in Alaska uses mosses in old-growth forests to form nests (Figure 69) atop tall spruce trees (Holleman 1997). One can hope that in our efforts to protect our national symbol we will learn to protect those aspects of its habitat that are important to its success. This, hopefully, will protect the mosses.

Figure 69. *Haliaeetus leucocephalus*, American Bald Eagle, landing on nest. Photo by Murray Foubister, through Creative Commons.

Gruiformes: Cranes, Rails, etc

Gruidae – Cranes

Wolf (2009) found one species of **Gruidae** whose members use bryophytes in their nests (Figure 70) in parts of North America of the USA: *Grus canadensis* (Sandhill Crane; Figure 71).

Figure 70. *Grus canadensis*, Sandhill Crane, tending eggs in nest. Photo by Andrea Westmoreland through, Creative Commons.

Figure 71. *Grus canadensis pratensis*, Sandhill Crane, a species that uses bryophytes in their nests. Photo by Albert Herring, USFWS, through Creative Commons.

Rallidae

Chestnut Forest-Rail (*Rallina rubra*)

The Chestnut Forest-Rail (*Rallina rubra*; see Figure 72) from the Tari Gap, Southern Highlands Province, Papua New Guinea, builds a large, globular nest (Frith & Frith 1990). This domed structure is made of mosses, leaves, and ferns. Its entrance is on the side and the nest sits ~2m above the ground in the crown of the pandanus

palm. Despite the large size of the nest, this rail places only one very large egg in the nest. Although both birds incubate the eggs for their 34-37 days of incubation, the eggs are often left alone long enough that they become cold.

Figure 72. *Rallina fasciata*, Red-legged Crake; the species *Rallina rubra* uses mosses in their nests in Papua New Guinea. Photo by J. Wee, through Creative Commons.

Figure 73. *Charadrius morinellus*, Dotterel male, a species that uses bryophytes in their nests. Photo by Helwig Brunner, through Creative Commons.

Charadriiformes

Charadriidae – Plovers, etc

Wolf (2009) found four species of **Charadriidae** that use bryophytes in their nests in parts of North America:

Charadrius semipalmatus (Semipalmated Plover; Figure 76)

Pluvialis apricaria (European Golden-Plover; Figure 77-Figure 78)

Pluvialis dominica (American Golden-Plover; Figure 79-Figure 80)

Pluvialis squatarola (Black-bellied Plover; Figure 81)

Dotterel (*Charadrius morinellus*)

In Scotland, the rare Dotterel (*Charadrius morinellus*; Figure 73) prefers the *Carex bigelowii*-*Racomitrium lanuginosum* (Figure 74) moss heath (Welch *et al.* 2005). It feeds largely on beetles, sawflies, and both larvae and adults of *Tipula montana* (a common moss inhabitant in its larval stage; see Figure 75) (Galbraith *et al.* 1993). The preferred feeding habitats for these birds are flat or gently sloping *Racomitrium lanuginosum* or *Juncus trifidus* heaths or the transition zone between moss heath and montane bog. The most frequently used habitats are those where the montane bogs with best food for juveniles were adjacent to the *R. lanuginosum* heaths with the best food for adults.

Figure 74. *Racomitrium lanuginosum*, a moss commonly used in nests of the Dotterel. Photo by Niels Klazenga, with permission.

Figure 81. *Pluvialis squatarola*, Black-bellied Plover, a species that uses bryophytes in their nests in parts of North America. Photo by Peter Wallack, through Creative Commons.

Scolopacidae – Sandpipers, etc

Wolf (2009) found eighteen species of **Scolopacidae** that use bryophytes in their nests in parts of North America:

- Tringa melanoleuca* (Greater Yellowlegs; Figure 82)
- Tringa flavipes* (Lesser Yellowlegs; Figure 83)
- Actitis macularia* (Spotted Sandpiper; Figure 84-Figure 85)
- Numenius phaeopus* (Whimbrel; Figure 86)
- Numenius tahitiensis* (Bristle-thighed Curlew; Figure 87)
- Limosa lapponica* (Bar-tailed Godwit; Figure 88)
- Arenaria interpres* (Ruddy Turnstone; Figure 89-Figure 90)
- Aphriza virgata* (Surfbird; Figure 91-Figure 92)
- Calidris mauri* (Western Sandpiper; Figure 93)
- Calidris minutilla* (Least Sandpiper; Figure 94)
- Calidris fuscicollis* (White-rumped Sandpiper; Figure 95)
- Calidris pilocnemis* (Rock Sandpiper; Figure 96)
- Tryngites subruficollis* (Buff-breasted Sandpiper; Figure 97)
- Limnodromus scolopaceus* (Long-billed Dowitcher; Figure 98)
- Gallinago gallinago* (Common Snipe; Figure 99)
- Phalaropus tricolor* (Wilson's Phalarope; Figure 100-Figure 101)
- Phalaropus lobatus* (Red-necked Phalarope; Figure 102-Figure 103)
- Phalaropus fulicarius* (Red Phalarope; Figure 104)

Figure 104. *Phalaropus fulicarius*, Red Phalarope, in shore vegetation, a species that uses bryophytes in their nests in parts of North America. Photo from USFWS, through public domain.

Broad-billed Sandpiper (*Limicola falcinellus*)

The Broad-billed Sandpiper (*Limicola falcinellus*; Figure 105) builds nests in fens dominated by mosses and wet sedges. The nests are built on shallow hummocks, typically in transition zones between vegetation types. Once the baby birds hatch, they are moved from the nest to wetter fen areas nearby. Rae *et al.* (1998) found one nest concealed between two small bryophyte hummocks – one of *Sphagnum cf. capillifolium* (Figure 107) and the other possibly *Aulacomnium* sp (Figure 108). One was in a *Carex* tussock in a wet fen with 30% *Hamatocaulis cf. vernicosus* (Figure 109). The nests were often surrounded by a high cover of dark brown bryophytes. The eggs (Figure 106) and chicks were both colored dark chocolate brown, a coloration that Rae and coworkers suggested was an adaptation of **crypsis** (ability to avoid detection) to protect them against predation. Importance of matching color patterns is known in other birds, such as the Stone Curlew (*Burhinus oedipnemos*; Figure 110-Figure 111) (Solis & Lope 1995). These researchers demonstrated that mismatches in coloration between eggs (Figure 112) and the ground in the Stone Curlew increase the predation rate; these birds benefitted by choosing both nest building materials and nest substrate that increased camouflage.

Laridae – Skuas, Gulls, Terns, & Skimmers

Wolf (2009) found seventeen species of **Laridae** that use bryophytes in their nests in parts of North America:

Stercorarius parasiticus (Parasitic Jaeger; Figure 114-Figure 115)

Stercorarius pomarinus (Pomarine Jaeger; Figure 116)

Stercorarius longicaudus (Long-tailed Jaeger; Figure 117-Figure 118)

Chroicocephalus philadelphia (Bonaparte's Gull; Figure 119-Figure 120)

Larus canus (Mew Gull; Figure 121-Figure 122)

Larus argentatus (Herring Gull; Figure 123-Figure 124)

Larus thayeri (Thayer's Gull; Figure 125)

Larus glaucoideus (Iceland Gull; Figure 126-Figure 127)

Larus hyperboreus (Glaucous Gull; Figure 128-Figure 129)

Larus marinus (Great Black-backed Gull; Figure 130-Figure 131)

Rissa tridactyla (Black-legged Kittiwake; Figure 138)

Rissa brevirostris (Red-legged Kittiwake; Figure 139)

Rhodostethia rosea (Ross's Gull; Figure 140)

Pagophila eburnea (Ivory Gull; Figure 141)

Hydroprogne caspia (Caspian Tern; Figure 142)

Sterna paradisaea (Arctic Tern; Figure 143-Figure 144)

Onychoprion aleuticus (Aleutian Tern; Figure 145)

Stercorarius spp. (Figure 114-Figure 118) prefer mosses, especially *Polytrichum juniperinum* (syn. = *P. alpestre*; Figure 113) (Deeming & Reynolds 2015). Over 60% of their nest material (Figure 115) is mosses.

Figure 122. *Larus canus*, Mew Gull, on nest amid mosses and stones. Photo by John Haslam, through Creative Commons.

Herring/Glaucous Gull Hybrid (*Larus argentatus/hyperboreus*)

Ólafsson (1982) found a pair of gulls, one a Herring Gull (*Larus argentatus*; Figure 123-Figure 124) and the other a Glaucous Gull (*Larus hyperboreus*; Figure 128-Figure 129). Their nest was in a small, collapsed cave. It was constructed almost exclusively of the common moss *Racomitrium* (Figure 74). Only one arthropod, a mite, was found among these nest materials.

Figure 123. *Larus argentatus*, Herring Gull, a species that uses mosses in their nests. Photo by Tony Brierton, through Creative Commons.

Figure 129. *Larus hyperboreus*, Glaucous Gull, nest with eggs. Photo by Peter Davis, USFWS, through public domain.

Kelp Gull (*Larus dominicus*)

In the Argentine Islands the primary constituent of the Kelp Gull (*Larus dominicus*; Figure 132) nest (Figure 133) is the grass *Deschampsia antarctica* (Figure 134) (Parnikoza *et al.* 2012). The researchers postulated that in making the nests the gulls were responsible for the spread of this grass species on the islands. But the Kelp Gull also uses mosses extensively in its nests. In the Argentine Islands, *Sanionia uncinata* (Figure 135) was common and likewise was common in nests. It is particularly suitable because of its pleurocarpous growth form and lack of attachment to its substratum. I would expect that these gulls are similarly able to disperse the mosses.

Figure 135. *Sanionia uncinata*, a moss commonly used in nests of the Kelp Gull. Photo by Hermann Schachner, through Creative Commons.

Lesser Black-Backed Gull (*Larus fuscus*)

When Surtsey arose from the ocean near Iceland in a volcanic explosion, no life existed (Magnússon *et al.* 2008). Slowly plants and flying animals arrived. Among the early bryophytes was the moss *Racomitrium* (Figure 74), and this serves as the main nesting (Figure 136) material for the Lesser Black-Backed Gull (*Larus fuscus*; Figure 137) during this austere period.

Figure 145. *Onychoprion aleuticus*, Aleutian Tern, a species that uses bryophytes in their nests in parts of North America. Photo by F. Deines, through Creative Commons.

Alcidae – Auks, Murres, & Puffins

Wolf (2009) found four species of **Alcidae** that use bryophytes in their nests in parts of North America:

Brachyramphus marmoratus (Marbled Murrelet; Figure 146-Figure 149)

Brachyramphus brevirostris (Kittlitz's Murrelet; Figure 154-Figure 155)

Ptychoramphus aleuticus (Cassin's Auklet; Figure 156-Figure 157)

Cerorhinca monocerata (Rhinoceros Auklet; Figure 158-Figure 160)

Marbled Murrelet (*Brachyramphus marmoratus*)

When mosses are endangered, few people care, but when a bird shows evidence of disappearance, environmentalists and nature-lovers join forces to protect them. Protecting these birds in pristine habitats can, however, protect mosses as well. The Marbled Murrelet (*Brachyramphus marmoratus*; Figure 146) provides one such story.

Figure 146. *Brachyramphus marmoratus*, Marbled Murrelet. Photo by Kiliiii Yu, through Creative Commons.

Figure 147. *Brachyramphus marmoratus*, Marbled Murrelet, on mossy nest high in a tree. Photo by Sierra Club, permission pending, site not found.

Figure 148. *Brachyramphus marmoratus*, Marbled Murrelet chick. Photo by Peter Halasz, through Creative Commons.

Some of our big trees have moss mats that are 30 cm deep on the old firs and Sitka spruce (Krajick 1995a). These mats take centuries to develop and supply

nourishment for canopy-specific birds such as the Marbled Murrelet (*Brachyramphus marmoratus*; Figure 147).

Tompkins (2004) reported that 17 million pounds of mosses had been harvested in 2003 in parts of North America, including Appalachia, with an estimated recovery rate of only 1% per year. The endangered and elusive seabird, the federally threatened Marbled Murrelet (*Brachyramphus marmoratus*; Figure 146), nests (Figure 149) on these moss mats (Figure 147) along the Pacific Coast of the USA (Donahue 1999; Tompkins 2004).

Figure 149. Nest of the Marbled Murrelet (*Brachyramphus marmoratus*) with common moss in the Willamette Valley of the Pacific Northwest, USA. Photo by JeriLynn Peck.

Neville Winchester (in Tompkins 2004) found more than 300 species of mosses in the canopy mats where the Murrelets live. They are so important to the Marbled Murrelet that these birds fly miles inland to build their nests on the mats (Skow 1998; Tompkins 2004). The nest is the size of a baseball and is fashioned into a cup nestled in mosses on a wide tree branch where overhanging branches hide it from its Raven (*Corvus corax*; Figure 150) and Steller's Jay (*Cyanocitta stelleri*; Figure 151) predators (Donahue 1999). The Murrelets prefer trees with high limbs that support wide moss beds. These must be camouflaged by branches to protect the chicks (Figure 148) from predators like jays (Krajick 1995b). Saving the current nesting sites of the birds is essential because these birds return to the same nesting site year after year and rarely change locations (Donahue 1999).

Figure 150. *Corvus corax*, Raven, a predator of the Marbled Murrelet. Photo by Frank Vassen, through Creative Commons.

Figure 151. *Cyanocitta stelleri*, Steller's Jay, eating; this is a predator on the Marbled Murrelet. Photo by Rick Leche, through Creative Commons.

The Marbled Murrelet (*Brachyramphus marmoratus*; Figure 146-Figure 148) is distributed from central California to Alaska, living in mature forests of large coastal conifers (Singer *et al.* 1991). Although most of the nests are simple depressions in the moss or lichen mats, others are more constructed. The Marbled Murrelet uses epiphytic mosses (especially *Isoetecium* spp.; Figure 152) extensively as nesting material (Hamer & Nelson 1995). In California the Marbled Murrelet prefers the moss *Brachythecium* (Figure 153) instead (Brian Dykstra, pers. comm. 10 December 2011). Where it is protected, lots of bryophytes are also protected.

Summary

The use of bryophytes in nests is much more common among the **Passeriformes** than among the non-**Passeriformes**. The latter are mostly ground-nesting birds. Some build their nests on the mosses and others gather bryophytes to include in their nests. In the Arctic and Antarctic, use of bryophytes in nest construction is common due to the limited vegetation available. There, even water birds commonly use bryophytes.

Burrowing birds may use bryophytes as liners in the burrows, sometimes providing a nest for rodents that move in later. Hummingbirds often use mosses and lichens on the outsides of nests, presumably as camouflage. The Picaflor Rubi is one of the birds that can make its entire nest with bryophytes.

Some birds require mossy wetlands nearby their nesting sites because those wetland sites provide food needed for the young.

Protection of birds such as the Marbled Murrelet, a species that flies inland to mossy habitats to nest, may effectively protect the bryophytes as well.

Acknowledgments

Thank you to Brian Dykstra for sending me the wonderful thesis on birds and epiphytes by Adrian Wolf, as well as other references and personal observations. David Dumond shared the references he got from Bryonettres. Tamás Pócs took a number of pictures of *Orthostichella rigida* just for this project.

CHAPTER 16-5

BIRD NESTS – NON-PASSERIFORMES, PART 2

Figure 1. Bird's nest with living moss in Malaysia rain forest at 110 m alt. Photo courtesy of Tamas Pocs.

Columbiformes: Pigeons & Doves

Columbidae – Pigeons & Doves

Wolf (2009) found only one species of **Columbidae** that uses bryophytes in their nests in parts of North America: *Patagioenas fasciata* (Band-Tailed Pigeon; Figure 2-Figure 3).

Figure 2. *Patagioenas fasciata*, Band-Tailed Pigeon, the only member of **Columbidae** that uses mosses in their nests in parts of North America. Photo by Gary Kramer, through public domain.

Figure 3. *Patagioenas fasciata*, Band-tailed Pigeon, on nest. Photo by Cgates326, through Creative Commons.

Cuculiformes: Cuckoos & Relatives

Cuculidae – Typical Cuckoos

Wolf (2009) found one species of **Cuculidae** that uses bryophytes in their nests in parts of North America: *Coccyzus americanus* (Yellow-billed Cuckoo; Figure 4). Unlike the European Cuckoo, the Yellow-billed Cuckoo usually builds its own nest, only occasionally laying eggs in the nest of another species (Wikipedia 2017).

Figure 4. *Coccyzus americanus*, Yellow-billed Cuckoo, a bird that uses mosses in nests. Photo by Factumquintus, through Creative Commons.

Strigiformes: Owls

Strigidae – Typical Owls

Wolf (2009) found five species of **Strigidae** that use bryophytes in their nests in parts of North America:

Bubo virginianus (Great Horned Owl; Figure 5-Figure 6)

Bubo scandiacus (Snowy Owl; Figure 7)

Glaucidium gnoma (Northern Pygmy Owl; Figure 8)

Strix nebulosa (Great Gray Owl; Figure 9-Figure 10)

Aegolius acadicus (Northern Saw-whet Owl; Figure 11-Figure 12)

Figure 5. *Bubo virginianus*, Great Horned Owls, in nest where mosses are often used. Photo by John Kees, through Creative Commons.

Figure 6. *Bubo virginianus*, Great Horned Owl chicks. Photo by G. M. Stolz, through Creative Commons.

Snowy Owl (*Bubo scandiacus*)

Snowy Owls (*Bubo scandiacus*; Figure 7) use mosses as nest liners (Giannetta 2000).

Figure 7. *Bubo scandiacus*, Snowy Owl. Members of this species use mosses to line their nests. Photo by David Syzdek, through Creative Commons.

Figure 8. *Glaucidium gnoma*, Northern Pygmy Owl, a species that uses bryophytes in their nests in parts of North America. Photo by Ken-ichi Ueda, through Creative Commons.

Figure 10. *Strix nebulosa*, Northern Pygmy Owl, on nest. Photo by Kuva, through Creative Commons.

Figure 11. *Aegolius acadicus*, Northern Saw-whet Owl. Members of this species use bryophytes in their nests in parts of North America. Photo by Robert L. Curtis, through Creative Commons.

Figure 12. *Aegolius acadicus*, Northern Saw-whet Owl, young. Photo by Kathy and Sam, through Creative Commons.

Burrowing Owls (*Athene cunicularia*)

Thomsen (1971) reminds us that Burrowing Owls (*Athene cunicularia*; Figure 13-Figure 14) decorate their burrows (Figure 15) with mosses, among other things. The burrowing owl often does not make its own burrow, but rather uses the underground village of a marmot or prairie dog (Rennie 1857). At St. Domingo the owl digs a burrow 70 cm deep and deposits its eggs on a bed of moss.

Figure 13. *Athene cunicularia*, Burrowing Owls, ground-nesting birds that use burrows. Photo by Travelwayoflife, through Creative Commons.

Figure 14. *Athene cunicularia hypugaea*, Burrowing Owl. Members of this species decorate their burrows with mosses. Photo by Teddy Llovet, through Creative Commons.

Figure 15. *Athene cunicularia*, Burrowing Owl, nest hole. Photo by USFWS, through Creative Commons.

Caprimulgiformes: Goatsuckers & Relatives

Caprimulgidae – Goatsuckers

Wolf (2009) found one species (*Chordeiles minor* – Common Nighthawk; Figure 16) of **Caprimulgidae** that uses bryophytes in their nests (Figure 17-Figure 18) in parts of North America.

Figure 16. *Chordeiles minor*, Common Nighthawk, on a bed of mosses. Photo by Gavin Keefe Schaefer, through Creative Commons.

Figure 17. *Chordeiles minor*, Common Nighthawk, eggs in nest of mosses. Photo by Mike Allen, through Creative Commons.

Figure 18. *Chordeiles minor*, Common Nighthawk, hatchlings in nest. Photo by Mike Allen, through Creative Commons.

Apodiformes: Swifts & Hummingbirds

Apodidae – Swifts

Wolf (2009) found only two members of the **Apodidae** that use bryophytes in their nests in parts of North America:

Cypseloides niger (Black Swift; Figure 19-Figure 20)

Aeronautes saxatalis (White-throated Swift; Figure 21-Figure 22)

Figure 19. *Cypseloides niger*, Black Swift, adult on mossy nest. Photo by Terry Gray, through Creative Commons.

Figure 22. *Aeronautes saxatalis*, White-throated Swift, in flight. Photo by Michael Woodruff, through Creative Commons.

Glossy Swiftlets (*Collocalia*)

Medway (1966) found that at least some of the European swiftlets (*Collocalia* and *Aerodramus*) build bracket-shaped nests of mosses and other bryophytes that are bound together. The Glossy Swiftlets (*Collocalia esculenta*; Figure 23) include bryophytes in their nests, along with horse-hair fungi and palm fibers (Sick 1957; Medway 1962).

Figure 23. *Collocalia esculenta*, Glossy Swiftlet, a species whose members build nests made entirely of bryophytes in the Philippines. Photo through Creative Commons.

In the Philippines, Tan *et al.* (1982) discovered three nests of *Collocalia esculenta* (Glossy Swiftlet; Figure 23) that contained only bryophytes. One was a nest of a single species of the leafy liverwort *Frullania* (Figure 24). One nest was constructed of stems of the tiny leafy liverwort *Mastigolejeunea* sp. (85%) with scattered mosses [*Papillaria fuscescens* (see Figure 25), *Meteorium* (Figure 26), *Acroporium* (Figure 27)]. The third nest had a large compartment of only the leafy liverwort *Frullania* and a small one of the mosses *Papillaria fuscescens* and *Aerobryidium* cf. *filamentosum* (Figure 28). In all three nests the bryophytes were neatly glued together with saliva from the birds. Some of the bryophytes continued to grow

in the nests, but the shoots were attenuated and the leaf shapes abnormal. Of the mosses, only pleurocarpous species were used, and all the bryophytes were epiphytic high in the canopy of a dipterocarp forest. Furthermore, the bryophytes used were only common close to the summit of the mossy forest. Abundant ground species were completely ignored.

Figure 28. *Aerobryidium filamentosum*, a moss species used in nests of *Collocalia esculenta* in the Philippines. Photo by Taiwan Liverworts Color Illustrations, through Creative Commons.

Unlike most birds I have seen, *Collocalia esculenta* carry their nesting materials with their feet, flying at the tufts of epiphytes, grabbing with their feet and leaning back (Medway 1962). They beat their wings and tug at the bryophyte fronds. Carrying the mosses in their feet makes

the birds tail-heavy and flying is laborious. Fragments are often dropped, and long strands may hang from the nest until the birds are able to weave them into the nest. The mosses are held in place by gumming them to the underlying debris or cave wall. Nests are often deep in caves. This species is able to echo-navigate, so total darkness in the cave is no hindrance.

Mossy-nest Swiftlet (*Aerodramus salangana*)

The moss use by the Mossy-nest Swiftlet (*Aerodramus salangana*; Figure 29) is obvious by its name. The Mossy-nest Swiftlet in Malaysia builds a rounded nest made of plant material (Figure 30) (Medway 1962). Among three nests examined by Medway, the components were *Selaginella* sp. (a lycophyte; Figure 31) 75%, *Piloecium pseudorufescens* 5%, *Piloecium pseudorufescens* 90%, *Octoblepharum albidum* (Figure 32) a little; *Neckeropsis lepineana* (Figure 33) 80%, *Pinnatella kuehliana* 10%. These are all epiphytic mosses except *Selaginella*, a genus that often resembles a moss. *Octoblepharum* is the only acrocarpous genus.

Mascarene Swiftlet (*Aerodramus francicus*)

Billiet and Jadin (1979, Jadin & Billiet 1979) reported that the **Mascarene Swiftlet** (*Aerodramus francicus*; Figure 34) uses mosses, liverworts, and lichens glued together with saliva.

Trochilidae – Hummingbirds

Wolf (2009) found eight members of the **Trochilidae** that use bryophytes in their nests in parts of North America:

Hylocharis leucotis (White-eared Hummingbird; Figure 36)

Eugenes fulgens (Magnificent Hummingbird; Figure 37)

Archilochus alexandri (Black-chinned Hummingbird; Figure 38- Figure 40)

Calypte anna (Anna's Hummingbird; Figure 43-Figure 46)

Stellula calliope (Calliope Hummingbird; Figure 47-Figure 48)

Selasphorus platycercus (Broad-tailed Hummingbird; Figure 49- Figure 51)

Selasphorus rufus (Rufous Hummingbird; Figure 52-Figure 53)

Selasphorus sasin (Allen's Hummingbird; Figure 54-Figure 55)

Ruby-throated Hummingbird (*Archilochus colubris*)

The Ruby-throated Hummingbird (*Archilochus colubris*; Figure 41) builds a tiny nest (Figure 42) to house two pea-sized eggs (Bell 2001). These nests are located on thin branches of understory trees. They consist of an inner cup lined with fine plant down and camouflaged on the outside with small pieces of mosses and lichens. These are held together with spider webs, which are also used to affix the nest to the branch.

Rufous Hummingbird (*Selasphorus rufus*)

The Rufous Hummingbird (*Selasphorus rufus*; Figure 52) breeds in open areas and forest edges of western North America (Wikipedia 2011). It nests the farthest north of any hummingbird and the female builds its nest (Figure 53) in a shrub or conifer where it is protected. The male aggressively defends this tiny nest. The nests are built in lower branches in spring, benefitting from the temperature amelioration by the canopy. In summer the nests are built higher in the tree (Horvath 1964).

Picaflor Rubí (*Sephanoides sephaniodes*)

The Picaflor Rubí, also known as the Green-backed Firecrown or Picaflor Chico, is a South American hummingbird named *Sephanoides sephaniodes* (Figure 57). This tiny bird uses mosses and lichens for its nest (Figure 56), including the moss *Ancistrodes genuflexa* (Figure 56-Figure 58) (Torres-Dowdall *et al.* 2007). It seems it prefers this to other pendent mosses in the same family, such as *Weymouthia cochlearifolia* (Figure 59) and *W. mollis* (Figure 60). On the other hand, in Chile, the Picaflor Rubí uses the tree fern *Lophosoria quadripinnata* (Figure 61) in all of the "garments" (materials located inside nest), providing a soft texture and a brown color to the nests (Osorio Zúñiga 2012). The pendent mosses *Weymouthia cochlearifolia*, *W. mollis*, and *Ancistrodes genuflexa* occur on the outside as 16.6, 26.6, and 100% of the nests, respectively. Among these latter species 20, 37.5 and 40% produced reproductive structures in the nests (Figure 62). In older nests, reproductive structures still occurred on *Eriodon conostomus* (Figure 63), *Ptychomnion ptychocarpon*, and *Dicranoloma robustum* (Figure 64). Most of these mosses were taken at heights of 10-18 m from the ground and were not the most abundant species found there. Thus, there is selectivity of the bryophytes used for nesting material.

In Patagonia, Argentina, *Sephanoides sephaniodes* (Figure 57) is known as the Green-backed Firecrown (Calvelo *et al.* 2014). This species, and the White-sided Hillstar, *Oreotrochilus leucopleurus* (Figure 65), likewise used primarily mosses in their nests, but they both interestingly selected mosses with **falcate** (sickle-shaped – see leaves of *Dicranoloma*; Figure 64) leaves. These were entangled with spider webs and concealed on the outside with spider cocoons, leprose lichens, feathers, and hairs.

Figure 65. *Oreotrochilus leucopleurus*, White-sided Hillstar. Members of this species like falcate mosses for their nests. Photo by Pablo Caceres Contreras, through Creative Commons.

Osorio-Zúñiga *et al.* (2014) determined that *Sephanoides sephaniodes* (Figure 57) was selective in its nesting materials. The bulk of the nest was made from the fern *Lophosoria quadripinnata* (Figure 61) (and the moss *Ancistrodes genuflexa* – Figure 58). Six other mosses were included in lesser quantities, although 19 species were

available in the area. The birds were further selective in collecting higher densities of reproductive mosses than that represented in the environment. These reproductive structures remained for more than a year, suggesting that this nest-building behavior could be an effective dispersal mechanism. By placing the sporophytes at a greater height, the birds enable dispersal to a greater distance.

More recently, Fontúrbel *et al.* (2020) reported that *Ancistrodes genuflexa* occurs in 100% of the nests, makes up 97% of the moss biomass in the nests, but is only 0.1% of the total moss biomass in the forest. The other two mosses that are present in any regularity are *Weymouthia mollis* (in 27% of nests) and *W. cochlearifolia* (in 17% of nests). These two species provide only 3% of the moss biomass in the nests, but comprise 94% of the moss biomass in the forest. Knowing that mosses often have antibiotic properties, reasoned that this attribute might account for the selection. Hence, the researchers tested the three primary nest components for their antibacterial agents. In *A. genuflexa*, they found 14 compounds. Of these, five are known to have antibacterial properties, one has antifungal properties, and one repels insects (Asakawa *et al.* 2013)! Although the two *Weymouthia* species are known to have antimicrobial properties, neither species was effective against the five common bacteria tested. Furthermore, when the mosses were kept in the lab at 4°C, both *Weymouthia* species were attacked by fungi and rotted after six months, whereas the *A. genuflexa* samples were unharmed for a year. Since *Sephanoides sephanioides* may reuse its nest for several years, it is likely that it experiences greater survival when it uses *A. genuflexa* at its primary nesting material. As Fontúrbel and coworkers titled their article, "Mamma knows best."

The hummingbirds commonly use mosses and lichens in their nests, so it is not surprising that the endemic Juan Fernandez Firecrown (*Sephanoides fernandensis*; Figure 66-Figure 67) makes its nest almost entirely of mosses (Figure 68) (Jaime Jimenez, pers. comm. 19 May 2020).

Trogoniformes

Trogonidae – Trogons

Wolf (2009) found only one species of *Tyrannidae* whose members use bryophytes in nests in parts of North America: *Trogon elegans* (Elegant Trogon; Figure 69).

Figure 69. *Trogon elegans*, Elegant Trogon, a species that uses bryophytes in nests in parts of North America. Photo by Dominic Sherony, through Creative Commons.

Summary

Burrowing Owls may use bryophytes as liners in the burrows, sometimes providing a nest for rodents that move in later. Some swiftlets make extensive use of mosses in their nests. Hummingbirds often use mosses and lichens on the outsides of nests, presumably as camouflage. The Picaflor Rubi is one of the hummingbirds that can make its entire nest with bryophytes, selecting *Ancistrodes genuflexa* in much greater proportion than its presence in the forest, apparently for its antibiotic properties.

Pleurocarpous bryophytes are the most common in nests, and tree-nesting tropical birds typically use epiphytic bryophytes, including pendent species.

Acknowledgments

Thank you to Brian Dykstra for sending me the wonderful thesis on birds and epiphytes by Adrian Wolf, as well as other references and personal observations. David Dumond shared the references he got from Bryonettors. Filipe Osorio Zúñiga provided me with information and images for the Picaflor Chico. Jaime Jimenez provided me with images and natural history information on *Sephanoides fernandensis*. Thank you to these and all the photographers who made their images available to me online or gave me permission.

CHAPTER 16-6

BIRD NESTS – PASSERIFORMES, PART 1

Figure 1. Moss nest from the Pacific Northwest, USA. The bryophytes include *Isoetes* and *Neckera*. Photo courtesy of Jerilyn Peck.

Passeriformes: Perching Birds

This is a large order (>5000 species) and comprises most of the birds that use bryophytes in their nests. But then, it also includes more than half the bird species in the world (Wikipedia 2017). The order is distinguished by having three toes pointing forward and one pointing back, permitting these to be perching birds. Passerines also are **altricial** (hatched or born in undeveloped state and requiring care and feeding by parents).

Richardson (1981) reports that a quarter of the bird species breeding in Great Britain use bryophytes in the construction of their nests. Hansell (2000) likewise reports that numerous small to medium-sized bird species use bryophytes.

Large passerine birds tend to build larger nests relative to their body size when compared to small birds (Slagsvold 1989). The depth of the inner nest cup size of these birds does not relate to the size of the bird. Birds that nest off the ground in open nests have a narrow nest cup, but those with a domed nest or which build in a cavity have a broad nest cup. Birds in exposed nests are less likely to survive than those reared in nest cavities (Nice 1937, 1957). There

seem to be no data on the success of birds reared in nests made totally of mosses. Mosses and lichens alter the nest cup size, with the inner nest cup being narrower when more are used (Slagsvold 1989). Use of mosses and lichens also depends on season, with those birds nesting early in the breeding season using significantly more mosses and lichens than are used in later nests.

In coniferous forests, bryophytes are often abundant. Several species of birds that breed there build nests exclusively of bryophytes. These include the Winter Wren (see below; Hejl *et al.* 2002), Marbled Murrelet (see Chapter 16-7; Nelson 1997), and Golden-crowned Kinglet (see Chapter 16-7; Ingold & Galati 1997). In addition, Sakai (1988) described a Hammond Flycatcher nest (see below) made with two epiphytic lichens and five bryophytes, including the epiphytic moss *Isoetes* sp. (Figure 11) and liverwort, *Porella navicularis* (Figure 17).

Tyrannidae – Tyrant Flycatchers

Wolf (2009) found fifteen species of **Tyrannidae** that use bryophytes in their nests in North America:

Contopus sordidulus (Western Wood-Pewee; Figure 2)
Empidonax flaviventris (Yellow-bellied Flycatcher; Figure 4)
Empidonax alnorum (Alder Flycatcher; Figure 5)
Empidonax minimus (Least Flycatcher; Figure 6)
Empidonax difficilis (Pacific-slope Flycatcher; Figure 7-Figure 8)
Empidonax hammondi (Hammond's Flycatcher; Figure 13)
Empidonax occidentalis (Cordilleran Flycatcher; Figure 18)
Sayornis nigricans (Black Phoebe; Figure 19)
Sayornis phoebe (Eastern Phoebe; Figure 20-Figure 21)
Sayornis saya (Say's Phoebe; Figure 26-Figure 27)
Pitangus sulphuratus (Great Kiskadee; Figure 28)
Tyrannus melancholicus (Tropical Kingbird; Figure 31)
Tyrannus couchii (Couch's Kingbird; Figure 32)
Tyrannus forficatus (Scissor-tailed Flycatcher; Figure 33)
Pachyramphus aglaiae (Rose-throated Becard; Figure 37)

Figure 2. *Contopus sordidulus*, Western Wood Pewee. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission.

Olive-sided Flycatcher (*Contopus cooperi*)

The Olive-sided Flycatchers (*Contopus cooperi*; Figure 3) typically hide their nests in a cluster of needles and twigs at distal ends of horizontal conifer branches (Johnsgard 2009). These may occur anywhere from 5-13 m above the ground. They use twigs, lichens, mosses, and needles to construct a cup ~12-15 cm in diameter.

Figure 3. *Contopus cooperi*, Olive-sided Flycatcher. Members of this species often include mosses in their nests. Photo by Jerry Oldenettel, through Creative Commons.

Yellow-bellied Flycatcher (*Empidonax flaviventris*)

In the eastern United States, Yellow-bellied Flycatcher (*Empidonax flaviventris*; Figure 4) nests close to mature stands of lowland coniferous forest (Harrison 1975; Hawrot & Niemi 1996). These forests often have a well-developed layer of mosses and these mosses appear to be necessary for the bird's nesting. The Yellow-bellied Flycatcher nests on the ground in a layer of mosses.

Figure 6. *Empidonax minimus*, Least Flycatcher. Members of this species often include mosses in their nests. Photo by MDF, through Creative Commons.

Pacific-slope Flycatcher (*Empidonax difficilis*)

The Pacific-slope Flycatcher (*Empidonax difficilis*; Figure 7-Figure 8) typically builds nests on ledges or crevices of canyon walls (Johnsgard 2009). These are often concealed by mosses or ferns. When the nest is built on trees, they are supported from below and from the rear, occurring in a crotch or on a limb that projects far from the main trunk. They contain a variety of materials, frequently including mosses (Figure 8-Figure 9).

Figure 7. *Empidonax difficilis*, Pacific-slope Flycatcher, a species that uses *Isotheicum* in their nests in Douglas fir forests of the Pacific Northwest, USA. Photo by Ron Knight, through Creative Commons.

Figure 9. *Empidonax difficilis*, Pacific-slope Flycatcher, nest with mosses and young bird. Photo by Don Loarie, through Creative Commons.

In the Pacific Northwest, USA, Wolf (2009) found a nest of the Pacific-slope Flycatcher (Figure 8) on a fractured piece of bark on the tree bole of *Pseudotsuga menziesii* (Figure 10) at ~4 m above the ground. The bird had woven strands of the moss *Isotheicum* (Figure 11) into the rim of the nest and decorated the exterior with fragments of the lichen *Sphaerophorus globosus* (Figure 12). The *Isotheicum* had been relocated from elsewhere in the forest understory.

Figure 14. *Dendroalsia abietina*, a nest component of the Hammond's Flycatcher in the Pacific Northwest. Photo by James Maughn, through Creative Commons.

Hammond's Flycatcher (*Empidonax hammondii*)

The Hammond's Flycatcher (*Empidonax hammondii*; Figure 13) has a nest that is distinctly different from that of the Pacific Slope Flycatcher (*Empidonax difficilis*; Figure 7-Figure 9) (Sakai 1988). The Hammond's Flycatcher nest is taller, more tightly woven, and mimics the surrounding substrate. The outer bowl of the only retrieved nest was made with mostly white scale lichens, mosses *Dendroalsia abietina* (Figure 14), *Homalothecium nuttallii* (Figure 15), *Isothecium* sp. (Figure 11), *Alsia* sp. (Figure 16), and the leafy liverwort *Porella navicularis* (Figure 17). By comparison, in the 22 Pacific-slope Flycatcher nests, the material was mostly mosses. They often lacked the camouflage effect because they used the same materials on all substrates. The nests were held together with spider webs that were also used to secure the nests to the substrate.

Eastern Phoebe (*Sayornis phoebe*)

I picked up my copy of "A Complete Field Guide to Nests in the United States" with eager anticipation. I quickly scanned the keys that depended on nesting location and materials and found several that mentioned mosses or peatlands. As I looked up each appropriate item in the key, I soon discovered only one bird was cited as a bryophyte user, the Eastern Phoebe – *Sayornis phoebe* (Figure 20) (Headstromn 1970). The Eastern Phoebe builds a cup-shaped nest (Figure 21) lined with mud and fibrous plant material. It uses mosses as a binding material with mud in the inner cup (Breil & Moyle 1976). It also uses mosses to line the cup. The outermost layer is also covered with moss (Headstromn 1970). Bent (1963) provided interesting bryological information. In a single nest, *Mnium stellare* (Figure 22), *Funaria* sp. (Figure 23), *Polytrichum* sp. (Figure 24), *Hypnum "cristatum,"* and *Climacium dendroides* (Figure 25) were used as construction materials.

Figure 28. *Pitangus sulphuratus*, Great Kiskadee. Members of this species often include mosses in their nests.. Photo by Tom Grey, with permission.

Eastern Kingbird (*Tyrannus tyrannus*)

The Eastern Kingbird (*Tyrannus tyrannus*; Figure 29) of the Great Plains typically lives in forests where the canopy level is uneven, providing high points for observation and foraging (Johnsgard 2009). The female picks the nest site and builds the nest (Figure 30). She places it on outer branches of shrubs or small trees and often incorporates mosses in the construction.

Yellow-bellied Chat-tyrant (*Ochthoeca diadema*)

Miller and Greeney (2008) described the nest of the Yellow-bellied Chat-tyrant (*Ochthoeca diadema*; Figure 34). They found a partially domed cup built into a vertical mat of mosses that hung from a horizontal vine. The cup was thick and composed of bryophytes with a sparse lining of feathers. The dome covered only about one-third of the cup. Closer examination revealed that the nest was actually built into the vertical sheet of mosses.

Figure 34. *Ochthoeca diadema*, Yellow-bellied Chat Tyrant. Members of this species sometimes build their nests into vertical hanging mats of mosses. Photo by Andres Cuervo, through Creative Commons.

Crowned Chat-tyrant (*Ochthoeca frontalis*)

Miller and Greeney (2008) found the Crowned Chat-tyrant (*Ochthoeca frontalis*) where it built its nest into a clump of mosses that was hanging 50 cm below a horizontal tree trunk (Miller & Greeney 2008). This provided good concealment by vegetation on the upper side. The nest was a partial dome made of mosses built into growing mosses and ferns.

Other species, such as Rufous-breasted Chat (*Ochthoeca rufipectoralis*; Figure 35) and Slaty-backed Chat-tyrant (*O. cinnamomeiventris*; Figure 36) also place their mossy cups on ledges (Hilty & Brown 1986; Greeney 2007).

Figure 37. *Pachyramphus aglaiae*, Rose-throated Becard. Members of this species often include mosses in their nests. Photo by Dominic Sherony, through Creative Commons.

Laniidae – Shrikes

Wolf (2009) found two species of **Laniidae** that use bryophytes in their nests in North America:

Lanius ludovicianus (Loggerhead Shrike; Figure 38)

Lanius excubitor (Northern Shrike; Figure 39)

Figure 38. *Lanius ludovicianus*, Loggerhead Shrike. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission.

Figure 39. *Lanius excubitor*, Northern Shrike. Members of this species often include mosses in their nests. Photo by Smudge 9000, with permission.

Vireonidae – Typical Vireos

Wolf (2009) found three species of **Corvidae** that use bryophytes in their nests in North America:

Vireo griseus (White-eyed Vireo; Figure 40)

Vireo cassinii (Cassin's Vireo; Figure 41-Figure 42)

Vireo huttoni (Hutton's Vireo; Figure 43)

Rhipiduridae – Fantails

The Grey Fantail (*Rhipidura albiscapa*) in Tasmania builds a tidy nest of grass, moss sporophytes, bark, other plant fibers, and spider webs (Lloyd 2013). The webs are used to attach the nest to a branch. The moss sporophytes are used to line the cup of the nest. These nests are built by the males and females in the understorey shrubs and small trees and both birds contribute to feeding.

Figure 44. *Rhipidura albiscapa* (Grey Fantail), a species that lines its nest with moss sporophytes. Photo by Patrick Kavanagh, through Creative Commons.

Figure 45. *Rhipidura albiscapa* (Grey Fantail) nest and nestlings. Photo by Benjamin444, through Creative Commons.

Monarchidae – Monarch Flycatchers

The Rarotonga Flycatcher (*Pomarea dimidiata*; Figure 46), an endangered species in the Cook Islands of Polynesia, makes a nest entirely from mosses (Figure 46-Figure 47), mostly *Meteoriaceae* (Figure 48) (John Game, Bryonet 22 June 2016).

Figure 46. *Pomarea dimidiata*, Rarotonga Flycatcher, at mossy nest. Photo by G. McCormack © CINHP <www.cookislands.bishopmuseum.org>, with online permission.

Figure 48. *Weymouthia mollis*, member of *Meteoriaceae* that is common in bird nests. Photo by Clive Shirley, Hidden Forest <www.hiddenforest.co.nz>, with permission.

Myiagra cyanoleuca (Migratory Satin Flycatcher; Figure 49) builds a nest on a dead horizontal branch 5-25 m

above ground (Lloyd 2013). It uses bark strips and moss tightly bound with spider webs, making it neat and well disguised.

Corvidae – Jays, Magpies, & Crows

Wolf (2009) found nine species of **Corvidae** that use bryophytes in their nests in North America:

- Perisoreus canadensis* (Gray Jay; Figure 50)
- Cyanocitta stelleri* (Steller's Jay; Figure 51)
- Cyanocitta cristata* (Blue Jay; Figure 52)
- Cyanocorax yncas* (Green Jay; Figure 53)
- Aphelocoma californica* (California Scrub-jay; Figure 54)
- Gymnorhinus cyanocephalus* (Pinyon Jay; Figure 55)
- Nucifraga columbiana* (Clark's Nutcracker; Figure 56)
- Corvus brachyrhynchos* (American Crow; Figure 57)
- Corvus caurinus* (Northwestern Crow; Figure 58)
- Corvus corax* (Common Raven; Figure 59)

Common Raven (*Corvus corax*)

The Raven (*Corvus corax*; Figure 59) uses mosses to line its nest (Giannetta 2000).

Figure 59. *Corvus corax*, Raven. Members of this species often include mosses in their nests. Photo by Dick Daniels, through Creative Commons.

Hirundinidae – Swallows

Wolf (2009) found only two species of **Hirundinidae** that use bryophytes in their nests in North America:

Tachycineta bicolor (Tree Swallow; Figure 60-Figure 61)

Stelgidopteryx serripennis (Northern Rough-winged Swallow; Figure 62)

Tree Swallow (*Tachycineta bicolor*)

Tree Swallows (*Tachycineta bicolor*; Figure 60) are known to construct a basket nest (Figure 61) of sticks with an "upholstery" of moss, grass, and animal fur (Heinrich 2000). Heinrich assumed these to provide insulation and to cushion the eggs.

Figure 60. *Tachycineta bicolor*, Tree Swallow, male. Members of this species use bryophytes in their treehole nests. Photo by Tom Grey, with permission.

Figure 62. *Stelgidopteryx serripennis*, Northern Rough-winged Swallow. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission.

Paridae – True Tits

Wesołowski (unpublished data) found that the tits typically gathered moss for their nests in the immediate vicinity of the nest cavity, but they also would travel up to 80 m to gather nesting materials. Wolf (2009) found eight species of **Paridae** that use bryophytes in their nests in North America:

Poecile atricapillus (Black-capped Chickadee; Figure 74)

Poecile gambeli (Mountain Chickadee; Figure 89)

Poecile rufescens (Chestnut-backed Chickadee; Figure 90)

Poecile hudsonicus (Boreal Chickadee; Figure 91)

Poecile cinctus (Gray-headed Chickadee; Figure 92)

Baeolophus inornatus (Oak Titmouse; Figure 93)

Baeolophus ridgwayi (Juniper Titmouse; Figure 94)

Baeolophus bicolor (Tufted Titmouse; Figure 95)

Wesołowski and Wierzcholska (2018) compared the nesting materials used by three species of tit (Figure 63) and demonstrated that they were selective. Furthermore, the selections differed among the species. They avoided the abundant *Brachythecium rutabulum* (Figure 64), and *Plagiothecium nemorale* (Figure 65) and almost never used *Anomodon longifolius* (Figure 66) or *Brachythecium oedipodium* (Figure 67). Of the 54 available species, 21 were never used. Most plots associated with the nests had an average of 10.2-11.6 moss species/plot. The liverwort *Metzgeria furcata* (Figure 68) was used exclusively by Marsh Tits, and in greater proportion than in the environment. *Brachythecium salebrosum* was used only by Blue Tits, who also used large quantities of two forms of *Hypnum cupressiforme* (Figure 103). Great Tits under-used *Hypnum cupressiforme* forms but used *Anomodon viticulosus* (Figure 69), and possibly also *Pleurozium schreberi* (Figure 70) in greater proportion than their

availability. Wesołowski and Wierzcholska found no difference in water uptake between used and unused mosses. The Great Tits used mosses (*Anomodon viticulosus*, *Isoetecium alopecuroides* (Figure 71), *Pleurozium schreberi*) with stems twice as thick as those used by the Marsh Tits [*Hypnum cupressiforme* mod. *filiforme* (Figure 72), *Neckera complanata* (Figure 73)].

Figure 63. Moss choice in nests of three species of tits in Poland. The percent represents to the percent of volume of mosses in the moss layer of nests that had mosses. Small squares represent the medians, boxes indicate 25-75% quartiles, and whiskers show the ranges. Numbers in parentheses are sample sizes. Modified from Wesołowski & Wierzcholska 2018.

Figure 73. *Neckera complanata*, a moss with thin stems and that is used for nest materials by Marsh Tits. Photo by Michael Lüth, with permission.

But why did these birds travel as much as 80 m to gather some species when unused ones were much closer? When Wesołowski and Wierzcholska (2018) used human

plucking of the mosses used in nests and compared them to plucking of the unused species, they found that the used species yielded larger (heavier) bundles of moss and contained longer shoots than of those mosses that were ignored by the birds. This suggests that there is an energy benefit when using the selected species.

Black-capped Chickadee (*Poecile atricapillus*)

Allen (2017) observed a Black-capped Chickadee (*Poecile atricapillus*; Figure 74) busily gathering dry moss for its nest, then flying to the nestbox. The stream had lots of moss, but the bird ignored these, preferring the dry patch next to the stream. The Robin, on the other hand, preferred the wet moss for its open, mud-lined nest.

Figure 74. *Poecile atricapillus*, Black-capped Chickadee. Members of this species gather dry mosses near a stream for their nests. Photo by Tattooed Dreamer, through Creative Commons.

Carolina Chickadee (*Poecile carolinensis*)

Erichsen (1919) describes the appearance of "down" on the cinnamon and royal ferns as a signal that the Carolina Chickadee (*Poecile carolinensis*; Figure 75) will begin its nest building (Figure 76). The Carolina Chickadee often begins this nest (Figure 77) by placing a thick mat of green moss (often *Hypnum*; Figure 78) from the tree trunks into the nesting cavity (Figure 77). This always occurs first, followed by the soft down of the ferns.

Figure 75. *Poecile carolinensis*, Carolina Chickadee. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission.

Figure 76. *Poecile carolinensis*, Carolina Chickadee, with nesting materials. Photo by Tom Grey, with permission.

Figure 77. *Poecile carolinensis*, Carolina Chickadee, nest. Photo courtesy of Diane Lucas.

Figure 78. *Hypnum imponens*, a common species in a genus used for nests of the Carolina Chickadee. Photo by Janice Glime.

Andreas (2010) observed nests of two Carolina Chickadees (*Poecile carolinensis*; Figure 75). These included ten mosses and two liverworts. The dominant species were the pleurocarpous moss *Platygyrium repens* (Figure 79) and the leafy liverwort *Frullania eboracensis* (Figure 80) plus a few others, which comprised 55% of the nesting material by volume. In another year, the bryophytes comprised 70.4% of the nest material. The selection of bryophytes was not in proportion to their abundance and all species used were epiphytic on bark. Andreas suggested that they may select *Frullania eboracensis* for its chemical properties, possibly protecting them from mites (Figure 113). Only corticolous (growing on tree bark) bryophytes were used, with the exception of a single piece of *Bryoandersonia illecebra* (Figure 81) in one nest. But even clumps of *acrocarpous* (mostly upright with archegonia and capsules forming at tip of stem) mosses were removed from the tree trunks as tiny tufts for nest usage, including *Orthotrichum ohioense* and *Dicranum montanum* (Figure 82). Other corticolous bryophytes, including *Anomodon attenuatus* (Figure 83), *Brachythecium laetum* (Figure 84), *Clasmatodon parvulus* (Figure 85), *Hypnum pallescens* (Figure 86), and *Ulota crispa* (Figure 87), were ignored.

Varied Tit (*Sittiparus varius*)

The Varied Tit (*Sittiparus varius*; Figure 96) lives in coniferous forests, mixed forests, and bamboo in eastern Japan, Korea, and some parts of northeastern China and extreme southeastern Russia (southern Kurile Islands). It is one of the birds that uses bryophytes for nesting material (Sakai 2007).

Figure 96. *Sittiparus varius*, Varied Tit. Members of this species often include mosses in their nests. Photo by Alpsdake, through Creative Commons.

Figure 97. *Parus major*, Great Tit. Members of this species often include bryophytes in their nests. Photo by Paul Gulliver, through Creative Commons.

Figure 98. *Parus major*, Great Tit, nest with bryophytes and eggs. Photo by Oh Wei, through Creative Commons.

Blue Tit (*Cyanistes caeruleus*), Great Tit (*Parus major*), and Japanese Tit (*Parus minor*)

The Great Tit (*Parus major*; Figure 97-Figure 98) and the Blue Tit (*Cyanistes caeruleus*; Figure 99-Figure 101) both use mosses to build their nests (Figure 98) (Hribek 1985). Likewise, Gustavo Tomás and Andrew Spink (pers. comm. 2010) have collected mosses from a large number of Blue Tit (*Cyanistes caeruleus*) and Coal Tit (*Periparus ater*; Figure 102) nests in the Netherlands. The most common species in the nest is the locally common *Hypnum cupressiforme* (Figure 103). But other locally common species are not common in the nests, suggesting a preference. It appears that different species may be used in different parts of the nest, but so far there is no quantitative analysis available to support this. Figure 108 demonstrates the use of a *Hypnum* species (with *Thuidium*) in the nest of an unknown bird in Pennsylvania, USA.

Figure 99. *Cyanistes caeruleus*, Eurasian Blue Tit. Members of this species build their nests with mosses. Photo by Francis C. Franklin, through Creative Commons.

Figure 102. *Periparus ater*, Coal Tit. Members of this species often include mosses in their nests, preferring *Hypnum cupressiforme*. Photo by Aviceda, through Creative Commons.

Although the population may use a wide variety of mosses, a few species of bryophytes typically comprise the nest. For example, the Japanese Tit, *Parus minor*, used 21 species of bryophytes in the nests, but among 91% of the 47 nests, more than 50% of the volume was comprised of only three bryophyte species (Hamao *et al.* 2016). In this case, the preference seems to relate to a potential food source. The Japanese Tits preferred pleurocarpous mosses. In these nests, seven species of moths emerged from the nesting material and were more frequent in nests with successful fledgine than in failed nests.

Figure 104. *Parus minor*, Japanese Tit, a species that seems to be selective in choice of mosses for its nests. Photo by Hyun-tae Kim, through Creative Commons.

In the Czech Republic, Hříbek (1985) found that Blue Tits (Figure 99-Figure 101) used mostly softer species (*Hypnum cupressiforme* (Figure 103), *Leptodictyum riparium* (Figure 105), whereas the Great Tits used mostly the large-stemmed mosses such as *Calliergonella cuspidata* (Figure 106) and *Rhytidiadelphus squarrosus* (Figure 107).

Álvarez *et al.* (2013) asserted that the properties and structure of a nest affect breeding performance. This drives the selection of behavior that produces nests characteristic of the species, including the appropriate nesting materials. Where preferred materials are low, birds select alternative materials, often at the cost of reduced breeding success.

The researchers set out to support this hypothesis with the Great Tit, a species that has a wide range of habitats, using populations in four different Mediterranean habitats. Interestingly, the clutch size decreased as moss mass increased in the four sites. However, hatching success increased as the moss mass increased in one site. And in all the habitats, the nestling condition was poorer in nests with a greater proportion of sticks and feathers.

Mainwaring *et al.* (2012) reported that the nests of Blue Tits (*Cyanistes caeruleus*) and Great Tits (*Parus major*; Figure 97-Figure 98) in Great Britain consist of a "pad of moss mixed with dry grass and other plant material placed at the base of the nest box" (Figure 109) (Cramp & Perrins 1993; Mainwaring *et al.* 2008; Mainwaring & Hartley 2008, 2009; Britt & Deeming 2011). The nest cup is lined with fine dry grass, hair, wool and feathers. In this case, it appears that the mosses may be used to regulate the temperature and insulate the eggs and young birds. When temperatures increase, the female reduces the amount of lining material.

Figure 108. *Hypnum* and *Thuidium* in unidentified nest. Photo courtesy of Jeri Peck.

Figure 109. *Parus major*, Great Tit, with eggs in nest on mosses. Photo by Notts Ex Miner, through Creative Commons.

When Great Tits (*Parus major*; Figure 97) built a second nest in nest boxes after rearing their first brood, they still used mosses in the nest, but there was no lining or inner layer – or any eggs (Slagsvold 1984).

Rydgren *et al.* (2023) compared the mosses used in nests of *Parus major* to those available nearby. There was a clear preference for highly branched pleurocarpous species, especially *Pleurozium schreberi* (Figure 70), *Rhytidiadelphus squarrosus* (Figure 107), and *Sanionia uncinata* (Figure 110). They avoid common species that are only sparsely branched. They also used the same species in the same nest boxes in subsequent years. The nesting materials were collected close to the nest, predominantly within 5 m, supporting the hypothesis that collecting nest materials is costly (Figure 111). The researchers suggested that studies are needed to reveal cost of gathering nest materials, to determine the suitability (advantages?) of the materials chosen, and to see if the choices are inherited. It would be interesting to run choice experiments with materials having a variety of properties and to compare nesting materials of the same species in different locations.

The Corsican Blue Tit (*Cyanistes caeruleus ogliastreae*; Figure 112) includes 1-5 aromatic herbs in its nest (Lambrechts & Dos Santos 2000). Herbs are included in a number of kinds of bird nests, and researchers have suggested that they may serve an anti-parasite function (Figure 113) (Wimberger 1984; Bucher 1988; Cowie & Hinsley 1988; Clark 1991; Banbura *et al.* 1995). Using an herb removal experiment when the young hatched, these

researchers found that the parents brought fresh aromatic greens to the nest. They proposed the Potpourri hypothesis that included at least seven functional causes for materials used in the nests. When the Blue Tits breed in cavities, they use predominately mosses, but also include other materials, including fresh herbaceous leaves. They suggested that mosses may optimize the microclimate in the nest cavity. The aromatic herbs are likely to serve an anti-parasitic function.

Ground Tit (*Pseudopodoces humilis*)

Ground Tit, also known as Hume's Jay, (*Pseudopodoces humilis*; Figure 114) has been considered the smallest member of the Jay and Crow family (Lipske 2004). But more recently it appears that it should be classified in the **Paridae** with the Chickadees. These birds are common in forests and woody suburbs of Europe and North America, but it appears that their ancestors lived on the dry, treeless Tibetan plateau. They nest in cavities where they build nests of grasses and mosses. Like Jays, they rarely fly, but they do not run like the Jays; rather, they hop.

Figure 114. *Pseudopodoces humilis*, Ground Tit. Members of this species build nests of grasses and mosses. Photo by David Blank, through Creative Commons.

Pipridae – Manakins, Piprites

Black-capped Piprites (*Piprites pileata*)

Only one example in this family has emerged. The Black-capped Piprites (*Piprites pileata*; Figure 115) builds a spherical nest made of mosses (Cockle *et al.* 2008).

Figure 115. *Piprites pileata*, Black-capped Piprites. Members of this species often build their nests of mosses. Photo by Bruno Lima, through Creative Commons.

Aegithalidae – Long-tailed Tits

Wolf (2009) found one species of Aegithalidae whose members use bryophytes in their nests (Figure 116) in North America: *Psaltiriparus minimus* (Bushtit; Figure 117).

Figure 116. *Psaltiriparus minimus*, Bushtit, at mossy nest. Photo by Walter Siegmund, through Creative Commons.

Figure 117. *Psaltiriparus minimus*, Bushtit, pulling on nest materials. Photo by Mikul, through Creative Commons.

Long-Tailed Tit (*Aegithalos caudatus*)

The Long-tailed Tit (*Aegithalos caudatus*; Figure 118- Figure 119) has been separated from other tits and has different feeding and nesting (Figure 120) habits from them. These are not seed-eaters, eating mostly insects from bark crevices and buds. The families stay together, so that a flock will contain only related birds. Relatives that have lost their family members will join the flock. Nests may be tended by 1-8 adults. The female sits on the eggs and the male brings the food. Once the dozen or more babies hatch, helper adults gather food to feed them.

Figure 118. *Aegithalos caudatus*, Long-tailed Tit, a species whose members build nests with mosses. Photo by drplokta, through Creative Commons.

Figure 119. *Aegithalos caudatus*, Long-tailed Tit juvenile. Photo by Charles J. Sharp, through Creative Commons.

Figure 120. *Aegithalos caudatus*, Long-tailed Tit, building her nest in a hedgerow. Photo by Gail Hampshire, through Creative Commons.

The nests are bag-shaped and woven from mosses, bound with spider webs (Burton 1996). The birds cover the outside of the nest with lichens, sometimes substituting plastic and newspaper in areas of human habitation. This nest is insulated on the inside with feathers. The tits may accumulate ~1130 km of travel to gather nest materials. Hansell (2002) reported a nest with 5000-6000 pieces of material, including short-leaved mosses and cocoons intertangled, creating a Velcro effect with a few hundred sprigs of mosses.

Sittidae – Nuthatches

Wolf (2009) found two species of **Sittidae** that use bryophytes in their nests in North America:

Sitta carolinensis (White-Breasted Nuthatch; Figure 121)
Sitta pygmaea (Pygmy Nuthatch; Figure 123)

Figure 121. *Sitta carolinensis*, White-breasted Nuthatch. Members of this species often include bryophytes in their nests. Photo by Tom Grey, with permission.

Red-Breasted Nuthatch (*Sitta canadensis*)

The Red-breasted Nuthatch (*Sitta canadensis*; Figure 122) builds its nest in tree holes, generally about 2.5 cm in diameter (Heinrich 2009; Moss Musings 2017). Inside the hole it lines the nest with mosses, down, and fibers. In fact, its nest can be recognized from those of woodpeckers because they never line their nests.

Figure 122. *Sitta canadensis*, Red-breasted Nuthatch, outside the mossy nest in the treehole. Photo by Cephas, through Creative Commons.

Figure 123. *Sitta pygmaea*, Pygmy Nuthatch, at tree hole. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission

Certhiidae – Holarctic Treecreepers

Wolf (2009) found one species of **Certhiidae** whose members use bryophytes in their nests in North America: *Certhia americana* (Brown Creeper; Figure 124-Figure 125).

Figure 124. *Certhia americana*, Brown Creeper, with a beak full of dinner. Photo by Alan and Elaine Wilson, through Creative Commons.

Figure 125. *Certhia americana*, Brown Creeper, a bird that uses mosses to construct its nests. Photo by Badjoby, through Creative Commons.

Troglodytidae – Wrens

Wolf (2009) found five species of **Troglodytidae** that use bryophytes in their nests in North America:

Salpinctes obsoletus (Rock Wren; Figure 126)

Catherpes mexicanus (Canyon Wren; Figure 127)

Thryothorus ludovicianus (Carolina Wren; Figure 128-Figure 129)

Thryomanes bewickii (Bewick's Wren; Figure 130)

Troglodytes pacificus (Pacific Winter Wren; Figure 133-Figure 135)

Figure 126. *Salpinctes obsoletus*, Rock Wren. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission.

Figure 127. *Catherpes mexicanus*, Canyon Wren. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission.

Carolina Wren (*Thryothorus ludovicianus*)

The tiny Carolina Wren (*Thryothorus ludovicianus*; Figure 128) is revered in places like Virginia because of its penchant for eating lots of insects (Harrison 2003). They nest mostly in nooks and crannies, so nest boxes are especially suitable for them. Their nests (Figure 129) often contain mosses, along with leaves, twigs, rootlets, weed stalks, and even cast-off snake skins. Both males and females are the nest builders, but it is she who lines the nest with feathers, hair, fine grass, and moss. These prolific breeders will typically lay a second set of eggs as soon as the young birds leave the nest and may even have a third set.

Figure 130. *Thryomanes bewickii*, Bewick's Wren. Members of this species often include mosses in their nests. Photo by Tom Grey, with permission.

Pacific Wren (*Troglodytes pacificus*) and Winter Wren (*T. hiemalis*)

The Winter Wren has been divided into two species, the Pacific Wren (*Troglodytes pacificus*; Figure 131) and the Winter Wren (*Troglodytes hiemalis*; Figure 132), the eastern species (Toews & Irwin 2008). Where their breeding ranges overlapped, the two species were distinguishable by their songs and lack of cross mating. This evidence was supported by DNA analysis.

Figure 131. *Troglodytes pacificus*, Pacific Wren. Members of this species often include mosses in their nests. Photo by Tom Talbott, through Creative Commons.

The Pacific Wren (*Troglodytes pacificus*; Figure 131) breeds in the coniferous forests of the Pacific Northwest and constructs a nest almost entirely of mosses (Hejl *et al.* 2002). These wrens protect their nests with a dome and small side entrance (Heinrich 2009). The winter wren places green mosses and small evergreen twigs on the outside. Some birds place their nests in hanging mosses near the ground, but more commonly they place them on tip-up mounds formed by roots of fallen trees.

The Pacific Wren builds a round nest of grass, moss, lichens, or leaves that it stuffs into a hole in a wall, crack in a rock, corner of a building, or tree trunk, but can also put it in bushes or overhanging boughs (Wikipedia 2010).

Eastern Winter Wren (*Troglodytes hiemalis*)

Piers (1897) reported two Winter Wren (*Troglodytes hiemalis*; Figure 132) nests in Nova Scotia, Canada, built in moss that was constantly saturated by water trickling from the bank above. Piers suspected that the second nest was a later one built by the same pair as the first.

Figure 132. *Troglodytes hiemalis*, Winter Wren. Members of this species often include mosses in their nests. Photo by Paul Stein, through Creative Commons.

Eurasian Wren (*Troglodytes troglodytes*)

Nests of the Eurasian Wren (*Troglodytes troglodytes*; Figure 133) can make its nest almost entirely of bryophytes (Figure 134). The Japanese variety (*Troglodytes troglodytes fumigatus*) likewise uses mosses (Figure 135).

Figure 135. *Troglodytes troglodytes fumigatus*, Japanese Winter Wren, shown here gathering mosses for its nest. Photo by Alpsdake, through Creative Commons.

Cinclidae – Dippers

Wolf (2009) found one species of **Cinclidae** whose members use bryophytes in their nests in North America: *Cinclus mexicanus* (American Dipper; Figure 136-Figure 137), also known as the Water Ouzel.

Figure 136. *Cinclus mexicanus*, American Dipper, on mosses on the streambank. Photo by Stephen Shunk, through Creative Commons.

Figure 137. *Cinclus mexicanus*, American Dipper, gathering moss for its nest. Photo by Frank D. Lospalluto, through Creative Commons.

The American Dipper (Figure 136-Figure 137) is the only aquatic songbird in North America (Rosentreter 2014). It is a year-round resident, maintaining its streamside territorial defense year-round. It is known for its diving ability, down to nearly 7 m below the surface, and lives along unpolluted streams with riffles, cascades, and waterfalls. It makes a ball-shaped nest with a side entrance, placed on a cliff face, in a crevice, or under a bridge abutment, positions that help it to avoid predators. The outer shell of this nest is moss with its inner chamber made of pine needles. It uses stream mosses that it dives to obtain, hence they are dripping wet. These are woven into the nest, still wet, and as they dry they tighten the weave and help to affix the nest to its vertical substrate.

I have seen the nest of an American Dipper (Figure 136-Figure 137) in Colorado with the busy expectant mother diving into the water to collect *Platyhypnidium*

riparioides (Figure 138) for the construction. The nest (Figure 139), wedged under the cliff behind a waterfall, appeared to be made entirely of mosses. Dan Norris (Bryonet 22 November 1995) reports that this bird is indeed selective, using mosses with a different frequency from that found in their habitat.

Figure 138. *Platyhypnidium riparioides*, a common moss used in nests of the American Dipper (*Cinclus mexicanus*). Photo by Stan Phillips, through public domain.

Figure 139. *Cinclus mexicanus*, American Dipper, nest of *Hygrohypnum* and *Hygroamblystegium*. Photo by Janice Glime.

Terry McIntosh (Bryonet 2 June 2010) identified mosses in Dipper (*Cinclus mexicanus*; Figure 136-Figure 137) nests from northern Idaho. To his surprise, he found only one species, *Scouleria marginata* (Figure 140), a somewhat rare moss, despite the much greater abundance of *S. aquatica* (Figure 141). He attributed this selection to the stronger plants of *S. marginata*. By contrast, Ellen Anderson (Bryonet 2 June 1010) found 30 moss species and 5 liverwort species (plus a few unknowns) in 7 dipper nests in the area around Juneau, Alaska, USA. Most of the nests had only traces of mosses, but nevertheless had quite a few species, numbering 1, 7, 10, 11, 13, 14, and 16 (plus 5 unknowns).

Figure 140. *Scouleria marginata*, a common component of the American Dipper nests. Photo by Martin Hutten, with permission.

Figure 141. *Scouleria aquatica*, a common moss that is ignored as nesting material for the American Dipper when *S. marginata* is present. Photo by Matt Goff, with permission.

Roger Rosentreter (pers. comm. 20 January 2014) observed numerous American Dipper (*Cinclus mexicanus*; Figure 136-Figure 137) nests on the Payette River, Idaho, USA, reaching up to 2 nests per kilometer. In this case, the nests were composed primarily of the aquatic moss *Scouleria aquatica* (Figure 141), an abundant moss in the river.

Brown Dipper (*Cinclus pallasii*)

The Brown Dipper, also known as the Pallas Dipper, (*Cinclus pallasii*; Figure 142), is an Asian dipper that uses mosses in its nests (Nishimura *et al.* 1980).

Figure 142. *Cinclus pallasii pallasii*, Brown Dipper, a bird that uses aquatic bryophytes in its nests. Photo by Alpsdake, through Creative Commons.

Summary

The Passeriformes is the largest order of birds and contains the majority of birds that use bryophytes in their nests. Nevertheless, they seem to be a small proportion of the total species in the order.

In this first part, the members using bryophytes include Tyrant Flycatchers, shrikes, Vireos, Jays and Crows, Swallows, Tits, Piprites, Nuthatches, and Wrens. Among these, the American Dipper is an aquatic bird that often dives for mosses to build its nest. Their selective choices may be energy savings by being able to gather larger bryophyte materials, providing nest-inhabiting food organisms, and in some cases possibly providing more constant moisture.

Acknowledgments

Thank you to Brian Dykstra for sending me the wonderful thesis on birds and epiphytes by Adrian Wolf, as well as other references and personal observations. David Dumond shared the references he got from Bryonet. Many photographers have provided permission or put their images in Creative Commons, for which I am deeply appreciative. Thank you to Tom Grey and Janet Marr for a critical reading of the manuscript. And thank you to

Bernard Goffinet for his continued support in sending me images and interesting publications.

CHAPTER 16-7

BIRD NESTS – PASSERIFORMES, PART 2

Figure 1. *Grallaricula peruviana* is a rare bird, shown here with bryophytes in its nest. Photo by Harold Greeney, through Creative Commons

Grallariidae

The Peruvian Antpitta (*Grallaricula peruviana*) is a rare species that uses bryophytes in its nest, as seen in Figure 1.

Regulidae – Kinglets

Wolf (2009) found two species of **Regulidae** that use bryophytes in their nests in North America:

Regulus satrapa (Golden-Crowned Kinglet; Figure 2)

Regulus calendula (Ruby-Crowned Kinglet; Figure 4)

The Golden-crowned Kinglet (*Regulus satrapa*; Figure 2) breeds in the coniferous forests (Figure 3) of the Pacific Northwest and constructs a nest almost entirely of mosses (Ingold & Galati 1997).

Figure 2. *Regulus satrapa*, Golden-crowned Kinglet. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Figure 3. Conifer forest, Garibaldi National Park, BC, home to the Golden-crowned Kinglet, *Regulus satrapa*. Photo by The Simkin, through public domain.

Figure 4. *Regulus calendula*, Ruby-crowned Kinglet. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Sylviidae – Old-World Warblers & Gnatcatchers

Wolf (2009) found one species of **Sylviidae** that use bryophytes in their nests in North America: *Phylloscopus borealis* (Arctic Warbler; Figure 5).

Figure 5. *Phylloscopus borealis*, Arctic Warbler. Members of this species use bryophytes in their nests. Photo by Osado, through Creative Commons.

Turdidae – Thrushes

Wolf (2009) found thirteen species of **Turdidae** that use bryophytes in their nests in North America:

- Luscinia svecica* (Bluethroat; Figure 6)
- Oenanthe oenanthe* (Northern Wheatear; Figure 7)
- Sialia mexicana* (Western Bluebird; Figure 8)
- Myadestes townsendi* (Townsend's Solitaire; Figure 9)
- Catharus fuscescens* (Veery; Figure 11)
- Catharus minimus* (Gray-Cheeked Thrush; Figure 12)
- Catharus bicknelli* (Bicknell's Thrush; Figure 13)
- Catharus ustulatus* (Swainson's Thrush; Figure 14)
- Catharus guttatus* (Hermit Thrush; Figure 15-Figure 16)
- Turdus pilaris* (Fieldfare; Figure 18-Figure 19)
- Turdus iliacus* (Redwing; Figure 20)
- Turdus migratorius* (American Robin; Figure 21-Figure 22)
- Ixoreus naevius* (Varied Thrush; Figure 38)

Figure 6. *Luscinia svecica*, Bluethroat. Members of this species use bryophytes in their nests. Photo by Andreas Trepte, through Creative Commons.

Figure 7. *Oenanthe oenanthe*, Northern Wheatear. Members of this species use bryophytes in their nests. Photo by Craig Nash, through Creative Commons.

Figure 15. *Catharus guttatus*, Hermit Thrush. Members of this species use bryophytes in their nests. Photo by Cephas, through Creative Commons.

Figure 16. *Catharus guttatus*, Hermit Thrush nest and hatchlings. Photo by Per ver Donk, with permission.

Hermit Thrush (*Catharus guttatus*)

Once again, the female is the sole nest-builder in the Hermit Thrush (*Catharus guttatus*; Figure 15-Figure 16) (Cornell Lab of Ornithology). Her bulky handiwork includes mosses in addition to twigs, bark strips, ferns, and

grasses. It is not lined with mosses, but rather with conifer needles, rootlets, and plant fibers.

Figure 17. Bird nest in Coast Range of the Pacific Northwest, USA, with mosses still growing. Photo by JeriLynn Peck.

Figure 18. *Turdus pilaris*, Fieldfare. Members of this species use bryophytes in their nests. Photo by Allan Drewitt, through Creative Commons.

Figure 20. *Turdus iliacus*, Redwing. Members of this species use bryophytes in their nests. Photo by Ómar Runólfsson, through Creative Commons.

American Robin (*Turdus migratorius*)

The American Robin (*Turdus migratorius*; Figure 21) uses mosses as a binding material with mud in the inner cup of the nest (Figure 22-Figure 23) (Breil & Moyle 1976). It also uses mosses to line the cup. It seems to have a preference for *Thuidium delicatulum* (Figure 24), *Plagiomnium cuspidatum* (Figure 25), *Brachythecium acuminatum* (Figure 26), *B. salebrosum* (Figure 27), and *Amblystegium varium* (Figure 28).

Figure 21. *Turdus migratorius*, American Robin. Members of this species sometimes use mosses as a binder for the mud linings of their nests. Photo by Tom Grey, with permission.

Figure 28. *Amblystegium varium*, a moss used as a mud binder to line the Robin's nest. Photo by J. C. Schou, through Creative Commons.

Other members of the genus, such as the Yellow-legged Thrush (*Turdus flavipes*; Figure 29-Figure 30), place bryophytes on the outside of the nest.

Figure 29. *Turdus flavipes*, Yellow-legged Thrush. Members of this species use mosses on the outsides of their nests. Photo by David R. Santiago, through Creative Commons.

Figure 30. *Turdus flavipes*, Yellow-legged Thrush, nest with eggs and bryophytes. Photo by David R. Santiago, through Creative Commons.

Chinese Thrush (*Turdus mupinensis*)

In a Chinese study (Zhao *et al.* 2005), nests of the Chinese Thrush (*Turdus mupinensis*; Figure 31) were collected from Xiaolongmen Nature Reserve of Beijing. Nests exhibited seven bryophyte species: *Anomodon* sp., *A. minor* (Figure 32), *Entodon* sp. (Figure 33), *Lindbergia sinensis* (see Figure 34), *Brachythecium* sp. (see Figure 27), *Herpetineuron* sp. (Figure 35), *Plagiomnium* sp. (see Figure 25), and *Myuroclada maximowiczii* (Figure 36). *Anomodon minor* was one of the major nest components.

Figure 36. *Myuroclada maximoviczii*, a species that is used in nests of the Chinese Thrush. Photo by Janice Glime

Blackbird (*Turdus merula*)

The Common Blackbird (*Turdus merula*; Figure 37) makes a bulky cup in its nest, using dry grasses, twigs, stalks, and yes, mosses (Snow 1958). These are plastered with mud or muddy leaves and lined with fine grass, thin dead stems, or rootlets. Mainwaring *et al.* (2014) found that as spring temperatures increased in the lower latitudes, the quantity of mosses used in the nests decreased, suggesting that mosses may be needed for insulation at cooler temperatures (Mainwaring *et al.* 2012).

Figure 37. *Turdus merula*, Common Blackbird, nesting. Members of this species use bryophytes in their nests. Photo by J. J. Harrison, through Creative Commons.

Nest size of birds is limited on the upper end by becoming more conspicuous and requiring more energy to prepare (Møller 1990). On the small end, it loses insulating ability, stability, and protection to prevent nestlings from falling out of the nest. Møller manipulated nest size of the Blackbird (*Turdus merula*; Figure 37), a species that makes an open-cup woodland nest. When nests were exchanged for smaller or larger nests, there was no effect on nest egg predation by the exchange itself, but larger nests experienced more predation. But real nests that experienced predation were not significantly larger than successful nests. Møller suggested that nest size in nature is dependent on nest site.

Figure 38. *Ixoreus naevius*, Varied Thrush. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Muscicapidae – Old World Flycatchers

In the same Chinese study (Zhao *et al.* 2005), nests of three members of this family [Narcissus Flycatcher (*Ficedula narcissina*; Figure 39), Blue-and-white Flycatcher (*Cyanoptila cyanomelana*; Figure 40-Figure 41), Daurian Redstart (*Phoenicurus auroreus*; Figure 42)] were collected from Xiaolongmen Nature Reserve of Beijing. These nests, like those of the Chinese Thrush, exhibited the same seven bryophyte species, with the moss *Anomodon minor* (Figure 32) as the main component of nests of all three bird species.

Figure 42. *Phoenicurus aureus*, Daurian Redstart male. Members of this species use bryophytes in their nests. Photo by Alpsdake, through Creative Commons.

Petroicidae – Australian Robins

Australian Pink Robin (*Petroica rodinogaster*)

The Australian Pink Robin (*Petroica rodinogaster*; Figure 43) includes both lichens and mosses in its nest (Figure 44) (Newman & Bratt 1976).

Figure 43. *Petroica rodinogaster*, Australian Pink Robin. Members of this species build their nests of mosses, especially *Thuidopsis sparsa*. Photo by J. J. Harrison, through Creative Commons.

Pharo and Meagher (2011) reported finding a Pink Robin's nest that was made almost entirely from mosses. It was located in a mountain ash forest in Victoria, Australia, in an area that had been lightly burned two years earlier. The nest was "extraordinarily tiny on a branch of *Olearia agrophylla*." The nest was woven exclusively from *Thuidopsis sparsa* (Figure 45) except for a few strands of grass. It is interesting that the moss was not even growing at the site. Therefore, the birds deliberately hunted that moss. The nest has a loose weave, but was strong, with

intertwined moss branches. The nest was attached to a branch by numerous strands that were wrapped around the main branch and a smaller branch.

Figure 44. The tiny Australian Pink Robin's nest woven from *Thuidopsis sparsa* (Figure 45), with Emma's index finger for 'scale.' Photo courtesy of Emma Pharo and David Meagher.

Figure 45. *Thuidopsis sparsa*, a moss used to make the nest of the Australian Pink Robin (*Petroica rodinogaster*). Photo through Creative Commons.

Sturnidae – Starlings, etc.

Wolf (2009) found one species of **Sturnidae** whose members use bryophytes in their nests in North America: European Starling (*Sturnus vulgaris*; Figure 46-Figure 47).

Figure 46. *Sturnus vulgaris*, European Starling, the only member of this family that uses mosses in its nest in North America. Photo by Ingrid Taylor, through Creative Commons.

Figure 47. *Sturnus vulgaris*, European Starling, at nest. Photo by Gynti 46, through Creative Commons.

The European Starling "prefers" to use the wild carrot *Daucus carota* (Figure 48) or the fleabane *Erigeron philadelphicus* (Figure 49) in its nest, both of which have known abilities to suppress parasitic mites in nests (Clark & Mason 1985). We can only wonder if the bryophytes might serve a protective role against mites and other parasites in forested sites.

Figure 48. *Daucus carota* leaves, a species included in nests of the European Starling, presumably to reduce parasite infections. Photo by Biolmages, through Creative Commons.

Figure 49. *Erigeron philadelphicus*, a species included in nests of the European Starling, presumably to reduce parasite infections. Photo by Fritzflohr Reynolds, through Creative Commons.

Motacillidae – Wagtails & Pipits

Wolf (2009) found one species of **Motacillidae** whose members use bryophytes in their nests in North America:

Motacilla alba (White Wagtail; Figure 50-Figure 51)

Anthus cervinus (Red-throated Pipit; Figure 54)

Anthus rubescens (American Pipit; Figure 55)

White Wagtail (*Motacilla alba*)

Des Callaghan (Bryonet 23 June 2016) reported that while in the wonderful north of Finland one summer, a fine place for *Splachnaceae*, he noticed an intriguing association between *Splachnum vasculosum* (Figure 52- Figure 53) and the insectivorous passerine bird *Motacilla alba* (Figure 50). Could the Wagtails be attracted by the odor? Are the mosses a food source? Or do the *S. vasculosum* and *Motacilla alba* simply like the same habitat? Callaghan recorded this interesting habitat <<https://youtu.be/DdlJ7n3Vg>>. Mosses are included in nests (Figure 51) of this wagtail species (Bouglouan 2016).

Figure 55. *Anthus rubescens*, American Pipit, with insect. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Small Kauai Thrush (*Myadestes palmeri*)

The Small Kauai Thrush or Puaiohi (*Myadestes palmeri*; Figure 56), a small Hawaiian endemic, builds a cavity nest (Figure 57) along a stream bank comprised mostly of bryophytes and tiny ferns, with a weave of fine grass (Kepler & Kepler 1983). The bryophytes trail out of the cavity mouth from the base of the nest, providing an opportunity for these bryophytes to attach and grow on the stream bank. Included bryophytes were the mosses *Dicranum speirophyllum* (Figure 58) and *Campylopus* sp. (Figure 59) and the liverworts *Bazzania* sp. (Figure 60) and *Lepidozia* sp. (Figure 61).

Figure 56. *Myadestes palmeri*, Small Kauai Thrush. Members of this species use bryophytes in their nests. Photo by Eike Wulfmeyer, through Creative Commons.

Figure 61. *Lepidozia* sp., a leafy liverwort representing a genus used in the Puaiohi (*Myadestes palmeri*) nest. Photo by Ken-ichi Uedo, through Creative Commons.

Bombycillidae – Waxwings

Wolf (2009) found two species of **Bombycillidae** that use bryophytes in their nests in North America:

Bombycilla garrulus (Bohemian Waxwing; Figure 62)

Bombycilla cedrorum (Cedar Waxwing; Figure 63-Figure 64)

Figure 62. *Bombycilla garrulus*, Bohemian Wax Wing. Members of this species use bryophytes in their nests. Photo by Randen Pederson, through Creative Commons.

Cedar Waxwing (*Bombycilla cedrorum*)

The Cedar Waxwing (*Bombycilla cedrorum*; Figure 63) nests in edge habitat, using small evergreens and deciduous trees to hold its nests (Figure 64) (Heinrich 2009). The nest is somewhat similar to that of a Robin in size and rough appearance, but it has no mud lining. The outside typically is decorated with lichens and mosses, probably providing camouflage.

Figure 63. *Bombycilla cedrorum*, Cedar Waxwing. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Figure 64. *Bombycilla cedrorum*, Cedar Waxwing, nest with moss & eggs. Photo by Rich Mooney, through Creative Commons.

Peucedramidae – Olive Warbler

Wolf (2009) found one species of **Peucedramidae** that uses bryophytes in their nests in North America: *Peucedramus taeniatus* (Olive Warbler; Figure 65).

Figure 65. *Peucedramus taeniatus*, Olive Warbler. Members of this species use bryophytes in their nests. Photo by Ron Knight, through Creative Commons.

Parulidae – Wood Warblers, etc.

Wolf (2009) found 27 species of **Parulidae** that use bryophytes in their nests in North America:

Oreothlypis ruficapilla (Nashville Warbler; Figure 67)

Oreothlypis celata (Orange-crowned Warbler; Figure 66, Figure 68)

Oreothlypis virginiae (Virginia's Warbler; Figure 69)

Dendroica coronata (Yellow-rumped Warbler; Figure 70)

Setophaga pitayumi (Tropical Parula; Figure 71)

Setophaga magnolia (Magnolia Warbler; Figure 72)

Setophaga tigrina (Cape May Warbler; Figure 73)

Setophaga caerulescens (Black-throated Blue Warbler; Figure 74-Figure 75)

Setophaga nigrescens (Black-throated Gray Warbler; Figure 76)

Setophaga virens (Black-throated Green Warbler; Figure 77)

Setophaga townsendi (Townsend's Warbler; Figure 78)

Setophaga occidentalis (Hermit Warbler; Figure 79)

Setophaga kirtlandii (Kirtland's Warbler; Figure 80)

Setophaga striata (Blackpoll Warbler; Figure 81)

Setophaga cerulea (Cerulean Warbler; Figure 82)

Setophaga ruticilla (American Redstart; Figure 83)

Setophaga citrina (Hooded Warbler; Figure 84-Figure 85)

Protonotaria citrea (Prothonotary Warbler; Figure 86)

Helmitheros vermivorum (Worm-eating Warbler; Figure 88)

Limnethlypis swainsonii (Swainson's Warbler; Figure 90)

Seiurus aurocapilla (Ovenbird; Figure 91-Figure 92)

Parkesia noveboracensis (Northern Waterthrush; Figure 97)

Parkesia motacilla (Louisiana Waterthrush; Figure 98)

Oporornis agilis (Connecticut Warbler; Figure 99)

Geothlypis trichas (Common Yellowthroat; Figure 100)

Cardellina pusilla (Wilson's Warbler; Figure 101)

Cardellina canadensis (Canada Warbler; Figure 102)

Figure 66. *Oreothlypis celata*, Orange-crowned Warbler. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Figure 77. *Setophaga virens*, Black-throated Green Warbler. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Townsend's Warbler (*Setophaga townsendi*)

Some birds have very specific uses for the bryophytes. The Townsend's Warbler (*Setophaga townsendi*; Figure 78) lines its nest with the *setae* (stalks of moss capsules) of mosses (and hair) (Baicich & Harrison 2005).

Figure 78. *Setophaga townsendi*, Townsend's Warbler. Members of this species use bryophytes in their nests. Photo by Jerry Oldenettel, through Creative Commons.

Figure 85. *Setophaga citrina*, Hooded Warbler. Members of this species use bryophytes in their nests. Photo by USFSW, through public domain.

Prothonotary Warbler (*Protonotaria citrea*)

The Prothonotary Warbler (*Protonotaria citrea*; Figure 86) nests in abandoned holes made by woodpeckers. Although it sometimes uses few mosses in the actual nest, it does build it on a bed of bryophytes, both mosses and liverworts (Bent 1953; Petit 1989; Blem & Blem 1992, 1994). When building in a nest box, the mosses go in first to form the bed. Then the nest is built on top of them. The bryophytes remain moist, but the cup is not. Blem and Blem found that 75-80% of the dry mass of the nests they studied is composed of mosses and liverworts. They identified five species of mosses and two liverworts (Table 1), with the moss *Anomodon attenuatus* (Figure 87) predominating. They suggested that the bryophytes maintain the needed environment within the nest cavity (e.g. Mertens 1977a, b). In addition to ameliorating the moisture, bryophytes may serve to reduce pathogens and parasites (Clark & Mason 1985). I have seen several pictures of these nests, but unfortunately I could not find the name of the photographer on those sites.

Figure 86. *Protonotaria citrea*, Prothonotary Warbler, a species that uses a bed of bryophytes under its nest. Photo by David Inman, through Creative Commons.

Table 1. Occurrence of bryophytes in Prothonotary Warbler (*Protonotaria citrea*) nests in nest boxes along the James River, Virginia, USA. From Blem & Blem 1994.

Species	Percent occurrence			
	Top	Mid- dle	Bot- tom	Total
Mosses				
<i>Anomodon attenuatus</i>	97.3	96.4	91.4	95.0
<i>Haplocladium microphyllum</i>	20.6	13.4	21.0	18.3
<i>Amblystegium varium</i>	6.7	7.6	1.3	5.2
<i>Plagiomnium cuspidatum</i>	2.7	1.3	3.1	2.4
<i>Thuidium delicatulum</i>	0.4	1.3	0.0	0.6

Figure 90. *Limnothlypis swainsonii*, Swainson's Warbler. Members of this species use bryophytes in their nests. Photo by Carol Foil, through Creative Commons.

Ovenbird (*Seiurus aurocapilla*)

The seclusive Ovenbird (*Seiurus aurocapilla*; Figure 91-Figure 92) may be dependent on mosses in its environment. Apfelbaum and Haney (1981) reported the disappearance of the Ovenbird from a severely burned Jack pine (*Pinus banksiana*; Figure 93-Figure 95) forest in the Great Lakes area. In that fire, ~80% of the feather moss (Figure 96) communities suffered severe loss due to the fire. But other factors related to the fire may have caused them to disappear.

Furnariidae – Neotropical Ovenbirds

In the Neotropical ovenbirds (**Furnariidae**) moss use in nesting materials seems to have at least somewhat followed evolutionary lines (Zyskowski & Prum 1999). *Premnoplex brunnescens* (Figure 103) builds a domed nest

of mosses (Figure 104-Figure 106). This nest may be suspended from structures such as logs.

Figure 103. *Premnoplex brunnescens*, Spotted Barbtail. Members of this species build domed nests of bryophytes. Photo by Murray Cooper, through Creative Commons.

Figure 104. *Premnoplex brunnescens*, Spotted Barbtail, nest of bryophytes. Photo by Juan Ignacio Areta, through Creative Commons.

Figure 105. *Premnoplex brunnescens*, Spotted Barbtail, nest of bryophytes. Photo by Harold Greeney, through Creative Commons.

Figure 106. *Premnoplex brunnescens*, Spotted Barbtail, nest of bryophytes. Photo by Gustavo Londoño, through Creative Commons.

In the Neotropical *Cranioleuca albiceps* group (see Figure 107), *Margarornis* (Figure 108-Figure 109), *Premnoplex brunnescens* (Figure 103-Figure 106), *Siptornis* (Figure 110), and Plain Softtail, (*Phacellodomus fusciceps*; see Figure 111), a "pensile" nest (Figure 109) is constructed (Zyskowski & Prum 1999). This is a large nest with a small brood chamber that is entered from below. It is constructed from top down by draping long strands of green mosses or strips of other plant material. The nest hangs down from a log or rocky overhang and in *Premnoplex brunnescens* it may also hang from vines. *Asthenes* (Figure 112) species construct an ovoid nest (Figure 113) using fresh *Sphagnum* (Figure 114). An outer shell of herbaceous stems loosely surrounds it.

Figure 107. *Cranioleuca pallida*, Pallid Spinetail, in Brazil. Members of the *Cranioleuca albipes* group build pensile nests that incorporate bryophytes. Photo by Ciro Albano, through Creative Commons.

White-browed Spinetail (*Hellmayrea gularis*)

In the Andean cloud forests, the White-browed Spinetail (*Hellmayrea gularis*; Figure 115) nests (Figure 116) were embedded in hanging masses of epiphytic mosses, but rather than being pendulous, the nests were supported from below or from the sides by stems (Greeney & Zyskowski 2008). These nests were ball-shaped with a side entrance. The exterior consisted of green moss, whereas the internal side consisted of dry bamboo leaves. The nest was lined with soft materials, either *Tillandsia* seed down (Figure 117) or tree-fern scales (Figure 118).

Figure 115. *Hellmayrea gularis*, White-browed Spinetail, bringing grub to nest. Photo by Murray Cooper, through Creative Commons.

Figure 118. Hairy tree fern frond showing scales and hairs used in nests of the White-browed Spinetail, *Hellmayrea gularis*. Photo by Janna Schreier <janna@jannaschreier.com>, with permission.

Thraupidae – Tanagers & Honeycreepers

Wolf (2009) found one species of **Thraupidae** that use bryophytes in their nests in North America: *Piranga ludoviciana* (Western Tanager; Figure 119).

Figure 119. *Piranga ludoviciana*, Western Tanager. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Yellow-bellied Dacnis (*Dacnis flaviventer*)

The Yellow-bellied Dacnis (*Dacnis flaviventer*; Figure 120) is a bird of the high canopy and nests in this genus are largely unknown. Sheldon and Greeney (2008) were fortunate enough to find one nest and describe it. Although most of the nest is made of ferns, mosses comprise the sparse lining of the cup, woven with rootlets and dried grasses in a circular fashion.

Figure 120. *Dacnis flaviventer*, Yellow-bellied Dacnis male. Members of this species line their nests with mosses. Photo by Patty McGann, through Creative Commons.

Emberizidae – Emberizines

Wolf (2009) found thirteen species of **Emberizidae** that use bryophytes in their nests in North America:

Spizella arborea (American Tree Sparrow; Figure 121-Figure 122)

Pooecetes gramineus (Vesper Sparrow; Figure 123-Figure 124)

Ammodramus savannarum (Grasshopper Sparrow; Figure 125-Figure 126)

Passerella iliaca (Fox Sparrow; Figure 127)

Melospiza lincolni (Lincoln's Sparrow; Figure 128)

Zonotrichia albicollis (White-Throated Sparrow; Figure 129)

Zonotrichia querula (Harris's Sparrow; Figure 130)
Zonotrichia leucophrys (White-Crowned Sparrow; Figure 131-
 Figure 132)
Zonotrichia atricapilla (Golden-Crowned Sparrow; Figure 133)
Junco hyemalis (Dark-Eyed Junco; Figure 134-Figure 137)
Junco phaeonotus (Yellow-Eyed Junco; Figure 138)
Calcarius lapponicus (Lapland Longspur; Figure 139-Figure 140)
Plectrophenax nivalis (Snow Bunting; Figure 141)

Junco (*Junco hyemalis*)

The common Junco (*Junco hyemalis*; Figure 134) spends its winter in snowy places in the northern USA, then returns to even more northern locations in late April to build its nest of grasses, moss, and rootlets nestled in a mossy bank (Figure 135) or along a woodland trail (Figure 136) (Harrison 2000). Ken-ichi Ueda found a similar construction in a stream bank (Figure 137).

Eastern Towhee (*Pipilo erythrophthalmus*)

The Eastern Towhee (*Pipilo erythrophthalmus*; Figure 142), formerly the Rufous-sided Towhee, nest (Figure 143) is somewhat unusual in its moss component. The lining can consist of a single material – 70-80 strands of *Polytrichum ohioense* setae (Figure 144) interwoven to form the lining (Breil & Moyle 1976). A few had gametophyte (leafy plants) fragments or capsules attached.

Figure 144. *Polytrichum ohioense* showing setae that can be used to line the nests of the Eastern Towhee (*Pipilo erythrophthalmus*). Photo by Bob Klips, with permission.

Savannah Sparrow (*Passerculus sandwichensis*)

Mosses comprised more than 30% of the mass of nesting materials in the southeastern Ontario, Canada, populations of the ground-nesting Savannah Sparrow (*Passerculus sandwichensis*; Figure 145-Figure 146) compared to less than 20% in the northern Manitoba populations (Crossman *et al.* 2011). Although these differences were not statistically significant ($p > 0.05$), they may reflect the somewhat smaller, more compact nests in the northern Manitoba population. But does it vary with climate as an adaptive means to maintain more favorable temperatures? Indeed Crossman and coworkers found that whereas the external dimensions of the nest did not differ, the inner nest cup was significantly shallower in northern Manitoba, indicating a thicker bottom that could provide greater insulation in the northern Manitoba population. But alas, we do not know if the mosses contributed to any insulating properties.

Figure 145. *Passerculus sandwichensis*, Savannah Sparrow, a species for which moss usage and nest size vary with latitude. Photo by Tom Grey, with permission.

Figure 146. *Passerculus sandwichensis*, Savannah Sparrow, nest with eggs. Photo by James K. Lindsey, with permission.

Figure 147. Nest composition for materials comprising $\geq 1\%$ of nest mass of the Savannah Sparrows (*Passerculus sandwichensis*; Figure 145-Figure 146) that bred in southeastern Ontario (white bars) and northern Manitoba (grey bars). Bars represent dominant nesting materials $\geq 1\%$ of nest dry mass. Those materials comprising $< 1\%$ of nest mass are combined into miscellaneous. Plots show means (\pm SD). Modified from Crossman *et al.* 2011.

Ipswich Sparrow (*Passerculus sandwichensis princeps*)

The Ipswich Sparrow (*Passerculus sandwichensis princeps*; Figure 148) is endemic on Sable Island, Nova Scotia, Canada. Dwight (1895; Mills & Lucas 2016) notes that mosses are included in their nests. As is typical in many kinds of nests, these are composed of two distinct parts. The outer shell is made of coarse materials including dead weed stalks, grasses, and "little bits" of mosses. The inner cup has finer materials, including hair of ponies and cattle, grasses, and sedges. These nests differ from those of the Savannah Sparrow on the mainland, where the nest is scraped out to form hollows and contain no mosses or lining materials.

Figure 148. *Passerculus sandwichensis princeps*, Ipswich Sparrow. Members of this subspecies are endemic to Nova Scotia and often include mosses in the linings of their nests. Photo through Creative Commons.

Icteridae – Blackbirds, Orioles, etc.

Wolf (2009) found three species of **Icteridae** that use bryophytes in their nests in North America:

Euphagus carolinus (Rusty Blackbird; Figure 149-Figure 150)

Euphagus cyanocephalus (Brewer's Blackbird; Figure 151)

Icterus bullockii (Bullock's Oriole; Figure 152-Figure 154)

Figure 149. *Euphagus carolinus*, Rusty Blackbird. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Figure 154. Hanging nest of *Icterus bullockii*, Bullock's Oriole. Members of this species use bryophytes in their nests. Photo by Eugene Zelenko through Creative Commons.

Fringillidae – Fringilline Finches

Wolf (2009) found eleven species of **Fringillidae** that use bryophytes in their nests in North America:

Leucosticte tephrocotis (Gray-crowned Rosy Finch; Figure 155)

Leucosticte atrata (Black Rosy Finch; Figure 156)

Leucosticte australis (Brown-capped Rosy Finch; Figure 157)

Pinicola enucleator (Pine Grosbeak; Figure 158)

Carpodacus purpureus (Purple Finch; Figure 159-Figure 160)

Loxia curvirostra (Red Crossbill; Figure 161)

Loxia leucoptera (White-winged Crossbill; Figure 162)

Carduelis flammea (Common Redpoll; Figure 163-Figure 164)

Carduelis pinus (Pine Siskin; Figure 165)

Carduelis psaltria (Lesser Goldfinch; Figure 166-Figure 167)

Coccothraustes vespertinus (Evening Grosbeak; Figure 168)

Figure 164. *Carduelis flammea*, Common Redpoll, feeding young in nest. Note mosses woven into the exterior. Photo by Peter Reese, through nzbirdsonline.org.nz, online permission.

Pine Siskin (*Carduelis pinus*)

The Pine Siskin (*Carduelis pinus*; Figure 165) breeds from SE Alaska to Newfoundland (Van Woerkom 1999). They remain year-round along the Pacific Coast where they prefer coniferous forests and mixed woodlands. Their nests are saucer-shaped, constructed with twigs, grasses, strips of bark, and lichens. These are lined with hair, moss, thistle-down, or feathers. The young leave the nest in two weeks. The female remains in the nest with the young and the male brings food for her and she regurgitates food for the nestlings.

Figure 168. *Coccothraustes vespertinus*, Evening Grosbeaks, getting drink. Members of this species use bryophytes in their nests. Photo by Tom Grey, with permission.

Brambling (*Fringilla montifringilla*)

The Brambling (*Fringilla montifringilla*; Figure 169) has a name that literally means "mountain fringilla" (Wikipedia 2016a). It lives in birchwoods and coniferous forests of northern Europe and Asia. It is migratory, overwintering in southern Europe, north Africa, north India, northern Pakistan, China, and Japan. This small passerine bird uses mosses, hair, and wool to line its nest (Stevenson 1987).

Figure 169. *Fringilla montifringilla*, Brambling. Members of this species use bryophytes in their nests. Photo by M. Nishimura, through Creative Commons.

Chaffinch (*Fringilla coelebs*)

Based on the pictures I have seen, the Chaffinch (*Fringilla coelebs*; Figure 170) commonly uses bryophytes extensively in its nests (Figure 171-Figure 173).

Figure 170. *Fringilla coelebs*, Chaffinch female. Members of this species use bryophytes in their nests. Photo by James K. Lindsey, with permission.

Figure 173. *Fringilla coelebs*, Chaffinch, nest of bryophytes. Photo by Nottsexminer, through Creative Commons.

Poo-uli (*Melamprosops phaeosoma*)

The Poo-uli (*Melamprosops phaeosoma*; Figure 174) is a Hawaiian honeycreeper, a rare species nearing extinction (Engilis *et al.* 1996;). Its nest is an open cup which it constructs from twigs and bryophytes. Coarse mosses are used to fill the spaces between the twigs, reminiscent of human uses of mosses for chinking. Both nests examined contained *Homaliodendron flabellatum* (Figure 175), *Thuidium plicatum*, *Trachypodopsis auriculata* (Figure 176). One nest also contained *Aerobryopsis wallichii*; the other contained *Floribundaria floribunda* (Figure 177). The lining is made from fern rootlets. Leaves and stems of graminoids and dicots constituted less than 5% of the material in the nest.

Figure 174. *Melamprosops phaeosoma*, Poo-uli, a rare species. Members of this species use bryophytes in their nests. Photo by Paul E. Baker, through public domain.

Figure 177. *Floribundaria floribunda*, a species used in the nest of the Poo-uli, *Melamprosops phaeosoma*. Photo through Creative Commons.

Kākāwahie or Moloka'i Creeper (*Paroreomyza flammea*)

Kākāwahie or Moloka'i Creeper (*Paroreomyza flammea*; Figure 178) is an extinct member of this family, originally native to Hawaii (Wikipedia 2016b). It fed primarily on larvae of beetles and Lepidoptera. The birds constructed a nest with an exterior of moss.

Figure 178. *Paroreomyza flammea*, Moloka'i Creeper (bottom 2 birds), an extinct bird that placed mosses on the exterior of the nest. Photo by Frederick William Frohawk, through Creative Commons.

Leiotherichidae – Laughing Thrushes

Nilgiri Laughing Thrush (*Trochalopteron cachinnans*)

The Nilgiri Laughing Thrush (*Trochalopteron cachinnans*; Figure 179) gathers bryophytes and uses them to build nests. These typically include several species.

Figure 179. *Trochalopteron cachinnans*, Nilgiri Laughing Thrush. Members of this species use bryophytes in their nests. Photo by Antony Grossy, through Creative Commons.

Ptilonorhynchidae – Bower Birds

Bower Birds have some of the most interesting mating behavior in the bird world. The male bower bird builds a mating tunnel or similar structure to attract his mate (Hansell 2000). This tunnel typically involves a column of sticks around a stem of a sapling or small fern that serves

as a central feature of the bower. Depending on the species, this bower is often decorated with blue objects.

Vogelkop Bowerbird (*Amblyornis inornata*)

The Vogelkop Bowerbird (*Amblyornis inornata*; Figure 180) of New Guinea and Australia builds a conical hut (Figure 181) up to 2 m wide by 3.3 m high (Uy 2002). The pathway to this doorway of this hut is paved with a carpet of moss. This mossy path is decorated with rhododendron flowers, red ginger berries, iridescent blue beetle carapaces, and feathers from other birds. One isolated population in the Kumawa Mountains builds a spire around saplings, forming an umbrella-like structure over a circular mossy foundation.

Figure 180. *Amblyornis inornata*, Vogelkop Bowerbird. Members of this species pave the pathways to their huts with mosses. Photo by Carmelo López Abad, through Creative Commons.

Figure 181. *Amblyornis inornata*, Vogelkop Bowerbird, bower with hut. Photo by Carmelo López Abad, through Creative Commons.

The females of the Vogelkop Bowerbird (*Amblyornis inornata*; Figure 180) are slightly smaller than the males (Lananhbirds 2010). The dull coloration is offset by one of the largest and most colorful bowers. The bower is a 100-cm-high cone with a 160-cm diameter. Like many human homes, the birds have a front lawn that is cleared and carpeted with mosses. The lawn is the site of flowers, fruit, beetle wings, dead leaves, and other objects in an "artistic" arrangement. Males maintain these objects, replacing ones that are no longer suitable or replacing ones stolen by neighbors.

Because of the dull plumage, this species is of less interest than other Bowerbird species and therefore is of Least Concern on the IUCN Red List (BirdLife International 2004). That is, if humans don't like it, they don't hunt it for its plumage.

Macgregor's Bowerbird (*Amblyornis macgregoriae*)

The Macgregor's Bowerbird (*Amblyornis macgregoriae*; Figure 182) contrasts with the Vogelkop Bowerbird by having the "simplest" bower (Hansell 2000). It builds a maypole tower that is 2-3X the height of the male. This is made of a few hundred fine, interlocked sticks in the center of a moss platform. The platform lacks other adornment.

Figure 182. *Amblyornis macgregoriae*, Macgregor's Bowerbird. Members of this species use bryophytes in their nests. Photo by Katerina Tvardikova, through Creative Commons.

Golden-fronted Bowerbird (*Amblyornis flavifrons*)

The Golden-fronted Bowerbird (*Amblyornis flavifrons*) builds a bower similar to that of Macgregor's Bowerbird, but the lawn is decorated by little piles of yellow, green, and fruit (Hansell 2000).

Acanthizidae – Scrubwrens, Thornbills, and Gerygones

The Brown Thornbills (*Acanthiza pusilla*; Figure 183) are very active birds, searching for tiny invertebrates (Lloyd 2013). They make an untidy nest (Figure 184) of bark shreds, grass, spider webs, spider egg sacs, and moss. This nest is hidden close to the ground in tussock grass, sags or bracken.

Figure 183. *Acanthiza pusilla* (Brown Thornbill), a bird that includes mosses in its nest. Photo by Patrick Kavanagh, through Creative Commons.

Figure 184. *Acanthiza pusilla* (Brown Thornbill) nest that often includes mosses. Photo by J. J. Harrison, through Creative Commons.

Rhinocryptidae – Tapaculos

Silvery-fronted Tapaculo (*Scytalopus argentifrons*)

In a Costa Rican cloud forest, the nest of the Silvery-fronted Tapaculo (*Scytalopus argentifrons*; Figure 185) was a "substantial" globular structure (Young & Zuchowski 2003). It was made mostly of mosses placed into a subterranean cavity at the end of a short, narrow tunnel.

Figure 185. *Scytalopus argentifrons*, Silvery-fronted Tapaculo, Members of this species put mosses in their underground nests. Photo by Francesco Veronesi, through Creative Commons.

Callaeatidae – New Zealand Wattlebirds

The Kōkako (*Callaeas wilsoni*; Figure 186), endemic to the North Island of New Zealand, sometimes includes moss capsules to line its nest (Figure 187). They use lichens, mosses, and liverworts, together with rotten wood and some mud in a central layer of the nest (Jessica Beever, Bryonet 2 May 2003).

Figure 186. *Callaeas wilsoni*, Kōkako, a New Zealand endemic species. Members of this species use moss capsules to line their nests. Photo through Creative Commons.

Figure 187. *Callaeas wilsoni*, Kōkako, in a nest with lots of mosses. Photo by Dick Veitch, © Department of Conservation, NZ, with limited online permission.

Zosteropidae – White-eyes

The White-eye (*Zosterops lateralis*; Figure 188-Figure 189) builds a nest (Figure 190) with mosses on the outside (Wikipedia 2017). This tiny nest is suspended from a fork in the branches.

Effect of Cavity-nesting Birds on Bryophyte Communities

We have already discussed dispersal of bryophytes by birds, but nesting birds can have other effects on bryophyte communities as well. Tatsumi *et al.* (2017) investigated the effects of birds on the tree bole surrounding cavities where birds have nested (Figure 191-Figure 194). They suggested that tree holes (Figure 195-Figure 198) that are inhabited can be enriched with nutrients from those organisms, and those nutrients can escape down the tree trunk. Using the trees *Aria japonica* and *Cercidiphyllum japonicum* in a Japanese temperate forest, they investigated the bryophyte and lichen communities above and below tree holes.

Figure 197. View of inside of tree hole. Photo courtesy of Wakana Azuma.

Figure 198. Close view of tree hole vegetation. Photo courtesy of Shinichi Tatsumi.

The richness of bryophyte and lichen species did not differ above and below the tree holes (Tatsumi *et al.* 2017). But the species composition of bryophytes differed significantly. The moss *Anomodon tristis* (Figure 199) and liverwort *Porella vernicosa* (Figure 200) were significantly more common below than above tree holes. On the other hand, the liverwort *Radula japonica* (Figure 201) and four lichen species were more frequent above than below the holes. Tatsumi and coworkers suggested nutrient and moisture differences as possible reasons for the species differences. I have to wonder how much the activity of the parents going in and out of the cavity could affect the bryophytes surviving there. These could have two impacts, dispersal and damage. More fragile species might not be able to survive the activity. Others might be transported there on feathers and feet.

Edible Nests

An interesting twist to the food concept is the use of bird nests as food for humans. I have not documented that any of those used contain mosses, but Salgado *et al.* (1998) found mosses in neotropical bird nests that they examined for **zoopharmacognosy** (behavior in which non-human animals apparently self-medicate by selecting and ingesting or topically using plants, soils, insects, or psychoactive drugs to prevent or reduce harmful effects of pathogens and toxins).

Summary

These passerine birds use mosses for a variety of purposes in their nests. Some put them inside as liners, some make the bottom of the nest thicker, and some weave them on the outside as camouflage. But in most cases we don't know what the function of the mosses really is – insulation, moisture, camouflage, or parasite protection. Or could it be all of these, or simply the mosses are the most available building materials?

The choice of bryophytes usually seems to depend on availability. But in other cases, the species chooses particular bryophytes, even if they are less abundant. Some bowerbirds use mosses to decorate their bowers – making a green path to the nest.

Birds can have an impact on the bryophytes themselves. Aside from being destructive by removing the bryophytes, and dispersing them to new locations, they have an impact on the species found above and below the tree holes where they nest.

Acknowledgments

Thank you to Brian Dykstra for sending me the wonderful thesis on birds and epiphytes by Adrian Wolf, as well as other references and personal observations. David Dumond shared the references he got from Bryonet. Thank you to Feng Chao, Wei Li, and Zhaojun Bu for providing me with the paper by Zhao *et al.* and to Zhaojun Bu for translating critical parts. Isabelle Charissou provided me with the paper by Tatsumi *et al.* Shinichi Tatsumi and his colleagues provided me with the images to illustrate their findings. Thank you to Tom Grey and Janet Marr for a critical reading of the manuscript and technical corrections.

CHAPTER 17-1

RODENTS – MUROIDEA: MURIDAE

Figure 1. Rodent among mosses and lichens, Auckland Island. Photo by James Russell, with permission.

Mammals

Scattered references to mammals using bryophytes for nests or habitat appeared early in the literature. However, until search engines were able to do the massive reading required to find these, bryologists were able to find little documentation of these uses.

Mammals are warm-blooded animals, so it is logical that in northern climates some of them would use bryophytes as nesting materials, taking advantage of their insulating properties. But as this chapter will reveal, they have found a variety of uses for bryophytes, especially in northern habitats.

Rodentia – Rodents

The term "rodent" is derived from the Latin word *rodere*, meaning to gnaw (Wikipedia 2017a). They comprise the order **Rodentia**, distinct in having a single pair of incisors (cutting teeth) that grow continuously. They comprise 40% of the mammal species and are common and abundant on all continents except Antarctica.

Even larger animals are known to use bryophytes for nesting purposes. But rodents seem to have the most uses. Le Blanc *et al.* (2010) determined that in eastern Canada, moss cover and vertical cover were the predominant influences on community structure of small mammals, whereas for forest birds it was conifer basal area, vertical cover, and snag availability. Kaminski *et al.* (2007), in the

Allegheny Mountains of West Virginia, USA, demonstrated through principal component analysis that moss cover and abundant seedlings were important for specialist rodents in habitats with coarse woody debris.

One can find numerous studies in which mosses were made available as nesting materials in the lab (*e.g.* McGuire & Sullivan 2001; Pulfer 2007). In trapping studies, mosses have been used for insulation and food in the trap (Lentfer 1975; Peterson & Batzli 1975). Those studies that describe actual wild nests are much fewer than might be expected from the lab. Nevertheless, mosses are not uncommon in nests, but they are usually only minor components.

Bryophytes as Food

Until somewhat recently, we assumed that mammals did not eat bryophytes. Batzli and Cole (1979) reported that mosses produced low metabolizable energy for **microtine** rodents (members of the subfamily **Microtinae**, with teeth adapted for herbivory).

Nevertheless, both bovines and rodents use mosses as part of their diets. Prins (1982) observed that in cold environments mosses are eaten by a variety of herbivores, suggesting that the mosses might provide the secondary compound arachidonic acid that would help to keep the membranes of the footpads pliable on the cold ground and snow.

Microtine rodents in northern climates select mosses as part of their diet (Batzli & Jung 1980). Batzli (1983) likewise suggests that it may be secondary compounds that drive these rodents to consume bryophytes – such compounds as arachidonic acid? Or might it be a sort of winter tonic that helps to prevent bacterial infections? The well-known cycling of these northern rodents does not seem to correlate with nutrient fluctuations, and mosses are more difficult for rodents to digest than flowering plants (Tahvanainen *et al.* 1991), but Batzli contends that we cannot rule out secondary compounds for the changes in diet. In addition to making use of arachidonic acid, a fatty acid not found in flowering plants, Prins (1982) reminded us that mosses are high in fiber, low in nitrogen, and low in digestible energy, seemingly giving the rodents little reason to eat them unless the mosses provided something special and important – like arachidonic acid.

This seemingly non-nutritional status of bryophytes is supported by the study of 35 bryophyte species from the high Arctic tundra (Figure 2) of Devon Island, Canada (Pakarinen & Vitt 1974). They demonstrated that the highest nitrogen content is in the green portion, and that the fraction is higher in hydric species than in mesic or xeric species. Mean contents (%) for the green portion of these species are total nitrogen, 1.00 (1.08 ash-free) and total carbon, 45.9 (48.7 ash-free). By contrast, the percent N content of *Nephrophyllidium crista-galli* (a dicot; Figure 3) in Alaska ranged ~3-3.8% in areas where Sitka deer gathered and 2-3% in areas where they were absent (Klein 1965). In the five Arctic tracheophyte species measured for carbon percentage by Tolvanen and Henry (2001), all were inferior to that in the Pakarinen and Vitt (1974) moss study except that of the shrub *Cassiope tetragona* (Figure 4), which was only slightly higher. Barkley *et al.* (1980) and Batzli and Pitelka (1983) consider mosses to have a nutrient content that does not differ from that of other plants in the same region.

Figure 2. Nunavut tundra, Canada. Photo by A. Diallya, through Creative Commons.

Turchin and Hanski (2001) suggested that interaction with the food supply was one possible explanation for rodent cycling in far northern habitats. Nevertheless, based on their models they concluded that predation was the best explanation for population cycling, but they allowed for the possibility of food to play a role in cycles of lemmings, rodents that rely on mosses for food.

Figure 3. *Nephrophyllidium crista-galli*, an Arctic plant with 3-3.8% nitrogen content in Alaska. Photo by Alpsdake, through Creative Commons.

Figure 4. *Cassiope tetragona*, an Arctic plant with nitrogen content only slightly higher than that of mosses. Photo by Bjoertvedt, through Creative Commons.

One example of the role of secondary compounds is the hormonal precursors found in graminoids (Hansson & Henttonen 1988). But that would fail to explain the cycles in shrub and moss eaters. Are we missing something? Both the arctic rodents and the bryophytes reproduce in early spring. Is there a time in winter, or late fall, when bryophytes produce a hormone precursor, if not the hormone itself? Or is it the shift to a greater percentage of bryophytes in the diet that triggers hormone production? Hansson and Henttonen concluded that the cycles are complex, that they are regular in only a minority of the rodents, and that extrinsic factors are important in regulating these cycles.

One of the mechanisms used by the woodrat genus *Neotoma* is that of caching to reduce toxin intake (Torregrossa & Dearing 2009). Although this study did not include bryophytes, it is a topic that should be considered in understanding bryophyte relationships. Among the three non-bryophyte feeders in the study, the white-throated woodrat (*N. albigula*; Figure 5) made a terpene-free cache. In nature, dismantled middens of this species revealed no alpha-pinene, despite its occurrence in the surrounding trees. The desert woodrat (*Neotoma lepida*; Figure 6) instead decreased total food intake, but did not decrease the terpene-containing food. The third species, Bryant's woodrat (*N. bryanti*; Figure 7), did nothing to regulate

terpene intake. Nevertheless, in the food cage all three species abandoned a greater amount of food when it contained terpene.

Figure 5. The white-throated woodrat, *Neotoma albigula*, a species that makes a terpene-free cache. Photo by J. N. Stuart, through Creative Commons.

Figure 7. Bryant's woodrat, *Neotoma bryanti*, a species that does nothing to regulate terpene intake. Photo by Alan Harper, through Creative Commons.

This raises the question of phenolic compounds in bryophyte food organisms. Some of these are aromatic, suggesting that they will evaporate from the bryophytes with time, or at least decrease in concentration. Do these phenolic compounds also decrease in winter when the bryophytes are mostly inactive? Do stored bryophytes in nests lose their phenolic compounds?

Little is known about seasonal variation in phenolic concentrations of bryophytes. Hribljan (2009; in prep) found no significant change in phenolic concentrations from September to November in the moss *Pleurozium schreberi* (Figure 8) in the Keweenaw Peninsula of Michigan, USA (Figure 9). But do concentrations decrease as the mosses rest under the snow of winter? Do they decrease during hot, dry periods of summer? And if so, do rodents change their feeding habits in response?

Figure 8. *Pleurozium schreberi*, a boreal forest moss that showed no change in phenolic content from September to November. Photo by Sture Hermansson, with online permission.

Figure 9. Seasonal phenolics in *Pleurozium schreberi*, leaves of a deciduous maple tree (*Acer*), and needles of the conifer *Pinus*. Drawn by John Hribljan, with permission.

Several studies have indicated that rodents eat moss capsules (see study by Matt Dami below under Dispersal). One reason for this food choice may be the high concentration of lipids (Gellerman *et al.* 1972; Pakarinen & Vitt 1974). It can be as high as 30% in the capsules, compared to 5% in the leafy gametophyte.

Impacts on Bryophytes

Rodents are common in mires (Bostrom & Hansson 1981) and can be a major influence on bryophyte dynamics there, particularly in boreal and northern climates. Their use of bryophytes as food, the trimming of runways, and uses for nesting materials all remove bryophytes, sometimes faster than the bryophytes can regrow.

Grazing

Ericson (1977) found that not only the dwarf shrubs and grasses, but also the mosses in northern Sweden were impacted by grazing by small rodents (moles and lemmings). Mean moss cover declined in 1974 and 1975, but experienced a strong increase in 1976. Ericson attributed these changes entirely to grazing and other activities of the microtine rodents. The rodents typically bite off tips of mosses in the snow-free season, but in the snow-covered season they bite the shoots close to the bases.

In 1974, the decrease in mosses was primarily the result of summer grazing and runways (Figure 10), whereas in 1975 it was a further response to these activities during the winter period until the rodent population crash (Ericson 1977). These rodents included primarily the wood lemming *Myopus schisticolor* (Figure 10), a species that prefers mosses (Kalela *et al.* 1963a). The strongest bryophyte declines included the mosses *Ptilium crista-castrensis* (Figure 11) (73%), *Dicranum scoparium* (Figure 12) (57%), *D. polysetum* (Figure 13) (53%), *D. majus* (Figure 14) (37%), *Hylocomium splendens* (Figure 15) (30%), and *Pleurozium schreberi* (Figure 8) (12 %). On the other hand, species on windthrows and tree stumps [*Dicranum montanum* (Figure 16), *Sanionia uncinata* (Figure 17)] were largely spared.

Figure 10. Wood lemming, *Myopus schisticolor*, by its path through *Hylocomium splendens*. Photo by Risto S. Pynnönen through Wikimedia Commons.

Although Kalela *et al.* (1963a) considered *Plagiothecium denticulatum* (Figure 18) to be a rejected species by *Myopus schisticolor* (Figure 10), this species was eaten at least sometimes in the Ericson (1977) study. Ericson also noted that *Pleurozium schreberi* (Figure 8) was not eaten as frequently as its abundance would suggest (see also Kalela *et al.* 1963a, b; Helminen & Valanne 1963). In 1975, the picture was reversed, with *Pleurozium*

schreberi decreasing by 19% while *Ptilium crista-castrensis* (Figure 11) increased by 43% and *Dicranum scoparium* (Figure 12) increased by 70%! This decrease-increase trend is a common phenomenon by forest floor mosses, demonstrating a one-year time lag relative to the microtine rodent peak years.

Weft and other dominant species growth forms benefit from the rodents through regeneration from rhizomes in *Polytrichum commune* (Figure 19) and *P. juniperinum* (Figure 20) (Meusel 1935; Wigglesworth 1947) and *Dicranum* spp. (Figure 12-Figure 14, Figure 16) (Meusel 1935), from broken or bitten tips of *Hylocomium splendens* (Figure 21) (Correns 1899), and from isolated leaves and leaf fragments of *Dicranum* spp. and *Polytrichum commune* (Correns 1899).

Figure 21. *Hylocomium splendens*, a species that exhibits broken and bitten tips when rodents feed on it. Photo by Amadej Trnkoczy through Creative Commons.

Hansson (1969) reports frequencies of 86, 90, and 50% mosses in the diet of the bank vole *Myodes glareolus* (Figure 22) in Sweden in three successive years, and mosses form a regular part of the diet in all seasons (Hansson 1971). Contrarily, Holisová (1966) found only traces of mosses in their diet in lowland oak forests. Kalela (1957) found that *Pleurozium schreberi* (Figure 8) is especially eaten by the grey red-backed vole *Myodes rufocanus* (Figure 23), although mosses form only a minor part of the diet.

Figure 22. *Myodes glareolus*, bank vole, eating mosses in the Netherlands. Photo by Andrew Spink, with permission.

Figure 23. *Myodes rufocanus* (grey red-backed vole), a vole that eats the moss *Pleurozium schreberi*. Photo by Zbyszek Boratynski, through Creative Commons.

Hansson (1969) likewise reported a high frequency of mosses in the diet of the field vole *Microtus agrestis* (Figure 24) at Ammarnäs in Scandinavia, although he found that they usually contribute only a minor part of the diet elsewhere. Grazing by rodents during their peak years was so great in Scandinavia that moss cover declined significantly, many plots by more than 50%, for two consecutive years (Ericson 1977).

Figure 24. *Microtus agrestis* (field vole) among mosses. Photo from Wikimedia Commons.

Experimental evidence in England supports the role that small rodents can have in altering the vegetation. Summerhayes (1941) used areas that were fenced with fine mesh wire to keep the field vole *Microtus agrestis* (Figure 24) out. Control plots were similar but lacked the fencing. The original plots had mostly the grass *Melica caerulea* (Figure 25), but also the grasses *Holcus mollis* (Figure 26) and *Deschampsia caespitosa* (Figure 27). The exclosures resulted in almost total disappearance of mosses within them during the sampling period of 1932 to 1939. Summerhayes attributed this to the increased competition by the dominant plants when the vole attack was prevented.

Virtanen *et al.* (1997) similarly established exclosures against the Norwegian lemming (*Lemmus lemmus*; Figure 28) in the late snowbeds of Finnish Lapland. Eight years later they found considerable changes in the vegetation. Mosses had expanded their coverage. *Polytrichum* (Figure 19-Figure 20) species had reached a carpet that was three times as thick as that in the open areas. The mosses experienced vertical growth in undisturbed conditions. Inside the exclosures the liverworts and some prostrate **tracheophytes** (lignified vascular plants) were absent. The open (disturbed) plots were the only place where the bryophytes with good colonizing ability occurred.

Figure 28. *Lemmus lemmus* on *Sphagnum*. Photo by Andreaze, through Creative Commons.

Lemmings in North America can consume up to 90% of the primary production during a peak population year (Schultz 1968; Moen *et al.* 1993). In Scandinavia, they consumed 66% of the mosses and only 33% of the graminoids during these peaks (Moen *et al.* 1993) Bryophytes are a winter staple for the Norwegian lemming (*Lemmus lemmus*; Figure 28) (Virtanen 2000). After 5 years in an exclosure (Figure 29) experiment in a mountain snowbed of northwestern Finland, absence of grazing by lemmings and reindeer (*Rangifer tarandus*; Figure 30) caused an increase in moss biomass (Figure 31). After 15 years, the moss family **Polytrichaceae** (Figure 19-Figure 20) still dominated, but some of the graminoids had also increased (Figure 31). On the other hand, the moss *Kiaeria* (Figure 32) decreased or became completely absent in the exclosures, apparently due to competition from

tracheophytes. Virtanen concluded that the assumption that herbivore grazing in low productivity environments was of little consequence was an incorrect assumption. Grazers can have a significant impact on both bryophytes and tracheophytes in these environments.

Figure 32. *Kiaeria starkei*, a moss that benefits from grazing by mammals. Photo by Michael Lüth, with permission.

Andersson and Jonasson (1986) conducted a similar study on rodent exclosures in the alpine heath of Lapland in northern Sweden. Several plants were greatly reduced by the rodents and flowering frequency of food plants decreased. The lemmings (*Lemmus lemmus*; Figure 28) and voles (*Myodes*; Figure 22-Figure 23) both eat the mosses *Polytrichum commune* (Figure 19) and *P. juniperinum* (Figure 20) (Kalela 1957, 1962; Koshkina 1962; Kalela & Koponen 1971; Kalela *et al.* 1971). Andersson and Jonasson (1986) found that *Polytrichum* declined, but they attributed the decline to depression by luxurious growth of tracheophyte species. The *Polytrichum* species have a slower growth rate than that of tracheophytes.

It is the lemmings that make mosses a large part of their diet, differing considerably from the vole diet (Kalela 1957, 1962; Koshkina 1962; Stoddart 1967; Kalela *et al.* 1971, Kalela & Koponen 1971, Baltruschat & Uberbach 1976). Hence, Andersson and Jonasson (1986) concluded that the voles and lemmings may not experience severe competition for food.

The grazing causes good and bad years for bryophytes, sometimes permitting tracheophytes to get established. These tracheophytes can sometimes out-compete the bryophytes. Thus, the rodents can have a major impact on the construct of the vegetation.

Runways, Burrows, and Nests

But consumption is not the only influence on the changing bryophyte communities. The runways and exposed tunnels (Figure 33) are colonized by mosses (Figure 34), especially *Ceratodon purpureus* (Figure 35), *Plagiothecium curvifolium* (Figure 36), *P. denticulatum* (Figure 18), *Pohlia nutans* (Figure 37), and *Brachythecium starkei* (Figure 38) (Ericson 1977). These small turf or mat species are unable to colonize the weft-moss-covered areas and benefit from the disturbance of the runways. The runway species also differ from those of windthrows that are colonized by *Amblystegium serpens* (Figure 39), *Sanionia uncinata* (Figure 17), and *Dicranum montanum* (Figure 16).

Figure 39. *Amblystegium serpens*, a colonizer of windthrows. Photo by Michael Lüth, with permission.

The role of these rodents in leafy liverwort population dynamics is less clear. Kalela *et al.* (1963a) reported that *Myopus schisticolor* (Figure 10) rejected *Ptilidium ciliare* (Figure 40), but it appears that *Barbilophozia lycopodioides* (Figure 41) experiences at least some foraging. Both species are poor competitors that are able to colonize the exposed substrate of the runways.

Figure 41. *Barbilophozia lycopodioides*, a leafy liverwort that is sometimes eaten by rodents. Photo by Michael Lüth, with permission.

Duncan (1954) found that rodents compress the *Sphagnum* (Figure 42) and reduce its growth rate. Duncan found more seedlings (11% germination) of black spruce (*Picea mariana*; Figure 43) on the "fine" mosses [*Mnium* (Figure 44), *Drepanocladus* s.l. (Figure 45), *Helodium* (Figure 46)] compared to non-compressed *Sphagnum* (4.5%). However, compressed *Sphagnum* mats appear to be the best of these substrata for black spruce seedlings.

Tabata and Iwasa (2013) found that Smith's red-backed vole, *Phaulomys smithii*, occurred in rocky terrains at the base of Mt. Fuji, Japan, where bryophytes were common. But the role of these rodents in promoting the growth of the bryophytes or in distributing them remains unknown.

Otomys sloggetti (Muridae; Figure 88) typically occupies rocky habitats, living in crevices in nests of weeds and grass (Lynch 1989). However, in boggy and spongy habitats of South Africa, they occupy extensive burrow systems similar to those of *Parotomys brantsii* (Figure 47). The area is characterized by numerous hummocks that are ~200 mm high and ~300 mm in diameter. Lynch (1992) suggested that the moles (*Cryptomys hottentotus*; Figure 48) were the engineers of the hummocks. But it appeared that *O. sloggetti* further enlarged and cleaned them, creating greater habitat variety and colonization by a greater variety of plants, including mosses. The mosses become repeatedly "top-dressed" with soil, creating the hummocky landscape. However, not all agree with this interpretation of the hummock origin, suggesting instead that such non-animal agents as freeze-thaw cycles could account for the hummocks (van Zinderen Bakker & Werger 1974).

The tiny moss *Acaulon triquetrum* (Figure 49) grows in calcareous grasslands in Southwest Germany (Ahrens 2003). The upper layer of the substrate is colonized by rhizomes that branch and from which young shoots develop. This species is able to colonize the bare surfaces of the loess soil that is created by burrowing small mammals (and these rodents could contribute to dispersal by carrying rhizoids, rhizomes, propagules, and leaf fragments on their footpads and fur.

Figure 49. *Acaulon triquetrum*, a moss species that occupies bare soil created by burrowing rodents. Photo by Michael Lüth, with permission.

Another possibility is that plant fragments are carried in the gut and deposited at a different location. The first question to arise here is whether they are viable after their adventure in the gut. John Hribljan (unpublished) cultured microtine rodent scat from Isle Royale, Michigan, and

several fragments germinated (Figure 50) to produce new plants.

Figure 50. Culture of *Funaria hygrometrica* derived from feces collected from moss from Alaska. The size of the feces suggests these were microtine rodents. Photo by John Hribljan, with permission.

Beavers (*Castor canadensis*; Figure 51) are not known to use mosses, but they are ecological engineers that can change whole habitats. Their disturbance is often instrumental in the creation of wetlands (Adams 1993; Ponomarenko & Ponomarenko 2003). Such disturbances often result in the invasion of bryophytes and graminoids from wetlands into upland habitats (Ponomarenko & Ponomarenko 2003).

Rodent Cycles

Rodent cycles have puzzled biologists for many decades (Turchin *et al.* 2000). The cycles were once understood to be 3-4 years, but now we understand that they are not so simple (Hansson 2002). They are characterized by lag phases and may be resource-driven. But lag phases can also be caused by predator effects. These drivers can force the population to spread to

suboptimal patches. Hansson reports that some rodents appear to be limited by food, especially mosses. The mosses recover slowly from overgrazing and are further limited by temperature.

Rodents can be responsible for considerable changes in the abundance of bryophytes (Rydgren *et al.* 2007). Early reports on increases in the bryophyte annual production and abundance suggest that climate change provides more favorable conditions (Økland 1997; Økland *et al.* 2004; Knorre *et al.* 2006). But more recently data suggest that in the boreal forests, rodent cycles impact the feather moss *Hylocomium splendens* (Figure 15). When rodents have long cycles, their peak years have the greatest impact, causing the greatest reduction in growth of the moss. The role of bryophytes in these ecosystems is typically as a food source (Hansson 1969; Tast 1991; Bondrup-Nielsen 1993), although bryophytes can also provide cover and nesting material. Further impact on moss persistence results from trampling (Rydgren *et al.* 2007). Runways open the carpet due to removal of tissue (Kalela & Koponen 1971; Ericson 1977). Furthermore, species such as *Brachythecium starkei* (Figure 38) and *Ceratodon purpureus* (Figure 35) rapidly colonize runways in the first year. Summer foraging on the shoot apex does not have a severe effect on the mosses, but winter grazing can exterminate a species clone, as seen in species of *Dicranum* (Figure 12-Figure 14, Figure 16) (Ericson 1977).

In Norway, fluctuations in rodent populations have profound impact on the success of the moss *Hylocomium splendens* (Figure 15) (Rydgren *et al.* 2007). The moss has its highest growth rate when the rodents are acyclic and becomes reduced when the periodicity and severity of the peak disturbance by rodents increases. Even its means of reproduction changes, with mature segments surviving in less variable environments, and regeneration from older branches responding to more variable environments. Rodent herbivory and trampling contribute to fragmentation from the mosses.

Such regeneration from older parts makes the population less fit than survival of mature stems (Rydgren *et al.* 2007). This is because large segments will survive for decades, but fragmentation results in small segments. These, in turn, have lower branching frequencies and lower probability of survival. Because of their small size, bryophytes such as *Hylocomium splendens* (Figure 15) may be able to use only two of the three resistance mechanisms known to tracheophytes (defense, escape, tolerance), lacking the size and lignin needed for physical defense against trampling and fragmentation. Rather, they seem to rely on tolerance through compensatory growth, greater photosynthesis, reallocation of resources, and activation of the meristem (Boege & Marquis 2005). The latter is triggered by damage to the apex that removes apical dominance, a phenomenon well known among many dicots.

For *Hylocomium splendens* (Figure 21), and many other large boreal mosses, reproduction by spores is rare, and growing tips provide the major form of reproduction (Økland 1995; Rydgren & Økland 2002; Cronberg *et al.* 2006). Fragmentation contributes to the diaspore bank, but there is a delay in growth, if it is successful at all (Rydgren *et al.* 2007). Nevertheless, it requires a severe impact of

30% loss of growing points and 15% loss of segments to reduce the population to a no-gain state under favorable growing conditions. Thus, with rodent cycles of 3-5 years and disturbance severities of only 15-30%, *Hylocomium splendens* (Figure 15) will survive.

Scenarios of climate effects on the microtine rodent cycles suggest that those cycles may change to become more irregular (Rydgren *et al.* 2007). Specifically studying the responses of the boreal moss *Hylocomium splendens* (Figure 15), Rydgren and coworkers found that the growth rates are higher in the acyclic scenarios, but that the population growth rates are progressively reduced when peak disturbance severities increase. When the environment is less variable, the mature segment of *H. splendens* (Figure 21) is the primary contributor to population growth rate. In a more variable environment, regeneration from branches of older parts becomes more important, a process that leads to reduced population fitness. Hence, if the cycles break down, abundance of *H. splendens* and other large bryophytes in boreal forests such as those of Norway will increase.

Snowbed bryophytes seem to be particularly vulnerable to rodents, perhaps because these sites are covered predominately by bryophytes. Moen *et al.* (1993) found that lemmings in northern Norway reduced the cover of graminoids by 33% and of mosses by 66% during the winter population peak. They considered this to be an important impact that helped to explain the snowbed vegetation dynamics.

As is usual in ecology, nothing operates alone. And the effects of large herbivores such as sheep can affect the impact of rodents on bryophytes, particularly in alpine ecosystems (Austrheim *et al.* 2007). Using exclosures, Austrheim and coworkers kept sheep out, but permitted access to rodents. This resulted in a significant increase in the grass *Deschampsia flexuosa* (Figure 52) within the exclosures. Frequencies of graminoids, herbs, and dwarf shrubs did not change in response to grazing, but of the 15 bryophyte species, cover of six bryophyte species groups changed, with three increasing and three decreasing significantly.

In their exclosure experiments, Austrheim *et al.* (2007) lumped bryophytes that were difficult to distinguish in the field to avoid taxonomic errors. Those that decreased in the exclosures were the *Plagiothecium* group [*P. nemorale* (Figure 53), *P. denticulatum* (Figure 18), *P. laetum* (Figure 54)] and the *Brachythecium* group [*B. reflexum* (Figure 55), *B. salebrosum* (Figure 56), *B. starkei* (Figure 38)], whereas *Straminergon stramineum* (Figure 57), *Pohlia nutans* (Figure 37), and *Cephalozia bicuspidata* (Figure 58) increased in the exclosures. At the same time, *Polytrichum* [*P. commune* (Figure 19), *Polytrichastrum formosum* (Figure 59), *P. longisetum* (Figure 60), *P. alpinum* (Figure 61)] increased in the grazed plots, whereas the leafy liverwort *Neoorthocaulis floerkei* (Figure 62) decreased in these grazed plots. The moss *Pleurozium schreberi* (Figure 8) and leafy liverwort *Ptilidium ciliare* (Figure 40) tended to increase in exclosures.

Figure 62. *Neoorthocaulis* (=Barbilophozia) *floerkei*, a species that is reduced in frequency by sheep. Photo by Janice Glime.

It was successional bryophytes that increased, along with the preferred fodder grass *Deschampsia flexuosa* (Figure 52) (Austrheim *et al.* 2007). The net result, however, was that neither tracheophyte nor bryophyte species richness was affected, nor was the total cover of either. It is interesting that when the sheep were excluded from grazing, the level of rodent grazing also diminished.

Austrheim and coworkers (2007) suggested four potential contributing factors for the changes in the bryophyte communities:

1. Exclusion of sheep reduces typical disturbance-favored pleurocarpous species such as the *Brachythecium* (Figure 38) and *Plagiothecium* (Figure 18, Figure 53-Figure 54) species groups.
2. Frequency of short-lived colonizers such as *Pohlia nutans* (Figure 37) and *Cephalozia bicuspidata* (Figure 58) increases.
3. Grazing favors grazing-resistant *Polytrichum* group species (Figure 19-Figure 20) (Helle & Aspi 1983; Väre *et al.* 1996; Virtanen 2000; Olofsson *et al.* 2004).
4. Herbivores cause a decrease in frequency of the leafy liverworts *Barbilophozia lycopodioides* (Figure 41) (sheep & rodents) and *Neoorthocaulis* (syn. = *Barbilophozia*) *floerkei* (Figure 62) (sheep).

Bryophyte recovery can influence the structure of the rodent cycle. In their comparison of rodent cycling at Barrow, Alaska, USA, with that of North Fennoscandian lemmings, Oksanen *et al.* (2008) considered that the contrasting population fluctuations between these two areas probably depended on the different growth rates of the mosses. Based on data from Barrow, Turchin and Batzli (2001) assumed that it would take only two years for a complete recovery of mosses, based on the data from the wet tundra there (Tieszen *et al.* 1980). However, in North Fennoscandian habitats where lemmings over-winter, recovery from grazing requires at least ten years (Oksanen 1983).

Dispersal

Feces created by the rodents have the potential to provide a means of dispersal. Vole digestion time varies considerably, depending on the diet (Lee & Houston 1993). Nevertheless, voles have a very efficient digestion for plants. This high efficiency in the digestion of vegetal matter may lie in their habit of **coprophagy**. That is, they consume their own feces and cycle their food through their digestive system a second time. Seed diets can take considerably longer than leaf diets. But how long does it take for a moss diet to traverse the gut?

Whatever the residence time, feces of rodents may be deposited in their habitat, including among the local bryophytes, but also along runways or on other soil. If the rodent fails to re-ingest these feces, the moss provides a suitable habitat for germination, and the rodent may carry it some distance to a new location. Hribljan (unpublished data) provides support for this possibility; mosses germinated from feces collected from among mosses in Alaska (Figure 63).

Figure 63. Developing *Funaria hygrometrica* from a culture of rodent feces collected from moss in Alaska. Photo by John Hribljan, with permission.

The experimental evidence of bryophyte dispersal by rodents is limited. Kimmerer and Young (1996) examined the effect of gap size and regeneration niche on the

coexistence of bryophyte species. Based on their study on two epixylic mosses, *Tetraphis pellucida* (Figure 64-Figure 65) and *Dicranum flagellare* (Figure 66), rodents appear to play a major role in both dispersal and distribution. Their activity creates gaps that *Dicranum flagellare* can colonize on the tops of logs. *Tetraphis pellucida* occurs primarily on the vertical surfaces at the sides of the logs. Both species produce propagules that can adhere to the rodents.

Figure 64. *Tetraphis pellucida*, a species that lives on vertical surfaces of logs and is dispersed by rodents. Photo by Jan-Peter Frahm, with permission.

Figure 66. *Dicranum flagellare* with brood branches, many of which are broken off and lying on the moss in this image. Photo by Janice Glime.

Determining the ability of rodents to disperse bryophyte propagules is a multistep process that often exceeds the time limits and expertise of graduate students. However, Matt Dami (2014) has succeeded in this multistep process to demonstrate that rodents (mice) eat moss capsules (Figure 67), pass them in feces, and that the spores in the feces germinate (Figure 68). For *Polytrichum commune* (Figure 19, Figure 68), most are able to develop to full plants, whereas for *Dicranum flagellare* (Figure 66), few are successful (Figure 69).

Figure 67. Laboratory mouse consuming *Dicranum scoparium* sporophytes. Photo courtesy of Matt Dami.

Figure 68. *Polytrichum commune* young plants cultured from spores in mouse feces in laboratory. Photo courtesy of Matt Dami.

Figure 69. Percentage of cultured *Polytrichum commune*, *Dicranum flagellare*, and unidentified field samples that formed gametophores. Modified from Matt Dami 2014.

Dami (2014) conducted the study in central New York, USA, where he trapped 77 rodents in three forested sites. He collected 6 fecal pellets in each site, then used centrifugation to separate the spores (Figure 70) to demonstrate natural feeding concentrations in the feces and to assess viability. They found an average of 1,626 unidentified bryophyte spores per 3-pellet sample in the field collections (Figure 71). In the lab they provided 20 sporophytes with associated gametophytes of the two mosses *Dicranum flagellare* (Figure 72) and *Polytrichum commune* (Figure 73) to each of 18 laboratory mice. They collected three pellets from each mouse every 24 hours for four days. In this case, they found an average of only 28 *D. flagellare* spores but 4,333 of *Polytrichum commune* (Figure 74). The two species likewise differed in number of samples exhibiting germination and growth, with only 1.4% of *D. flagellare* and 40.3% of *P. commune* samples reaching gametophore stage. On the other hand, none of the spores from the field samples produced gametophores. On the other hand, *D. flagellare* samples contained many more vegetative fragments (Figure 66) than did *P. commune* (Figure 19).

Figure 73. *Polytrichum commune* capsules, food for rodents. Photo by Michael Lüth, with permission.

Figure 74. Number of spores detected in laboratory feces samples over the four collection days. Modified from Matt Dami 2014.

Field collections revealed additional insight into the role rodents could play in bryophyte dispersal. After capturing 77 rodents in one summer, Dami (2014) found that 37.66% carried spores and 12 individuals also carried gametophyte fragments. Two were identifiable as *Platygyrium* sp. (Figure 75) and *Sphagnum* sp. (Figure 43). Attempts to sterilize the fragments made them inviable.

Figure 75. *Platygyrium repens* showing masses of bulbils at the tips, structures that easily dislodge and adhere to fur and hair. Photo by Jan-Peter Frahm, with permission.

This still calls into question the viability of these spores in feces in the field where they must endure the feces conditions until decay permits them to reach a suitable substrate. My own experience with fish feces suggests that what might be viable at the time of expulsion may not retain viability with continued exposure to the conditions of the feces.

Muroidea – Hamsters, Voles, Lemmings, and New World Rats and Mice

Muridae – Mice, etc.

This is the largest family of rodents and the largest of mammals (Wikipedia 2016). Although the family name is derived from the Latin *mus*, meaning mouse, it also includes some kinds of voles, rats, and others. None is native to North America, but a number of species have arrived here, presumably with humans.

Micromys minutus – Eurasian Harvest Mouse

The Eurasian Harvest Mouse (*Micromys minutus*; Figure 76-Figure 78) has a wide distribution in the temperate and humid climate zone of East Asia and western Europe (Harris & Trout 1991). In urban environments, the habitat may differ, but Dickman (1986) found that even in such a setting fecal pellets can contain small amounts of moss.

Figure 78. Completed summer nest of *Micromys minutus*. Photo by Alexis Martin, through Creative Commons.

***Myodes* = *Clethrionomys* – Red-backed Voles**

It seems that there is no agreement among systematists as to the preferred generic group name for these voles. I have chosen to use *Myodes*, but with nothing more than convenience to back up my choice. Furthermore, rodents with the common name of vole are in both the **Muridae** and the **Cricetidae** (covered in the next subchapter).

Longton (1992) states that mosses are "freely consumed" by Arctic and alpine voles. Voles seem to at times make important uses of mosses. In her messages to Bryonet on 3 December 2004 and 12 January 2008, Kate Frego described some of the relationships of the voles to bryophytes. She reported that they clipped the *Dicranum polysetum* (Figure 13) they had earlier avoided as food. Frego states that this is only anecdotal data, but she observed quite extensive "clipped" pathways of *Dicranum polysetum* as the snow melted, with some areas resembling "rooms" with nests, others with copious mouse droppings.

In the sub-nivean tunnels that they made, they had trimmed off all the moss tips into neat, compact carpets!

Mosses are able to offer other advantages to both the rodents and their food plants. The moss layer provides a temperature stabilizing factor (Fuller *et al.* 1969). The temperature lag is greater in the moss than in the layer under the snow. Furthermore, when snow melts and refreezes, the structure of the snow changes, causing a sharp increase in its thermal conductivity. Hence, the snow layer experiences wide temperature fluctuations, whereas these are considerably damped in the moss layer (Figure 79).

Figure 79. Daily moss (cross-hatched box), snow 5 cm above moss (open box), and air temperatures (vertical line). Beginning 1 April, physical structure of the snow was changing. Redrawn from Fuller *et al.* 1969.

In the Alaskan Arctic tundra, experiments in which mosses were removed demonstrated that *Sphagnum* (Figure 42) removal permitted an increase in the shrub *Betula nana* (Figure 80) (Gough *et al.* 2007). Hence, vole activity could change the vegetation patterns in these Arctic systems. Unfortunately, Gough *et al.* (2007) did not have any data on the relationship of *Sphagnum* to vole activity.

Figure 80. *Betula nana*, a shrub that benefits when a rodent damages the *Sphagnum*. Photo by Foledman, through Creative Commons.

The diet of *Myodes* differs among species, but also differs within species among habitats (Hansson 1985). For example, *Myodes glareolus* (Figure 24) feeds mostly on seeds in the deciduous forest and on fungal tissues in coniferous forests.

***Myodes rufocanus* – Grey Red-backed Vole**

The grey red-backed vole (*Myodes rufocanus*; Figure 23) extends through a large range in the northern Palearctic from northern Fennoscandia through northern Russia, and northeastern and northern Korea and the islands of Sakhalin (Russia), and Japan (Abe *et al.* 2005), then far south to northern parts of Mongolia and China (Wilson & Reeder 2005).

Myodes rufocanus (Figure 23) is often common in areas where Norwegian lemmings (*Lemmus lemmus*; Figure 28) reside, but unlike the lemmings, the voles do not usually eat the mosses, preferring blueberry plants (*Vaccinium myrtillus*; Figure 81) and other dicots instead (Kalela 1957; Virtanen *et al.* 1997). This separation of diets keeps them from competing for food in this food-limited environment.

Figure 81. *Vaccinium myrtillus*, common food of *Myodes rufocanus*, the grey red-backed vole. Photo by Anneli Salo, through Creative Commons.

The summer nest of *Myodes rufocanus* is constructed of grass, leaves, lichens, and moss (Chester 2016).

***Myodes rutilus* – Northern Red-backed Vole**

The northern red-backed vole (*Myodes rutilus*; Figure 82) is distributed in the northern Holarctic, including northern Fennoscandia, European Russia, Siberia, north Xinjiang Province in China, through Mongolia, to northeast China and northern parts of the Korean peninsula, the islands of Sakhalin (Russia), Hokkaido (Japan), Alaska (USA), and Canada (Linzey *et al.* 2016). It lives in the subarctic birch forest zone and in northern parts of the boreal forest zone. Its greatest abundance is in productive (eutrophic or mesotrophic) forests, with a dense understory of grasses, herbs, or moss. It prefers mature old-growth forests, but, unlike other *Myodes* species, it is absent from clear-felled areas. It is herbivorous, eating green parts of grasses and herbaceous plants, nuts, seeds, bark, lichen, fungus, and insects, storing food for winter. In the autumn it stores seeds.

Figure 82. *Myodes rutilus*, a species that lives in mossy spruce forests. Photo by Zbyszek Boratynski, through Creative Commons.

The habitat of the northern red-backed vole (*Myodes rutilus*; Figure 82) can change with seasons. In the Daisetsu Mountains of Japan, the vole was captured in areas with dense cover of the bamboo *Sasa* and a thin cover of mosses in July (Onoyama 1989). However, in September it showed a preference for dense tree cover.

In Alaska, West (1977) found a seasonal difference in the dispersion pattern of the northern red-backed vole. In summer, they lacked any pattern of aggregation. During midwinter they had moved to just one section of the trapping grid. In early spring, they once more dispersed with no pattern of aggregation. When West analyzed the vegetation structure, he found that the area of winter aggregation had a significantly thicker moss layer than the areas used in the summer. West considered this to indicate that the aggregation was the result of a limited area of suitable moss cover for overwintering.

The food of *Myodes rutilus* (Figure 82) is primarily seeds from dwarf shrubs and forbs, lichens, and above and belowground fungi (West 1982). I found no evidence that the voles eat bryophytes, so it is likely that the mosses serve to provide space for moving around between the snow and the frozen ground.

***Myodes gapperi* – Southern Red-backed Vole**

The southern red-backed vole (*Myodes gapperi*; Figure 83) is also known as *Clethrionomys gapperi*, living in Canada and the northern United States (Wikipedia 2017b). Pivorum and Bunch (2005) stated that its ideal habitat would be mesic with an abundance of litter, rotting logs, moss-covered rocks, exposed roots, and rock crevices. It often is restricted to mossy habitats (Headstrom 1970). It may burrow beneath *Sphagnum* (Figure 42) to make its nest, concealing it from view (Headstrom 1970). In peatlands it uses moss, among other bits of vegetation, to line the nest (Linzey & Brecht 2002).

In these peatlands and elsewhere it uses natural runways among the mosses, roots, and rocks (Linzey & Brecht 2002). *Myodes gapperi* (Figure 83) uses runways in warm weather, but tunnels through the snow in winter (Wikipedia 2017b). In New Jersey, USA, the red-backed vole lives only in *Sphagnum* peatlands of the pine barrens, where during winter, the moss is often frozen, necessitating using food gathered earlier for its winter supply (Stone & Cram 1902).

Figure 83. *Myodes gapperi*, southern red-backed vole, with *Sphagnum*. Photo by Phil Myers, through Creative Commons.

In humid forests it often occurs among mossy rocks (Komarek & Komarek 1938). Craig *et al.* (2014) hinted at the possibility that mosses may contribute to needed cover in areas with limited or no downed wood. It is the most abundant mammal among the tundra vegetation on Mt. Washington, New Hampshire, USA, where it lives among mosses, rocks, and dwarf willows. In a study comparing this species with *Peromyscus keeni* (mice) in Alaska, the southern red-backed vole preferred habitats with more moss cover than that of *P. keeni* (Smith *et al.* 2005). In fact, the growth of the young mice is inversely correlated to the percent cover of mosses on the forest floor. But in spring, even the voles have a negative correlation with moss, perhaps due to those sites being wetter.

Hodson *et al.* (2010) found that the southern red-backed voles responded to moisture availability. When moss cover was low, the voles had either reduced maximum potential fitness or an increased relative rate of decline of fitness with density. This species has high water requirements (Getz 1968) and generally occurs in mesic forests with moist microclimates and moss cover (Morris 1996; Orrock *et al.* 2000). The most abundant mosses in their habitats were *Pleurozium schreberi* (Figure 8), *Ptilium crista-castrensis* (Figure 11), and *Sphagnum* spp. (Figure 42). Hodson and coworkers (2010) found that in cut vs uncut forest stands, moss cover was the most important parameter in determining success of *Myodes gapperi* (Figure 83). They did not determine if the moss was essential, but rather it could be that the moss also occurred in the most moist habitats.

The red-backed voles (*Myodes* spp.) are both omnivorous and opportunistic, with a diet that changes with the seasons and availability (Boonstra & Krebs 2012). In North America in spring and late fall, they mainly feed on dicot leaves. In summer and fall they eat seeds, berries, fruits, and insects. Throughout the year they also include monocots, mosses, and lichens (Perrin 1979; Vickery 1979; Merritt & Merritt 1978; Merritt 1981; Martell 1981).

Côté *et al.* (2003) reported 3% or more bryophytes in the gut of *Myodes gapperi* (Figure 83) in a black spruce

(*Picea mariana*; Figure 84) forest. In a study in West Virginia, USA, small amounts of moss were retrieved from a few red-backed vole stomachs, but these never formed a major food source (Schloyer 1977). Maser and Maser (1988) emphasized that lichens were particularly important in winter in the Cascade Mountains of North America. However, these become depleted under the snow, forcing the voles to eat vascular plants and mosses. This is especially important because these voles do not hibernate, but are active year-round.

Myodes glareolus – Bank Vole

The bank vole, known by *Myodes glareolus* (Figure 85) and *Clethrionomys glareolus* (depending on your perspective), occurs from Europe through Central Asia (Jonsson *et al.* 2000; Macdonald 2001). This species builds its nest in a hole under the ground, but spends much of the day active above ground (EOL 2017a).

Figure 85. *Myodes glareolus* peering out of a tree hole. Photo by Johan Dierckx, Nature Diary.

In Poland, *Myodes glareolus* (Figure 85) was present in live and snap traps in *Sphagnum* (Figure 42) peat bogs and were predominant in that type of trapping (Cienchanowski *et al.* 2012). Torre and Arrizabalaga (2008) determined the habitat preferences of *Myodes glareolus* in a Mediterranean mountain range. They found that mosses accounted for far more (90%) of the variance than other measured environmental parameters. The bank voles preferred moist habitats where mosses were more abundant. But were the mosses important to them, or was it that the same habitat suited both the mosses and the bank voles? This is a recurring question with the voles and needs to be experimentally tested.

Myodes glareolus (Figure 85) does not appear to eat mosses as a regular diet component, but it is a herbivore, eating leaves of woody plants, soft fruits and seeds, and leaf litter (in winter) (Watts 1968). The mosses do occasionally enter consumption Figure 86), perhaps because it is an easier means to get the seeds or the springtime arthropods when they are present among the mosses. Bank voles in northern Sweden consumed mosses at a frequency of about 20% of their diet (Hansson 1979), suggesting that habitat, and perhaps latitude, may influence diet choices.

Figure 86. *Myodes glareolus*, bank vole eating mosses in the Netherlands. Photo by Andrew Spink, with permission.

In European forests, the bank vole is the dominant small rodent species (Hansson 1983). It uses the moss *Mnium hornum* (Figure 44) for winter cover, as well as odd decaying logs (Kikkawa 1964). In these habitats, it consumes small amounts of moss, but bark is its primary food, especially in some winters (Hansson 1983). Gębczyńska (1976) likewise found mosses in gut analyses, being present in 30% of the vole stomachs in spring in an oak hornbeam forest. Nevertheless, vegetative parts of plants and insects comprised the major portion of the diet.

***Apodemus sylvaticus* – Wood Mouse**

The ubiquitous wood mouse, *Apodemus sylvaticus* (Figure 87), is distributed throughout Europe (with the exception of Finland and northern parts of Scandinavia, the Baltic, and Russia) and parts of North Africa (Schlitter 2016). It uses mosses, leaves, and grass to construct its nest (Duke 2011). In Berkshire, UK, winter cover is provided by the moss *Mnium hornum* (Figure 44) (Kikkawa 1964). The wood mouse does not appear to eat

mosses as a regular diet component, but rather is a seed eater (Watts 1968). The mosses do occasionally enter consumption, perhaps because it is an easier means to get the seeds and the springtime arthropods when they are present among the mosses.

Figure 87. *Apodemus sylvaticus*, wood mouse, a species that uses mosses in its nest. Photo by Mick E. Talbot, through Creative Commons.

***Pseudohydromys* and *Mirzamys* – Moss Mice**

These little-known genera have several species in the mossy forests of New Guinea (Helgen & Helgen 2009). I have been unable to find out why these are called moss mice. Perhaps it is because many of the species live in mossy forests. Likewise, little is known of their biology. We can only infer that mosses have some importance in the choice of habitat by some species. These moss-dwelling Papua New Guinea species include *Pseudohydromys eleanorae*, *P. murinus*, and *P. ellermani* in mossy montane forest; *P. occidentalis* (Indonesia and Papua New Guinea) and *P. fuscus* in mossy mid and upper montane forest; *P. musseri* in mossy upper montane forest (Helgen & Helgen 2009; Helgen & Wright 2017).

The related genus *Mirzamys* likewise is known from mossy upper montane forests in New Guinea (Helgen & Helgen 2009). *Mirzamys louiseae* occurs here and *M. norahae* lives in mossy rainforest habitats that can be characterized as elfin or upper montane forest.

***Otomys sloggetti* – Sloggett's Vlei Rat**

The Sloggett's Vlei Rat (*Otomys sloggetti*; Figure 88) occurs typically in habitats with xeric soils and rocky outcrops of South Africa, but Lynch (1992) found it to be in large numbers in a mesic bog with no rocky outcrops. In the bog habitat, it was a burrower, occupying an extensive burrow system. The young are born during the warm wet months of October to March.

Figure 88. *Otomys sloggetti*, a species that lives in boggy habitats. Photo by Terry Rosenmeier, through Creative Commons.

The boggy habitats are characterized by numerous hummocks about 20 cm high and 30 cm in diameter. Lynch (1992) suggested that these were originally formed by burrowing by *Cryptomys hottentotus* (Figure 48). Then the *O. sloggetti* (Figure 88) enlarged and cleaned the tunnels. These excavated areas are colonized by various tracheophytes, especially dwarf sedges, and mosses. The activity of the voles adds soil to the top, creating the hummock landscape. Others consider the hummocks to originate from freeze-thaw activity and not by the rodent activity.

***Rattus rattus* – Black Rat**

The black rat (*Rattus rattus*; Figure 89) has travelled with humans, earning it the alternative name of ship rat. As a result of this human association, it is known from all continents (EOL 2017b).

Figure 89. *Rattus rattus*, black rat, in tree in New Zealand, a species that includes mosses in its varied diet. Photo by James Russell, with permission.

The diet of the black rat is almost as varied as its distribution. Clout (1980) found that in a *Pinus radiata* plantation it consumed invertebrates, fungi, and plant material, including mosses and pine needle fragments. Unlike many of the voles, no seeds or fruits were eaten.

Tobin *et al.* (1994) found seasonal changes in the diet of rats in a Hawaiian macadamia orchard. Mosses occurred in 48% of the rat stomachs, with a mean of 4% of the diet. The moss *Sematophyllum caespitosum* was a ubiquitous moss there on branches and tree trunks.

Leptomys – Water Rats

The genus *Leptomys* (Figure 90) generally occurs in mossy locations where it is endemic in New Guinea (Musser *et al.* 2008). Their habitats are often in the montane forests where they tend to be terrestrial but amphibious and are often similar to small-bodied mice or shrews that specialize on foraging among dense mosses and litter. Both *Microhydromys* (Figure 91) and *Pseudohydromys* (Figure 92) in New Guinea seem to be similarly adapted for foraging in dense moss and leaf litter. *Paraleptomys* likewise has a body form similar to that of *Leptomys*. Musser and coworkers suggested that their small size and movements adapt *Leptomys* species to moving over the forest floor by hopping, and they have the ability to escape predators by "leaping in unexpected directions." The genus is nocturnal and carnivorous. Members live underground in nests they dig in the forest floor of tropical lowland evergreen and tropical montane evergreen rainforests.

Shrew Rats

Tucked away in the mossy forest of Sulawesi (Figure 93) in Indonesia is a group of Muridae known as shrew rats (Esselstyn *et al.* 2012). These are unique in lacking cheek teeth. They furthermore lack gnawing incisors, but instead have bicuspid upper incisors.

Figure 93. Sulawesi Moss Forest Gandangdewata. Photo courtesy of Kevin C. Rowe, Museums Victoria

Sulawesi is an island of Indonesia, formerly known as the Celebes. Approximately 62% of the mammalian species are endemic (Wikipedia 2018). The shrew rats are among these endemic species (Esselstyn *et al.* 2012). They run about among the mossy forest, and one must wonder if their peculiarities have been selected for the structure of their habitat.

Paucidentomys vermidax

The generic name *Paucidentomys* of this unusual mouse translates into few-toothed mouse, while *vermidax* refers to it as a worm devourer (Pappas 2012). These shrew rats were trapped in pitfalls in wet mossy forests at high elevations on Sulawesi Island in Indonesia.

Figure 94. *Paucidentomys vermidax* in Sulawesi. Photo courtesy of Kevin C. Rowe, Museums Victoria.

The newly described *Paucidentomys vermidax* (Figure 94) was collected in two pitfall traps in the mature forest. The diet of soft-bodied earthworms is consistent with the lack of grinding teeth. Esselstyn *et al.* 2015) suggested that *P. vermidax* was a specialist on earthworms of the moist forests above ca 1500 m. The researchers conjecture that the mouth was used only for food capture, not for processing it.

Hyorhinomys stuempkei

Paucidentomys (Figure 94) was not the only shrew rat to be running around among the mosses in Sulawesi forests. In 2015, Esselstyn *et al.* named *Hyorhinomys stuempkei* (Figure 95-Figure 96) as another shrew rat there. It has a distinctive large, flat, pink nose in which the nares face forward like a pig's (Figure 94). It is further distinctive in having especially large ears. But alas, so far only five of these are known, so habitat needs are speculative.

Figure 95. New genus and species (*Hyorhinomys stuempkei*) of hognose rat in Sulawesi. Photo by Kevin C. Rowe, Museums Australia, with permission.

Figure 96. *Hyorhinomys stuempkei* in Sulawesi. Photo courtesy of Kevin C. Rowe, Museums Victoria.

In addition to *Paucidentomys* (Figure 94) and *Hyorhinomys* (Figure 95-Figure 96), shrew rats on Sulawesi include *Echiothrix* (Figure 97), *Melasmothrix* (Figure 98), *Sommeromys* (Figure 99), and *Tateomys* (Figure 100-Figure 101) (Esselstyn *et al.* 2015). The addition of *Paucidentomys* brings the number of shrew rats on Sulawesi to six genera and eight species. The habitat for this latest species is undisturbed lower montane forest where mosses are abundant and cover much of the surfaces, including canopy epiphytes.

Figure 97. *Echiothrix centrosa* from lowland forest of Sulawesi; some members of this genus occur in the mossy forest, but not this one. Photo courtesy of Kevin C. Rowe, Museums Victoria.

Figure 100. *Tateomys macrocercus* in a Sulawesi mossy forest. Photo courtesy of Kevin C. Rowe, Museums Victoria.

Figure 101. *Tateomys rhinogradoides* in a Sulawesi mossy forest. Photo courtesy of Kevin C. Rowe, Museums Victoria.

Gracillimus radix

The slender root rat, *Gracillimus radix* (Figure 102-Figure 103), was discovered in 2016 in the Indonesian island of Sulawesi (Rowe *et al.* 2016). This species forages among the roots (Phillips 2016), where it eats both plants and animals (Rowe *et al.* 2016). Phillips suggested that its excessive whiskers (Figure 104-Figure 105) may help it find food (presumably roots and insects) among the mosses and roots of its native forest.

Figure 102. *Gracillimus radix* in Sulawesi mossy forest. Photo by Kevin C. Rowe, Museums Victoria, with permission.

Figure 103. *Gracillimus radix* in Sulawesi, showing the small digits on the paw. Photo by Kevin C. Rowe, Museums Victoria, with permission.

Bunomys

Eight species of *Bunomys* are present on Sulawesi (Musser 2014). All are nocturnal, terrestrial, and endemic to the island. Not enough is known about the physiology or behavior of the genus to generalize on the importance of the mosses to its habitat. They could maintain the moisture needed for the *Bunomys*, or for its food organisms. They could be important cover against predators. They might

provide nesting materials – mosses were used in nests made in cages in the lab. But the *Bunomys* species may simply prefer the same habitats where these mosses thrive.

Figure 104. *Gracillimus radix* in Sulawesi mossy forest, showing the long whiskers. Photo by Kevin C. Rowe, Museums Victoria, with permission.

Figure 105. *Gracillimus radix* in Sulawesi, showing the unusual nose. Photo by Kevin C. Rowe, Museums Victoria, with permission.

Bunomys chrysocomus is relatively widespread on the island, occurring in both lowland tropical evergreen and montane rainforests, occupying an elevational range of 250-2200 m (Musser 2014). It was found one night in a runway beneath a rotting, moss-covered tree trunk of the forest floor. On another occasion it was 1.5 m above a stream in a damp, moss-covered rock cliff face. Others were in dense undergrowth with no mosses. The *B. chrysocomus* seem to have a broad diet of invertebrates, small vertebrates, and fruit, with earthworms appearing to be one of the preferred foods. The latter are broken into pieces in the mouth.

Figure 106. *Bunomys chrysocomus* in mossy forest of Sulawesi. Photo courtesy of Kevin C. Rowe, Museums Victoria.

Bunomys coelestis is endemic to montane forests on Gunung Lompobatang, the high volcano at the southern end of the southwestern peninsula of Sulawesi (1829-2500 m) (Musser 2014).

Bunomys prolatus is only known from the mountain forest on Gunung Tambusisi (1982 m), where it has been captured among mosses (Musser 2014). The habitat is one of short trees (4 m) with a heathlike vegetation and deep moss cover. All but one individual was trapped at night. That one was in deep moss during the day, suggesting the mosses may serve as daytime cover.

Bunomys torajae is from montane forest on Gunung Gandangdewata (2500-2600 m) (Musser 2014).

Bunomys fratorum (Figure 107) seems to be restricted to the northeastern end of the northern peninsula, occupying lowland tropical evergreen and montane rainforests (coastal plain to 1982 m) (Musser 2014).

Bunomys andrewsi occurs mainly in lowland tropical evergreen rainforests in the core of Sulawesi and the coastal plain to 1600 m (Musser 2014). It is not restricted to primary forest, occurring also in secondary growth and even village gardens. Some of its habitats are very mossy. Stomach contents included figs, seeds, termites, and insects, especially larvae. In one case fragments of moss were found in the stomach, possibly being consumed along with insects.

Bunomys penitus (Figure 108) seems to be restricted to montane regions of the west-central mountain block and Pegunungan Mekongga (1285-2287 m) (Musser 2014). It was collected in a runway beneath a moss-covered tree trunk on the forest floor. Among the collections, many were caught in traps placed in runways in the spaces beneath the moss-covered tree roots or associated with decaying moss-covered trunks. However, in an area with thick mosses (2.5 cm), there was no path worn in the moss. Nevertheless, in the primary tropical lower and upper montane rain forest (1740-2287 m) this species frequently was trapped beneath old treefalls that had become covered with dense moss, decaying into the wet forest floor or in

other association with mosses. The mosses may actually have been an impediment to food capture. Earthworms and other invertebrates would require excavation from beneath the thick moss mat. *Bunomys penitus* has short front claws compared to those of *B. chrysocomus*, *Melasmothrix*, and *Tateomys*, making it difficult for *B. penitus* to extract the food items. Snails were eaten by biting away edges of the shell to get at the soft body. Bits of moss were sometimes consumed when they adhered to consumed fungi.

Figure 107. *Bunomys fratorum* in mossy forest of Sulawesi. Photo courtesy of Kevin C. Rowe, Museums Victoria.

Figure 108. *Bunomys penitus* in mossy forest of Sulawesi. Photo courtesy of Kevin C. Rowe, Museums Victoria.

Bunomys karokophilus is currently known only from lowland tropical evergreen rainforest in the northern portion of the west-central mountain block (823-1150 m)

(Musser 2014). It is often associated with mossy habitats. It gets its name because it seems to feed almost exclusively on karoko, an ear fungus, *Auricularia delicata* (Figure 109). The karoko grows only on wet, decaying tree trunks and limbs on the ground. These are usually free of other kinds of fungi and lack extensive moss cover.

Figure 109. *Auricularia delicata* group, primary food for *Bunomys karokophilus*. Photo by Josef Papi, through Creative Commons.

Summary

Rodents can have major impacts on the bryophyte communities, especially in the Arctic. Many rodents have mosses in the gut and feces, but these often seem to be the result of accidental intake. Nevertheless, some rodents seem to include bryophytes as an important part of the diet, often increasing the percentage of intake in winter. Researchers have suggested that this switch may be a need for nitrogen, arachidonic acid, or fiber. In other cases, it may be a simple matter of availability. A number of **Microtine** rodents consume mosses in the winter, even though the mosses are poorly digested, being high in fiber, and providing little nitrogen or digestible energy, but often the nutrient content in the Arctic is superior or differs little from that of tracheophytes in the region.

The shoot tips seem most desirable for food, but in winter the moss may be clipped at the bottom. Some records indicate that moss capsules are also eaten. Such grazing in northern habitats can have severe impacts on the moss communities, as indicated by exclosures. A 1-year time lag between feeding and the evidence of bryophyte species changes is common. Weft and other large species can benefit from regeneration from rhizomes and dispersal of fragments or propagules.

Many rodents use mosses in the construction of nests, particularly as part of the lining. In bogs, several species may coexist in a single bog, some using them for food or to make nests, tunnels, or runways.

Bryophytes are impacted by the rodents in multiple ways. Negative impacts include diminished cover and competition from flowering plants. But at other times

they may benefit through exposed soil and removal of taller grasses. The rodents can also serve as dispersal agents, and runways open new habitats where colonizers can grow, increasing diversity.

Moss users in the **Muridae** include *Micromys minutus* (minor food), *Myodes rufocanus* (among nest materials), *M. rutilus* (aggregate in mosses in winter), *M. gapperi* (mossy habitats, minor food), *M. glareolus* (mossy habitats, winter cover, minor food), *Apodemus sylvaticus* (minor food, winter cover), *Pseudohydromys* (mossy rainforest), *Mirzamys* (mossy rainforest), *Otomys sloggetti* (makes hummocks in bogs), and *Rattus rattus* (minor food).

Shrew rats seem to be primarily associated with mossy areas and some seem to be physically adapted to foraging among the bryophytes. There is no evidence thus far that they choose bryophytes as food.

Acknowledgments

This chapter has benefitted greatly from anecdotal records sent to me by bryologists and friends who observed these small rodents interacting with mosses in the field. Kate Frego has provided invaluable anecdotal experience to me. Kevin Rowe was particularly helpful in sharing papers, photographs, and personal observations.

CHAPTER 17-2

RODENTS – MUROIDEA: NON-MURIDAE

TABLE OF CONTENTS

Cricetidae – Hamsters, Voles, Lemmings, and New World Rats and Mice	17-2-2
<i>Chionomys nivalis</i> – Snow Vole	17-2-2
<i>Microtus agrestis</i> – Field Vole	17-2-3
<i>Microtus pennsylvanicus</i> – Gull Island Vole	17-2-3
<i>Microtus oeconomus</i> – Tundra Vole	17-2-5

CHAPTER 17-2

RODENTS – MUROIDEA: NON-MURIDAE

Figure 1. This exposed runway of the heather vole (*Phenacomys intermedius/ungava*) shows the clippings of mosses and barren nature of their path. According to Kate Frego, this appearance is common when the snow melts in the spring. Photo courtesy of Kate Frego.

Cricetidae – Hamsters, Voles, Lemmings, and New World Rats and Mice

The voles, lemmings, and muskrats are known as the microtine rodents, the **Microtinae**. This subfamily comprises the largest numbers among the **Rodentia** in the Northern Hemisphere. They are distinguished by their molar teeth, which have prismatic cusps in the shape of alternating triangles. These sharp teeth are suitable for grinding and are an adaptation to the herbivorous diet. Batzli and Jung (1980) demonstrated that microtine rodents near Atkasook, Alaska, eat mosses.

Chionomys nivalis – Snow Vole

The snow vole (*Chionomys nivalis*; Figure 2) is distributed from southern Europe to the Near and Middle East (Castiglia *et al.* 2009), extending to the Caucasus, Turkey, Israel, Lebanon, Syria, and Iran (Shenbrot & Krasnov 2005). The European populations are restricted to

rocky and mountainous areas at mostly higher elevations (Castiglia *et al.* 2009).

Figure 2. *Chionomys nivalis*, a species that may suffer from heavy metal toxicity by eating bryophytes and lichens. Photo by Svíčková, through Creative Commons.

Janiga *et al.* (2016) reminded us of the role mosses could play in consumption of lead and other pollutants by this and other microtine species. The concentrations of Pb, Cd, Zn, and S in mosses from the Alps revealed rising levels with altitude, despite the scarcity of pollutants at higher elevations (Zechmeister 1995; Šoltés 1998). These pollutants seem to have arrived with the precipitation through long-distance transport. Several researchers have suggested that mosses (and lichens) may have a significant influence on the lead concentrations in *Chionomys nivalis* (Figure 2) (Sivertsen *et al.* 1995; Belcheva *et al.* 1998; Metcheva *et al.* 2008; Janiga *et al.* 2012). Janiga and coworkers considered this to be a special problem due to winter consumption of mosses.

***Microtus agrestis* – Field Vole**

The field vole (*Microtus agrestis*; Figure 3) is a widespread European Palaearctic species, ranging from western Europe eastwards through Russia to Lake Baikal in south-east Siberia.

Figure 3. *Microtus agrestis* among mosses. Photo from Wikimedia Commons.

It is not just in the Arctic that rodents eat mosses. Ferns (1976) found that *Microtus agrestis* (Figure 3) eats both mosses and liverworts in a larch plantation in Great Britain. The mosses comprised 20% of the area of materials in the feces (scat) under the microscope. *Microtus agrestis* exhibits seasonal differences in diet. Grasses are the primary food, with the greatest consumption rate in winter (Faber & Ma 1986). Herbs and mosses are also important, especially in spring and summer. Considerable variability occurs in the diet, depending on the kind of habitat and time of year. The moss *Hypnum cupressiforme* (Figure 4) forms an important part of the diet, but it is interesting that it seems not to be consumed in winter.

In a study of small rodents in Scandinavia, Hansson (1971) demonstrated the need of more water by herbivores than that needed by granivores. This can explain their choice of mossy habitats and may even explain their consumption of the mosses.

Microtus agrestis (Figure 3) in Fennoscandia exhibits population cycles (Turchin & Hanski 2001). Many researchers have attempted to model these cycles, but causes are still controversial. Turchin and Hanski concluded that their evidence supports the predation hypothesis. Many models have considered food to be the

driving factor, but Turchin and Hanski considered this to hold only in systems like the moss-eating lemmings. Nevertheless, a disappearance of mosses due to consumption, runways under snow, or fires could make the habitat unsuitable for these small, moisture-dependent rodents.

Figure 4. *Hypnum cupressiforme* var *cupressiforme*, an important food for *Microtus agrestis*. Photo by David Holyoak, with permission.

Like *Chionomys nivalis* (Figure 2), *Microtus agrestis* (Figure 3) are subject to consumption of heavy metals that have become incorporated into their food items (Ma *et al.* 1991). And these can enter their bodies with mosses as the carrier. Fortunately, *Microtus agrestis* consumes only small amounts of *Hypnum cupressiforme* (Figure 4) in these areas, a moss known to contain considerably more lead and cadmium than the flowering plants in the diet.

***Microtus pennsylvanicus* – Meadow Vole**

The meadow vole (*Microtus pennsylvanicus*; Figure 5) is the North American counterpart of *M. agrestis* (Figure 3). It occurs throughout most of Canada and Alaska, USA, south through the northern half of the United States, to Oregon, northern Utah, central New Mexico, Kansas, northern Missouri, Georgia, and South Carolina; it is disjunct (by 500 km) in Florida, USA, and Chihuahua, Mexico (Hall 1981; Cassola 2016a).

Figure 5. *Microtus pennsylvanicus*, a species that makes paths among mosses. Photo by John White, with permission.

These voles occupy a wide variety of habitats, ranging from dry pastures and wooded swamps to marshes and orchards (Cassola 2016a). The soil needs to be loose and organic to permit tunneling. Their underground tunnels are extensive. In Wisconsin, Getz (1970) found that the meadow vole inhabits areas that have a dense, spongy mat comprised of several moss species. The voles make paths among these mosses, but the paths do not have the character of distinct runways.

The meadow vole seems to prefer introduced species over native ones for its food (Thompson 1965), perhaps indicative of its European ancestors. When given 30 plant species choices from a variety of habitats, eight of the top ten chosen foods were introduced species. By contrast, the native boreal plants and bog plants occupied the last eight positions of preference. Peat moss (*Sphagnum*; Figure 6) was scarcely touched.

Figure 6. *Sphagnum capillifolium*, in a genus among the least preferred among the 30 plants provided to *Microtus pennsylvanicus* as food choices. Photo by David Holyoak, with permission.

Kate Frego relates that during her summer PhD research in the boreal forest of northern Ontario, Canada, she observed both red-backed voles (*Myodes*) and meadow voles (*Microtus pennsylvanicus*; Figure 5) eating moss shoots, tips first. "I did a little test with the meadow voles (which are placid enough to sit on my hand and eat!), and offered them choices which I ranked. I have to say it was a small sample size, 4 voles as I recall, but they were very consistent! They seemed to 'prefer' *Ptilium crista-castrensis* (Figure 7), and *Pleurozium schreberi* (Figure 8), would occasionally take *Ptilidium ciliare* (Figure 9), and politely declined all the *Dicranum* spp. I had at hand [*D. polysetum* (Figure 10) and *D. scoparium* (Figure 11)]. Unfortunately, I have no info on whether the munched vegetative bits survived passage through their guts. (I actually have photos of one meadow vole scoffing down a *Ptilium* shoot)."

Figure 7. *Ptilium crista-castrensis*, a moss eaten by *Phenacomys intermedius*. Photo by Janice Glime.

Figure 11. *Dicranum scoparium*, one of the preferred forest mosses for the wood lemming. Photo by Janice Glime.

Linzey (1984) cautioned that estimates of mosses in fecal samples of this and other rodents may be overestimates of the diet percentage because they, along with monocots, have poor digestibility (Batzli & Pitelka 1971), giving them over-representation. Linzey found that mosses were only eaten by *Microtus pennsylvanicus* in winter, whereas Frego observed them eating mosses in summer.

***Microtus oeconomus* – Tundra Vole**

The tundra vole, *Microtus oeconomus* (Figure 12), has the northernmost distribution of any of the North American species of *Microtus*, and is common also in the northern parts of Eurasia (known there as root voles) (EOL 2017a). Although the habitat preference is moist meadows near water, the tundra vole can also inhabit *Sphagnum* bogs (Figure 13) (Ciechanowski *et al.* 2012).

Alaskan populations of the tundra vole consume mosses, but these comprise less than 10% of the diet (Batzli & Jung 1980). Batzli and Jung (1980) suggested that grazing pressure by the tundra voles may be competitive with both the brown lemmings (*Lemmus sibiricus*; Figure 14) and collared lemmings (*Dicrostonyx torquatus*) because of overlapping food niches, thus restricting the distribution of the voles through competition with lemmings.

***Microtus pinetorum* – Pine Vole, Woodland Vole**

The woodland vole (*Microtus pinetorum*; Figure 15) is distributed from extreme southern Ontario, Canada, and throughout the eastern United States with the exception of peninsular Florida and the coastal plains of the southeastern

states; there is a disjunct population in Texas (Cassola 2016b). The rock vole (*Microtus chrotorrhinus*; Figure 16) and the woodland vole (*Microtus pinetorum*) both live where there are rocks, mosses, ferns, and forbs in North America (Kirkland & Knipe 1979; Christian & Daniels 1985; Merritt 1987). This relationship suggests that these voles may depend on the bryophytes, but detailed studies seem still to be needed.

Figure 15. *Microtus pinetorum*, a woodland vole that lives in habitats with bryophytes and uses them in nesting and runways. Photo by Phil Myers, through Creative Commons.

Pine voles (*Microtus pinetorum*; Figure 15) use bryophytes for nest sites and runways (Rhodes & Richmond 1985). Given the choice of mixed loam with peat moss (3:1 vol/vol), base mixture with added gravel (3:2 v/v), or (1:1 v/v), the moles chose the loam/peat moss mixture for subsurface tunnels and nests over the other choices. In fact, they always avoided the soil/stone mix. One reason for their choice of mossy habitats may be their need for temperatures below 30°C (Rhodes & Richmond 1985). I would expect dark soil to heat more readily than moist, aerated mosses. We need data to support this, however, because we also know that mosses easily reach temperatures higher than that of air, especially at the surface (Nørgaard 1951; Hribljan & Glime, unpublished data). On the other hand, the sub-surface temperature can experience a much smaller diurnal temperature range (Nørgaard 1951).

***Microtus xanthognathus* – Taiga Vole**

The taiga vole (*Microtus xanthognathus*) inhabits northwestern Canada to Alaska (Wikipedia 2017). It lives in forested habitats near streams, lakes, or bogs. Its runways are a combination of underground and surface runways (EOL 2017c). These voles construct communal nests and food caches in August and September. The nests are made of dry grasses and are located ~15-20 cm underground. The food supply must be reached through the nest. The taiga voles huddle together in groups of 5-10 individuals, keeping each other warm and sharing the food during winter. The life span is short, as in most other voles. The young voles are born in the summer and breed the next summer. They do not survive the following winter.

The taiga vole (*Microtus xanthognathus*) requires an abundant supply of rhizomes for winter food (Wolff & Lidicker 1980; Conroy & Cook 1999). In summer it feeds on horsetails, grasses, and berries. But mosses provide it with ground cover and are a necessary part of its habitat.

***Microtus chrotorrhinus* – Rock Vole**

The rock vole (*Microtus chrotorrhinus*; Figure 16) is distributed in Canada from Labrador through the Gaspé Peninsula, New Brunswick, west to Ontario, and in the USA from northeastern Minnesota southward at higher elevations to New England, New York, and northeastern Pennsylvania, and disjunctly in the southern Appalachians to Virginia, western North Carolina, and eastern Tennessee (Kirkland & Jannett 1982; Handley & Pagels 1991).

Figure 16. *Microtus chrotorrhinus*, a species that is most abundant in moist mossy areas. Photo by Roger W. Barbour, Smithsonian Institutes, with online permission.

The rock vole in Virginia, USA, lives in sites with abundant vegetation, mosses, talus- and rock-laden slopes, typical of the habitats for this species (Orrock *et al.* 1999). In contrast to these rocky sites, in Labrador and other areas they are most common in moist mossy areas near streams and ponds, thick brush, and open-canopy forests (Buech *et al.* 1977; Kirkland & Knipe 1979; Kirkland & Jannett 1982; Lansing 2005).

Orrock and Pagels (2003) found that more mosses were present in yellow birch and other forests with rock voles than those without these rodents. The ability of mosses to ameliorate the effects of air temperature may contribute to their preference for mossy habitats (Fuller *et al.* 1969). Kirkland and Jannett (1982) considered the moss cover of yellow birch and rock vole sites to be indicative of the cool, moist microclimate there, but suggested that the mosses also may serve as a reserve food source.

One rock vole (*Microtus chrotorrhinus*; Figure 16) in New York, USA, was actually snap-trapped with the moss *Atrichum undulatum* (Figure 17) in its mouth! (Whitaker & Martin 1977). The stomach also contained the same moss in a relatively unchewed state. Among those voles examined, leafy portions of *A. undulatum* comprised 5.2% of the stomach contents.

Figure 17. *Atrichum undulatum*, a moss that forms part of the diet of *Microtus chrotorrhinus*. Photo by Brian Eversham, with permission.

These voles also pull clumps of *Sphagnum* (Figure 6) for building their nests (Martin 1971), which are lined with grass and have multiple entrance tunnels (North Carolina GAP Analysis Project 2005). In the Appalachian and Adirondack Mountains of eastern North America, this species occurs in small populations that live among large, moss-covered rock fragments (Kilpatrick & Crowell 1985).

***Phenacomys intermedius* – Western Heather Vole**

Phenacomys intermedius was once considered to include the eastern North America populations, but some authors have separated the eastern populations into *Phenacomys ungava* (Cassola 2016c). Nevertheless, some consider *P. ungava* to be only a subspecies. Since it is not always clear which species is included in the study, I will use *Phenacomys intermedius/ungava* to designate my uncertainty.

The distribution of the western heather vole (*Phenacomys intermedius*; Figure 18) extends across northern Canada from Labrador to the Yukon Territory and in the USA from the western mainland south to New Mexico (Banfield 1974; Fitzgerald *et al.* 1994). It is active both night and day.

Kate Frego (Bryonet) relays her experience with heather voles in northern Ontario, Canada: "In the summer, while trying to photograph a Heather Vole (in my hand; Figure 18), I tickled its nose with a sprig of moss, and was stunned when it grabbed the moss and ate the whole sprig."

Figure 18. *Phenacomys intermedius/ungava*, eastern heather vole. Photo courtesy of Kate Frego.

The western heather vole (*Phenacomys intermedius*; Figure 18) lives in mountains in the areas near or above **timberline** (altitude at which trees cease to grow into actual trees; treeline; Figure 19) (EOL 2017d). Their food is typically leaves, seeds, berries, and bark of willow and other shrubs. Their summer nests are underground, but winter nests occur at ground level next to a bush, rock, or stump. Their nests are comprised of twigs, leaves, and grass. Males are territorially aggressive during mating season, but in winter they may nest together to maintain warmth.

Figure 19. Treeline on mountain over Firth River in Ivvavik National Park, YT. Photo by Daniel Case, through Creative Commons.

In Minnesota, USA, the heather vole (*Phenacomys intermedius/ungava*; Figure 18) occurs in a wide range of habitats. These include open pine and spruce forests with an understory of heath, shrubby vegetation, and moist, mossy meadows (Banfield 1974; Christian 1999). These locations are not above timberline, but winters are long, cold, and snowy.

It appears that the connection of heather voles with mosses may be accidental in some cases, at least in some cases. Côté *et al.* (2003) reported that *Phenacomys intermedius/ungava* in a black spruce forest in eastern Canada had 3% or more bryophytes among the material retrieved from the gut. Other observations demonstrate that this species does indeed eat mosses (Glime 1996). It was caught in the act grabbing and nibbling the moss *Ptilium crista-castrensis* (Figure 7), from tip down to base. This vole also ate *Pleurozium schreberi* (Figure 8) and *Ptilidium ciliare* (Figure 9). On the other hand, it rejected *Dicranum polysetum* (Figure 10). The winter runways, constructed at the ground surface under the snow, were conspicuous after snowmelt by the closely clipped *Dicranum* with its clippings lying nearby (Figure 1).

***Phenacomys ungava* – Eastern Heather Vole**

The eastern heather vole (*Phenacomys ungava*; Figure 20-Figure 21) is widely distributed across Canada, but its populations seem to be sparse (EOL 2017e), partly due to its avoidance of traps. Recently most authors consider it to be part of the species *P. intermedius* (Figure 18) (Cassola 2016c). It seems to avoid traps, making it hard to estimate the population sizes (EOL 2017e). These voles often pile their food near their burrows at night,

making it accessible for daytime food. They don't hibernate, and their winter food source is unknown. Nevertheless, they clip mosses in their runways (Figure 22), potentially dispersing them to other locations.

Figure 20. *Phenacomys ungava*, a species that uses mosses in its nests. Photo by Gerda Nordquist, MN DNR.

Figure 21. *Phenacomys intermedius/ungava*, heather vole, a species that clips *Dicranum* (Figure 10) species in winter and is known to eat other boreal bryophytes. Photo courtesy of Kate Frego.

Figure 22. Close view of heather vole runway in May, showing moss clippings. Photo courtesy of Kate Frego.

Phenacomys ungava (Figure 20-Figure 21) constructs its nests just below the ground surface, using grass, moss, and other materials (Foster 1961). Braun *et al.* (2013) described the summer nests similarly as constructed of soft materials, including grass, moss, leaves, and plant down.

Its habits are poorly known because of the difficulty of trapping it and of keeping it alive.

***Arborimus albipes* – White-footed Vole**

The white-footed vole (*Arborimus albipes*; Figure 23) lives in trees in dense forests of the Pacific Northwest of North America, seldom seeing direct sunshine through the canopy (Jewett 1920). They commonly live near rivers or streams (EOL 2017f). Their home is on the moss-covered forest floor (Jewett 1920). Their burrows have never been observed, but their claws suggest that they are adapted for burrowing (EOL 2017f). They are active year-round.

Figure 23. *Arborimus albipes*, white-footed vole, an inhabitant of moss-covered forests. Photo by Michael Durham, through Creative Commons.

The abundant mosses in their native forests provide them with some of their food; seeds, fruits, fungi, and animals were absent among their ingested material (Verts & Carraway 1995).

***Arborimus longicaudus* – Red Tree Vole**

The red tree vole (*Arborimus longicaudus*; Figure 24) is another native of the Pacific Northwest (Manning & Maguire 1999). It is likely that *Arborimus longicaudus* is not a committed moss user. It eats conifer needles. Nevertheless, the nests (see discarded resin ducts in Figure 25) can contain mosses (Biswell *et al.* 2017). "From the ground, red tree vole nests generally appear as dark haphazard accumulations of twigs, needles, moss, and/or lichens on the topside of a large branch or whorl of branches against the bole of a tree." Some are known to nest under the mosses that cover large branches of old trees (Carey, in Wilson & Ruff 1999).

Figure 25. Discarded resin ducts from Douglas fir, discards from nest-making activity of *Arborimus longicaudus* (tree vole). Photo by Petrelharp, through Creative Commons.

***Peromyscus maniculatus* – Deer Mouse**

Deer mice (*Peromyscus maniculatus*; Figure 26) are the most widespread of the North American rodents (EOL 2017g), extending from the northern treeline in Alaska and Canada southward to central Mexico, but absent in the eastern United States (Baker *et al.* 1983). They likewise have a wide range of habitats, occupying almost every kind of habitat available (EOL 2017g). They can easily climb, tunnel through snow, or run about on the surface. Nests in this species are typically located in dead trees, under logs and stumps, or among mosses (Sharpe & Millar 1991). Their association with humans includes nesting in such human creations as mattresses (EOL 2017g).

Figure 26. *Peromyscus maniculatus* in a spruce tree. Photo by Phil Myers, through Creative Commons.

I opened my email one day to find a delightful story unfolding from a former undergraduate student of mine, Steve Juntikka. A fat little mouse, which was later identified as *Peromyscus maniculatus* (Figure 27), on Isle Royale was busily consuming capsules from the moss *Funaria hygrometrica* (Figure 28). Isle Royale National Park is the largest island in Lake Superior on the border of USA and Canada. The mice most likely arrived as stowaways.

Figure 27. Juvenile *Peromyscus maniculatus* on Isle Royale, Michigan, devouring capsules of *Funaria hygrometrica*. Photo courtesy of Steve Juntikka.

Figure 28. *Funaria hygrometrica* one day after the mouse dined on it, showing the orange tips of setae where capsules have been removed. Photo courtesy of Steve Juntikka.

Juntikka described the lurching behavior of the mouse (Figure 27), "Looks like the capsules were the best tasting and you have never seen those little whiskers move so fast. I could not believe the front feet moving with a doggy paddle motion to rake in the capsules. The hind legs were spread apart to balance the weight while each capsule disappeared with delight." The next day there weren't many capsules left (Figure 28).

Like most of the rodents, deer mouse populations fluctuate, typically 3-5 years, and this seems at times to be correlated with food availability (EOL 2017g). Deer mice are night active, feeding opportunistically on seeds, nuts, fruits, berries, insects, and other animal matter, as well as any human food scraps they find.

Bryophytes are not a major part of the diet, but Côté *et al.* (2003) found that the gut contained 3% or more mosses

in their black spruce habitat. The diet changes between juveniles and adults (Van Horne 1982). In a coniferous forest, the adults consumed more hard-bodied insects than did juveniles. They ate few monocots, including grasses, concentrating on dicots and ferns, but a few mosses were eaten.

***Neotoma cinerea* – Bushy-tailed Woodrat**

The bushy-tailed woodrats (*Neotoma cinerea*; Figure 29) extend from the Yukon Territory and Northwest Territories of Canada south to Arizona and New Mexico, USA, and from California east to the Badlands in South Dakota (EOL 2017h). They are very territorial, with both males and females marking their territories with a musky scent and white color on rock ridges. They pile vegetation and other collected items, making middens of a conspicuous size. These are not mere temporary constructions, but edifices on which the animals may defecate or urinate. When the middens bake in the sun, they become as hard as rocks and can last for tens of thousands of years!

Figure 29. *Neotoma cinerea*, a species that uses dry mosses and grasses in its nests. Photo by Ken Cole, USGS, through public domain.

Based on observations in five localities, Brown (1968) found that the nests themselves must be dry, relatively dark, and create inaccessibility to would-be predators (Figure 30). The portion constructed by the woodrat is often an open, cup-shaped nest composed of dry mosses and grass.

Figure 30. *Neotoma* sp., Packrat, midden in Nevada, USA. Photo by Toiyabe, through Creative Commons.

Foraging occurs at long distances from the nest, up to 470 m for females (Topping & Millar 1996). Topping and Millar suggested that this long distance may be related to availability of appropriate food. This nighttime activity is affected by the brightness of moonlight, most likely avoiding the increased predation in bright moonlight as they cross open areas to reach foraging areas with greater cover (Topping *et al.* 1999). Morton and Pereyra (2008) verified nighttime haying behavior of these rodents in Wisconsin, USA, where they gathered mostly poisonous flowering plants. They found that the food plants were cut and stacked to dry before they were placed within the dens, possibly decreasing the toxicity.

***Neotoma fuscipes* – Dusky-footed Woodrat**

The dusky-footed wood rat (*Neotoma fuscipes*; Figure 31) lives in the extreme western United States, from the Columbia River in western Oregon south to the inner Coastal Range of west-central California, and the north Sierra Nevadas, east-central California (EOL 2017k). It typically lives in woods that have a dense understory. Even though they are very small, they build large (up to 1 m in diameter and height), elaborate houses made of sticks (Figure 32). These may be located on the ground, in the tree canopy, on rocky slopes, or even in abandoned buildings. These "houses" typically include several nesting and resting chambers as well as several used for storing food and "treasures" collected from among human creations. English (1923) reported that this species uses mosses to line compartments of its nests, keeping them clean and well kept. The toilet may be within the house or outside it (EOL 2017k). Although the woodrats are solitary, these houses may be used successively by a number of woodrats. Mosses do not seem to be part of the diet.

Figure 31. *Neotoma fuscipes*, a species that uses mosses to line its nests. Picture by Mbmceach, through Creative Commons.

Figure 32. *Neotoma fuscipes* nest. Photo by Donna Pomeroy, through Creative Commons.

***Neotoma magister* – Allegheny Woodrat**

The Allegheny woodrat (*Neotoma magister*; Figure 33), an endangered species (Mengak 2002), is the only woodrat in the Appalachian Mountain range in eastern USA (EOL 2017j). The species is able to occupy a wide range of macrohabitat conditions (Castleberry *et al.* 2002). On the other hand, it chooses its habitat based on conditions of the microhabitat. Castleberry and coworkers suggested that this selection may relate to the high mobility of the species and its herbivore diet.

Figure 33. *Neotoma magister*, a species that ingests a small amount of moss. Photo by Alan Cressler, through Creative Commons.

The Allegheny woodrat forages only at night, consuming primarily fruits, nuts, seeds, leaves, and fungi (EOL 2017j). Castleberry *et al.* (2002) found that the diet typically had more than 2% moss in the Allegheny Plateau of West Virginia and Virginia, USA. There are no studies to indicate if this is digested, or if it simply comes along with seeds and fungi found among the moss stems.

***Lemmus* – Lemmings**

Lemmings (*Lemmus*) are well known moss consumers, in addition to sedges and grasses (Batzli 1993). The story of the importance of mosses to their survival has been evolving over the many years of my career.

Ever since Walt Disney filmed lemmings plunging over cliffs into the ocean during mass migrations, lemmings have gotten the reputation of being suicidal. But rumors claim that the suicidal tendency is mere fiction and that the Disney crew drove the lemmings off with helicopters.

Mosses may actually help to explain the Disney film that shows lemmings committing suicide (Ekerholm *et al.* 2001). It is doubtful that they really have any intention of committing suicide, but lemmings do tend to eat themselves literally out of house and home during the winter, then become fully exposed when the snow melts. That means they must scurry to a new location for both food and shelter. And sometimes they **might** scurry too far and reach the fiords where they **could** plummet to the ocean and be unable to climb the steep cliffs to safety. But there seems to be no scientific documentation that they actually do plummet to their deaths (Turchin *et al.* 2000). In fact, Ekerholm *et al.* (2001) contend that those lemmings that do not "jump the cliff" are actually the ones that commit suicide.

It was 1924 when Charles Elton reported that lemming populations reach the maximum density their environment permits, remain there until their predators catch up, then crash because the predator overeats. But Turchin *et al.* (2000) claim this is not true for lemmings, although it is true for voles. We do know, however, that lemmings cycle through mass migrations as a result of overpopulation that depletes their habitat. And Turchin and coworkers (2000) claim that it is the absence of mosses that triggers this moving carpet of furry bodies. Foraging on mosses on the rocky tundra, lemmings soon remove these slow-growing plants faster than the mosses can re-grow, say Turchin and coworkers. Hence, they are forced to move elsewhere or starve. Unfortunately, many fail to negotiate the dangers and energy required to cross rivers and lakes, ultimately drowning and adding credence to the Disney story.

In a 20-year study in northern Norway, Ekerholm and colleagues (2001) found a "vague" 10-year cycle for the highland lemmings. This cycle corresponds with the time required for snowbed mosses to recover from their grazing and reach a 100 g m⁻² biomass (Kyllönen & Laine 1980; Oksanen 1983). Furthermore, the crashes in lemming populations correspond to times of massive destruction of the highland mosses (Oksanen & Oksanen 1981; Moen *et al.* 1993; Ekerholm *et al.* 2001). In some areas, the lemming population can recover using grassy habitats, but in the more northern areas, recovery of mosses is necessary before a real "outbreak" of lemmings can occur (Ekerholm *et al.* 2001).

Batzli (1983), in reviewing the responses of Arctic lemmings to nutritional factors, concluded that the availability of high quality forage drives the differences in densities of the Arctic rodents between habitats and in different seasons. But in addition to nutritional quality, fluctuations in plant secondary compounds may also play a major role. The Norwegian lemming (*Lemmus lemmus*; Figure 34) continues to eat monocots in winter, but it increases its intake of mosses (Koshkina 1962; Batzli & Pitelka 1983), even though the monocots are more digestible than the mosses (Batzli & Cole 1979). As Prins (1982a) suggested, perhaps it was the secondary compound arachidonic acid that made mosses desirable, especially in preparation and duration of winter, by providing better protection against the cold.

Figure 34. *Lemmus lemmus*, the Norwegian lemming, a species that supplements its winter diet by increasing moss consumption. Photo by Argus Fin, through Creative Commons.

Turchin *et al.* (2000) questioned whether it was prey or predation that controlled lemming numbers. As predators, these rodents eat mosses, especially in winter. The lemmings (*Lemmus*; Figure 34, Figure 43) can destroy ~90% of the moss cover and cut off all the monocot shoots in their habitats (Batzli 1981), creating an open field where they must run to find food. The mosses regrow slowly, leaving the lemmings exposed when the snow melts, particularly in large populations (Turchin *et al.* 2000). This causes the predators to have a particularly easy time finding and catching the lemmings as prey. The extra food results in an increase in the predator population (Snowy Owl and others) resulting from highly successful reproduction. The Snowy Owls are strong fliers. When the lemming population subsequently crashes from the owl predation, the owls are able to migrate to other areas where prey is sufficiently abundant (Line 1997). Using graphic models of the population dynamics, Turchin and coworkers (2000) concluded that the various rodent cycles are not due to a single mechanism, making a universal explanation unlikely.

Based on the low amounts of digestible energy that lemmings appear to derive from mosses, Prins (1982a) suggested that lemmings and other vertebrates of cold climates eat mosses for reasons other than nutrition. He hypothesized that ingestion of a highly unsaturated fatty acid, arachidonic acid, may be an adaptive mechanism that helps protect against low temperatures, making the footpads more pliable. Animals do not synthesize arachidonic acid and its concentration in mosses (up to 35 % of fatty acids) is the highest reported in plants.

In addition to the leaves and stems of mosses, high Arctic lemmings also consume the capsules of mosses (Catherine La Farge, Bryonet 15 January 2008); the mosses have often been decapitated (Catherine La Farge, Bryonet 30 March 2016). Little is known about the secondary compounds of capsules, particularly with regard to seasonal changes in them.

In addition to gut analyses, flattened moss beds, and observations of lemmings eating mosses, habitat choice supports the importance of mosses in the life of a lemming (Oksanen 1983). The sites where lemmings (*Lemmus* sp.; Figure 34) were observed have five times as much moss meadow as sites where lemmings did not visit. Following the population crash of the lemmings, there was an 8.4-fold increase in the moss biomass.

Lemmings have the disadvantage of being attacked from above. They are the main food of the Snowy Owl (*Bubo scandiacus*; Figure 35), a powerful bird with a 1.5 m wingspan (Line 1997). The lemmings protect themselves in summer by living in shallow burrows or under lichen-covered rocks. However, in winter these same lemmings curl up in balls of grasses and mosses under the snow and ice. They create a maze of tunnels and emerge only to feed on buds, twigs, and bark of the dwarf tundra shrubs. It is on these feeding forays that the Snowy Owl is able to catch them for food. An adult Snowy owl will eat 3-5 lemmings per day; a pair of owls with its brood will consume 1900 to 2,600 lemmings in the period of May to September. Their breeding success is tied to years when the lemmings are numerous.

In addition to the effects of harvesting mosses for food, lemmings affect the bryophyte diversity of their Arctic habitats through the construction of runways and burrows. Lemming runways and burrows provide openings in the tundra that provide some bryophyte species with the reduced competition they need. Among these are *Bryum wrightii* (Figure 36), *Desmatodon leucostoma* (Figure 37), and *Funaria polaris* (Steere 1976).

Dale Vitt (pers. comm. January 2018) has shared his lemming experiences with me. On the Canadian Arctic Devon Island (Figure 38-Figure 39), he found that both *Funaria polaris* and *F. microstoma* (Figure 40) grew on the openings to lemming burrows (Figure 41).

Although some lemmings partition their niches by having different diets, there can be considerable overlap. Soininen *et al.* (2015) used DNA metabarcoding of feces to demonstrate diet overlap among high Arctic lemmings in the winter. Contrasting to previous analyses, they found that *Salix* dominated the diets of both collared lemmings (*Dicrostonyx groenlandicus*) and brown lemmings (*Lemmus trimucronatus*) on Bylot Island, whereas mosses were a relatively minor contribution. *Salix* is abundant on the island, and feeding by the two lemming species has little impact on its cover. Despite the paucity of bryophytes in the winter diet, Dominique Fauteux (pers. comm. January 2018) has observed the lemmings on Bylot Island eating *Polytrichum* and *Aulacomnium* heads "many, many times."

Gruyer *et al.* (2008) found, using exclosures (Figure 42)), that on Bylot Island the lemmings have little impact on plant biomass, even in peak years. This contrasts with the effects of other herbivores on the island.

***Lemmus lemmus* – Norwegian Lemming)**

The Norwegian lemming (*Lemmus lemmus*; Figure 43) is the only **endemic** (not occurring outside a restricted area) vertebrate species in Fennoscandia (Tast 1991). It typically lives in the alpine tundra (Eurola *et al.* 1984), but may expand to forests during peak population years (Tast 1991). The species faces potential extinction as a result of climate warming. It is adapted for cold weather, and geography prevents it from moving to colder regions.

Figure 43. *Lemmus lemmus*, the Norwegian lemming, a moss eater. Photo through Creative Commons.

Norwegian lemmings reproduce year-round and often reproduce under snow (Tast 1991). They can have up to 100 offspring per pair in one year (EOL 2017k). The Norwegian lemmings consume mosses year round as their primary food item, including all habitats (Tast 1991; Turchin & Batzli 2001). Nevertheless, the proportion in the diet decreases toward the end of the main breeding season. When moss consumption again rises, breeding resumes. These mosses grow even in winter in the Arctic, providing fresh food all year.

At the highest population peaks, winter consumption by various lemming species can remove the growing portions of 90-100% of both mosses and graminoids (Thompson 1955; Pitelka 1957; Koshkina 1961; Schultz 1968; Kalela & Koponen 1971; Kiryuschenko 1979;

Henttonen & Jävinen 1981; Chernyavsky *et al.* 1981; Moen *et al.* 1993). In the Kilpisjärvi region, Finnish Lapland, no large invasion of *Lemmus lemmus* (Figure 43) occurred between 1971 and 1984, resulting in continuous increase in the bryophyte biomass (Eurola *et al.* 1984). Timo Koponen (Bryonet 13 January 2008) considered *Dicranum* (Figure 10) species essential for these lemmings to survive.

Further evidence of lemming-moss relationships comes from enclosure experiments in snowbeds at Kilpisjärvi in Finnish Lapland. Despite low lemming densities during the study period, Virtanen (2000) and coworkers (1997) found "profound" changes in an 8-year enclosure, with a three-times thicker cover of haircap mosses [Polytrichaceae: *Polytrichastrum alpinum* (Figure 44), *P. sexangulare* (Figure 45), *Polytrichum commune* (Figure 46), *P. hyperboreum* (Figure 47), *P. juniperinum* (Figure 48), *P. piliferum* (Figure 49)] and a few graminoids (Figure 50). After 15 years, polytrichaceous mosses in the enclosures had a large number of dead shoots and Virtanen (2000) suggested that they may actually depend on grazing for maintenance (Figure 50). Virtanen *et al.* (1997) suggested that polytrichaceous mosses had the advantage of a significant subterranean rhizome that permitted their survival during periods of heavy grazing. Outside the plots, one could find plants of low stature (Figure 50), including liverworts [*Cephalozia* spp. (Figure 51), *Gymnomitrium* spp. (Figure 52), *Moerckia blyttii* (Figure 53)] and the low moss *Kiaeria starkei* (Figure 54). *Kiaeria* was absent in the enclosures after 15 years (Virtanen 2000). It was only in the open that colonizing species such as *Pohlia nutans* (Figure 55) and *P. drummondii* (Figure 56) were present (Figure 50). Hence, the lemmings had a strong influence on the species composition of the moss communities. Thus, in this enclosure experiment in a mountain snowbed, the biomass of mosses increased within the enclosures during 5 years of experiments (Virtanen 2000).

Do lemmings control the mosses, or do mosses control the lemmings? Oksanen (1983) found five times as much moss on a site visited by lemmings (*Lemmus* sp.; Figure 57) as found at a site they did not visit. But it appears that it was in fact a two-way control; after a population crash at Kilpisjärvi, Finland, there was an 8.4-fold increase in moss biomass on the site the lemmings had grazed. When the

moss "dies," lemmings leave or die. When lemmings leave, mosses rebound.

Ims *et al.* (2008) considered the suggestion that Norwegian lemmings (*Lemmus lemmus*; Figure 57) are especially sensitive to winter climatic conditions. They reasoned that this may be due to their reliance on mosses. These low plants exist at the base of the snow collection and are probably locked in ice when adhering water refreezes after a melt, making periods of time when even this food is unavailable. Hence, warmer climates where freezing and thawing are common throughout the winter may be unfavorable because of food unavailability.

The Norwegian lemming (*Lemmus lemmus*; Figure 57) in forest tundra eats more mosses than the less available grasses and sedges (Koshkina 1961), and the Nearctic brown lemming (*Lemmus trimucronatus*; Figure 58), a species of circumpolar tundra, eats more mosses in winter when monocots are least available (Batzli 1975).

One should expect that grazing would change the structure of the bryophyte community, but in fact, the predicted changes did not occur on the Arctic islands studied (Virtanen 2000). *Sanionia uncinata* (Figure 59) is common on Arctic islands lacking grazers, but in the 15 years of exclosure experiments it remained a subordinate species in both exclosures and non-exclosures. Furthermore, the expected change in colonizing species – small liverworts and *Pohlia* spp. (Figure 55-Figure 56)

(Oksanen & Ranta 1992) did not occur in either treatment (Virtanen 2000).

Figure 59. *Sanionia uncinata*, a species that is common when grazers are absent, but that was only a subordinate species after 15 years in exclosures. Photo by Michael Lüth, with permission.

In some locations, the Norwegian lemming (*Lemmus lemmus*; Figure 34, Figure 43, Figure 57), along with reindeer, can have a profound effect on bryophyte vegetation. They eat the competing graminoids, resulting in more space for bryophytes to obtain sufficient sunlight. In exclosure experiments, Virtanen (2000) showed that mosses such as *Kiaeria* (Figure 54) were reduced to low biomass or total absence after 15 years of exclusion of these herbivores. The *Polytrichaceae* (Figure 44-Figure 49) still dominated the habitat, but its litter had increased. But in the shorter experiment of only five years, mosses increased, no doubt due to the absence of winter feeding by lemmings. This suggests that the 4-5-year cycles of lemmings in many areas may be in tune with the growth rate of the bryophytes, affording them sufficient recovery time. Virtanen concluded that even in such a low productivity environment as the Norwegian Arctic, herbivory has a major impact in controlling the ecosystem, a system where mosses and lichens are typically the dominant vegetation.

Another study in the Fennoscandian mountain range of northernmost Sweden and Norway likewise demonstrated that Norwegian lemmings (*Lemmus lemmus*; Figure 57) can have a significant impact on the vegetation (Olofsson *et al.* 2004). Both *Dicranum* (Figure 10) and *Polytrichum* (Figure 46-Figure 49) species increased significantly in the exclosures. These are preferred winter forage for lemmings (Kalela 1961). The liverwort *Ptilidium ciliare* (Figure 9), on the other hand, became greatly reduced when herbivory disappeared in the exclosures. Liverworts are known to be weak competitors that benefit from grazing (on competing plants) and disturbance (Gjaerevoll 1956; Moen *et al.* 1993; Virtanen *et al.* 1997); presumably, grazing on the surrounding plants provided the *P. ciliare* with the exposure it needed.

Not only do the lemmings reduce the mosses by foraging, but they also use them in nests. The Norwegian lemming builds a dry nest lined with mosses and lichens, then includes mosses as the bulk of its diet (Anonymous 2005). A moss population crash occurs when the lemmings exhaust the moss flora, which regrows slowly, leaving the

lemmings to seek new locations to forage (Turchin *et al.* 2000). Thus, lemmings can be seen running in large numbers in search of food and shelter.

We have seen that metal pollutants accumulated by mosses have been detrimental to populations of other small rodents. Kataev *et al.* (1994) further reported that the decline in *Lemmus lemmus* (Figure 43, Figure 57) in regions with high SO₂ and heavy metal emissions may be due to the decrease in abundance of mosses due to the pollution.

Apparently capsules also form part of the diet. Olga Belkina (pers. comm. 13 November 2012) observed *Oligotrichum hercynicum* (Figure 60) with setae but no capsules (Figure 61) in a Lapland State Nature Biosphere Reserve. Feces of *Lemmus lemmus* were nearby (Figure 62). On another occasion, her research team identified fragments of *Hylocomium splendens* (Figure 63) and *Sanionia uncinata* (Figure 59) in the gut. Kalela *et al.* (1961) found that the forest populations of the Norwegian lemming typically survives winter by eating *Pleurozium schreberi* (Figure 64) and *Hylocomium splendens*.

Lemmus sibiricus/trimucronatus – Brown Lemmings

The brown lemming (*Lemmus sibiricus*; Figure 14) has been divided into subspecies, and the North American (Nearctic) portion of the species has been named as a separate species, *Lemmus trimucronatus* (Figure 58)

(Wilson & Reeder 2005); the Nearctic brown lemming, *Lemmus sibiricus* s.s. (black-footed lemming) is distributed in the Palaearctic tundra zone from the White Sea to Kolyma (Russian Federation). Unfortunately, I have found no lemming studies mentioning mosses for the eastern Palaearctic.

Brown lemmings near Barrow, Alaska, (presumably *Lemmus trimucronatus*; Figure 58) eat mosses, as well as grasses and sedges, in winter, and in drier habitats the mosses form up to 40% of the diet (Batzli & Pitelka 1983). When lemming numbers peak in their 4-6 year cycle, such mosses as *Calliergon* (Figure 65), *Dicranum* (Figure 10), and *Polytrichum* (Figure 46-Figure 49) species can form 5-20% of the diet in summer and 30-40% in winter (Bunnell *et al.* 1975). Lemmings actually prefer mosses (Chapin *et al.* 1986). Mosses show seasonal carbohydrate fluctuations, with a decline in brown tissues in summer and an increase in autumn. *Aulacomnium* (Figure 66) species show greater seasonal fluctuation of carbohydrate concentration in brown material than do *Polytrichum*/*Pogonatum*/*Polytrichastrum*? (Figure 44-Figure 49) species. Mosses have the highest concentrations of lignin-like materials, whereas *Eriophorum* (cottongrass; Figure 67) and lichens have the lowest. The preference ranking of the lemmings, who specialized on mosses and graminoids, correlate positively with fiber and negatively with mineral nutrient contents, suggesting that fiber may be important in the diet.

Figure 65. *Calliergon giganteum*, in a genus that forms up to 40% of the diet of the brown lemming in Alaska. Photo by A. Neumann, Biopix, through Creative Commons.

Figure 67. *Eriophorum vaginatum*, a genus with low concentrations of lignin-like materials. Photo by Roger D. Bull, through Creative Commons.

Schultz (1968) estimated that in their peak years, brown lemmings (*Lemmus sibiricus*; Figure 68) consume up to 90% of the primary production in their North American habitats; Batzli (1975) found the same 90% consumption in the low Arctic, where mosses and monocots were the primary winter food. In Scandinavia, Norwegian lemmings consume 66% of the mosses (Moen *et al.* 1993).

Figure 68. *Lemmus sibiricus*, a species that eats mostly mosses and grasses in winter. Photo by Ansgar Walk, through Creative Commons.

In northern Alaska, *Lemmus trimucronatus* (Figure 58) specializes on monocots and mosses, whereas the other small rodents eat primarily flowering plants (Batzli & Jung 1980; Batzli 1983). *Lemmus trimucronatus* continues consuming monocots in the winter, leaving behind the basal 1 cm and permitting regrowth. However, their moss consumption increases (Koshkina 1962; Batzli & Pitelka 1983; Batzli 1983; Rodgers 1990; Turchin & Batzli 2001), reaching up to 40% of the diet (Batzli & Pitelka 1983). Batzli (1983) determined that mosses are the least digestible group for the rodents (Batzli & Cole 1979), providing much less energy. Nevertheless, they can be up to 40% of the diet in drier habitats, where they are more important than in moist habitats (Batzli & Pitelka 1983). Batzli (1983) reasoned that instead they must provide a nutrient supplement. On the other hand, Rodgers (1990) suggests that when graminoids become senescent at the end

of summer, the lemmings are forced to eat a greater proportion of mosses. In cafeteria-style experiments, lemmings that had been fed artificial diets chose mosses in the same proportion as those individuals that had been raised on a natural diet, indicating the choice of mosses was genetically based (Rodgers & Lewis 1985). Food choice indicated that preference was based primarily on macronutrients and caloric content. Habitat made no difference in diet choices (Rodgers & Lewis 1986).

Nevertheless, the Alaskan brown lemmings (*Lemmus trimucronatus*; Figure 58) cannot survive and reproduce on a diet exclusively of mosses. It appears that in Barrow, Alaska, USA, the summer digestibility is poor and the consumption by these lemmings is low (Batzli & Cole 1979). But in winter, if densities are medium to high (~30 lemmings per hectare), they rapidly exhaust the graminoids and must live on a diet of 100% mosses (Turchin & Batzli 2001).

With the low digestibility of mosses (Batzli & Cole 1979), it is not surprising that captive Nearctic brown lemmings (*Lemmus trimucronatus*; Figure 58) lost weight on a moss-only diet, supporting the suggestion that mosses must serve some function other than as a source of energy. Batzli and Cole (1979) suggest that the high concentrations of calcium, magnesium, and iron may be beneficial.

In a feeding experiment using *Funaria hygrometrica* (Figure 28), the lemmings of Devon Island ate only the capsules (Pakarinen & Vitt 1974). Pakarinen and Vitt suggested that the choice of capsules may have been related to the high lipid content of the spores. The availability of the highly polyunsaturated fatty acid arachidonic acid (Gellerman *et al.* 1972) almost exclusively in mosses (and also *Equisetum*) may be especially important to these small mammals that must run about on and under the snow (Prins 1982b). Northern climates seem to increase the predation on mosses, perhaps because the arachidonic acids might help to keep the fats in the foot pads from changing from a liquid to a solid phase on the cold ground in winter (Prins 1982a), or perhaps because there are fewer choices for food. Arachidonic acid has a low melting point of -49.5°C, supporting the foot pad theory. Few other plants have arachidonic acid, yet it is present in high concentrations in the blood of Arctic animals, perhaps contributing to increased limb mobility and protecting cell membranes at low temperatures. Interestingly, Hansen and Rossi (1991) found that arachidonic acid comprised 30% of the fatty acids in *Rhytidadelphus squarrosus* (Figure 69) and *Eurhynchium striatum* (Figure 70) at 20°C, but concentrations shifted toward more eicosapentaenoic acid at lower temperatures, with a slight decrease in arachidonic acid.

***Synaptomys borealis* – Northern Bog Lemmings**

The range of the northern bog lemming (*Synaptomys borealis*; Figure 71) extends from Alaska, USA, eastward to Labrador, Canada, and southward to southeastern Manitoba, then southward in the USA to Washington, Montana, and northern New England (Clough & Albright 1987; Cassola 2017).

Figure 69. *Rhytidadelphus squarrosus*, a species in which dominance of arachidonic acid is shifted to dominance of eicosapentaenoic acid at low temperatures. Photo by Johan N., through Creative Commons.

Figure 71. *Synaptomys borealis*, a species that prefers mossy habitats. Painting by Todd Zalewski, Smithsonian Institutes, through public domain.

Mosses seem to play a prominent role in habitat preference. In the Athabaska-Mackenzie Region of Canada, Preble (1908) reported habitats for the northern bog lemming (*Synaptomys borealis*; Figure 71). These

included the border of a small meadow, a wet, swampy area, proximity of small muskeg ponds, and a marsh. To these, Banfield (1974) reported Canada black spruce bogs as the primary habitat, but also wet subalpine meadows, alpine, and sagebrush. In Churchill, Manitoba, Scott and Hansell (1989) found them in the *Carex*-moss-*Salix* community and the *Salix* community; Wrigley (1974) similarly found them in a sedge-moss tundra (Figure 72). Cowan (1939) found them in muskegs in British Columbia, Canada. Booth (1947) also considered them to be inhabitants of wet, boggy places in the North Cascades, Canada, as did Manville and Young (1965) and Osgood (1904) for Alaska, USA. Groves and Yensen (1989) (also Bursik 1993) reported them from *Sphagnum* bogs (Figure 73) in Idaho, USA, as did Johnson and Cheney (1953) for Idaho and Washington and Layser and Burke (1973) for Washington. In Montana, Reichel and Beckstrom (1993, 1994) found them in thick mats of *Sphagnum* (Figure 74), and found this habitat to be the best predictor for finding them. For Minnesota, USA, Coffin and Pfannmuller (1988) listed the habitat as dominated by *Sphagnum* and graminoids, including forested bogs and open ericaceous shrublands.

Christian *et al.* (1999) concurred, but expanded the Minnesota habitats to include spruce forest (Figure 73) with moss on the forest floor, wet alpine meadows, and alpine tundra. Clough and Albright (1987) reported them from wet sedge meadows in the northeastern USA. Near the base of Mount Washington, New Hampshire, USA, Preble (1899) found them in swampy habitats densely carpeted with moss. On the other hand, in Montana, USA, Pearson (1991) found them in an old-growth hemlock *Tsuga heterophylla* forest (Figure 75) that lacked the typical bog/fen habitat, although most of the sites were more typical.

Figure 72. Sedge-moss tundra, Nunavut, northern Canada. Photo by A. Diallya, through Creative Commons.

In British Columbia, Canada, Cowan (1939) found that *Synaptomys borealis* (Figure 71) creates a honeycomb of tunnels in the mossy carpets of the muskegs. These tunnels are strewn with fecal pellets, indicating where feeding occurred. The nests are above ground in winter and below ground in summer (Banfield 1974).

Figure 75. *Tsuga heterophylla* forest. Photo by pxhere, through Creative Commons.

The "house" that is less likely to disappear is a house of *Sphagnum* (Figure 74) (Cowan 1939). The bog lemmings *Synaptomys borealis* (Figure 71) usually live in small colonies among the wet mosses (Osgood 1904). Their runways are among the mosses rather than among the

grasses and other weeds. Although rare even in Alaska, they tend to be more common in peatlands (Preble 1908; Osgood 1909), where they make nests beneath the moss (Headstrom 1970). For these lemmings in their more southern extensions of their range, where they are also rare, it is in the peatlands that they survive (Coffin & Pfannmuller 1988).

Runways not only carry clippings of new bryophyte species, but open habitat to mosses that otherwise could not occur there. Among these in Arctic Alaska is the colonizing species, *Funaria polaris* (Batzli *et al.* 1980).

While it is clear that mosses, especially *Sphagnum* (Figure 74), are important in defining the habitat of the northern bog lemming, it is less clear why. Perhaps a small indication is the presence of *Hylocomiastrum pyrenaicum* (Figure 76) in the mouth of one individual (Harper 1961), but this may just be a gathering to line the nest. Moisture could be an important factor, but there seem to be no physiological studies to test this idea.

Figure 76. *Hylocomiastrum pyrenaicum*, a species that has been seen in the mouth of a northern bog lemming (*Synaptomys borealis*). Photo by Michael Lüth, with permission.

Rand (1945) provides examples that support this suggestion of the importance of moisture. In this study, seven individuals were captured in wet grassy glades and twelve in marshy sedges of dwarf birch flats (Yukon and Northwest Territories, Canada), although another seven trapped by Rand were in typical spruce swamps with mosses. The common factor is moisture.

***Synaptomys cooperi* – Southern Bog Lemming**

The bog lemming (*Synaptomys cooperi*; Figure 77), as its name implies, is a bog species (Connor 1959; Banfield 1974), ranging from southern Manitoba, Canada, south to Arkansas and Tennessee, USA (EOL 2017m). Nevertheless, it can occupy a wide range of habitats, including grasslands, mixed deciduous and coniferous woodlands, spruce-fir forests, and freshwater wetlands (EOL 2017m). In Minnesota, USA, Christian *et al.* (1999) found that it was significantly more abundant in bogs than in sedge meadows or lowland conifer habitats. Connor (1959) reported it from New Jersey. Goodwin (1932) found this species in Connecticut, USA, on a dark forest floor that was overgrown with ferns, *Sphagnum* (Figure 74), and other mosses. No surface runways were visible, but there were definite tunnels beneath the surface.

Figure 77. *Synaptomys cooperi*, bog lemming, makes tunnels under *Sphagnum*. Photo by Phil Myers, through Creative Commons.

Despite its typical bog habitat, Hamilton (1941) found this species in quite different circumstances in Albany County, New York, USA. These "bog" lemmings were in a beech-hemlock forest with a forest floor of spring perennials and lots of black leaf litter. Mosses were apparently not an important component.

The bog lemming eats grasses, sedges, mosses, fungi, fruit, bark, and roots (EOL 2017m). Using fecal analysis, Linzey (1984) found that even in southwestern Virginia, USA, the bog lemming subsisted on the broom grass *Andropogon* (Figure 78) in the summer but on mosses in winter. Both of these foods are low in digestible nutrients.

Figure 78. *Andropogon virginicus*, summer food for the bog lemming (*Synaptomys cooperi*) in Virginia, USA. Photo by P. B. Pelsler, through online permission.

***Dicrostonyx* – Collared Lemming**

Once again, we encounter recent changes in our understanding of the species. *Dicrostonyx torquatus sensu stricto* (Figure 79) is now considered to be distributed only in the Arctic and sub-Arctic tundra and forest-tundra in the Palaearctic region – *i.e.*, in Northern Europe and Asia (Wilson & Reeder 2005). *Dicrostonyx* is the only rodent (order **Rodentia**) that changes to white for the winter.

Figure 79. *Dicrostonyx torquatus*, the collared lemming in the Palearctic region. Photo by Ellicrum, through Creative Commons.

***Dicrostonyx groenlandicus* – Northern Collared Lemming**

The northern collared lemming (*Dicrostonyx groenlandicus*; see related species in Figure 80) is distributed in northern Greenland and Queen Elizabeth Islands to northern North America above the tree line, including northern Alaska, USA (Musser & Carleton, in Wilson & Reeder 2005).

Like other genera of lemmings, mosses form part of the diet of *Dicrostonyx*. Not just any moss will do either. It is perhaps not surprising to learn that northern collared lemmings (*Dicrostonyx groenlandicus*) graze on *Polytrichum* (Figure 46-Figure 49) gametophytes during summer on both Devon Island and Ellesmere Island (Pakarinen & Vitt 1974; Longton 1980). But when they were offered fruiting material of *Funaria arctica*, only capsules were eaten (Pakarinen & Vitt 1974). Pakarinen and Vitt suggested that this preference may be related to the high lipid content of some moss spores.

Mosses generally provide less than 10% of the diet of the collared lemming (cf. Figure 79) in Alaska (Batzli & Jung 1980). It appears that this Alaskan lemming must now be *Dicrostonyx groenlandicus*, although it was reported as *D. torquatus*. The common sedge *Carex aquatilis* (Figure 81) contains one or more compounds that are deleterious to collared lemmings (Batzli & Jung 1980). The common evergreen shrub (*Ledum palustre*; Figure 82) is likewise deleterious to the collared lemming, but also to the tundra vole (*Microtus oeconomus*; Figure 83) and brown lemmings (*Lemmus sibiricus*; Figure 68). Differing secondary compounds separate the diets of the two lemmings, but the tundra vole is more of a generalist, overlapping the diets of both lemmings.

Figure 83. *Microtus oeconomus*, a species that suffers deleterious effects from eating *Ledum palustre*. Photo by аймаина хикари, through Creative Commons.

Gut content analysis indicates that moss capsules form a substantial part of the diet of several North American and Eurasian Arctic lemming species (Batzli & Jung 1980).

And Ron Lewis Smith (Bryonet, 21 November 2006) reports large-scale grazing by lemmings on the capsules of *Polytrichum* (Figure 46-Figure 49) and *Polytrichastrum* (Figure 44-Figure 45) in northern Sweden. When grazing on capsules, lemmings prefer mature capsules in which the spores have a high lipid content (Pakarinen & Vitt 1974).

Wooding (1982) reported the diet of Canadian brown lemmings (*Lemmus trimucronatus*?; Figure 58) was comprised of willow buds, fruits, flowers, grasses, and twigs. However, in captivity they will eat mushrooms and mosses. This supports the concept that availability is an important determinant of the diet. Rodgers and Lewis (1985) came to an interesting conclusion regarding diet differences between the brown lemming (*Lemmus trimucronatus*; Figure 58) and the northern collared lemming (*Dicrostonyx groenlandicus*). The brown lemming preferred graminoids and moss, whereas the northern collared lemming preferred shrubs and herbs. They demonstrated that diet preferences were heritable. The diet preferences for both species were based on macronutrients and caloric content, but the differences between the species depended on secondary compounds and physical characteristics of the plants. They concluded that the northern collared lemming has a greater capacity to deal with secondary compounds or the presence of plant hairs than does the brown lemming.

***Myopus schisticolor* – Wood Lemming**

Wood lemmings, *Myopus schisticolor* (Figure 84), are distributed in the northern Palearctic, ranging from western Norway, through Sweden and Finland through northern and central Russia to the Pacific coast and Sakhalin Island (Russia) (Shenbrot & Krasnov 2005). They live in mossy bogs and coniferous forests in cool climates. In the Ural Mountains, they are rare and are restricted to swampy moss habitats (Bolshakov & Berdjugin 1990). Their runways often traverse moss beds as well as under fallen trees and roots.

Figure 84. *Myopus schisticolor* by its path through the moss *Hylocomium splendens*. Photo by Risto S. Pynnönen, through Wikimedia Commons.

Using food preference experiments, Kalela *et al.* (1963a, b) showed that in northern Sweden, the wood lemmings highly preferred a large number of the most abundant forest mosses, including *Brachythecium*

reflexum (Figure 85), *Dicranum fuscescens* (Figure 86), *D. polysetum* (Figure 10), *D. scoparium* (Figure 11), *Hylocomium splendens* (Figure 63), *Pleurozium schreberi* (Figure 8), *Ptilium crista-castrensis* (Figure 7), *Pohlia nutans* (Figure 55), *Polytrichum commune* (Figure 46), *P. juniperinum* (Figure 48), and *Rhodobryum roseum* (Figure 87). In eastern Finland, *Dicranum* and *Polytrichum* seem to be their favorites, which happen also to have the highest nitrogen content, even though *Pleurozium schreberi* and *Hylocomium splendens* are more abundant (Eskelinen 2002). They rejected most herbaceous species, but only rejected a few bryophytes such as *Ptilidium ciliare* (Figure 9) and *Plagiothecium denticulatum* (Figure 88) (Kalela *et al.* 1963a, b). In one area this species used *Aulacomnium palustre* (Figure 89) extensively, but this seems to be a rare occurrence (Lepp 2008).

Figure 88. *Plagiothecium denticulatum*, one of the rejected forest mosses of the wood lemming. Photo by Christian Peters, with permission.

Figure 89. *Aulacomnium palustre*, a species that is sometimes eaten as a major food source by the wood lemming. Photo by Kristian Peters, through Creative Commons.

During the snow-free season *Myopus schisticolor* (Figure 84) feeds on only the green topshoots of the mosses, whereas during the snow-covered season, these lemmings bite off the shoots at the base (Kalela *et al.* 1963a, b). Their order of preference in Sweden seems to be

Dicranum scoparium (Figure 11) > *Hylocomium splendens* (Figure 63) > *Pleurozium schreberi* (Figure 64) > *Sphagnum girgensohnii* (Figure 90). This order provides an interesting contrast to the choices of the heather vole (*Phenacomys intermedius*; Figure 18, Figure 21-Figure 22) that Kate Frego described. That vole seemed uninterested in *Dicranum scoparium*. The wood lemming in Finland had some similar preferences to those in Sweden, with *Dicranum* and *Polytrichum* (Figure 46-Figure 49) as top choices, despite a greater availability of *Pleurozium* and *Hylocomium* (Lepp 2008; Figure 91).

Figure 90. *Sphagnum girgensohnii*, a preferred moss for food by *Myopus schisticolor*. Photo by Hermann Schachner, through Creative Commons.

Figure 91. Percent grazing vs cover represented in a lemming habitat in Sweden. Based on data from Lepp 2008.

The species choices changed somewhat in the winter storage holes, which were located in drier sites (Lepp 2008). About 85% of their stored mosses were *Dicranum* (Figure 10), 11% *Pleurozium schreberi* (Figure 64), and only 3% *Hylocomium splendens* (Figure 63). They did still forage in winter, still preferring *Dicranum*, but their second highest nibblings were on *Ptilium* (Figure 7), which occurred in only 30% of the study plots. In fact, for whatever reason, they did not forage on *Polytrichum* (Figure 46-Figure 49) in winter, despite its greater abundance than that of *Ptilium*.

The wood lemming will graze for a long time on the same moss species, hence making it possible to identify its recent food by the color of the feces (Lepp 2008). Those with *Pleurozium schreberi* (Figure 64) and *Hylocomium splendens* (Figure 63) are light brown, *Polytrichum*

(Figure 46-Figure 49) dark brown, *Dicranum* (Figure 10) dark green, and *Ptilium crista-castrensis* (Figure 7) light green.

One explanation for the choice of mosses for the wood lemming may be the nitrogen content (Lepp 2008). *Dicranum* (Figure 10) and *Polytrichum* (Figure 46-Figure 49) have the highest nitrogen content among the mosses in the study area. Secondary compounds such as phenols may discourage consumption of some species that are abundant, but no data are available for the study site. Since such content could differ based on environmental conditions, we can only speculate. On the other hand, Eskelinen (2002) suggested that the high carbon:nitrogen content of *Dicranum* (Caut *et al.* 2009; Codron *et al.* 2011) might account for *Dicranum* as the preferred food, and sometimes only food, for this species in Finland.

Ericson (1977) found that *Myopus schisticolor* (Figure 84) had a high preference for many forest moss species in preference experiments. Their preferred mosses were *Dicranum scoparium* (Figure 11), *Hylocomium splendens* (Figure 63), *Pleurozium schreberi* (Figure 64), and *Sphagnum girgensohnii* (Figure 90). In fact, they rejected most of the herb species. Some bryophytes were also rejected, including the leafy liverwort *Ptilidium ciliare* (Figure 9) and the moss *Plagiothecium denticulatum* (Figure 88). In summer the wood lemming eats only the green tops of shoots, but in winter when the bryophytes are snow covered, they eat them down to the base.

Young wood lemmings cannot survive on mosses alone; to grow faster, they need to eat other plants as well (Andreassen & Bondrup-Nielsen 1991; Lepp 2008). Adults, however, can subsist on mosses alone. Nevertheless, both growth and reproduction are negatively affected when the diet is 100% moss, compared with a diet that also includes grasses and shrubs.

Bathyerigidae – Blesmoles and Mole Rats

Cryptomys hottentotus – Hottentot Mole-rat

The Hottentot mole-rat (*Cryptomys hottentotus*; Figure 92) is widely distributed in South Africa (Bishop *et al.* 2004). Colonies have 2-14 individuals that permanently live in a network of burrows, locating their food as they burrow (Spinks 1998). The Hottentot mole-rat builds hummocks through its burrowing activity (Lynch 1992) in mesic bog soils (Bishop *et al.* 2004). It may not need a mossy habitat, but some mosses seem to benefit from its presence. The excavated soil is colonized by a lawn-like cover that includes mosses (Lynch 1992).

Myoxidae – Dormice and Hazel Mice

Muscardinus avellanarius – Hazel Dormouse

In England, the hazel dormouse (*Muscardinus avellanarius*; Figure 94), a somewhat rare nocturnal rodent, gets its name from the Anglo-Norman term *dormeus*, which means "sleepy" (Wikipedia 2008). This refers to its habit of becoming torpid and cold in the winter, waking only occasionally to eat food stored nearby. Hibernation is triggered by temperatures below 16°C (Habrill & Passig 2008).

Figure 94. *Muscardinus avellanarius* – hazel dormouse, a species that uses mosses in its winter hibernacula. Photo by Danielle Schwarz, through Creative Commons.

Its habitat is typically an unshaded understory where there is high species diversity (Bright & Morris 1990). Bright and Morris (1991) contend that this species is entirely arboreal, detouring considerable distances to avoid crossing open ground. They seldom venture more than 100 m from the nest. They seem to prefer nesting in tree hollows, but when these are scarce they select a location with shrub cover and proximity to the forest edge (Berg & Berg 1998). Despite living in trees, they do not seem to include mosses in the diet (Bright & Morris 1993).

Mosses may be more important for a **hibernaculum** (shelter occupied during the winter by a dormant animal). The hazel dormice hibernate in winter, 6-7 months in Lithuania (Juškaitis 1999). Bright and Morris (1996) reported that the dormice covered their surface hibernaculum with a thin layer of mosses or leaves. Such shallow surface hibernacula make the hibernating animals vulnerable to floods, trampling, and predation (Juškaitis 1999).

In a Ukraine study, Zaytseva (2006) found that mosses comprise about 5% of the nesting material in nest boxes used by the hazel dormouse, which sleeps there throughout the day. The globose summer nest is shaped much like a wren's nest with a door (Habrill & Passig 2008). Both summer and winter nests often have mosses in them, but the winter nest is more likely to be in a tree hollow or stump. Some dormice may spend their winter on the ground under moss and litter.

Van Laar and Dirkse (2010) examined the nesting materials and found that this species used the epiphytic mosses *Brachythecium rutabulum* (Figure 95) and *Orthotrichum lyellii* (Figure 96). But they also used the primarily ground-dwelling species *Cirriphyllum piliferum* (Figure 97), *Hypnum cupressiforme* (Figure 4), *Calliergonella cuspidata* (Figure 98), *Eurhynchium hians* (Figure 99), and *Thuidium assimile* (Figure 100). All nest materials were pleurocarpous mosses. Van Laar and Dirkse considered the moss choice to be due to the physical properties of the moss that helped the hazel dormouse to maintain a certain degree of humidity in the nests.

Gliridae – Dormouse

Glirulus japonicus – Japanese Dormouse

The Japanese dormouse (*Glirulus japonicus*; Figure 101), an endemic to Japan, is nocturnal, searching a relatively large area to find food at night (EOL 2017b). Its name derives from the Anglo-Norman word *dormeus*, which means sleepy one. However, it is not its daytime sleeping that gives it this name, but rather its long hibernation period. The males awaken in May to find a mate.

Figure 101. *Glirulus japonicus*, a species that uses bryophytes in its lair. Photo by Katuuya, through Creative Commons.

It easily climbs trees, where it feeds on seeds, fruits, insects, and bird eggs (EOL 2017b). It can run as easily on the lower side of a branch as on the upper side. This species lacks a caecum, and thus should not be expected to digest cellulose, making mosses an inefficient food and explaining their absence in the dormouse diet.

The Japanese dormouse (*Glirulus japonicus*; Figure 101) uses bryophytes in its lair (Figure 102) (Watanabe

1978), a fact noted much earlier in Britain by Tripp (1888). These bryophytes are useful in building suitable nests. Even in arboreal habitats at warmer latitudes, the Japanese dormouse uses bryophytes for its lair (Watanabe 1978; Minato & Doeï 1995; Doeï & Minato 1998). After examining 21 nests, Minato and Doeï (1995) reported 42 species of mosses and 15 species of liverworts as constituting the majority (53.1% by weight) of the nest materials. Like most of the bird nest bryophytes, the majority of those used by the Japanese dormouse were pleurocarpous, and consistent with the dormouse habitat, they were mostly epiphytic. The six most commonly used species were the leafy liverwort *Frullania tamarisci* subsp. *obscura* (Figure 103), and the mosses *Hypnum tristoviride* (Figure 104), *Isothecium subdiversiforme* (Figure 105), *Anomodon rugelii* (Figure 106), *Entodon scabridens*, *Anomodon longinervis*. The leafy liverwort *Frullania tamarisci* subsp. *obscura* was often the most abundant bryophyte in the nest. This species is typically abundant nearby, spreading over the surface of tree trunks in large mats, often making it easier for the dormouse to harvest.

Figure 106. *Anomodon rugelii*, a pleurocarpous moss used for nesting material by the Japanese dormouse (*Glirulus japonicus*). Photo by Janice Glime.

Watanabe (1978) found 25 bryophyte species in 8 nests. He found an average of 4 bryophyte species per nest, whereas Minato and Doei (1995) found an average of 6.8 species.

***Myoxus glis* – Fat Dormouse; Edible Dormouse**

The fat dormouse (*Myoxus glis*; Figure 107) occurs throughout much of mainland western Europe and on a number of Mediterranean islands (Milazzo *et al.* 2003).

Figure 107. *Myoxus glis*, a species that eats mosses, but most likely accidentally. Photo by Marcus Ostermann through Creative Commons.

Gigirey and Rey (1998) reported that 12 of 32 stomachs of the fat dormouse, *Myoxus glis* (Figure 107), had moss remains. Gigirey and Rey (1999) subsequently found mosses of this species in the feces. However, in both cases they considered these mosses to be ingested accidentally.

Whereas mosses may not be a desirable diet item, they do provide nesting materials (Drăgoi & Faur 2013). They typically construct these nests using leaves and mosses (Grzimek 2003). The mosses are typically pleurocarpous mosses, including the epiphytes *Brachythecium rutabulum* (Figure 95), *Isothecium myosuroides* (Figure 108), and *Eurhynchium praelongum* (Figure 109), but also nearby forest floor species including *Brachythecium glareosum* (Figure 110), *Ctenidium molluscum* (Figure 111), *Eurhynchium striatum* (Figure 70), and *Eurhynchium hians* (Figure 99) (van Laar & Dirkse 2010).

Figure 111. *Ctenidium molluscum*, a pleurocarpous ground species used for nesting by the edible dormouse (*Myoxus glis*). Photo by Michael Lüth, with permission.

They locate their nests high in trees, using the cup formed by branching, although some may use abandoned bird nests (Juškaitis 2006).

Dryomys nitedula – Forest Dormouse

The forest dormouse (*Dryomys nitedula*; Figure 112) lives in Switzerland through eastern and southern Europe, Asia Minor and the Caucasus to central Russia and central Asia. It is a tree dweller, living in forests (EOL 2017n).

Figure 112. *Dryomys nitedula*, the forest dormouse. Photo by Domodi, through Creative Commons.

Like *Myoxus glis* (Figure 107), *Dryomys nitedula* (Figure 112) uses mosses in its nests (Drăgoi & Faur 2013). The nests are round with either a side or top entry. The exterior is rough, constructed of branches, but the interior is padded, using grasses, feathers, hair, or mosses. And like the fat dormouse, *Dryomys nitedula* sometimes uses empty bird nests (Adamik & Kral 2008).

Summary

Many rodents have mosses in the gut and feces, but these seem to be the result of accidental intake. But some seem to include them as an important part of the diet, often increasing the percentage in winter. Researchers have suggested that this switch may be a need for nitrogen, arachidonic acid, or fiber. In other cases, it may be a simple matter of availability. The shoot tips seem most desirable for food, but in winter the moss may be clipped at the bottom. Some records indicate that moss capsules are eaten.

Known consumers of mosses include *Chionomys nivalis*, and several members of *Microtus*, *Phenacomys*, *Peromyscus maniculatus* (capsules). Lemmings, in particular, are dependent on mosses in the diet. These may provide arachidonic acid, a more pliable fatty acid at cold temperatures. When their population peaks, they may destroy their moss cover under the snow, making them dangerously visible to predators when the snow melts.

Many rodents use mosses in the construction of nests, particularly as part of the lining. In bogs, several species may coexist in a single bog, some using them for food or to make nests, tunnels, or runways. Pleurocarpous mosses are preferred by most of the rodents that use mosses as nesting materials.

Bryophytes are impacted by the rodents in multiple ways: diminished cover, competition from flowering

plants. But at other times they may benefit. The rodents can serve as dispersal agents, and runways and burrow openings open new habitats where colonizers like *Funaria* can grow, increasing diversity.

Acknowledgments

This chapter has benefitted greatly from anecdotal records sent to me by bryologists and friends who observed these small rodents interacting with mosses in the field. Steve Juntikka, a former plant taxonomy student of mine, sent me an excited email from Isle Royale after observing the young mouse devouring capsules of *Funaria hygrometrica*. Leah Vucetich and Rolf Peterson, Isle Royale researchers, provided me with the identification of the juvenile *Peromyscus maniculatus* based on the picture alone.

Soricomorpha

Soricidae – Shrews

In 25 bogs and ombrotrophic mires of Poland, Ciechanowski *et al.* (2012) found that shrews dominated among the mammals captured in pitfall traps. The traps produced 598 individuals distributed among 12 mammal species. Typical wetland species included *Neomys fodiens* (Eurasian water shrew; Figure 2), *Neomys anomalus* (Mediterranean water shrew; Figure 3), and *Microtus oeconomus* (tundra vole; Figure 4). The most numerous species was the Eurasian pigmy shrew (*Sorex minutus*; Figure 5), and it was sometimes the only rodent present in the habitat. It was most common in undisturbed, treeless parts of bogs where *Sphagnum* (Figure 6) dominated.

***Sorex cinereus* – Long-tailed Shrew**

The long-tailed shrew (*Sorex cinereus*; Figure 7) occurs from Alaska, USA, east to Labrador/Newfoundland, Canada, south in the USA to Washington, Utah, New Mexico, Northern Great Plains, southern Indiana and Ohio, through the Appalachian Mountains to northern Georgia and western South Carolina, and on the east coast to New Jersey and northern Maryland, where it commonly occurs with mosses (Youngman 1975; Whitaker 2004). It seems often to be present in traps set for lemmings. Hamilton (1941) found *Sorex cinereus* near the summit of Big Black Mountain in Harlan County, Kentucky, USA, at ~1220 m. Of these, six of the seven specimens were taken from runways at the sides of moss-covered logs in damp, deciduous thickets. In the thickets of Maine and New Hampshire, USA, traps set for lemmings also captured shrews (Clough & Albright 1987). These included *Blarina brevicauda* (northern short-tailed shrew; Figure 8) and *Sorex cinereus*. Groves and Yesen (1989) likewise found species of *Sorex* in lemming traps in a *Sphagnum* "bog" in Idaho, USA (Figure 9), as did Pearson (1991) in Glacier National Park and Reichel and Beckstrom (1993) in western Montana.

Figure 9. Mountain bog (poor fen?) in Idaho, USA. Photo by Robert Marshall, through Creative Commons.

Sciuromorpha

Sciuridae

Records indicating that squirrels use mosses to line their nests are old (Tripp 1888). But sometimes, the mosses use squirrel activity to their advantage (Ken Adams, Bryonet 30 April 2020). In the Epping Forest, UK, *Zygodon viridissimus* competes with *Z. forsteri* for space on the grooves created by squirrel gnawing. The former often out-competes the latter.

Tamias merriami – Merriam Chipmunk

The Merriam chipmunk (*Tamias merriami*) has a small distribution in central and southern California, USA (Harvey & Polite 1999). There seems to be little documentation of chipmunks eating or using mosses. Imagine the surprise when Brent Mishler and his team (Mishler & Hamilton 2002) caught a chipmunk (Figure 10-Figure 11) grabbing a chunk of the moss *Syntrichia princeps* (Figure 12-Figure 13) from the very middle of their field of view (Figure 12) through a CAMcorder (see Grant *et al.* 2006 for setup). Mishler (pers. comm. 12 January 2008) suggests that the Merriam chipmunk (*Tamias merriami*; Figure 10-Figure 11) may have been after the water adhering to the moss (*Syntrichia princeps*), as it had just been moistened earlier in the day for an experiment; the surroundings were dry.

Figure 13. *Syntrichia princeps* with capsules. Photo by F. Guana, Modoc National Forest.

Tamiasciurus hudsonicus – American Red Squirrel

The American red squirrel (*Tamiasciurus hudsonicus*; Figure 14) seems to eat just about anything. It is more tame than most squirrels, and I have even had a confused squirrel climb my leg! It also seems to like decorating its

abode, using paper, moss, and other local objects it can find (Hanrahan 2012).

Figure 14. *Tamiasciurus hudsonicus* (American red squirrel) uses mosses to decorate its home. Photo by Cephas, through Creative Commons b

***Sciurus vulgaris* – Eurasian Red Squirrel**

The Eurasian red squirrel (*Sciurus vulgaris*; Figure 15-Figure 16) is distributed across the northern parts of Europe (Greene 1887). It makes a nest in the fork of a tree. This nest is an interwoven structure of twigs, leaves, and mosses.

Figure 15. *Sciurus vulgaris*, a species that uses pleurocarpous mosses in its nest boxes. Photo from Saxifraga – Mark Zekhuis, with online permission.

Nest boxes used by the Eurasian red squirrel (*Sciurus vulgaris*; Figure 15-Figure 16) displayed pleurocarpous mosses (van Laar & Dirkse 2010). Two of these were ground species [*Hypnum cupressiforme* (Figure 17), *Homalothecium sericeum* (Figure 18)]. The Eurasian red squirrel used only one epiphytic species (*Orthotrichum* sp.; Figure 19), but van Laar and Dirkse suggested that all of the mosses may have been collected from a nearby tree. The nest included ~470 g spruce twigs and ~180 g of these mosses. In addition, the squirrel had included insulation material from the roof of a nearby house. Quinton (1997) reported finding a nest under *Sphagnum* (Figure 6) in the boreal forest of North America.

Figure 16. *Sciurus vulgaris*, a species that uses pleurocarpous mosses as nesting materials. Photo from Saxifraga – Mark Zekhuis, with online permission.

Figure 17. *Hypnum cupressiforme*, a moss used in nests of *Sciurus vulgaris*. Photo by Michael Lüth, with permission.

Figure 18. *Homalothecium sericeum*, a moss used in nests of *Sciurus vulgaris*. Photo by Michael Lüth, with permission.

Figure 19. *Orthotrichum cupulatum* with capsules, a moss used in nests of *Sciurus vulgaris*. Photo by Jutta Kapfer, with permission.

Pulliainen and Raatikainen (1996) studied the effect of various nesting materials on nest temperature of the red squirrel in Finland. The wind speed had a large effect on differences between inside and outside the nest. During windless times, the temperature difference could be as much as 30°C in nests made of mosses, proving mosses to be superior insulators to the beard lichen (*Usnea*; Figure 20). Juniper bark provided the poorest insulation among the materials tested. A plastic plate under grass greatly increased the inside temperature by restricting the air current throughout the nest.

Figure 20. *Usnea filipendula*, a nest material that has less insulating ability than the tested mosses. Photo by Jerzy Opiola, through Creative Commons.

TalkTalk (2011) describes the nest of the red squirrel as having a layer of twigs with a layer of moss or bark fragments. It is likely that availability is a major influence on the nest materials used.

***Sciurus carolinensis* – Grey Squirrel**

The grey squirrel (*Sciurus carolinensis*; Figure 21-Figure 22) lives in the eastern USA, but is an invasive in Europe (Steele *et al.* 1996; Goheen & Swihart 2003). It builds a nest the size of a football (YPTE 2011). It is comprised of twigs, often with their leaves remaining attached, and is perched high in a tree. The squirrels line the nest with dry grass, shredded bark, moss, and feathers.

The summer nest is typically flimsy and located among small branches.

Figure 21. *Sciurus carolinensis*, grey squirrel, a species that uses mosses as one of its nest lining materials. Photo by Janice Glime.

Figure 22. *Sciurus carolinensis*, a species that uses mosses as one of its nest lining materials. Photo by John White, with permission.

***Spermophilus parryi* – Arctic Ground Squirrels**

Like the pikas, it appears that Arctic ground squirrels (*Spermophilus parryi*; Figure 23-Figure 24) survive winter in the "warmth" of hibernacula (Barnes 1989). These rodents can wake up and run around when their core temperature is as low as -2.9°C. Temperatures much lower than that can be lethal for such small homeotherms. Maintenance of a temperature as low as -3°C could save up to ten times as much energy as maintenance of a body temperature above 0°C. It is quite possible that for the pikas, the mosses permit the maintenance of sufficiently "warm" temperatures to survive.

Figure 23. *Spermophilus parryii* and tunnel entrances. Photo from National Park Service, through public domain.

Figure 24. *Spermophilus parryii*, Arctic ground squirrel, a species that seems to benefit from the insulating ability of mosses in the nest. Photo Jim McCarthy, through public domain.

Arctic ground squirrels actually cache bryophytes. They preferentially decapsulate bryaceous mosses and store the capsules in their nests for winter food reserves (Zazula *et al.* 2006).

Nest materials for these Arctic ground squirrels in the Yukon include mosses and lichens and these are the most common materials found in the pouches of females (Gillis *et al.* 2005). Carrying these materials was most common prior to and during lactation. These mosses and lichens are absent in male pouches.

***Glaucomys* – Flying Squirrels**

Glaucomys are active all year, but have little resistance to cold (Marchand 2001). Instead, they keep warm by huddling together in tree cavities lined with grass, moss, or bark. The nests can be as much as 30° warmer than the surrounding air outside the nest. These huddles typically have about 10 squirrels, but there may be as many as 50.

***Glaucomys sabrinus* – Northern Flying Squirrel**

The northern flying squirrels (*Glaucomys sabrinus*; Figure 25) has a wide distribution throughout northern North America from Alaska, across Canada to the eastern provinces, with several extensions into northern USA. Like the southern flying squirrel, this squirrel is nocturnal (IUCN 2017).

Figure 25. Northern flying squirrel, *Glaucomys sabrinus*, a species that uses mosses in its nests. Photo by Phil Myers, through Creative Commons.

The northern flying squirrel (*Glaucomys sabrinus*; Figure 25) builds a cavity nest, using various mosses (Patterson *et al.* 2007). Patterson and coworkers found trace amounts of peat moss (*Sphagnum*; Figure 6), dried grasses, cedar leaves, and twigs in the nests in southern Ontario.

***Glaucomys volans* – Southern Flying Squirrel**

The smaller southern flying squirrels (*Glaucomys volans*; Figure 26) occur along the southern USA north to New England (Marchand 2001). They have tiny bodies, weighing only 57-113 g. They are nocturnal, thus most people have never seen them. Nevertheless, they are the most abundant squirrel in the eastern US.

Figure 26. Southern flying squirrel, *Glaucomys volans*, a species that uses mosses in its nests. Photo by Ken Thomas, through Creative Commons.

Lagomorpha – Hares, Rabbits, and Pikas

Leporidae – Rabbits and Hares

***Lepus arcticus* – Arctic Hare**

In the high Arctic, the Arctic hare (*Lepus arcticus*; Figure 1, Figure 27) seems to prefer eating developing bryophyte capsules (Catherine LaFarge, Bryonet 30 March 2016). LaFarge often found decapitated sporophytes, although the lemmings helped in the consumption.

Figure 27. *Lepus arcticus* in white phase. Photo by Chmee2, through Creative Commons.

***Oryctolagus cuniculus* – European Rabbit**

The European rabbit (*Oryctolagus cuniculus*) is present in all Western European countries, Ireland and UK, Austria, Sweden, Poland, Czech Republic, Hungary, Romania, Ukraine, and Mediterranean, Croatia, and Slovakia (Smith & Boyer 2008).

Rabbits, with their noses to the ground, would seem ideally suited for nibbling on bryophytes. However, it seems they may not find them to their liking. Bhadresa (1977) reported that in a food preference test, the rabbit *Oryctolagus cuniculus* (European rabbit – the only domesticated rabbit; Figure 28) in Norfolk – actually disliked *Dicranum scoparium* (Figure 29). But then, that is only one moss. Davidson *et al.* (1990) found leaf fragments of *Mnium* (Figure 30-Figure 31), *Brachythecium* (Figure 32), *Hypnum* (Figure 17), and *Polytrichum* (Figure 36) species in feces of rabbits in southeast England, but never forming more than 5% of the plant material in a fecal pellet. Rabbits eat a mixed diet (European Rabbit 2009), and it appears that mosses may be part of it – or they are ingested accidentally.

Figure 32. *Brachythecium rutabulum*, in a genus found in the feces of the European rabbit. Photo by J. C. Schou, with permission.

Rabbits can have a negative impact on bryophytes. After a fire in the heathlands of Brittany, rabbits, along with roe-deer, damaged the bryophytes by scraping (Clément & Touffet 1981). The bryophytes were important as initial colonizers after the fire, so the scraped areas suffered from their loss in succeeding plant and animal colonization. The mosses *Funaria hygrometrica* (Figure 33) and *Ceratodon purpureus* (Figure 34) are important in rebuilding the organic matter following fires and their loss is unfavorable to invertebrate development. *Polytrichum* s.l. species have a strong competitive ability compared to tracheophytes in colonizing these nutrient-poor sites. In particular, *Polytrichastrum formosum* (Figure 35) and *Polytrichum commune* (Figure 36) have a higher density and growth rate and can produce 7-8 tons ha⁻¹ yr⁻¹, preventing new species from becoming established and retarding the growth of those already present. As in cases with other rodents, the rabbits may facilitate the development of these **Polytrichaceae** colonies.

Figure 36. *Polytrichum commune*, a species that is highly competitive on nutrient-poor sites opened up by browsing. Photo by Michael Lüth, with permission.

But rabbits (*Oryctolagus cuniculus*; Figure 28) can also create habitat for bryophytes. Callaghan (2015) reports that some mosses thrive due to grazing activities by rabbits in the UK. A more spectacular find occurred at an old tin works in Cornwall, where the rare copper moss *Scopelophila cataractae* (Figure 37) benefits by the creation of habitats by rabbits. As succession proceeds on the exposed mineral soil, the tracheophytes replace the bryophytes. However, when the rabbits arrive, the rabbits

create a network of runways and tunnels, exposing the metal-rich soil where the copper moss thrives. These serve as refugia for this moss species that is disappearing as the more coarse vegetation develops. The entrances to burrows are clothed in a mat of protonemata (Figure 38) that have abundant gemmae (Figure 39). Callaghan speculates that the rabbits must disperse thousands of these gemmae on their fur, and the entrance to the tunnel is often the benefactor substrate.

The European rabbit has multiplied from the 24 introduced to Australia in 1859 to over 600 million in less than a century (European Rabbit 2009), suggesting that this rapid multiplier could present considerable destruction to mosses, or could favor their increase by destroying lichens. In areas where rabbits have been introduced, they often have no natural enemies. Australia is a case in point. In such cases, the virus causing **myxomatosis** may be their only enemy. While this has been used successfully to help control the rabbits, the ones currently remaining in Australia are now immune to it.

In a dune system in Wales, the advent of myxomatosis caused changes in the vegetation. This area had been the site of severe rabbit grazing. In 1954, myxomatosis began to spread to the area and Ranwell (1960) anticipated the loss to the rabbit population. In May of 1955 rabbit pellets were common and thick on the transects across turf areas. Mosses were very evident among the 1-2 cm high turf, but were much less evident in the deep turf. During the succeeding years of rabbit decline, grasses, sedges, and pleurocarpous mosses [*Ditrichum flexicaule* (Figure 40), *Pseudoscleropodium purum* (Figure 41), *Rhytidiadelphus squarrosus* (Figure 42), *R. triquetrus* (Figure 43)] increased, surviving in the ungrazed turf. *Eurhynchium praelongum* (Figure 44) and *Plagiomnium undulatum* (Figure 45) also increased during the study period. At the same time, decreases were evident in the acrocarpous mosses *Bryum* sp. (Figure 46), *Climacium dendroides* (Figure 47), *Dicranum scoparium* (Figure 29), *Syntrichia ruralis* (Figure 48). *Rhodobryum roseum* (Figure 49) disappeared from 1955 to 1958. Overall, the bryophyte richness remained unchanged. The greatest losses of mosses occurred only after 3-4 years of recovery from grazing.

The results of Ranwell (1960) differ somewhat from those of Watt (1957), who showed that disappearance of rabbits resulted in the decrease of mosses in ungrazed pasture over long periods of time. Watt found 29 bryophyte species, but *Rhytidiadelphus squarrosus* (Figure 42) is found only in the ungrazed community. This is in contrast to its common presence in grazed pasture on the South Downs and other locations in Breckland, England. On the other hand, 11 species occur exclusively in the

grazed area. These are all small and 10 of the 11 are acrocarpous. As in the Ranwell (1960) study, Watt found that mosses in the ungrazed turf are tall and mostly pleurocarpous. The small mosses seem to be unable to survive competition with taller vegetation, including competition for light. The larger mosses, on the other hand, seem to thrive in the ungrazed conditions. Watt considered these results to support the hypothesis that "in the grazed community the competitive power of the potentially taller growing plants is reduced by grazing sufficiently to allow the smaller species to survive and that in the ungrazed the unchecked growth of taller growing species eliminates or tends to eliminate the smaller, whether they are annual or perennial of varied life-forms."

Gillham (1955) also stressed the importance of rabbit grazing, considering it to be less important than exposure. This contention was supported by the abundance of mosses that are intolerant of extreme exposure, but that are able to reach their maximum in the "closely nibbled swards." Heavy grazing caused moss cover to reach 25%, mostly of the moss *Ceratodon purpureus* (Figure 34) – a moss that is not shy of sunlight. In early spring, when the rabbits were most hungry, the lanes between the grazed heather bushes were dominated by the mosses *Rhytidiadelphus squarrosus* (Figure 42) and *Hypnum cupressiforme* (Figure 17). Gillham (1954) found that bryophyte fragments were only occasionally present in the rabbit dung and concluded that they were probably only eaten when mixed with other plant material. Although the bryophytes are important components of the turf in heavily grazed inland areas, they have little importance on sea cliffs due to their exposure to wind and salt there (Gillham 1955).

Ochotonidae – Pikas

Ochotona princeps – American Pika

The American pika (*Ochotona princeps*; Figure 50) is distributed widely in British Columbia and the western USA (Defenders of Wildlife 2017). Mosses are often a dominant feature of their landscape.

Figure 50. *Ochotona princeps* among mosses. Photo courtesy of Mallory Lambert, through Johanna Varner.

The presence of pikas is usually a good indicator of regions with rocky, mesic, cool habitat (Figure 51) with long winters and short summers (Simpson 2009). Although

the American pikas (*Ochotona princeps*; Figure 51) are a high elevation species in western North America, in the Columbia River Gorge they live near sea level (Horsfall 1925; Varner & Dearing 2014a, b). But at low elevations in the southern part of the Columbia River Gorge, Oregon, USA, the known temperature range was extended and the long winters and typical snow accumulation were not present.

Figure 51. *Ochotona princeps* among the rocks and mosses of a talus slope. Photo courtesy of Johanna Varner.

Dr. Erik Beever (pers. comm.), research ecologist for the National Park Service Inventory & Monitoring program, reported to me that pikas occur at low elevations (less than 150 m) in a valley fed by a snowmelt river in the Cascade Range of western USA. The valley is cold, and he theorizes that their ability to survive the winter without their usual snow cover is due to the thick (>20 cm) moss mats that provide cover and insulation for them (Figure 52).

Figure 52. *Ochotona princeps* emerging from tunnel covered with *Hylocomium splendens* and *Selaginella* sp. Photo courtesy of Johanna Varner.

Varner and Dearing (2014b) supported this assessment, finding that the moss cover insulates the interstices of the talus slopes from temperature fluctuations. Varner and Dearing (2014a) speculated that the mosses could cool the microclimates of the talus in the valley (Figure 51), making the climate suitable for the pikas. The

pikas are able to travel long distances beneath the thick moss cover. Even their extensive moss consumption only removes about 0.002% of the moss in their home ranges in one year. Hence, unlike the lemmings, the pikas can enjoy the cover of the mosses without the danger of eliminating it.

In this unusual habitat they subsist on what is for most rodents an unusual food – mosses (Varner & Dearing 2014a, b). These mosses comprise more than 60% of the diet at the two sites studied. At this rate, the pikas consume ~7.31 g/day and 2.67 kg/year of mosses. The mosses are available all year, thus making food caches unnecessary.

Richardson (1981) considered mosses to be a difficult food for mammalian herbivores, having a high fiber content, low nitrogen, and low digestible energy compared to other food choices. Varner and Dearing (2014a) reported the same high fiber and low nitrogen (<1%) in the mosses of the Columbia River Valley. But the pikas re-ingest their fecal pellets. As a result, the **caecal pellets** (partially digested foods passed as fecal pellets, then re-ingested) of these pikas were far more nutritious, having low fiber content and high nitrogen content, thus allowing the pikas to gain greater nutritional value than that available to other herbivores that do not re-ingest their fecal material.

At high elevations, these talus dwellers forage on the surrounding vegetation (Figure 53) (Huntly *et al.* 1986). Their foraging intensity decreases with distance from the **talus** (rock fragments accumulated at base of cliff or slope), but their selectivity increases with distance, consistent with the "central place foraging theory." In this case, plant abundance increased with distance from the talus. The pikas would travel greater distances to harvest plants for caching (Figure 54) rather than for immediate consumption. For these haying forays, higher proportions of forbs and tall grasses were selected. The haypiles serve to sustain the pikas during winter (Dearing 1997a).

Figure 53. *Ochotona princeps* eating a sedge in the Rockies, a rodent that runs around under the moss layer. Photo by Sevenstar, through public domain.

Figure 54. *Ochotona princeps* (pika) hay pile. Photo courtesy of Bob Krear.

Dearing (1996) tested the hypothesis that plant secondary compounds may be higher in the winter diet either because they function as preservatives or because pikas delay consumption of these species until the toxins degrade. Dearing found little evidence suggesting that morphology excluded any plants from the winter diet, nor was plant size of importance. Even nutrient content showed only a weak relationship. On the other hand, the winter diet was significantly lower in water content and higher in total energy content, but no other nutrients had any consistent pattern. The manipulation of secondary compounds was, however, important. The winter diet contained more total phenolics and had greater astringency.

Dearing (1996) suggested that these secondary compounds helped to preserve the cache, but it also made an additional (initially toxic) food source available. In a follow-up study, Dearing (1997b) found that following 10 months of storage, the winter diet retained 20.5% more biomass with a higher level of energy while being lower in fiber and equal in nitrogen when compared to the summer diet of these pikas. Experiments demonstrated that the pikas preferred foods with a lower phenolic content compared to species with a high content, and they delayed eating those high phenolic species in the haypile until the phenolic content had decreased (due to microbial activity). This need to store a winter cache occupied almost 55% of the surface activity and the evolution of territoriality most likely relates to the need for sufficient vegetation for the winter food cache (Conner 1983).

Behavioral differences between high elevation and low elevation populations of pikas also contributed to their survival at the lower elevations (Smith 1974). At high elevations (3,400 m) the pikas were active throughout the day. At a lower altitude site (2,550 m) they were mostly active in the morning and late afternoon. During their inactive times at high temperatures, survival made it necessary for them to retreat to favorable microclimates among the rockslides. While onset of vocalization and parturition occurred about six weeks earlier at the low altitude site, as one might expect, it seems strange that the onset of hay storage likewise occurred six weeks earlier. But the timing of vocalization and haying were actually correlated with the amount of precipitation during the previous winter. When the winter was dry with little snow and spring was early, the pikas responded by earlier vocalization and haying. [Perhaps the earlier haying was to

ensure more moisture or higher nutrient content of the food items?]

In warm weather, the American pikas have only short bursts of surface activity, typically less than 2.5 minutes at a time (MacArthur & Wang 1974). Instead, they remain in the cooler microclimate beneath the rocks and regulate their body temperature to only 2-3°C below their upper lethal temperature.

The mean body temperature of a pika ranges 37.9-42.7 in an ambient temperature range of -9.3 to 24°C (MacArthur & Wang 1973). Hyperthermia causes death after only two hours of exposure to ambient temperatures higher than 28°C. Its ability to maintain a high body temperature through high metabolism and thick insulation permits it to survive in its high elevation habitat where food storage is limited. Climatic shifts that cause warmer temperatures put the pikas in peril of at least local extinctions (Beever *et al.* 2010). Such local extinctions have already occurred for the American pika living in the Great Basin (Beever *et al.* 2010, 2011). The survival of mosses that ameliorate the high temperatures will be critical to the survival of pikas in these habitats.

Ochotona collaris – Collared Pika

The collared pika (*Ochotona collaris*; Figure 55) is distributed in Alaska and the Yukon (Defenders of Wildlife 2017). They live on a diet of grasses and grass-like plants called sedges, but will include flowering plants, twigs, moss, and lichens among food items. Koju and Chalise (2014) assumed that the poor quality of food in winter caches for this species were due to predation pressure that limited their foraging radius to 10 m.

Figure 55. *Ochotona collaris*, a species that will include some mosses among its food items. Photo by Jacob W. Frank, through public domain.

An interesting mechanism by at least some collared pikas is the selection of food that has previously experienced herbivory by caterpillars (Barrio *et al.* 2013). Could they be seeking food that had higher levels of secondary compounds, stimulated by the herbivore attacks? Or were these herbivore activities signals of suitable food of high quality?

Like *Ochotona princeps* (Figure 50-Figure 54), *O. collaris* (Figure 55) can run across the talus slope under the moss cover (Morrison *et al.* 2004) in its Yukon, Canada, home (Morrison *et al.* 2009). This most likely reduces predation risk as well as modulating the temperatures they

experience (Morrison *et al.* 2004). Nevertheless, choice of food nutrition level does not seem to be dictated by predation risk. On the other hand, in experiments total amount of forage removed by the pikas was inversely related to predation risk.

Erinaceidae – Hedgehogs

The European hedgehog (*Erinaceus europaeus*) is a nocturnal species of Europe and Central Asia. As its name implies, it is common in hedgerows. The hedgehog (*Erinaceus europaeus*; Figure 56) is the only British mammal to have spines (Wildscreen 2010). They have fairly short tails, long legs, and small ears. They eat mostly insects, but may include other small animals, like frogs and rodents.

Figure 56. The hedgehog, *Erinaceus europaeus*, a species that uses pleurocarpous mosses for nesting materials. Photo by Jörg Hempel, through Creative Commons.

When young hedgehogs are born, they have a coat with soft, white spines under the skin to protect the mother during birth. After a few hours these emerge. After about 36 hours, a second coat of dark-colored spines emerges, then later a third set emerges. By day eleven, the hedgehogs are able to curl into a ball, and finally after 14 days their eyes open. They are nocturnal, having large eyes, but they may also be active in the daytime (Wikipedia 2017a). They are solitary animals, and only the female takes care of the young.

They rest in the daytime in nests made of twigs, leaves, grass, pine needles, and other foliage. The "other foliage" includes mosses (Figure 57), sometimes in large quantities! Fortunately, the nest is re-used by another individual. The hedgehog selects pleurocarpous mosses that are available near the nest among its nesting materials (van Laar & Dirkse 2010). The authors suggest that the mosses may be selected to maintain a suitable humidity in the nest.

Figure 57. *Erinaceus europaeus*, hedgehog, carrying moss, presumably for a nest. Photo through Creative Commons.

CHIROPTERA – Bats

Pteropidae – Flying Foxes

Pteropus conspicillatus – Spectacled Flying Fox

The flying fox of Australia is really a kind of bat associated with the rainforest habitats of the Wet Tropics bioregion of northeastern Queensland, Australia (Parsons *et al.* 2007). The spectacled flying fox (*Pteropus conspicillatus*; Figure 58-Figure 59) seems like an unlikely candidate for eating mosses, but... this bat ingests mosses, as evidenced by feces (**splat**) comprised of 14% moss (Andi Cairns, pers. comm. 4 December 2004). Samples from the wet complex notophyll vine forest had the greatest occurrence of bryophytes in fecal samples (22.8% of 685 samples) (Parsons *et al.* 2007). The fragments represented a diversity of bryophytes (15 families of mosses, thallose and leafy liverworts) and ranged from whole plants to detached leaves. The bryophytes evidenced effects of being eaten: highly fragmented, abraded, tightly interwoven with hair and fiber content. The bryophytes mixed with hair suggested that they may have been ingested during grooming.

Figure 58. *Pteropus conspicillatus*, the spectacled flying fox, with folded wings. This bat is a moss disperser. Photo by Shek Graham, through Wikimedia Commons.

Figure 59. *Pteropus conspicillatus* showing the bat wings. Photo by Bernard Dupont, through Creative Commons.

The use of bryophytes as food may be accidental or at least of only minor significance. On the other hand, the flying fox appears to be an effective dispersal vector. Using material from the interior of the feces (Figure 60-Figure 61), Parsons (Figure 60) and coworkers (2007) demonstrated that 52% of 48 fragments developed rhizoids and/or shoots in culture. Seasonal effects were evident, with those collected early in the season having greater germination success (17 of 28 fragments) than those collected later in the growing season (7 of 20).

Summary

Larger rodents make use of bryophytes, particularly for nesting materials, but a few eat them. Bryophytes make habitats for some of these, especially in bogs, fens, and other wetlands, and in Arctic regions. Such common bog dwellers include shrews,

The Merriam chipmunk gathers mosses, presumably for nesting material, but it could possibly be for food. The Eurasian red squirrel uses mosses in its nest, possibly to buffer the temperature, and possibly also explaining use by the Arctic ground squirrels in their hibernacula. Flying squirrels include mosses in the nest, presumably for the same purpose. The grey squirrel includes mosses to line the nest. The red squirrel uses mosses to decorate its home. Pikas use the mosses as a cool cover during hot days. Pleurocarpous mosses are often preferred for nesting.

Uses for food are less common among these larger rodents, but the Arctic ground squirrels cache moss capsules for winter food. The Arctic hare likewise consumes moss capsules. The European rabbit eats the leafy portions, but it is choosy about which species it eats. Pikas eat mosses when they are abundant. They re-ingest their feces, permitting them to obtain more nutrients from ingested mosses. Even the flying fox (actually a bat) ingests mosses, and in the process it serves as a dispersal agent.

Scraping activity by rabbits can destroy bryophytes, but this favors the growth of *Polytrichum* species and creates disturbed habitats suitable for *Funaria* and *Ceratodon*. And a rabbit burrow provided a suitable habitat (and probably dispersal) for the rare *Scopelophila cataractae*. In Australia, rabbits caused the disappearance of some species and appearance of others, maintaining similar bryophyte species richness. *Rhytidadelphus squarrosus* benefits from grazing in England, but disappears with rabbit grazing in Australia.

Acknowledgments

This chapter has benefitted greatly from anecdotal records sent to me by bryologists and friends who observed these small rodents interacting with mosses in the field. Steve Juntikka, a former plant taxonomy student of mine, sent me an excited email from Isle Royale after observing the young mouse devouring capsules of *Funaria hygrometrica*. Leah Vucetich, an Isle Royale researcher, provided me with the tentative identification of a juvenile *Peromyscus* based on the picture alone. Andi Cairns alerted me to the study on the spectacled flying fox. Johanna Varner helped me get images of pikas. Thank you to Brent Mishler for helping me to get all the information I needed regarding the CAMcorder observations of the Merriam chipmunk and to Des Callaghan for helping me retell the story of the role of rabbits in making a habitat for *Scopelophila cateractae*.

CHAPTER 18-1

LARGE MAMMALS: RUMINANTS – CERVIDAE

Figure 1. *Rangifer tarandus groenlandicus* scraping and browsing in the Arctic. Photo by Erwin and Peggy Bauer, U.S. Fish and Wildlife, through public domain.

Ruminantia - Ruminants

Tiny bryophytes seem unlikely foodstuffs for large ruminants, but there are in fact records of their consumption by a variety of these cud-chewing beasts (Figure 2). What seems unlikely is that bryophytes ever provide a major portion of the diet of these animals, and their consumption may often be accidental.

If you have read about "reindeer moss," notably eaten by reindeer and caribou, you have been fooled by an inappropriate common name. The moss in this case is not a moss at all, but a lichen. And a lichen is not even a plant. Rather, it is a fungus with a partner. That partner can be one of the algae (usually Chlorophyta) or one of the Cyanobacteria. Together, they make a whole new type of organism that often can live in places where neither partner can live alone. The fungi provide protection from UV light and from desiccation. The photosynthetic algae or Cyanobacteria provide the carbohydrate energy source through photosynthesis.

Figure 2. Domestic cow (*Bos taurus*) chewing cud. Photo by foxypar4, through Creative Commons.

Wild ungulates may deliberately eat mosses or ingest them accidentally along with a preferred browse. Even large animals such as the Mylakhchinsk bison (Figure 3) have been found with mosses in the alimentary tract (Ukrantseva *et al.* 1978). Peary caribou (*Rangifer tarandus pearyi*; Figure 6) in the Canadian Arctic archipelago can have up to 58% mosses in their rumen (Thomas & Edmonds 1983), hardly indicative of accidental ingestion. Nevertheless, the nutritive value of bryophytes for warm-blooded animals has been questioned (Sugawa 1960).

High concentrations of polyphenolic lignin-like compounds in cell walls of bryophytes make the cellular contents less accessible to digestive enzymes (Prins 1982). They furthermore often have polyphenols that have antibiotic properties, thus inhibiting the ability of digestive bacteria in ruminants to break down the bryophytes.

Prins (1982) observed that in cold environments mosses are eaten by a variety of herbivores, both mammals and birds, including the ruminants Peary caribou (*Rangifer tarandus pearyi*; Figure 6), Spitsbergen reindeer (*Rangifer tarandus platyrhynchus*; Figure 7), Soay sheep (*Ovis orientalis*; Figure 8-Figure 9), and musk-oxen (*Ovibos moschatus*; Figure 10). Although mosses have similar caloric values to those of tracheophytes, they are difficult for these ruminants to digest (Hegnauer 1962).

Figure 10. Musk-ox (*Ovibos moschatus*), a herbivore that eats mosses. Photo through Creative Commons.

One explanation that has been suggested for ruminant herbivory on mosses is that mosses contain high concentrations of highly polyunsaturated fatty acids such as arachidonic acid (Gellerman *et al.* 1972). This fatty acid is also a component of animal cell membranes and other multi-unsaturated C-20 and C-22 fatty acids (Gurr & James 1971; Huneck 1983; Hegnauer 1986). Arachidonic acids have 4 double bonds, whereas the others have 5 double bonds. These are unique in mosses, being absent in seed plants where the highest level of unsaturation is usually two or three double bonds (Swanson *et al.* 1976). Mosses, on the other hand, may have up to 35% of their fatty acids as arachidonic acid, the highest known in any plants (Gellerman *et al.* 1972; Suire & Asakawa 1979). Gellerman *et al.* (1972) and Swanson *et al.* (1976) suggest that in mosses this acid contributes to the special properties of the chloroplast and other tissues that enable them to survive extreme environmental conditions.

Prins (1982) suggested that consumption of mosses with their arachidonic acids permits Arctic animals to have

a higher activity level at low temperatures by making their cell membranes, especially in foot pads, more fluid at low temperatures. These fatty acids decrease the temperature at which the membrane undergoes a phase change from a liquid crystalline state to a solid or gel-like state. This behavior of membranes has been demonstrated for cold-acclimated fish; these fish show a higher degree of unsaturation in the lipids of the cell membrane than do warm-acclimated fish (Caldwell & Vernberg 1970; Cossins *et al.* 1977; Smit 1980). Nevertheless, no direct evidence is available to demonstrate the real fate of arachidonic acid derived from a diet including mosses (Prins 1982). If the Arctic animals do eat mosses to gain arachidonic acid, they may have to eat large quantities because of the limited digestibility of the moss.

Some seeds have been protected from mammal predation by neighboring bryophytes (Ukrainitseva 1979). In the late Pleistocene, bryophytes reduced post-dispersal predation, whereas ^{14}C dating indicated that some animals had consumed bryophytes.

Van der Wal and Brooker (2004) found that few studies on the impacts of herbivores on the vegetation addressed impacts in the Arctic. They specifically sought understanding of the impact of the moss layer. This layer maintains warmer soils that potentially benefit the tracheophytes. Their results suggest that grazers impact the moss depth, subsequently altering soil temperature, and that this temperature change may impact some tracheophyte abundance. These impacts vary with growth form of the tracheophytes. The moss layer is altered by both grazing and trampling. Furthermore, the feces and urine benefit the tracheophytes, encouraging their expansion.

Impact of Ruminants on Bryophytes

Grazing

A number of studies have indicated that heavy grazing reduces bryophyte and lichen dominance in both oceanic and continental areas (Austheim *et al.* 2007). Such reductions favor the establishment or increase of more resistant bryophytes such as *Dicranum* (Figure 11) species and members of the large mosses in the *Polytrichaceae* (Figure 5) (Helle & Aspi 1983; Väre *et al.* 1996; Virtanen 2000; Olofsson *et al.* 2004).

Hanley (1982) considered food selection by ungulates to involve four morphological parameters:

1. body size
2. type of digestive system (caecal or ruminant)
3. rumino-reticular volume to body weight
4. mouth size.

They considered large ungulates and caecal digesters to be limited by time compared to small ungulates and ruminant digesters. The high **rumino-reticular** (part of a cow's four stomachs) volume to body weight ratio adapts them to gaining nourishment from plants such as graminoids with thick cell walls and high cellulose content. Conversely, a low rumino-reticular volume to body weight ratio adapts those animals to thriving on browse plants (leaves, twigs, or other high-growing vegetation) with thin, lignified cell walls.

Figure 11. *Dicranum scoparium*, in a genus favored by heavy grazing. Photo by Michael Becker, through Creative Commons.

Milchunas and Noy-Meir (2002) suggest that such environments as cliffs and other small geological formations that prevent herbivory are likely to have greater diversity. They found that 86% of studies in small refuges indicated positive effects of these refuges on plant diversity, whereas only 50% of large refuges had such an impact.

Takala and coworkers (2012) demonstrated the importance of reestablishing herbivory to restore bryophyte communities that were familiar from the days of pasturing large herbivores in the area. They identified three of these restored bryophyte species as suitable indicators of "valuable" grassland habitats: *Abietinella abietina* (Figure 12), *Climacium dendroides* (Figure 13), *Syntrichia ruralis* (Figure 14). In addition, *Rhytidiadelphus squarrosus* (Figure 15) is indicative of rich soil and survives at least moderate grazing (Ingerpuu *et al.* 1998).

On the other hand, van der Wal and Brooker (2004) demonstrated that in the High Arctic, mosses can mediate the impact of grazers on the abundance of grasses through their effects on soil temperature.

White-tailed deer (*Odocoileus virginianus*; Figure 16-Figure 17) is among a number of ungulates that have a strong impact on the vegetation in its habitat (Rooney & Waller 2003). Herbivory can cause trophic cascades and even modify the physical structure of the habitat. In the Great Lakes region of North America and elsewhere, the white-tailed deer has experienced population surges due to the annihilation of its natural predators. In response, herb diversity is declining while grasses, sedges, and some ferns are increasing. We can expect that these changes will eventually impact the bryophyte communities (Rooney 2009).

Peatlands (Figure 18) seem to be especially susceptible to damage from large herbivores (Bleasdale 1998). The white-tailed deer (*Odocoileus virginianus*; Figure 16-Figure 17), in particular, often enters ombrotrophic bogs and minerotrophic fens in search of food or cover (Pellerin *et al.* 2006). These researchers compared five peatlands (Figure 18) that had been subjected to heavy deer browsing for 75 or more years with five peatlands on deer-free islands. They found that the deer had little impact on cover and species composition in the bogs, but cover of lichens was reduced and that of grasses and sedges increased. But the surface area of bare peat also increased. By contrast, the grazed fens differed significantly from the ungrazed

fens. The floristic composition differed, with plant diversity being greater in undisturbed fens, especially for shrubs, sedges, and liverworts (Figure 29-Figure 31). Dunne and Doyle (1998) documented changes in *Molinia*-dominated (Figure 19) blanket bogs in Ireland, where the impact was caused by Kerry cattle, likewise citing impacts on liverworts.

Figure 19. *Molinia* (= *Melica*) *caerulea* in wetland, a blanket bog species where cattle can change the bryophyte vegetation. Photo by Lamiot, through Creative Commons.

The effects are not the same in all ecosystems. Olofsson *et al.* (2002) used exclosures against herbivores in two Arctic-alpine (Figure 20) plant communities. Exclosures in the snowbed (Figure 21-Figure 22) resulted

in significant biomass increases of both tracheophytes and cryptogams (including bryophytes), but no corresponding changes occurred in the tall herb meadow. The least competition occurred in the open snowbed plots, a condition the researchers attributed to the mammalian herbivores. Excluding the herbivores permits the plant biomass to build up and eliminate the competitive differences.

Figure 20. Arctic landscape. Photo from USFWS, through Creative Commons.

In northwestern Finnish Lapland, Pajunen *et al.* (2008) used exclosures from 1999-2006 to compare the effects of reindeer grazing in a forest-tundra ecotonal area (Figure 21). The area included tundra heath, frost heath, and riparian habitats. They found a general increase in total cover in all exclosures. However, while the dominant tracheophyte groups increased, the bryophytes diminished in both cover and species richness within the exclosures. Like the cattle, it appears that the reindeer maintain a habitat suitable for bryophytes by reducing tracheophyte competition for light.

Figure 21. Forest-tundra ecotones in Rocky Mountain National Park, USA. Photo by Michael Kirsh, through Creative Commons.

Van der Wal and Brooker (2004) investigated the impact of large herbivores on Arctic plant communities (Figure 22-Figure 23), particularly with attention to the impact on the depth of the moss layer. They found that grazing had a domino effect by impacting the depth of the moss layer (Figure 22-Figure 23), subsequently causing a rise in the soil temperature (see Figure 25 for moss effect on soil temperature). That, in turn affected the seed plant abundance and community structure, especially promoting

growth of grasses. The grazing and trampling are both effective in reducing the depth of the moss layer. The grasses benefit not only from the warmer temperatures, but also from the added nutrients from grazer feces (poop) and urine.

Similarly, Elkington (1981) found that sheep and rabbit enclosures on limestone grasslands (Figure 26) in Teesdale, England, caused the grassland structure to become more open, largely through the loss of the grass *Festuca ovina* (Figure 27) and reduction of bryophyte and lichen cover. In Utah, USA, the cryptogamic crust (Figure 28) suffered "considerably" from domestic grazing (Anderson *et al.* 1982a, b). In this sensitive ecosystem, the cryptogamic cover was able to recover in 14-18 years.

Figure 26. Limestone grassland in Swindale Wood, England. Photo by Andrew Curtis, through Creative commons.

Porley and Rose (2001), being bryologists, expressed regret that the liverwort mat (*Scapanietum asperae*; Figure 29-Figure 39) was disappearing in English chalklands, dropping from 30 known localities 50 years earlier to 8 or fewer. These communities consisted of the bryophytes *Scapania aspera* (Figure 29), *Frullania tamarisci* (Figure 30), *Porella arboris-vitae* (Figure 31), *Hypnum lacunosum* (Figure 32), *Ctenidium molluscum* (Figure 33), *Dicranum scoparium* (Figure 11), *Pseudoscleropodium purum* (Figure 34), *Calliergonella cuspidata* (Figure 35), *Neckera crispa* (Figure 36), *Homalothecium lutescens* (Figure 37), and occasionally *Ditrichum gracile* (Figure 38) and *Tortella tortuosa*

(Figure 39). These communities have suffered from release from grazing, being replaced by other species. The loss for bryologists is supported by the absence of these communities on the continental chalklands and the conservation importance of the community.

As late as 1997, Bullock and Pakeman voiced concerns over the effects of reintroducing grazing to lowland heath (Figure 40) in England, citing the lack of information to guide management in these ecosystems. They found that introducing grazing or increasing stocking rates caused a general increase in plant species richness, grass, forb, bryophyte, and lichen cover, and area of bare ground. At the same time, litter depth and cover of dwarf shrubs and scrubs.

Figure 40. Lowland heath in England, a habitat that suffers from the effects of over-grazing. Photo by Roger Key, with permission.

One source of understanding the impact of browsers is through introductions. The Sitka black-tailed deer (*Odocoileus hemionus sitkensis*; Figure 41-Figure 42) to Haida Gwaii in the Queen Charlotte Islands, BC, Canada, in the late 19th Century provided such an opportunity (Stockton *et al.* 2005). The temperate rainforest is a habitat where little information exists on the impact of herbivory by large mammals. This system fortunately gave us a time table because among the 7 islands, there was representation of no deer, deer for less than 20 years, and deer for more than 50 years. When the deer were introduced, their natural predators (wolves and cougars) were absent. Where deer were never present, lower vegetation cover exceeded 80%, whereas it was less than 10% on islands that had

experienced deer browsing for more than 50 years. Interestingly, species richness was similar on all 7 islands, whereas diversity at the plot scale (314 m²) was 20-50% lower on islands with more than 50 years of deer browsing. Hence, the deer have simplified the ecosystem. This raises the question of the effects on bryophytes in this temperate rain forest. Typically, bryophyte cover is high, and the forests on Queen Charlotte Island are draped in bryophytes (Figure 43) (*e.g.* Hong & Glime 1997).

Figure 41. Sitka black-tailed deer (*Odocoileus hemionus sitkensis*), a species that has devastating effects on vegetation on some islands among the Queen Charlotte Islands, British Columbia, Canada. Photo by D. Gordon E. Robertson, through Creative Commons.

Figure 43. Hoh rainforest, with epiphytes on maples, a scene similar to that on the nearby Queen Charlotte Islands. Photo by Kevin Muckenthaler, through Creative Commons.

Contrary to many of these studies, Suominen *et al.* (1999) demonstrated in two Swedish pine forests (Figure 44) that moss cover was higher in unbrowsed plots (by moose, *Alces alces*; Figure 45), and lichen cover was higher in browsed plots. They considered this difference to be a response to the differences in the amount of light reaching the forest floor. In the greater light, the drought-resistant lichens could outcompete the shade-tolerant mosses, reaffirming the differences in response between habitats. Invertebrates differed as well, with higher numbers in unbrowsed plots, but diversity was higher in the browsed plots. This is an aspect that has not been examined relative to bryophyte communities of invertebrates. It also raises the question of the impact of moose browsing on the epiphytic bryophyte flora. Even if the mosses are not eaten, the higher light and lower moisture levels caused by browsing on trees could have an impact.

Figure 44. Pine forest in Sweden. Photo from Pixabay, through Creative Commons.

Figure 45. *Alces alces* bull moose grazing among shrubs. Photo from Denali National Park, Alaska, USA, through Creative Commons.

Brotherson *et al.* (1983) examined the long-term effects of grazing on **cryptogamic crusts** (bryophytes, lichens, algae, and bacteria; Figure 28) in the Navajo National Monument, Arizona, USA. They found that grazing over 40 years had greatly impacted both the

tracheophyte (plants with lignified vascular tissue) and cryptogamic communities. The cryptogamic community suffered the most, exhibiting the greatest reduction in cover. Algae were much more tolerant than the lichens and bryophytes. In Idaho, Hilty *et al.* (2004) suggested that following fire in these rangelands, a resting period from livestock grazing would reduce invasive grasses and benefit the native mosses.

Not surprisingly, air pollution, in particular nitrogen pollution, plays a role in the relationship of grazing and bryophytes. Van der Wal *et al.* (2003) found that as livestock grazing increased concurrently with increased N deposition, large-scale degradation of both natural and seminatural ecosystems occurred. Using an experimental approach, these researchers demonstrated that the interplay between grazing and N deposition has led to the replacement of moss-dominated habitats by those dominated by grasses and sedges.

Trampling

Even when large mammals don't eat bryophytes, they can impose serious damage through trampling (Figure 46). Liddle (1997) considered mosses to be particularly sensitive to disturbances such as trampling. Thus, when trampling is reduced, we should expect bryophyte abundance to increase (Jónsdóttir 1991; Økland 1997; van der Wal *et al.* 2003). But the response is not quite so simple, because it also depends on the response of the rodent community (Austrheim *et al.* 2007). This trampling effect becomes most important in sensitive, slow-growth ecosystems such as those in the Arctic (Callaghan *et al.* 2001).

Figure 46. Introduced reindeer on South Georgia, Ocean Harbour, showing how hoofs could kick up and trample the vegetation. Photo by Roger S. Key, with permission.

In addition to trampling, some hoofed mammals such as roe deer (*Capreolus capreolus*; Figure 47) scrape the ground (Figure 48), dislodging the bryophytes and often exposing bare ground (Clément & Touffet 1981).

Although the role in destruction creates a major impact, trampling and scraping (Figure 1) can at times facilitate dispersal of bryophytes. Péntes-Kónya (2003) documented the role of disturbance in dispersal of the cushion moss, *Leucobryum juniperoideum* (Figure 49), in the Bükk Mountains of northern Hungary where it is the

dominant bryophyte on the ground. Both deer (*Cervidae*) and mouflons (*Ovis orientalis orientalis*, a subspecies of wild sheep) are instrumental in turning over whole cushions during the extremely dry spring. But *L. juniperoideum* actually benefits somewhat from this behavior. It responds to the change in light direction and gravitational pull by growing in a ball (Figure 50). And it has **caducous** (able to break off) leaves that behave like gemmae for reproduction (Figure 51).

Figure 47. Roe deer (*Capreolus capreolus*) male and female. Photo by Juan Lacruz, through Creative Commons.

Figure 50. *Leucobryum juniperoideum* cushion that has been turned upside down and experienced new growth on its new top side. This ball-shaped form is typical after such disturbance. Photo courtesy of Erika Péntzes-Kónya.

Figure 51. Leaf of *Leucobryum juniperoideum* that was turned to under side of clump, showing the development of rhizoids. Photo courtesy of Erika Péntzes-Kónya.

While the stems of *L. juniperoideum* are upside down, rhizoids form on the leaf tips (Figure 51). These plants, and their detached tips, form new plants and can be dispersed by the hooves. Even the leaf lamina cells can produce filaments when the plants are turned over (Figure 52). Nevertheless, during the dry season the disturbance is greater than the regeneration. The new growth occurs faster in the rainy periods. *Leucobryum glaucum* (Figure 53-Figure 54) has similar behavior when turned upside-down (Erika Péntzes-Kónya, Bryonet 13 June 2011).

But cryptogamic crusts (Figure 28) are not so fortunate (Anderson *et al.* 1982b). Domestic grazing greatly reduces the lichens, mosses, and algae forming the crusts. This destruction coincides with soils with heavier texture and greater salinity. Recovery seems to be moderately fast, with crusts usually becoming re-established within 14-18 years.

In three sagebrush communities (Figure 55) in east-central Idaho, USA, cryptogamic crusts (Figure 28; Figure 55) are important in maintaining the ecosystem (Kaltenecker *et al.* 1999). These biological crusts typically

have bryophytes that help to retain water and collect it from dew. Following ~10 years of enclosure to browsing, the crust doubled compared to areas where browsing continued. However, in the area of low sagebrush (*Artemisia arbuscula*; Figure 56), there was the least crust cover and this cover did not differ in exclusion areas there, apparently limited by the gravelly soil surface and dominance of rhizomatous grasses.

Yet another response to trampling can be found in fens (Figure 57) (Stammel & Kiehl 2004). Low light availability limits seed germination, accompanied by litter accumulation and competition by mosses.

Figure 57. Fen, sometimes referred to as a flow-through bog. Photo through Creative Commons.

Manuring

We use manure (Figure 58) to fertilize crops, so it is reasonable to ask what effect ruminant manure has on the one-cell-thick moss leaves. Vanderpuye *et al.* (2002) examined the effects in the *Luzulion nivalis* (Figure 59) snowbeds (Figure 60 at Sassendalen, Svalbard. This location has a low water table, whereas moss tundras usually have no standing water. In these cold environments, manure seems to explain the moss tundra vegetation. The mammals contributing this manure are non-migratory Svalbard reindeer (*Rangifer tarandus platyrhynchus*; Figure 7).

Figure 59. *Luzula nivalis*, the species for which the *Luzulion nivalis* is named. Photo by Jeffery M. Saarela, through Creative Commons.

Figure 60. Late snowbeds, Great Britain. Photo by Nigel Brown, through Creative Commons.

Several authors have demonstrated that manure from mammalian grazers and enhanced nutrient cycling resulting from grazing can cause an increase in the graminoids and a concurrent decrease in bryophyte abundance in Arctic-alpine tundra (Olofsson *et al.* 2001; Stark *et al.* 2002).

Van der Wal *et al.* (2004) tested the hypothesis that large herbivores manipulate their own food supply by modifying soil nutrient availability. To do this in a Spitzbergen tundra, they added feces of the reindeer *Rangifer tarandus platyrhynchus* (Figure 7) for four years, thus simulating the effect of feces impact by a larger herd. After the third year, the standing crop of grasses had clearly increased in both shoot density and biomass per shoot. At the same time, the increase in feces and grass productivity did not result in increased grazing pressure. The added feces caused an increase in soil microbial biomass carbon and nitrogen, especially under wet conditions that promoted decay rates. Under dry conditions, the grasses benefitted from the fecal additions. On the other hand, the moss layer depth was significantly impacted by the fecal addition. Areas with the greatest soil microbial biomass likewise had the greatest reduction in moss depth. Van der Wal and coworkers suggested that the moss reduction was due to greater decomposition of the mosses by the enhanced microbes. It is common for Arctic seabirds to affect the tundra vegetation, but here the non-migratory Svalbard reindeer have replaced the seabirds and created an intense manuring effect (Vanderpuye *et al.* 2002). This illustrates yet another mechanism by which grazers impact the bryophyte community, especially in the tundra (van der Wal *et al.* 2004). But Vanderpuye and coworkers consider the reindeer manuring to explain the presence of moss tundras in this Spitzbergen landscape where seabird colonies are absent. Perhaps it is all about the size of the herd.

Life on Manure – Splachnaceae

A discussion of manuring and bryophytes would not be complete without describing the fascinating relationships of the moss family **Splachnaceae** with manure.

While some bryophytes suffer from the manure of reindeer and caribou, others find these to be their most suitable habitat. These dung mosses include, in particular, many members of the **Splachnaceae**. Included are *Aplodon wormskjoldii* (Figure 61), *Splachnum luteum* (Figure 62), *S. sphaericum* (Figure 63), *Tayloria* spp. (Figure 64), *Tetraplodon mnioides* (Figure 65), *T. paradoxus* (Figure 66), and *Voitia hyperborea* (Figure 67) (Steere 1976). See also Volume 1, Chapter 4-9, Adaptive Strategies: Spore Dispersal Vectors.

Figure 67. *Voitia hyperborea* with capsules, a dung moss in the Arctic. Photo by Michael Lüth, with permission.

I am most familiar with these mosses on moose droppings. My first experience was spectacular. I was walking along a path on Isle Royale (Figure 68-Figure 69), Michigan, USA. This is the largest island in Lake Superior (Figure 68) and has a large moose (*Alces alces*) population. My student was ahead of me, searching for the *Splachnum rubrum* (Figure 70-Figure 71) he had seen before I arrived. Suddenly an iridescent purplish red caught my eye! My immediate response was "What in the world?...IT'S SPLACHNUM!"

Figure 68. Lake Superior, with Isle Royale indicated by the arrow. Photo from NASA, through public domain.

Figure 70. Winter moose dung with *Splachnum rubrum* on Isle Royale. Photo by Janice Glime.

Figure 71. *Splachnum rubrum* capsules on Isle Royale, Michigan. Photo by Janice Glime.

Splachnum rubrum (Figure 70-Figure 71) is picky, occupying only the winter dung (Figure 72), the dung that drops as small cylinders. It differs from the large, moist "cow pies" of summer because the winter food consists of twigs and branches and other foods low in nutrients and moisture content.

Figure 72. Moose (*Alces alces*) winter scat. Photo by Cephas, through Creative Commons.

In spring, the capsule odor attracts flies. With luck, the flies have visited another patch of these dung cylinders where *Splachnum rubrum* (Figure 70-Figure 71) has grown and produced capsules. In their mature stage, these capsules smell like dung and attract the flies that subsequently get spores on them. These are transferred to the next patch of dung they encounter. Details of this wonderful family will be provided later in the Habitats volume.

Cervidae – Deer, Elk, Moose, and Caribou

In the Arctic, members of this family are often dependent on mosses for food, but some members of the family may also impact bryophytes in lower latitudes. Chollet *et al.* (2013) reported that the deer family **Cervidae** has increased in abundance in temperate and boreal forests. The impact of these over-abundant deer is well documented (Kirby 2001), but little is known about the impact on bryophytes (Chollet *et al.* 2013).

White-tailed Deer – *Odocoileus virginianus*

The white-tailed deer (*Odocoileus virginianus*; Figure 73) has a significant impact on the tracheophyte vegetation, damaging forest vegetation and crops (Horsley *et al.* 2003). Using exclosures (Figure 74), Stewart and Burrows (1989) found that the lichen-moss cover changed little between exclosures and non-exclosures from 1979 to 1985.

Figure 73. *Odocoileus virginianus*, white-tailed deer, seems to have little effect on the bryophyte vegetation. Photo by Scott Bauer, USDA, through public domain.

Figure 74. Exclosures, near for reindeer, far (with young trees) for both rodents and reindeer, at Abisko in sub-Arctic Sweden. Photo by Monteux, through Creative Commons.

In many parts of the eastern USA the increases in deer populations indicate that effects on plant communities may increase in the future (Stromayer & Warren 1997). The impact of heavy deer browsing seems to be particularly exacerbated in swamps by the mossy and soupy peat. Quantitative studies are needed to assess the impact of the white-tailed deer on bryophyte communities.

Black-tailed Deer – *Odocoileus hemionus*

Chollet *et al.* (2013) compared the impact of browsing by the black-tailed deer (*Odocoileus hemionus*; Figure 75-Figure 76) in two island groups, one with the deer and one without, in the Haida Gwaii archipelago of British Columbia, Canada. In this case, the deer totally avoided browsing, as determined by observations on their feeding. The islands with the black-tailed deer had greater density, cover, and diversity of bryophytes than the islands with no deer. This presumably is due to reduced competition with tracheophytes for light and the total avoidance of foraging on bryophytes by the black-tailed deer.

Reindeer/Caribou – *Rangifer tarandus*

Reindeer and caribou (*Rangifer tarandus*; Figure 77) are different names for the same ungulate in different parts of the world. Their browsing on lichens, especially those

known as reindeer "mosses" (*Cladina* spp.; Figure 78), is well known (Väre *et al.* 1995; Olofsson *et al.* 2004), but their consumption of bryophytes is less well understood.

Importance of Mosses in Diet

Several authors claim that reindeer/caribou seldom eat mosses, despite the limited availability of other foods (Person *et al.* 1980; White & Trudell 1980; Olofsson *et al.* 2004). In a study of food preferences in northern Sweden, Danell *et al.* (1994) found that these animals had a high preference for lichens in winter, but a low one for the common moss *Pleurozium schreberi* (Figure 79). The researchers were unable to explain this difference by nitrogen content, organic matter digestibility, or fiber.

Figure 79. *Pleurozium schreberi*, a common moss often avoided by reindeer and caribou. Photo by J. C. Schou, with permission.

Crête *et al.* (1990) compared lactating caribou in two tundra habitats (Figure 80), one where lichens occupied more than 50% of the ground cover and one where mosses, bare soil, and graminoids dominated the vegetation. The rumen contents reflected the differences in the two habitats. Fewer lichens were eaten in the habitat dominated by mosses and graminoids. Nevertheless, selection for lichens was intense, with lichen cover 25X less but only 1.5-2X less abundant in the rumina.

Figure 80. Barren-ground caribou (*Rangifer tarandus groenlandicus*) grazing in the tundra. Photo from USFWS, through public domain.

Klein (1979) found that the Peary caribou (*Rangifer tarandus pearyi*; Figure 6, Figure 82) – a subspecies in the high Arctic islands of Canada's Nunavut and Northwest territories – eat a smaller percentage of lichen than do caribou on the mainland. Rather, they rely on vascular plants and a greater quantity of mosses. Rumen contents contained an average of 58% mosses in Peary caribou of five regions of the Canadian Arctic archipelago during winter, representing five regions (Thomas & Edmonds 1983). Nevertheless, they still prefer the rather scarce foliose lichens in winter (Klein 1979).

In Arctic ecosystems (Figure 81), tracheophyte food can be scarce and mosses subsequently form a major component of the diet of many vertebrate herbivores. In addition to the rodents and birds already discussed in earlier chapters as bryophyte herbivores, ruminants in the Arctic also depend on mosses as a component of their diet. These include reindeer and caribou (*Rangifer tarandus*; Figure 80-Figure 82) and muskox (*Ovibos moschatus*; Figure 83) (Prins 1982; Prop & Vulink 1992; Longton 1997; van der Wal *et al.* 2000; Joly *et al.* 2007).

Figure 83. Muskox (*Ovibos moschatus*), a tundra moss eater. Photo through Creative Commons.

Manseau *et al.* (1996) considered the habitat of caribou (*Rangifer tarandus*; Figure 80) to be very susceptible to both grazing and trampling by the caribou. In fact, it appears that the herd size is regulated by the amount of available forage in its summer range. They found that the lichen mat was absent in grazed areas of the shrub tundra and that those areas were either bare or occupied by fragments of dead lichens and mosses.

On the other hand, lichens are very important to the caribou diet. Pharo and Vitt (2000) reported that in the montane forests of western Canada, the lichens preferred by the endangered woodland caribou (*Rangifer tarandus caribou*; Figure 84) were abundant, but the ground cover was dominated by feather mosses, especially *Pleurozium schreberi* (Figure 79).

Figure 84. Caribou (*Rangifer tarandus caribou*) feeding in tundra, Northwest Territories, Canada. Photo by Robert Berdan, with permission.

The Svalbard reindeer (*Rangifer tarandus platyrhynchus*; Figure 7) includes coprophagy among its feeding strategies (van der Wal & Loonen 1998). That is, they feed on the feces of barnacle goose (*Branta leucopsis*; Figure 85). In fact, the majority of the reindeer in the research area were seen feeding on these droppings instead of vegetation. The number of goose droppings eaten were enough to supply the daily energy requirements for 68 reindeer. But they were very selective in their choice of droppings, choosing those containing grass and avoiding those with moss fragments. There did not appear to be important differences in nitrogen, phosphorus, magnesium, calcium, sodium, potassium, or energy content between the two types of feces. Fiber, on the other hand, differed between grass- and moss-dominated droppings, with less fiber associated with the mosses. Thus, the grass-dominated droppings were more digestible.

Nevertheless, Arctic herbivores, including *Rangifer tarandus*; Figure 80, Figure 84), do consume substantial quantities of bryophyte biomass (van der Wal & Brooker 2004) and further damage them through trampling. Liddle (1997) has shown that trampling can be particularly destructive to mosses in Arctic ecosystems because of their slow growth rate and recovery (Callaghan *et al.* 2001).

Figure 85. Barnacle Geese (*Branta leucopsis*); Svalbard reindeer eat the feces of this goose, but avoid feces with mosses. Photo by Allan Hopkins, through Creative Commons.

Digestibility

Several authors have attributed the usual lack of consumption to the low digestibility of mosses (Person *et al.* 1980; White & Trudell 1980; Thomas & Kroeger 1981). Nevertheless, on Arctic islands with little lichen availability, the caribou herds eat mosses (Staland *et al.* 1979).

Robert Pegau, in correspondence with Howard Crum, reported that reindeer in Alaska scarcely digest mosses (Crum 1973), although they do graze on *Polytrichum* (Figure 5), *Aulacomnium turgidum* (Figure 86), and *Hylocomium splendens* (Figure 87) (Bland 1971). A high content of moss (up to 12%) in winter in the rumen of reindeer at Hardangervidda, Norway, may be ingested unavoidably while grazing on lichens (Gaare & Skogland 1975). Lichens, on the other hand, are readily digested (Crum 1973).

Figure 86. *Aulacomnium turgidum* in Norway, a moss species eaten by Alaskan reindeer. Photo by Jutta Kapfer, with permission.

Figure 87. *Hylocomium splendens*, a moss species eaten by Alaskan reindeer. Photo by Rob Routledge, through Creative Commons.

Nevertheless, when lichens are overgrazed, reindeer may turn to mosses. On Svalbard, where desirable lichens are scarce, Svalbard reindeer (*Rangifer tarandus platyrhynchus*; Figure 7) had a rumen content of 32-39% mosses, hardly an accidental accompaniment to lichens (Reimers 1977). In fact, van der Wal (2006) considers Svalbard reindeer to be moss specialists, consuming up to 54% of their winter diet as mosses, a figure similar to that of Peary caribou (*Rangifer tarandus pearyi*; Figure 6, Figure 82) in northern Canada (Klein 1979). Rather than eating lichens, reindeer in the High Arctic seem to have replaced lichens as winter forage with bryophytes (Staal and *et al.* 1983; Staal and 1986; Longton 1997). Staal and *et al.* (1983) found that the mosses on Svalbard provided a higher mineral content than the food available in Norway, but at the same time, the mosses had lower digestibility than the lichens and browse in Norway.

In a different study, Bjorkvoll *et al.* (2009) found that the winter diet of Svalbard reindeer (*Rangifer tarandus platyrhynchus*; Figure 7) was only 22-30% mosses during the three-year period of the study. Effects of snow cover in late winter affected the dietary composition. *Polytrichum* (Figure 5) was the most common bryophyte and comprised a relatively high proportion in the early winter diet.

In the southern Northwest Territories, Canada, the barren-ground caribou (*Rangifer tarandus groenlandicus*; Figure 1, Figure 88) included mosses, lichens, and shrubs in its diet (Thomas *et al.* 1984). Using fermentation in ruminal fluids in test tubes, Thomas and coworkers found that the dry matter biomass of shrubs was reduced by 37-51%, whereas the bryophytes were reduced only 7-28%. The lichens averaged 49% reduction in 180 hours. In a different case, Thomas and Kroeger (1981) examined *in vitro* digestion in ruminal fluids from *Rangifer tarandus groenlandicus* that had been shot in its winter range in southern Northwest Territories, Canada. This animal had poor digestion (15-27%) of two species of mosses and a liverwort.

Figure 88. Barren-ground caribou (*Rangifer tarandus groenlandicus*) herds. Such numbers cause considerable damage to the vegetation, including bryophytes. Photo from U.S. Fish and Wildlife, through public domain.

In Aoluguya, Great Khingan Mountain Range of Inner Mongolia, Feng and Bai (2011) examined factors related to bryophyte consumption and digestion. The bryophytes have high concentrations of acid-detergent fiber, making them indigestible. This raises the question, what permits some reindeer to subsist largely on bryophytes, especially in winter?

Staal and coworkers (1979) suggest that the reindeer (*Rangifer tarandus platyrhynchus*; Figure 7) on Svalbard may be adapted to eating mosses. These reindeer have an enlarged caecum-colon complex that appears to be an adaptation to a bryophytic diet by using the assistance of bacteria. These reindeer also have a high number of fiber-digesting rumen bacteria (Orpin *et al.* 1985), facilitating digestion. The rumen bacteria of the Svalbard reindeer are very effective in facilitating fiber digestion and nitrogen metabolism, providing an important adaptation for living in high Arctic habitats with poor nutritional conditions.

The Svalbard reindeer (*Rangifer tarandus platyrhynchus*; Figure 7) eat mosses in the winter because they are unable to migrate to forested lichen habitat (Longton 1992). Nevertheless, digestibility of mosses by these caribou is typically low, only 11-35% in summer and 3-11% in winter (Thomas & Kroeger 1980). Thus, one must ask just what the mosses provided for the animals. If ruminants, with their massive digestive bacteria flora, are unable to digest the mosses, one would assume they would be even less digestible for most other large mammals. There are likely to be other populations with similar winter grazing problems. Callaghan *et al.* (2004) considered deep snow to be a deterrent from winter grazing in some Arctic areas in some years. Areas of deep snow could force these ruminants into lower elevations or lower latitudes and prevent them from finding enough of the desired winter food source of lichens.

If mosses are difficult to digest and provide limited nutritional value, why are they heavily consumed in the Arctic? Ardea and Sage (1982) claim that the reindeer must consume 7 kg of mosses to extract the same energy they would get from just 0.5 kg of tundra grass.

We have seen that Prins (1982) suggested that they eat mosses for their arachidonic acid because of its ability to remain flexible in winter. These acids are major constituents of animal fats, especially in phospholipids of

cell membranes (Ardea & Sage 1982). These make the membranes more fluid, especially at the low temperatures of winter.

Feng and Bai (2011) added to the arachidonic acid possibilities. Reindeer are not able to synthesize arachidonic acid, but that which is ingested can provide several benefits to them. This acid is a precursor for some prostaglandin hormones, it has a low melting point that could lower the freezing point of the reindeer extremities, and it provides protection to cell membranes in the cold.

Effects on Soil Temperature

In the wet meadow vegetation of Barrow, Alaska, USA, Miller *et al.* (1980) found that in exclosures (Figure 74) the moss increased and the thaw depth decreased, suggesting that the mosses insulated the permafrost (Figure 89) against warming, and thus against thawing. Van der Wal and Brooker (2004) examined effects of reindeer herbivory on a moss layer of *Sanionia uncinata* (Figure 90), *Tomentypnum nitens* (Figure 91), and *Aulacomnium* spp. (Figure 92). Moss depth in the grazed controls was 38 ± 6 mm compared to 57 ± 10 mm in the ungrazed exclosures. Furthermore, $\text{NH}_4\text{-N}$ was considerably lower inside the exclosures, but nitrogen mineralization potential was reduced by greater moss depth. A 10-cm-thick mat of mosses causes $\sim 4.4^\circ\text{C}$ drop in soil temperature, with the temperature decreasing with moss depth (Figure 93). Manipulating the soil temperature had no effect on moss growth, but the grass *Poa arctica* and flowering plant *Cardamine nymmanii* (Figure 94) both were reduced by 50% biomass in the chilled soils (van der Wal *et al.* 2001). These temperature decreases not only affect roots and rhizomes of tracheophytes, but they also affect decomposer communities by affecting the soil microbes and consequently affecting nutrient cycling (Harrison & Bardgett 2008).

Microbial Responses to Grazing

Väre *et al.* (1996) found that microbial activity was significantly depressed at sites grazed by reindeer. This seems to be the result of reduced soil moisture at the grazed sites, especially during dry periods. Furthermore, grazing reduced the levels of all exchangeable nutrients by 30-60% in the organic layer of the soil. These factors contributed to the reduction of fine roots.

Temporal Differences

Both food choice and digestibility vary by season. Thomas and Kroeger (1980) found summer digestibility of mosses to range 11-35%, whereas winter digestibility ranged only 3-11%.

Thompson and McCourt (1981) studied the phenology of diet in the porcupine caribou herd (*Rangifer tarandus granti*; Figure 95) in the northern Yukon. The winter diet was dominated by lichens (66.7%) with most of the remainder being mosses (28.8%). In summer they shifted to primarily tracheophytes, especially sedges in spring, but shrubs dominated (>98%) after calves were born. The diet of shrubs declined and lichens again became prominent beginning in August.

Figure 95. Porcupine caribou (*Rangifer tarandus granti*) grazing. Photo by Dean Biggins, through public domain.

In the Great Khingan Mountain Range of Inner Mongolia, bryophyte consumption by reindeer also varied by season (Feng & Bai 2011). In April bryophytes comprised 5.63% of the feces, dropping to 2.2% in June, and rising to 12.9% in September. The four most common genera of bryophytes were *Pleurozium* (Figure 79), *Dicranum* (Figure 11), *Aulacomnium* (Figure 86, Figure 92), and the leafy liverwort *Ptilidium* (Figure 96). *Pleurozium schreberi* (Figure 79) comprised over 70% of the bryophyte total. But some seasonal differences are present. *Polytrichum juniperinum* (Figure 97) only occurred in large amounts in September. Despite the seasonal changes in amount of bryophytes eaten, the relative proportions among the other bryophyte species did not change appreciably between seasons. Nevertheless, sampling of the dominant forest floor bryophytes revealed that the reindeer are selective. *Hylocomium splendens* (Figure 87), *Sphagnum* spp. (Figure 98), and *Pleurozium schreberi* (Figure 79) are dominant bryophytes in the four types of forests investigated, but of these only *Pleurozium schreberi* was eaten. Additionally, *Didymodon* (Figure 99) and *Racomitrium* (Figure 100) occurred only occasionally in the feces.

Figure 100. *Racomitrium* in grey-green mounds, a genus that occasionally is consumed by Mongolian reindeer. Photo by Manfred Morgner, through Creative Commons.

In the five regions studied, Thomas and Edmonds (1983) found that monocots and mosses comprised 13% and 58%, respectively, of the rumen content of Peary caribou (*Rangifer tarandus pearyi*; Figure 6) in the Canadian Arctic archipelago. However, the digestibility of mosses for caribou is low, with the summer digestibilities of mosses ranging 11-35%, whereas lichens range 18-86% (Thomas & Kroeger 1980, 1981). In winter the mosses drop to 3-11% digestibility, suggesting they are not being consumed primarily for their nourishment. Perhaps it fools the caribou into "thinking" that they are full.

Thomas *et al.* (1984) also found that the dry matter disappearance of 22 plant species was significantly higher in March of 1981 than in tests performed one year earlier. The variation in the ruminal fluids coincided with differences in the physical condition of the caribou, which may have resulted from their nutritional history.

Site Differences

Based on these observations, we can expect the diet to differ by location. Pearce (1997) found that in the Kara area of Russia, 14% of the moss sites and 10% of the lichen sites experienced severe damage from reindeer activity. On

the other hand, in Norway, 73% of the moss sites and 85% of the lichen sites suffered from grazing and trampling. The reindeer populations of Norway had doubled in the previous years, resulting in soil erosion in 75% of the sites. Only 8% of the Russian sites suffered from erosion.

Sørmo *et al.* (1999) examined fragments in the rumen of Svalbard reindeer (*Rangifer tarandus platyrhynchus*; Figure 7) in the western parts of Spitsbergen at Nordenskiöld where tundra vegetation is somewhat abundant and on the island of Nordaustlandet where they live in a polar desert with scarce vegetation. On Nordenskiöld the rumen contents were primarily mosses and grasses, whereas on Nordaustlandet they were primarily the flowering plants *Saxifraga* spp. (Figure 101).

Figure 101. *Saxifraga cespitosa* on Svalbard. This genus is the primary food of the Svalbard reindeer on Nordaustlandet. Photo by Victor M. Vicente Selvas, through Creative Commons.

Grazing Effects on Bryophytes and Vegetation

Van der Wal (2006) considered the ruminant herbivores to cause predictable changes in the ecosystem vegetation. Van der Wal points out that reindeer can deplete the lichens and switch to mosses (Staaland *et al.* 1993) with no detrimental effects to the reindeer population (Cooper & Wookey 2001). In fact, the carrying capacity for large ungulates increases when the vegetation switches to mosses, and increases again when it converts to grasses after extensive herbivory on mosses. A similar succession from lichens to mosses to graminoids is known where caribou (reindeer) range in Greenland (Thing 1984), Russia (Vilchek 1997), North America (Palmer & Rouse 1945; Klein & White 1987; Manseau *et al.* 1996), Fennoscandia (Helle & Aspi 1983, Gaare 1997), and the high arctic islands (Van der Wal *et al.* 2001). Even domesticated reindeer in boreal forest ecosystems cause the conversion of lichen vegetation to mosses (Väre *et al.* 1996; Mäkipää 1998). And in Norway the moss-dwarf shrub heath gives way to grass domination under the pressure of reindeer grazing (Olofsson *et al.* 2001, 2004). Thing (1984) interpreted this progression of species as ecosystem damage.

Sarvas (1937) found that mosses like *Polytrichum juniperinum* (Figure 97) can survive feeding and trampling because they have rhizomes and rhizoids that can survive

the above-ground feeding. These underground parts are able to germinate and form new plants. Oksanen (1978) found that *Polytrichum hyperboreum* (Figure 102) in northern Norway is very resistant to trampling by reindeer. It is likely that *Polytrichum* species are also dispersed by the reindeer, and some of these are delivered to areas where competition with species of *Cladonia* (Figure 103) is avoided (Helle & Aspi 1983).

Van der Wal (2006) suggests the change in species begins with selection of lichens over mosses, causing greater lichen losses. This change is further promulgated by trampling, which is more damaging to lichens than to mosses, especially when they are dry (Cooper *et al.* 2001). If grazing is suppressed, the system may change back to lichen domination, but the change is slow (Crettenden 2000; Cooper & Wookey 2001; Den Herder *et al.* 2003). In fact, as lichens recover, they may "smother" the mosses (Gaare 1997; Van der Wal *et al.* 2001). A more likely explanation is the allelopathic effect of the many lichen secondary compounds (Lawrey 1995).

In *Pinus sylvestris* forests (Figure 104) of Fennoscandia, in 50-year-old exclosures indicate that

certain bryophytes benefit from reindeer grazing (Väre *et al.* 1995). This was particularly true for *Dicranum* spp. (Figure 11) and *Pleurozium schreberi* (Figure 79). In heavily grazed sites, the food lichen species *Cladina* spp. (reindeer "moss"; Figure 78) disappears. However, in ungrazed sites, *Cladina* species replace the *Cladonia* (Figure 103) lichen species and small bryophytes like *Barbilophozia* spp. (Figure 105), *Pohlia nutans* (Figure 106), and even *Polytrichum* spp. (Figure 102).

Virtanen (2000) used exclosures to determine the effects of herbivory on vegetation of a mountain snowbed in northwestern Finland. Unlike Sarvas (1937) and Oksanen (1978), Virtanen found that the dead plant material of *Polytrichaceae* (Figure 97, Figure 102) in the 15-year exclosures had increased; the moss *Kiaeria* (Figure 107) had disappeared. His results contradicted the assumption of other researchers that herbivory was unimportant in areas of low productivity. In these snowbeds, it clearly had an impact.

Figure 107. *Kiaeria starkei*, a moss species that disappears in exclosures. Photo by Hermann Schachner, through Creative Commons.

Olofsson *et al.* (2001) examined the effects of summer grazing on the tundra heath vegetation in northern Norway. Comparing winter grazed, lightly summer grazed and heavily summer grazed vegetation at four different sites. They concluded that the highest productivity occurs at intermediate grazing pressure. They found that intensive grazing may be responsible for the transition from a moss-rich heath tundra to a productive grass-sedge-dominated steppe-like tundra vegetation. Intermittent grazing can actually enhance summer productivity.

In the sub-Antarctic on South Georgia, experimental reindeer exclosures demonstrated the changes to the vegetation after 1 year (Leader-Williams *et al.* 1987). Native grasses (*Poa flabellata*; Figure 108) and dwarf shrubs (*Acaena magellanica*; Figure 109) increased in response to the absence of grazing. The moss *Polytrichum* (Figure 97, Figure 102) likewise increased, but to a lesser extent. This is reminiscent of the responses in rodent exclosures (see Chapter 17). Macrolichens showed little change, as did moss-bank communities. The lichen cover is likely to require decades to recover.

Using approximately 3000 permanent plots in Finland and more than 10,000 plots in all in three different surveys, Mäkipää and Heikkinen (2003) measured changes in the vegetation. During this time, the forest floor moss *Hylocomium splendens* (Figure 87) decreased in abundance while *Dicranum polysetum* (Figure 110) increased. In the northern part of Finland, grazing by semi-domestic reindeer coincided with a decline of *Cladina* (Figure 78) lichens, a favorite food, while the mosses *Dicranum* spp. increased. *Polytrichum juniperinum* (Figure 97), *Pohlia nutans* (Figure 106), and *Brachythecium* sp. (Figure 113), moss species typical of disturbed sites, increased. *Sphagnum* (Figure 98)

abundance decreased, especially in western Finland where the moss *Pleurozium schreberi* (Figure 79) also was favored.

Hansen *et al.* (2007) followed vegetation changes for 26 years following the reintroduction on the northwest coast of Spitsbergen, Svalbard, of the Svalbard reindeer (*Rangifer tarandus platyrhynchus*; Figure 7). The population size fluctuated, and when it reached high numbers, it caused a top-down effect on the vegetation that included a decrease in the cover of mosses. The preferred winter forage, fruticose lichens, almost disappeared. When the grazing pressure was relieved, the mosses not only recovered completely, but within six years they exceeded the pre-reindeer levels.

In the Arctic and alpine tundra, reindeer (*Rangifer tarandus*; Figure 77) consume 22-30% of their winter diet as moss (Heggberget *et al.* 2010). These researchers expressed concern that climate change, predictably greater in these northern areas, could compromise the available winter forage. Lichens are likely to be impacted, forcing the reindeer to seek other forage. In some populations, a larger alimentary tract has adapted to the reindeer diet.

Roe Deer – *Capreolus capreolus*

Several studies have revealed the ability of hoofed mammals to transport bryophyte propagules. One such study demonstrated the **epizoochorous** dispersal of bryophyte fragments by roe deer (*Capreolus capreolus*; Figure 111) (Heinken *et al.* 2001). They found 106 bryophyte fragments, almost all stem fragments, lodged in the coats and hooves of 15 roe deer and 9 wild boar (*Sus scrofa*; Figure 112). These represented 12 bryophyte species, with the most abundant being *Brachythecium velutinum* (Figure 113), *Hypnum cupressiforme* (Figure 4), and *Eurhynchium hians* (Figure 114). These were typically about 3.6 mm long, but ranged 0.5-35 mm. The species that were most common were slender pleurocarpous mosses (growing horizontally) with erect, acute leaves. Robust acrocarpous mosses (growing upright) that formed tall turfs were generally absent.

Roe deer can do considerable damage to bryophyte vegetation (Clément & Touffet 1981). Following fire in the Brittany heathlands, roe deer were responsible for bryophyte disappearance due to scraping by roe deer.

Figure 114. *Eurhynchium hians*, one of the most abundant moss species carried by roe deer (*Capreolus capreolus*). Photo by Michael Lüth, with permission.

Bryophytes do not appear to serve as food for this species (Tixier *et al.* 1997). Although they are generalist feeders by using a variety of types of food, they are selective within the food types. Their use of food species correlates negatively with fiber content. Bryophytes were specifically avoided in all seasons. Even so, they preferred plants that had high concentrations of protein-binding

phenolic compounds, leading Tixier and coworkers to suggest that they might have specific mechanisms for deactivating these compounds. For many animals, protein-binding compounds prevent the animals from obtaining nutrition from the proteins they eat, even from accompanying foods that don't have the binding compounds.

Hog Deer – *Axis porcinus*

In southeastern Australia, both introduced mammals and native species consume plants (Davis *et al.* 2008). Whereas the swamp wallabies (*Wallabia bicolor*; Figure 115) consume the largest proportion of tree browse, the hog deer (*Axis porcinus*; Figure 116) consume the largest proportion of mosses, however only removing less than 0.01%.

Summary

Bryophytes and ruminants interact in various ways. Some of these animals eat the bryophytes, particularly reindeer in Arctic regions, and most are capable of creating disturbance that can damage the bryophytes. Trampling and scraping break and dislodge the

bryophytes, but at the same time these activities can contribute to dispersal as the fragments adhere to hooves and fur/hair/wool.

Reindeer/caribou (*Rangifer tarandus*) typically cannot digest bryophytes well, but on Svalbard, where they have no place to go for winter, mosses are a staple in the diet. They seem to have adapted by being able to absorb more of the nutrients from the mosses through an enlarged caecum-colon complex.

Both black-tail (*Odocoileus hemionus*) and white-tail (*Odocoileus virginianus*) deer and roe deer (*Capreolus capreolus*) apparently avoid eating bryophytes.

When grazing is light, it can favor such mosses as *Rhytidiadelphus squarrosus*, *Polytrichaceae*, and *Brachythecium*. Colonizers like *Pohlia nutans* can benefit from disturbance and increased light. Leafy liverworts like *Barbilophozia floerkei* decrease with grazing. But the bryophyte communities depend on the site, with Arctic and alpine communities responding differently from more temperate ones. Rodents likewise can have a profound effect on the bryophytes, with communities responding differently depending on the foraging ruminants present.

Bryophytes suffer from manuring and urine, perhaps due to increased microbial decomposition, or to greater competition from the enriched tracheophytes.

Acknowledgments

Thank you to Robert Berdan for giving me permission to use his beautiful images, and to all the photographers who have put their images into Creative Commons or public domain. Others have given me permission to use their images, as noted under each picture. Rolf Peterson helped me to straighten out the scientific nomenclature for moose. Eileen Dumire provided a critical review of the chapter, identifying text that was unclear.

CHAPTER 18-2

LARGE MAMMALS – RUMINANTS

Figure 1. *Ovis aries* (Soay sheep) resting on mat of mosses and grasses. Their herbivory on grasses can benefit the mosses. Photo from Biopix, through Creative Commons.

Moschidae – Musk Deer – *Moschus*

Green (1987) found that for Himalayan musk deer (*Moschus chrysogaster*; Figure 5), the choice of mosses as food was highly seasonal and usually avoided. They preferred forbs and woody plants in autumn and winter, positively avoiding bamboo leaves and mosses.

Ihl and Barboza (2007) compared the digestible value of a typical ruminant food for Arctic muskoxen (*Ovibos moschatus*; Figure 2) with that of the mosses *Hylocomium splendens* (Figure 3) and *Tomentypnum nitens* (Figure 4) from two locations in Alaska, USA. First they acclimated the muskoxen to mosses for 15 consecutive days. Using forages from ruminally fistulated muskoxen (having passageway cut from rumen to outside) they determined that ruminal degradation was not affected by previous acclimation to mosses.

Ruminal digestion caused a loss of dry matter during 48 hours of ruminal incubation of grasses (-49%), but mosses actually gained dry matter (44-57%) (Ihl & Barboza 2007). These changes were unaffected by

suspending the forages in the rumen for 15 consecutive days, a procedure that could induce digestive enzymes in response to previously uneaten food sources. The incubated mosses gained 435-680% N and 18% fiber!

Figure 4. *Tomentypnum nitens*, a species common in the habitat of Arctic musk oxen. Photo by Jutta Kapfer, with permission.

Ihl and Barboza (2007) suggested that the gain in mass by the mosses was due to microbial colonization and adsorption of fibrous particles onto the absorbent mosses. When digested with acid-pepsin, the ruminally incubated mosses lost little nitrogen, whereas the hay lost 23% nitrogen. Ihl and Barboza suspected that winter consumption of mosses may be the result of selecting other plants that grow mixed within the moss community, thus explaining the presence of mosses in feces. The times when mosses occurred in the feces of these animals indicated low availability of preferred foods. As noted in an earlier chapter, Arctic birds likewise experience periods of low availability of desired foods, but their digestive processes differ, so studies on ruminants may not be indicative of digestibility for birds, or *vice versa*.

Bovidae – Antelopes, Cattle, Gazelles, Goats, Sheep, and Relatives

Sheep – *Ovis*

Sheep can have a serious impact on the bryophyte communities. Downing (1992) suggested their impact on limestone bryophyte vegetation at Attunga, Australia. Rieley *et al.* (1979) reported that sheep graze in Welsh oakwoods on grasses until ultimately the bryophytes increase in abundance. Austrheim *et al.* (2007) found a similar increase in bryophytes, particularly *Plagiothecium* (Figure 6) and *Rhodobryum roseum* (Figure 7), under heavy grazing pressure of sheep in an alpine habitat in southern Norway.

Figure 7. *Rhodobryum roseum*, a moss species that increases under heavy grazing of sheep in alpine areas of southern Norway. Photo by Hermann Schachner, through Creative Commons.

In a study of ruminants from the Canary Islands, Rodríguez Suárez *et al.* (1990) found that mouflons [wild sheep; *Ovis aries musimon* (Figure 8) – an endangered species that has been successfully cloned (Loi *et al.* 2001; Trivedi 2001)] and Barbary sheep (*Ammotragus lervia*; Figure 9), native of northern Africa and introduced to Europe in the late 1800's) consumed bryophytes. Rodríguez Suárez and coworkers examined the stomach contents of 46 Corsica mouflons and 19 Barbary sheep from the highest area of La Palma and Tenerife islands. They found that 11 stomachs contained *Grimmia laevigata* (Figure 10), *Grimmia* sp., *Racomitrium heterostichum* (Figure 11), and 2 *Didymodon* sp. (Figure 12). These species grow on rocks in very dry habitats where other plants usually considered more suitable for consumption are generally absent. This suggests that the consumption of mosses is deliberate.

Like the roe deer (*Capreolus capreolus*; Figure 13), grazing sheep are often transporters of bryophyte fragments and other propagules (Müller & Heinken 2011). Pauliuk *et al.* (2011) compared transport by two breeds of sheep. The twelve sheep in the study carried 16 species of mosses, but these represented only 40% of the moss species in the pasture (Figure 14). The belly and tail (Figure 13) were especially good at transport. The two breeds favored different species and frequencies. Those sheep that had a dense, curly fleece were able to carry larger species and more fragments than the breed with a fine, smooth fleece. The horizontally growing pleurocarpous mosses, as with roe deer, were more common than upright acrocarpous species; small species and mats were likewise more common than other forms. Large species, acrocarpous species, wefts, and turfs were underrepresented. Hooves, on the other hand, carried primarily acrocarpous colonist species.

Figure 13. Roe deer (*Capreolus capreolus*) lying down, a position that can put bryophyte fragments on the underbody and tail. Photo through Creative Commons.

Figure 14. Comparison of bryophyte transport by two breeds of sheep: Skudden (n = 5, 117 fragments) and Pomeranians (n = 7, 2096 fragments). Grey bars indicate relative cover in the vegetation of the study site. Modified from Pauliuk *et al.* 2011.

It appears that at least some bryophytes receive other benefits from the sheep. They appear to maintain a habitat where these bryophytes can thrive. When the pasture is abandoned, bryophytes disappear due to their limited ability to compete with the invading tracheophytes (Takala *et al.* 2012). In southwestern Finland, cover, species richness, species density, and species diversity of bryophytes were all significantly higher in pastures that had been continuously grazed than those in abandoned grasslands. Takala defined three grassland habitats: (1) continuously grazed pastures, (2) previously abandoned pastures where grazing was re-established during 1990s, and (3) abandoned pastures. Among these, 17 species of bryophytes were suitable indicators of the three grassland types. Four of these indicated valuable grassland habitat.

In some areas, sheep graze in bogs (Rawes 1983). In two high altitude blanket bogs in the North Pennine uplands of England, cessation of sheep grazing led to major changes in the species composition, vegetation pattern, and structure of the bogs. Colonization of bare peat was slow in the exclosures. In particular, the leafy liverwort *Diplophyllum albicans* (Figure 15) declined, whereas it had previously been a constant companion for the cottongrass *Eriophorum* (Figure 16).

Figure 15. *Diplophyllum albicans*, a leafy liverwort species that declines in the absence of sheep. Photo by Hermann Schachner, through Creative Commons.

Figure 16. Cottongrass (*Eriophorum vaginatum*), member of a common genus in peatlands of English uplands. Photo through Creative Commons.

Lee *et al.* (2013) examined blanket bog plant communities following various types of disturbance, including low-intensity sheep grazing. In the low-intensity grazing areas, *Hypnum jutlandicum* (Figure 17) cover and bryophyte species richness both increased in the least-disturbed plots. Overall bryophyte cover, however, did not. In fact, low-level grazing had little impact on the bryophyte communities. The most-disturbed plots, with a 10-year burn cycle, had an increase in *Sphagnum* spp. (Figure 18) over a 10-year period. I have to wonder if drafts created by the burning contributed to dispersal from neighboring communities.

Figure 18. *Sphagnum girgensohnii*, representing a genus that increases in number of represented species following fire disturbance. Photo by Jutta Kapfer, with permission.

A common bryophyte in northern open areas is the moss *Racomitrium lanuginosum* (Figure 19). On a Scottish montane plateau, an area was fenced to provide a ski corridor (Scott *et al.* 2007). This area was used to establish permanent quadrats for a 12-year study. The fencing created a gradient in snow-lie and sheep use. *Racomitrium lanuginosum* cover was initially lower immediately adjacent to the fence. After 12 years, cover was reduced significantly in the 10 m adjoining the fence, whereas it was relatively stable further away. Scott and coworkers attributed the decline near the fence to greater snow-lie and heavier sheep usage. Grass cover near the fence increased. At the same time, *Dicranum fuscescens* (Figure 20) increased significantly near the fence. At more interior locations, there was a significant increase in *Polytrichastrum alpinum* (Figure 21) (Welch *et al.* 2005).

Figure 20. *Dicranum fuscescens*, a moss species that increased near the exclosure fence. Photo by Michael Lüth, with permission.

During and Willems (2003) reported that many species of mosses have disappeared "almost completely" from the Dutch chalk grasslands (see Figure 22) after grazing ceased. These included characteristic acrocarpous mosses such as *Tortella* spp. (Figure 23), *Trichostomum* spp. (Figure 24), *Aloina* spp. (Figure 25), and *Pleurochaete squarrosa* (Figure 26), but also the pleurocarpous species *Abietinella abietina* (Figure 27) and *Homalothecium lutescens* (Figure 28) have experienced drastic reductions. Litter indicator species such as *Brachythecium rutabulum*

(Figure 29) are concurrently increasing. As in other studies, these changes seem to be the result of cessation of grazing.

Maelfait *et al.* (2007) similarly found that when dune vegetation was short-grazed by sheep (*Ovis aries*; Figure 30), the previously lichen-moss domination decreased. But one site changed during the same time to a cover of ~95% clipped grasses, mosses, and herbs, a physiognomy created by the grazing of sheep.

Figure 30. *Ovis aries*, domestic sheep that causes lichen-moss domination to decrease. Photo through Creative Commons.

One of the operators in the moss vs tracheophyte story in pastureland is nitrogen (van der Wal *et al.* 2003). Air pollution has increased nitrogen deposition, causing massive invasion of grasses, sedges, and rushes in habitats ranging from forests to upland heaths. At the same time, grazing by livestock has increased in many locations, further degrading natural ecosystems. In the Scottish montane ecosystem, grazing and nitrogen deposition interact, causing a loss of the moss-dominated habitat and takeover by grasses and sedges.

One of our techniques to maintain diversity is to create green spaces where normal (non-pasture) vegetation is allowed to grow. However, even in these situations adjacent land use can significantly alter the bryophyte (and tracheophyte) communities of the natural vegetation (Piessens *et al.* 2008). Fortunately, these effects occur only within 5 m or less of the borders into heathland patches. In these transition zones adjacent to the borders, the invasive moss *Campylopus introflexus* (Figure 31) is common at grazed sites.

Figure 31. *Campylopus introflexus*, an invasive moss species common in transition zones of grazed areas. Photo by Fitis-Sytske Dijkse, with online permission through <freenatureimages.com>.

Hill *et al.* (1992) found that *Polytrichum commune* (Figure 32) declined steadily in sheep exclosures (Figure 34) in Snowdonia, Wales. When sheep were fenced out of some areas, *Polytrichum commune* declined consistently,

presumably due to competition for light by larger tracheophytes. Subsequent to sheep exclosure (Figure 33–Figure 35), voles became dominant among the herbivores and considerable growths of pleurocarpous mosses like *Hylocomium splendens* (Figure 3) and *Pleurozium schreberi* (Figure 36) invaded the mats of dead grass.

But do sheep eat bryophytes? Rodríguez Suárez *et al.* (1990) reported 15 cryptogams in the stomachs of goats and sheep. The winter diet of feral Soay sheep (*Ovis aries*; Figure 30) at St. Kilda, Scotland, is comprised of 20-30% mosses (Milner & Gwynne 1974). When Virtanen and Crawley (2010) assessed the relationships of bryophytes with these St. Kilda sheep, they found that bryophytes and tracheophytes had opposite trends relative to elevation and sheep preference. The bryophytes reached their highest species richness at mid to high elevations and were negatively correlated with levels of sheep preference.

In a 1500 m² plot in a sheep pasture of the Netherlands, the moss layer disappeared almost totally, concomitant with the introduction of artificial fertilizer application and liquid manure (Arnolds 1989). This coincided with changes in the fungal populations, and those fungi associated with litter or bryophytes decreased in numbers.

In the alpine communities of the Scottish Highlands (Figure 37), one can find rare species (Miller *et al.* 2010). Nevertheless, this community is often heavily grazed by sheep. Many have suggested that the sheep hold the community in a **plagioclimax** (habitat or area in which influences of humans have prevented further ecosystem development). By excluding sheep from spring until fall for 10 years, Miller and coworkers found that graminoids initially increased in cover and the vegetation became taller. However, this stage did not last, and a decline in

graminoid cover followed, with bryophytes becoming much more abundant. Permanent removal of sheep could cause a shift to a bryophyte-rich habitat tall-herb or scrub vegetation.

Figure 37. Alpine area in Scotland, where sheep often graze. Photo through Flickr Creative Commons.

Large herbivores can have an especially severe effect on bryophytes and other plants in Arctic and alpine regions (Austrheim *et al.* 2007). Using exclosures in an oceanic alpine ecosystem to stop sheep grazing, Austrheim and coworkers found that tracheophyte height increased, but the grass *Deschampsia flexuosa* (Figure 38) was the only tracheophyte that increased in cover in these exclosures. At the same time, six bryophyte species changed in abundance, favoring successional bryophytes. The mosses *Straminergon stramineum* (Figure 39) and *Pohlia nutans* (Figure 40) and the leafy liverwort *Cephalozia bicuspidata* (Figure 41) increased when sheep grazing ceased.

Figure 41. *Cephalozia bicuspidata*, a leafy liverwort species that increases when sheep grazing stops. Photo by Botany Website, UBC, with permission.

For *Pohlia nutans* (Figure 40), this is a surprise as it tends to occur in open, disturbed sites, and it also typically disappears when reindeer are fenced out (see above). Species of the mosses *Brachythecium* (Figure 29) and *Plagiothecium* (Figure 6) likewise decreased in the exclosures, while *Polytrichum* (Figure 32) species actually

increased with grazing, as already noted in Wales by Hill *et al.* (1992) and elsewhere (Helle & Aspi 1983; Väre *et al.* 1996; Virtanen 2000; Olofsson *et al.* 2004), causing Austrheim *et al.* (2007) to consider the genus to be grazing resistant. The leafy liverworts *Barbilophozia lycopodioides* (Figure 42) and *B. floerkei* (Figure 43) decreased with grazing, whereas the latter disappeared in the exclosures in the Arctic reindeer study by Väre *et al.* (1995), where it was replaced by the lichen *Cladina* (Figure 44), a preferred food of reindeer. Nevertheless, exclosures did not result in changes in tracheophyte or bryophyte species richness or total cover of bryophytes and lichens in the Austrheim *et al.* study. A side effect of the exclosures and cessation of sheep grazing was that rodent grazing was also reduced.

Goats – *Capra*

Goats are known to eat everything, right? So we shouldn't be surprised that in Washington State's Olympia National Park (Figure 45), invasive goats, introduced from Canada and Alaska for hunting, were destroying the sensitive ecosystem (Wright 1996). In particular, the very rare Olympic Mountain milk vetch (*Astragalus cottonii*; Figure 46) was a favorite food. But like we might expect of goats, these goats ate everything, including mosses. They further affected the habitat by trampling and wallowing. Rodriguez Suárez *et al.* (1990) also found that goats on the Canary Islands consumed mosses.

Figure 45. Olympic rainforest, Washington, USA, with bigleaf maples and epiphytic mosses. Photo from NPS, through public domain.

Figure 46. *Astragalus cottonii*, a rare but favorite food of goats in the Olympic Mountains, USA. Photo by Paul Slichter, with permission.

Nevertheless, feral goats (*Capra hircus*; Figure 47–Figure 48) in New Zealand avoided mosses, even though mosses were very abundant compared to preferred foods like *Schefflera digitata* (Figure 49) and ferns (Mitchell *et al.* 1987).

Cattle – *Bos*

It is hard to imagine a big cow choosing to eat mosses, but Esteban *et al.* (2012) reported that in the Southern Patagonian *Nothofagus* forests (Figure 50), mosses, along with grasses, were the most grazed vegetation by cattle (*Bos taurus*; Figure 51). But contrasting with many rodent herbivores, the cattle consumed erect herbs and mosses in the summer, switching to shrubs in spring and winter. In fact, while sheep primarily grazed prostrate herbs, cattle grazed mosses, except in autumn.

With this kind of preference for mosses, it might be surprising that removing cattle herbivory can cause a decline in bryophytes. But further examination in southwestern Finland reveals that these weak moss competitors are actually disappearing as tracheophyte biomass increases (Takala *et al.* 2012). By contrast, in continuously grazed grasslands, bryophyte cover, species richness, species density, and species diversity were significantly higher than in abandoned grasslands. The importance of cattle grazing for maintaining the bryophyte species richness is further supported by Humphrey and

Patterson (2000) in a riparian pasture and an upland conifer forest of the UK. Furthermore, they found almost no evidence that trampling had any effect on the bryophytes.

Yet Ludvíková *et al.* (2014a, b) found that in their experimental comparisons in temperate *Agrostis capillaris* (Figure 52) grassland, it was the non-trampled plots that had the highest composition of bryophytes, with *Rhytidiadelphus squarrosus* (Figure 53) being the dominant species (95%). However, the non-trampled plots also had the lowest evenness index, indicating few dominant species and lots of uncommon species. Soil compaction played an important role in determining species composition (Ludvíková *et al.* 2014b).

Ingerpuu and Sarv (2015) studied 15 Estonian coastal meadows (Figure 54) to compare effects of two different grazing pressures. During a 10-year period, the intensive grazing area experienced an increase in bryophyte diversity, but tracheophyte diversity did not increase, nor did that of the diaspore bank. Litter cover suppressed tracheophyte diversity. Nevertheless, tracheophyte and bryophyte diversity were positively correlated. And species composition remained unaffected by grazing intensity.

The Austrian agricultural landscapes (Figure 55) are rich in bryophytes, with a total of 506 species, 135 of which are considered to be endangered (Zechmeister *et al.* 2002). The upland landscapes dominated by moderately intensive cattle farming have significantly more endangered species than do the lowland landscapes with primarily intensive farming styles. Similarly, in comparing 24 grazed and 24 abandoned sites, Oldén *et al.* (2016) demonstrated that grazing had more impact on tracheophytes than on bryophytes in boreal wooded pastures. These are low-intensity livestock grazing areas in forested sites.

In Finnish seminatural grasslands, Takala *et al.* (2014) used 420 plots in 21 grasslands to examine species richness and cover of bryophytes. They found that grazing promotes bryophyte species richness, with colonists and perennial bryophytes in particular increasing. As expected, colonists were strongly associated with sites having a high proportion of bare ground.

Among the most sensitive ecosystems that must endure grazing are the cryptogamic crusts (Figure 56) in prairie areas. In a study in southeastern British Columbia, Rosentreter (2006) found that rock cover decreased significantly(?), $p > 0.10$, in the Cattle Only Area from 1994 to 2004, whereas in the Wildlife Only Area there were no significant changes in litter, soil, bryophyte, or rock cover. Bryophytes and litter provided the predominant soil cover. But bryophyte cover overall increased nearly 70% from

1991 to 2003 ($p < 0.10$), somewhat complicating the comparisons. Decreases in bryophyte cover in the exclosure area was driven by the increases in vascular plants and litter cover. Hence, bryophyte cover decreased with time in the exclosure, only the bryophytes increased in the wildlife and cattle area, and bryophytes did not change in the cattle only or wildlife only areas. Bryophytes are important contributors to these ecosystems by providing soil stability, nitrogen fixation, maintaining greater soil moisture, preventing runoff, facilitating infiltration, and enhancing seed germination and subsequent plant growth (Anderson *et al.* 1982a, b; Johnston 1997; McCune 2000).

Some endangered species are benefitted by cattle and pony grazing. The disturbance by the cattle and wheel ruts in salt marshes (Figure 57) where they graze creates open soil patches that can be colonized by *Bryum marratii* (Figure 58) (Holyoak 2015). But the occurrence of the species in wheel tracks was short-lived because grazing was light and competitive grasses (*Agrostis stolonifera*; Figure 59) excluded it within two years (Callaghan 2017). In Ireland, when salt marsh grazing stopped, a dense saltmarsh grass cover developed, leading to extinction of the moss in Northern Ireland and threatening the species in other Irish locations (Lockhart *et al.* 2012).

Bison – Bison

Even large, herbivorous, late Pleistocene mammals such as the Mylakhchinsk bison (see Figure 60-Figure 61) have died with bryophytes in their alimentary tract (Ukrantseva *et al.* 1978; Ukrantseva 1979).

Ukrantseva (1981) examined the gastrointestinal tracts of a variety of herbivorous mammals, including *Bison* (Figure 60-Figure 61), preserved from various periods during the Kargin interglacial period in the Indigirka River basin (Wisconsin period, 45,000-30,000 BP). During that time bogs spread, concurrent with the reduction of herbaceous communities suitable for pasturing. At the same time, rumen analysis indicated that the food composition changed for these large mammals, shifting to plants (Ukrantseva *et al.* 1978), including *Sphagnum* (Figure 62), from moist and water-logged communities (Ukrantseva 1981). These plants had considerably different nutrient quality, and the diet change led to the extinction of some of the herbivores.

Summary

Activities of sheep and other ruminants can contribute to dispersal of bryophytes as the fragments adhere to hooves and fur/hair/wool.

Many goats eat mosses, but feral goats in New Zealand seem to avoid them. Musk oxen may actually lose nutrients due to adsorption onto mosses they accidentally ingest. On the other hand, some sheep (*Ovis*) will eat bryophytes as a significant portion of their diet. Some goats (*Capra*) will eat them and others

avoid them. In southern Patagonia, cattle (*Bos taurus*) will eat mosses in summer, but not in winter.

When grazing is light, it can favor such mosses as *Rhytidiadelphus squarrosus*, *Polytrichaceae*, *Brachythecium*, and *Plagiothecium*. Colonizers like *Pohlia nutans* can benefit from disturbance and increased light. Leafy liverworts like *Barbilophozia lycopodioides* and *B. floerkei* decrease with grazing. Similarly, the moss *Straminergon stramineum* and the leafy liverwort *Cephalozia bicuspidata* benefit from exclosures. But the bryophyte communities depend on the site, with Arctic and alpine communities responding differently from more temperate ones. Rodents likewise can have a profound effect on the bryophytes, with communities responding differently depending on the foraging ruminants present.

Bryophytes suffer from manuring and urine, perhaps due to increased microbial decomposition, or to greater competition from the enriched tracheophytes.

Acknowledgments

Thank you to Robert Berdan for giving me permission to use his beautiful images, and to all the photographers who have put their images into Creative Commons. Others have given me permission to use their images, as noted under each picture. Rolf Peterson helped me to straighten out the scientific nomenclature for moose. Eileen Dumire critically reviewed the chapter.

CHAPTER 18-3

LARGE MAMMALS – NON-RUMINANTS

Figure 1. *Ursus americanus*, black bear cubs playing in mosses. Photo through public domain.

Canidae – Dogs

When we think of the impacts of dogs (*Canis lupus familiaris*) on bryophytes, we tend to think of their habit of urinating (Figure 2) to mark their territory and record their presence. This raises concerns about permitting dogs on nature trails.

I was surprised to find a statement in 2012 that "very little is known about the nutrient composition of dog urine and its impacts on habitats" (White *et al.* 2012). Instead, these researchers refer to the ability of urine to "scald" vegetation, while acknowledging that it provides some enrichment of soil nitrogen (Taylor *et al.* 2005). White and coworkers also stated that dog urine does more damage on dry soils because the salts are unable to disperse quickly. Gilbert (1989) reported that dog urine has significant effects on algal crusts and lichen communities at tree bases. Unfortunately, bryophytes were not mentioned.

Webb (2002) studied the effects of human traffic, including dog walkers, in Lye Valley, Oxford, England. She found that the effect of dog urine was especially damaging to plants in very low nutrient ecosystems, like the calcareous fen areas and the dry calcareous grasslands.

The implication is that these negative effects included damage to fen mosses. Some fast-growing grasses benefit.

Figure 2. *Canis lupus familiaris* marking territory. Photo by Daniel Mott, through Creative Commons.

In urban areas, it is mostly *Bryum argenteum* (Figure 3) that finds its way into the cracks in the sidewalks and along their borders (Sam Bosanquet, Bryonet 8 June 2011). But in natural areas, rarer species may be affected. Bosanquet asked if anyone knew of the impacts of dog urine and feces on bryophytes, citing the known negative impacts of human urine on the leafy liverwort *Lepidozia cupressina* (Figure 4) and the filmy fern *Hymenophyllum tunbrigense* (Figure 5), often killing both.

Figure 3. *Bryum argenteum* in crack in parking lot. Photo by Paul Davison.

Figure 4. *Lepidozia cupressina*, a species that is negatively impacted by dog urine. Photo by Michael Lüth, with permission.

Figure 5. *Hymenophyllum tunbrigense*, a fern that is negatively impacted by urine. Photo through Creative Commons.

In her moss gardens, Annie Martin (Bryonet 9 June 2011) has observed frequent visits from a St. Bernard who left sizeable deposits of feces. Fortunately, this does not seem to have caused any harm to the garden, even if left there for several days.

Rod Seppelt (Bryonet 8 June 2011) relays his own experience. Mosses such as *Eurhynchium* (*Kindbergia*; Figure 6) and *Brachythecium albicans* (Figure 7) are able to regrow rapidly after urine damage, probably initially through lack of competition from the grasses that die off, but later come back. But dog urine is concentrated, so some bryophytes are likely to experience toxic effects. What seems to be the worst component for plants is ammonia, particularly the high concentration of nitrogen <www.dogster.com>. In the Arctic (Figure 8), urine enriches the nutrients, and if these nutrients are too high, seed plant vegetation benefits, to the detriment of the poorly competing bryophytes (see Chapter 18-1).

Figure 6. *Eurhynchium praelongum*, a species that regrows quickly after being sprayed with urine. Photo by Juan Larrain, with permission.

Figure 7. *Brachythecium albicans*, a species that regrows quickly after being sprayed with urine. Photo by Michael Lüth, with permission.

Figure 8. Tundra with dwarf willow, blueberry, and bearberry in Alaska, a habitat enriched by nutrients in urine of large mammals. Photo by Nathanael Coyne, through Creative Commons.

Bryophytes are known to require lower nutrient concentrations than that of tracheophytes. Cape and coworkers (2009) presented evidence that we should re-evaluate our perspective on the critical ammonia levels for plants. They suggested $1 \mu\text{g NH}_3 \text{ m}^{-3}$ for bryophytes, whereas they suggested $3 \pm 1 \mu\text{g NH}_3 \text{ m}^{-3}$ was appropriate for herbaceous tracheophytes.

As I read these comments about the lack of response of bryophytes to dog urine, I must wonder about the impact of climate on this seeming lack of response. In a humid climate where bryophytes remain hydrated and rain is frequent, might the urine be washed away before enough of it enters the moss to harm it? On the other hand, might a dry climate result in concentration and dose the moss with lots of it at once when rehydration occurs, especially with fog or night-time dew? Would the urine convert to uric acid and hence be more harmful in that state?

Macropodidae – Wallabies and Kangaroos

Most wallabies don't seem to have a direct interaction with bryophytes, but they can have a major impact on them by damaging and browsing or grazing on competing vegetation. Unlike the damage done by deer and goats in other areas of New Zealand, the damage to vegetation on Kawau Island, New Zealand, is the result of four species of introduced Australian wallabies [*Macropus eugenii* – Dama wallaby (Figure 9), *Macropus parma* – parma wallaby (Figure 10), *Petrogale penicillata penicillata* – brush-tailed rock wallaby (Figure 11), and *Wallabia bicolor* – swamp wallaby (Figure 12)] (Wilcox *et al.* 2004). The activities of these wallabies in the forest damage the tracheophyte vegetation and create a lawn of bryophytes (Figure 13). This appears to be the result of greater tolerance on the part of bryophytes, rather than superior competition. The most common species are the mosses *Campylopus clavatus* (Figure 14), *Dicranoloma billardierei* (Figure 15), *Leucobryum candidum* (Figure 16), and *Ptychomnion aciculare* (Figure 17), especially *Dicranoloma billardierei*. A few patches of the large liverwort *Chandonanthus squarrosus* (Figure 18) are also present, with large areas of *Cladina* (Figure 19) and *Cladia* (Figure 20-Figure 21) lichens. The researchers consider

this lawn to be the result of superior tolerance of stress by the bryophytes and lichens.

Sankaran *et al.* (2008) found that the eastern grey kangaroo (*Macropus giganteus*; Figure 22) and the common wombat (*Vombatus ursinus*; Figure 23), on the other hand, are more effective at increasing woody plant abundance than the introduced hog deer (*Axis porcinus*; Figure 24) or native swamp wallabies (*Wallabia bicolor*; Figure 12), both of which are browsers. The hog deer is the largest consumer of mosses (less than 0.01%) in southeastern Australia (Davis *et al.* 2008).

Hobbs (1996) likewise considered that browsing by herbivorous ungulates on grasses, forbs, and shrubs could give competitive advantage to trees, ferns, and mosses. This assumption is partly supported on Yanakie Isthmus (connecting Wilsons Promontory to mainland Victoria, Australia) by the observed increase in moss cover in their presence, while grass cover decreased (University of Ballarat 1999).

Dendrolagus – Tree-kangaroo

The Lumholtz tree-kangaroo (*Dendrolagus lumholtzi*; Figure 25) is known from the rainforests of Northeast Queensland, Australia. It is the smallest (~0.5m body length) of the tree-kangaroos and is somewhat territorial. It consumes mosses, as well as lichens, ferns, and flowers (Heise-Pavlov 2017).

Figure 25. *Dendrolagus lumholtzi*, a moss consumer. Photo by Kenneth Bader, through Creative Commons.

Mosses seem to be more commonly consumed among the tree-kangaroos than among other wallabies. The Huon tree-kangaroo (*Dendrolagus matschiei*; Figure 26) is a generalist leaf eater, including leaves, fruits, and mosses in its diet (Betz 2001). In the rainforests of their native Papua New Guinea, they live where the forest floors are covered by a variety of moss species (Porolak 2008). Lichens and **lianas** (vines) are uncommon at the altitudinal range (1,000-3,000 m) where they live.

Figure 26. *Dendrolagus matschiei*, a generalist plant eater, including mosses. Photo by Cyndy Sims Parr, through Creative Commons.

Macropus – Australian Wallabies (and others)

Species of *Macropus* (Figure 27) make **hip holes** to use as resting sites, especially in hot weather (Eldridge & Rath 2002). **Hip holes** are shallow, kidney-shaped depressions these kangaroos construct next to trunks of many trees and shrubs in arid and semi-arid Australia. Although these hip holes average less than 10 cm deep (Eldridge & Rath 2002), that is enough digging to cause considerable destruction to the thin cryptogamic crust of lichens, bryophytes, and bacteria (Eldridge & Greene 1994).

Figure 27. *Macropus parma*, a species introduced to New Zealand, that destroys the ground vegetation, which is replaced by bryophytes. Members of this genus destroy bryophyte vegetation by digging hip holes. Photo by Mistvan, through Creative Commons.

Vombatidae – Wombats

Jones and Pharo (2009) questioned the importance of bryophytes in the buttongrass moorland in Australia following fire. Moss patches there become visible between the charred tussocks of grass. These researchers established twenty wire cages (30 cm x 30 cm x 20 cm) as exclosures that permitted insect access but not vertebrates. In addition, 20 patches with a minimum diameter of 10 cm of either of the mosses *Campylopus* spp. (Figure 14) or *Dicranoloma* spp. (Figure 15) were divided by a cage to test whether these mosses would become food to large herbivores after the fire. However, using stem length measurements, they were unable to find any differences in mosses inside and outside exclosures.

One possible reason for the absence of evidence is that suitable feeding grounds were close enough to the burned area that wombats did not need to rely on poor quality food sources such as mosses (Jones & Pharo 2009). For wombats, the mosses are hard to digest. They are hindgut fermenters (Hume 1999). Polyphenolic compounds in mosses can have antibiotic properties that inhibit the digestion of hindgut fermenters (Prins 1982). Interestingly, the Parks & Wildlife Service (2008) considered mosses to be a "particular delicacy" for the wombats, with native grasses being their primary food, as well as shrubs, roots,

sedges, bark, and herbs.. Triggs (1996) considered that some mosses provide the wombats with water when they are moist and green; they are ignored when they are dry.

Jones and Pharo (2009) also considered the possibility that the wombats might only consume the capsules, but no capsules were observed at the study site. However, in a different buttongrass moorland they had observed evidence of grazing on capsules of the moss *Tayloria tasmanica* (Figure 28). In another report, Lyn Cave (in Fife 2015) concluded that the primary habitat of *Tayloria tasmanica* is wombat dung. For some reason, little attention has been given to the potential of moss capsules as food.

Figure 28. *Tayloria tasmanica*, a dung moss species possibly grazed on by wombats. Photo by Niels Klazenga, with permission.

When large herbivores live at high elevations with deep snow cover, they face a challenge getting enough of the right foods to balance their needs. This is further complicated by the slow regrowth of alpine plant species following disturbance. Thus, Green *et al.* (2015) hypothesized that responses of wombats (*Vombatus ursinus*; Figure 23) to disturbance by fire at high elevations would differ from those at low elevations. To test their hypothesis, they examined the winter diet of common wombats in the Snowy Mountains of Australia in the ten years following a fire. Optimal foraging theory predicts that these herbivores should respond to scarce food resources by widening their food choices. However, these wombats expanded their diet choices only slightly at the higher elevations compared to those at the lower elevations, with no expansion in number of food species. Rather, they are able to exploit the improved food quality resulting from nutrients released by fire.

Wombats may actually contribute to bryophyte diversity. I have observed *Mittenia plumula* (Figure 29) growing at the entrance (Figure 30-Figure 31) of a wombat burrow. The opening provided the disturbed soil and cave environment needed by this species.

Figure 29. Close view of *Mittenia plumula*. Photo by David Tng, with permission.

Figure 31. *Mittenia plumula* in wombat burrow opening in Australia. Photo by Janice Glime.

Phalangeridae

Common Brushtail Possum – *Trichosurus vulpecula*

I doubt that the Australian possum uses bryophytes, but the moss uses it. I have seen the moss *Tayloria octoblepharum* (Figure 32) growing on the dung of the common brushtail possum (*Trichosurus vulpecula*; Figure 33) in Australia. Like other members of the *Splachnaceae*, this species uses dung as its substrate and the capsules smell like dung at maturity, attracting flies that disperse the spores.

Elephantidae – Elephants, Mammoths

Elephants – *Elaphus*

One might expect elephants, the giants of the four-legged creatures, to be destructive of bryophytes, but in a *Sphagnum* (Figure 34) bog of Peninsula Malaysia, elephants (*Elephas maximus*; Figure 35) maintain the plant communities with their trampling (Yao *et al.* 2009).

Figure 35. *Elephas maximus* (Asian elephant). Ancestors of this genus perished in the Wisconsin era, perhaps due to the conversion of suitable pasture into bog habitat. Photo by Bernard Dupont, through Creative Commons.

Mammoths – *Mammuthus*

The prehistoric woolly mammoth (*Mammuthus primigenius*; Figure 36) ate mosses – and became entombed in the ice with a meal of *Polytrichum* (Figure 37) and *Hypnum* (Figure 38) in its stomach (Bland 1971).

Figure 36. Woolly mammoth (*Mammuthus primigenius*), a prehistoric moss consumer. Image from Flying Puffin, through Creative Commons.

Figure 37. *Polytrichum commune*, possibly food of the woolly mammoth. Photo by J. R. Crellin, through Creative Commons.

On the other hand, van Geel *et al.* (2011) considered the mosses in the Palaeo gut sample from a mammoth calf from Yamal Peninsula, northwest Siberia, to be accidental. They considered that a one-month-old calf most likely ate fecal material that had been deposited on mosses and that associated mosses were consumed at the same time.

Figure 38. *Hypnum lindbergii*, possibly food of the woolly mammoth. Photo by Michael Lüth, with permission.

Ukrantseva (1981) similarly examined the gastrointestinal tract of large mammals from the Pleistocene, looking for possible causes of extinction. He found, using C^{14} analysis from the horse (*Equus*; Figure 39), mammoth (*Elaphas*; Figure 35), and bison (*Bison*; Figure 40), that these animals perished during the Wisconsin period, 45,000-30,000 BP. During that time period, bogs and forests spread while herbaceous communities (pastures) diminished, changing the quality of the food they consumed. Instead of their usual pasture food, they had to feed in water-logged sedge, cottongrass, grass, moss, and *Sphagnum* (Figure 34) communities. Hence their nutrient consumption changed, a change that Ukrantseva considered to be the cause of their extinction.

Ursidae – Bears

Researchers have questioned whether bears consume bryophytes by choice. Elgmork and Kaasa (1992) contended that they are consumed only accidentally. But Dalen *et al.* (1996) reported that brown bear (*Ursus arctos*; Figure 41) feces contained 50-90% bryophytes, hardly an accidental percentage. Nevertheless, Dalen and coworkers found this only in May for a bear and her two cubs, again suggesting that bryophyte consumption was not a normal occurrence. At other times, some feces contained 15% *Brachythecium reflexum* (Figure 42), but it appeared that these mosses were consumed when the bears ate ants. Nevertheless, Wilson and Ruff (1999) noted that bears are omnivores, thus eating a variety of plant foods, including mosses.

Figure 41. *Ursus arctos arctos* (brown bear), a subspecies that eats lots of bryophytes. Photo by Jiří Bukovský, through Creative Commons.

Figure 42. *Brachythecium reflexum*, a species reaching as much as 15% of content in feces of the brown bear (*Ursus arctos*). Photo by Michael Lüth, with permission.

Iversen (2011; Iversen *et al.* 2013) studied the diet of polar bears (*Ursus maritimus*; Figure 43) from Svalbard. She reported 13 species of mosses in the feces, with *Polytrichastrum alpinum* (Figure 44) being the most frequent. Only 32.8% of the feces contained terrestrial vegetation. Of these, 27% contained mosses. Not only

were mosses relatively frequent, they also made up a significant portion of the biomass. Only two scats could be attributed to juveniles, but both contained mosses. On the other hand, Lønø (1970) found moss in only 2 of the 172 stomachs examined from Svalbard polar bears.

Figure 43. *Ursus maritimus* (polar bear), a moss consumer. Photo courtesy of Bob Krear.

Figure 44. *Polytrichum alpinum*, food of the polar bear on Svalbard. Photo by David Holyoak, with permission.

It appears that brown bears (*Ursus arctos*; Figure 41) have found another use for *Sphagnum* (Figure 48). The bears sometimes put peat mosses with carcasses that they cache, a behavior suggesting that the moss may be used to reduce bacterial and fungal attack on their food (Elgmork 1982). Hyvönen (1990) reported that bears often bury their prey in forests with mats of *Polytrichum* (Figure 37). Hyvönen reported on the Finnish coin that has a bear on one side and *Polytrichum* on the other side, suggesting that the association of these two organisms on the same coin related to the habit of the bears to bury their food in forests with *Polytrichum* ground cover.

Hyvönen (1990) reminds us that Linnaeus reported that bears (*Ursus arctos arctos*; Figure 41) gather *Polytrichum* (Figure 37) tufts to cushion their winter holes, whereas Dr. Erik Nyholm contends that bears are indiscriminate in choosing padding, using the more abundant species of *Pleurozium schreberi* (Figure 45) and *Hylocomium splendens* (Figure 46). They also seem to

use bryophytes for napping, as I have seen in several photographs posted on the internet.

Figure 45. *Pleurozium schreberi*, a species used by brown bears (*Ursus arctos arctos*) to pad their winter holes. Photo by Rob Routledge, through Creative Commons.

Figure 46. *Hylocomium splendens* on spruce forest floor, a species used by brown bears (*Ursus arctos arctos*) to pad their winter holes. Photo by Janice Glime.

Grizzly bears (*Ursus arctos* ssp; Figure 47) are a subspecies of brown bears, but are carnivorous (Wilson & Ruff 1999). Nevertheless, they reputedly eat moss, especially when they come out of hibernation, a report I have been unable to verify. Storie (1973) and Compton (1993) reported that grizzly bears eat unidentified mosses (Figure 48). It seems these bears eat mosses along with ants and soil when they are desperate, which doesn't say much for a discriminating appetite at that time!

Bears could damage some of the epiphytic bryophytes. They at times rip bark off trees to find insects for food (Zyśk-Gorczyńska *et al.* 2015). If bryophytes are growing there, they will come off with the bark. This leads me to wonder if the bears ever attempt to get insects from the mats of bryophytes on trees, another potential source of bryophyte destruction.

Bears are also known to contribute to the nutrient regime of bryophytes, but not as you might expect. They catch fish, then transport them to land (Figure 49) before consuming them. The remainder of the carcass provides a nitrogen source (Wilkinson *et al.* 2005).

Hominidae – Primates

Chimpanzees

Eggar (1997) examined the habitats of China's monkeys, past and present. The environmental changes in the last 50 million years forced the animals to adapt to changing food availability. Some remained in the "diminishing rainforests" where they could find enough fruits and protein to survive. But others adapted to new

habitats. Among these adapters was the Yunnan snub-nosed monkey (*Rhinopithecus bieti*; Figure 50-Figure 51) that moved to the high-altitude pine forests (Figure 50). Here the most consistent food sources were hanging mosses and lichens on rocks.

Figure 50. Yunnan snub-nosed monkey (*Rhinopithecus bieti*), a species that eats hanging mosses and lichens when it is forced to move to the mountains. Photo from EOL China Regional Center, through Creative Commons.

Figure 51. Close view of the Yunnan snub-nosed monkey (*Rhinopithecus bieti*). Photo from EOL China Regional Center, through Creative Commons.

But monkeys are smarter than most other animals. Lamon *et al.* (2017) were studying the behavior of wild chimpanzees (*Pan troglodytes*; Figure 52) in Budongo Forest Reserve in Western Uganda and discovered an unusual tool use. They were using mosses as sponges! This was a new behavior that first appeared in the population in 2011. Three years later, they found that the sponging behavior was still present and had spread to some of the other members of the community. Hanging mosses are common in areas inhabited by chimpanzees (Figure 53-Figure 56). The moss species used were *Pilotrichella cuspidata* (Figure 54), *Racopilum africanum*, and *Pinnatella minuta*, as well as two leafy liverworts – *Plagiochila strictifolia* and *Plagiochila pinniflora* (Hobaiter 2014).

Figure 53. Hanging moss from Riparian forest, home of chimpanzees, Chappal Hendu, border of Cameroon, Taraba State Nigeria at 2000 m asl. Photo courtesy of Bup-Olu Oyesiku.

Three years after the initial 2011 moss sponging behavior, Lamon and coworkers (2017) decided to experiment to see if the mosses were a preferred method to obtain water. Using the same population that had learned the behavior, they selected a site where a clay pit had two ground water holes at the bottom of two trees. These cavities contained rainwater enriched with minerals. The experimenters hung the moss *Pilotrichella welwitschii* (see Figure 54), collected in swamp areas within the natural range of the chimpanzees, in trees around the clay pit. A wide choice of leaves was available naturally. Of 40

chimpanzees included in the study, 33 used moss sponges during at least one of the experimental trials. Five of these were among the original 8 sponge users and 17 were new at this behavior. Those who had tried the mosses seemed to prefer that method, as 18 of those 22 used only moss sponges to obtain water. Furthermore, Hobaiter *et al.* (2014) had noted only 8 of 32 individuals using moss sponges; leaf sponging was the predominant technique, with 83% of the individuals using it at least once and 18 were exclusive leaf spongers, although 22 chimpanzees used the mosses at least once. Three years later, mosses seemed to be the preferred tool among those that had learned the behavior.

Figure 54. *Pilotrichella* sp., one of the mosses available to chimpanzees for moss sponges. Photo by Lena Struwe, through Creative Commons.

A similar sponging behavior occurred in chimpanzees (*Pan troglodytes*; Figure 55) in the Virunga National Park in the Democratic Republic of the Congo (Lanjouw 2002). When water was scarce, the chimpanzees gathered water from that collected in tree branches. When they could not access it directly, they prepared tools, including the use of sponges developed from mosses. The chimps collected mosses from trees. They then rolled them into a bundle about the size of a golf ball. These balls were inserted into the hollow of the branches. When the chimpanzees extracted the moss sponge, it had absorbed water. The chimpanzees sucked the water from the moss sponge, repeating this procedure to get additional drinks.

The chimpanzees are known for getting water from the many hanging mosses in the rainforests (Min Chuah-Petiot, pers. comm. 1 March 2018). Among these hanging water sources (Figure 56) are *Pilotrichella cuspidata* (Figure 54), *Squamidium brasiliense* (Figure 57-Figure 58), and *Papillaria africana* (Figure 59-Figure 60).

Humans

Humans can suffer from contact with some bryophytes (Schmidt (2000)). In addition to fungal diseases from contact with *Sphagnum* (Figure 34, Figure 48) inhabitants, members of *Frullania* can cause wood cutter's disease. Contact with this leafy liverwort can cause dermatitis even for others who handle the clothing. Bancons and Maleville (1967) found that *Frullania* is a powerful allergen that can cause asthmatic attacks as well as skin reactions. The allergen is very volatile, permitting it to cause infections at a distance with no contact. In young trees, the fraction that diffuses through the bark is sucked into the sapwood.

Mitchell (1981) reported 112 cases of allergic contact dermatitis caused by *Frullania* in British Columbia during a 10-year period. Mitchell *et al.* (1970) found that sesquiterpene lactones with alantolactone as the most active compound. Quirce *et al.* (1994) found similar results among 7 infected persons who apparently contracted the condition during a stroll in the park. All tested positive to *Frullania dilatata* (Figure 61-Figure 62) and three also tested positive to *F. tamarisci* (Figure 63-Figure 64).

Figure 64. *Frullania tamarsici*, a leafy liverwort that grows on trees and causes allergic contact dermatitis. Photo by Claire Halpin, with permission.

The genus also causes allergy skin problems in places like France where charcoal is burned (Jeff Duckett, pers. comm. 21 December 2017). See also Bonhôte *et al.* 2000.

Whales

Whales seem like an unlikely animal to interact with bryophytes. However, whale bones can serve as a substrate for at least some species (Figure 65-Figure 66). Jeff Duckett (2017) reported *Bryum argenteum* (Figure 67), *Ceratodon purpureus* (Figure 68), *Rhytidiadelphus squarrosus* (Figure 68), *Tetraplodon mnioides* (Figure 69), and *Ulota phyllantha* (Figure 67) among a number of others. His publication summarizes reports of bryophytes on whale bones around the world.

Summary

Large vertebrates may use bryophytes or harm them – or both. Dogs can damage them with urine and feces, but we have little scientific knowledge of these effects. Wallabies and kangaroos can damage the leafy vegetation, making the habitat suitable for bryophytes. *Dendrolagus* species, the tree-kangaroos, eat mosses. On the other hand, *Macropus* species, Australian wallabies, make hip holes, damaging the bryophytes as they dig.

Wombats make burrows, and mosses like *Mittenia* are able to establish on the recently disturbed soil at the opening. Some researchers suggest that wombats might consume mosses for their adhering water. They also consume capsules of the dung moss *Tayloria tasmanica*.

The dung moss *Tayloria octoblepharum* grows on the dung of the common brushtail possum (*Trichosurus vulpecula*).

Elephants can actually maintain some bryophyte communities through their trampling. And Pleistocene mammoths were preserved in ice with bryophytes in

their gut. But a change from pasture habitats to boggy and mossy habitats may have led to their extinction.

Bears use the bryophytes to line the winter "nest." Others use growing bryophytes for napping. Bryophytes also occur in feces, but may be there through consumption of inhabiting ants. However, polar bears can eat large quantities of bryophytes. Brown bears also bury mosses with their food, presumably to help preserve the food. Bears can also drag fish into the forest to eat them, with the remains providing nutrients that benefit bryophytes.

The Yunnan snub-nosed monkey (*Rhinopithecus bieti*) subsists in a habitat where hanging mosses and rock lichens are the primary food source. Some chimpanzees (*Pan troglodytes*) in African rainforests have learned to use the pendent mosses as sponges to gather water from tree holes and other difficult to reach places.

Acknowledgments

Ron Porley kindly notified me of the publication on chimpanzees using mosses as sponges to drink. Jessica Beever provided me with the paper and helped me obtain the image of the moss lawn on Kawau Island, kindly provided by Mike Wilcox. Eileen Dumire critically reviewed the chapter. Thank you to David Taylor for notifying me of an error in the text.

CHAPTER 19-1

BACTERIAL EFFECTS ON BRYOPHYTES

Figure 1. Nodules of the nitrogen-fixing bacterium *Bradyrhizobium* with mosses on *Acacia koa*. Photo courtesy of James Leary.

This is the most exciting chapter I have written thus far! The study of bacterial interactions between bryophytes and bacteria is quite new, and fascinating relationships are unfolding.

Nomenclature for phyla in this are from Oren and Garrity (2021) (see Euzéby 1997)

There have been few explorations of the bacteria that are naturally associated with bryophytes (Koua *et al.* 2015). Koua and coworkers explored the bacteria on eight bryophyte species. They identified 42 bacterial species in 90 DGGE gel bands. The bacterial genus *Clostridium* (Figure 2) predominated, comprising 21.4% of the total bacterial community.

Bacteria could influence their bryophyte substrates in a number of ways. For dead and dying bryophytes, they could contribute to decomposition. For living bryophytes, they could block light needed for photosynthesis. But at the same time they could produce CO₂ through respiration, contributing to higher photosynthetic rates. But beyond these more easily conceived roles, they can contribute hormones and other substances that might influence the development of the bryophytes or the community where

they both live. And even more interesting relationships are unfolding.

Figure 2. *Clostridium difficile*, a predominant bacterial genus on some bryophytes. Photo through Creative Commons.

Bacteria Communities on Bryophytes

During and van Tooren (1990, 2008) reminded the ecologists that bryophytes in the ecosystem may be influenced by their interactions with other organisms, including bacteria. Such interactions might involve mineral nutrition, carbon economy, herbivory, and growth and development of gametophytes.

Among the abundant bacteria associated with bryophytes in Japan are strains of *Burkholderia* (ubiquitous obligately aerobic, rod-shaped, Gram-negative, genus of **Pseudomonadota** (previously Proteobacteria); Figure 3), *Hafnia* (facultatively anaerobic, rod-shaped, Gram-negative genus of **Pseudomonadota**; Figure 4), *Methanobacterium* (nonmotile, anaerobic genus of **Archaea**; Figure 5), *Methylobacterium* (pink-pigmented, facultatively anaerobic, straight rod-shaped, Gram-negative genus of **Pseudomonadota**; Figure 6), *Pantoea* (yellow-pigmented, Gram-negative genus of **Pseudomonadota**; Figure 7), and *Serratia* (facultatively anaerobic, rod-shaped, Gram-negative genus of **Pseudomonadota**; Figure 8), occurring as endophytes, epiphytes, or both (Opelt & Berg 2004; Bragina *et al.* 2013; Koua *et al.* 2015).

Figure 10. *Pseudomonas aeruginosa*; *Pseudomonas putida* is antagonistic toward bryophytes. Photo by Janice Haney Carr, CDC, through Public domain.

On the other hand, some bacteria are antagonistic toward the bryophytes, including species such as *Bacillus* sp. (*Bacillota* – syn. = *Firmicutes*; Figure 9), *Pseudomonas putida* (*Pseudomonadota*; see Figure 10), *Serratia* sp. (Figure 8), and *Xanthomonas* sp. (*Pseudomonadota*; Figure 11) (Opelt *et al.* 2007). *Serratia liquefaciens* (see Figure 8), predominant in the mosses *Sphagnum* (Figure 12) and *Aulacomnium* (Figure 13), and *Serratia proteamaculans* (see Figure 8) are the most effective antagonists among the bacterial isolates from these same mosses (Opelt & Berg 2004).

Koua and coworkers (2015) found bacterial colonizers of bare-rock bryophytes in their Japanese collections to be γ -Proteobacteria (Pseudomonadota) [*Buttiauxella*, *Enterobacter* (Figure 14), *Erwinia* (Figure 15), *Pantoea* (Figure 7), *Pseudomonas* (Figure 10), and *Salmonella* (Figure 16)] and Bacillota [*Anaerobacter* (Figure 17), *Clostridium* (Figure 2)] – a group that can survive extreme conditions, especially desiccation, through production of endospores. *Citrobacter* (Pseudomonadota; Figure 18), *Clostridium* (Bacillota), *Pseudomonas* (Pseudomonadota), and *Serratia* (Figure 8) were common among highly populated soil and bare-rock-associated bryophytes. *Anaerobacter* (Bacillota), *Buttiauxella* (Pseudomonadota), *Erwinia*, and *Pantoea* were limited to the bryophytes associated with bare rocks.

Figure 18. *Citrobacter freundii* SEM; some members of *Citrobacter* are common bacteria among highly populated soil and bare-rock-associated bryophytes. Photo through public domain.

Some bryophyte-dwelling bacteria, especially **Proteobacteriaceae**, are fussy, selecting only bryophytes of highly populated soil habitats: *Dickeya* (Figure 19), *Klebsiella* (Figure 20), *Obesumbacterium*, and *Pectobacterium* (Figure 21) (Koua *et al.* 2015). *Serratia proteamaculans* (see Figure 8) occurred exclusively in the moss *Trachycystis microphylla* (Figure 22) of both bare rocks and highly populated soils. These contrast with *Clostridium* (**Bacillota**; Figure 2), which was present on all species of bryophytes in all habitats in the Japanese study.

Scheirer and Dolan (1983) found an unidentified bacterium, similar to *Agrobacterium* (**Pseudomonadota**; Figure 23), on both surfaces of *Polytrichum commune* (Figure 24) leaves. The terminal cells of the moss lamellae act like a pseudoepidermis (Figure 25), providing a microhabitat suitable for the bacteria and other microorganisms. The bacteria did not occur in the cell interiors.

Tang *et al.* (2016) again noted that our understanding of the relationships of the abundant bacteria on bryophyte hosts is largely lacking. They analyzed the bacterial community associated with ten liverwort and ten moss host species in Tibet, China. They found no obvious differences in bacterial richness between mosses and liverworts. Nevertheless, the diversity was significantly higher with liverworts than with mosses. The bacteria that were most constantly present were members of the phyla **Acidobacteriota**, **Actinomycetota**, **Armatimonadota**, **Bacteroidota**, **Planctomycetota**, and **Pseudomonadota**. Those in the phyla **Chloroflexota**, **Fibrobacterota**, **Gemmatimonadota**, and **Chlamydiota** appeared among only some of the bryophytes. The most constant genera among the bryophytes were *Burkholderia* (**Pseudomonadota**; Figure 3), *Frankia* (**Actinomycetota**; Figure 26), *Froniathitans*, *Granulicella* (**Acidobacteriota**), *Hafnia* (Figure 4), *Haliangium* (**Pseudomonadota**; Figure 27), *Mucilaginibacter* (**Bacteroidota**), *Novosphingobium* (**Pseudomonadota**; Figure 28), *Rhizobacter* (**Pseudomonadota**), and *Sorangium* (**Pseudomonadota**). Eleven of the bacteria couldn't be classified, suggesting that there may be many new bacteria to be identified among the bryophytes. Tang

and coworkers concluded that the phylogeny of hosts has a strong influence on the associated bacterial community and that niche also plays an important role when the hosts are phylogenetically more similar.

Schauer and Kutschera (2013) concluded that some methylobacteria (Figure 6) prefer to colonize bryophytes. *Methylobacterium funariae* (see Figure 6) was described as a new species from *Funaria hygrometrica* (Figure 29). Further evidence suggests that *Methylobacterium* species (Figure 6) prefer gametophytes (1n tissues), including liverwort and moss protonemata and fern prothalli. They appear to be symbionts, a relationship already known for some species of the genus living on tracheophyte leaves, where they consume the methanol emitted from stomatal pores and supply growth-promoting phytohormones.

Tani and Sahin (2013) named two new species *Methylobacterium haplocladii* (see Figure 6) and *Methylobacterium brachythecii* (see Figure 6) from bryophytes. These pink bacteria were isolated from *Haplocladium microphyllum* (Figure 30) and *Brachythecium plumosum* (Figure 31), respectively.

Saumya *et al.* (2019) added to our knowledge by examining the bacterial flora of the mosses *Anoetangium clarum* (see Figure 32), *Atrichum undulatum* (Figure 33), and *Hyophila involuta* (Figure 34) on Mount Abu in India. Like the study by Koua *et al.* (2015) in Japan, they found the bacteria to belong mostly to the family **Methylobacteriaceae** and phylum **Bacillota**, with **γ -Proteobacteria** predominating. Genera that are most common in the various habitats of soil, near water, and on rocks are *Aeromonas* (**Pseudomonadota**; Figure 35), *Halobacillus* (**Bacillota**), *Pseudomonas* (**Pseudomonadota**; Figure 10), and *Raoultella* (Figure 36).

Alcaraz *et al.* (2018) noted that microbiomes influence plant establishment, development, nutrient acquisition, pathogen defense, and health. They compared the microbiomes of *Marchantia polymorpha* (Figure 37) and *Marchantia paleacea* (Figure 38) to the microbiomes on their soil substrates and to plants grown from gemmae

collected in the same populations of *Marchantia*. They identified *Bryobacter* (Acidobacteriota; Figure 39), *Lysobacter* (Pseudomonadota; Figure 40), *Methylobacterium* (Figure 6), *Paenibacillus* (Bacillota; Figure 41), *Pirellula* (Planctomycetes), *Rhizobium* (Pseudomonadota; Figure 42), and *Steroidobacter* (Pseudomonadota; Figure 43) associated with the *Marchantia*, genera that contribute to plant-growth promotion, complex exudate degradation, nitrogen fixation, methanol conversion, and disease suppression. They suggested that these *Marchantia* species could be used as surrogates for testing the roles of bacteria in plants.

Marks *et al.* (2018) compared the bacterial community of *Marchantia inflexa* (Figure 44-Figure 45) between sexes and among habitats. Using common garden conditions, they found that the bacterial community associated with the liverwort is abundant and diverse. The particular taxonomic assemblages of bacteria may serve functional roles that allow the liverworts to better acclimate to their local environment. Furthermore, the differences in communities on the two sexes of the plants may contribute to subtle differences in their physiology and form.

Aschenbrenner *et al.* (2017) compared communities associated with different substrata of bark, mosses, and lichens in Austria and revealed significant differences in community structures. The lichen microbial communities are less complex and less densely interconnected than the moss- and bark-associated communities. Generalists were mostly *Pseudomonadota*, with *Sphingomonas* (Figure 46) being the most abundant genus. The researchers suggested that the generalists benefitted each other and the community by maintaining a pool of species that were available to colonize new plants where they provided nitrogen fixation and other supporting functions. This sharing of hosts lends stability to the microbial community.

Figure 48. *Grimmia montana*, a species with high bacterial richness in a Chinese study, with **Pseudomonadota** and **Bacteroidota** being the most dominant phyla. Photo by Des Callaghan, through Creative Commons.

Tian and Li (2017) similarly found **Pseudomonadota** and **Bacteroidota** to be the most dominant phyla in their study of the mosses *Entodon compressus* (matrix under tree; Figure 47), *Grimmia montana* (exposed rock surface; Figure 48), and *Hygroamblystegium noterophilum* (stream bank; Figure 49) at the Beijing Songshan National Nature Reserve, China. The greatest species richness occurred on *Entodon compressus*, followed by *Grimmia montana* and *Hygroamblystegium noterophilum*, based on 16s rDNA libraries. On the other hand, the 16s rRNA libraries indicated that richness was of the order 73, 18, and 45, respectively. The **Pseudomonadota** comprised 33.7-86.1% of the communities and **Bacteroidota** 8.4-54.9% as the dominant phyla regardless of moss species. Nevertheless, the ratio and composition of the groups varied widely.

Figure 47. *Entodon compressus*, a species with the greatest bacterial richness in a Chinese study, with **Pseudomonadota** and **Bacteroidota** being the most dominant phyla. Photo by Martin Hutten, with permission.

Figure 49. *Hygroamblystegium noterophilum*, a species with less bacterial richness than *Entodon compressus* or *Grimmia montana* in a Chinese study, with **Pseudomonadota** and **Bacteroidota** being the most dominant phyla. Photo by Jean Faubert, with permission.

Actinomycetota and **Acidobacteriota** were abundant on *Entodon compressus* (Figure 47) (Tian & Li 2017). This moss supported a community of *Sphingomonas* (Figure 46), *Pseudonocardia* (**Actinomycetota**; Figure 50), *Bryobacter* (**Acidobacteriota**; Figure 39), *Flavisolibacter* (**Bacteroidota**), *Acidiphilium* (**Pseudomonadota**), and *Roseateles* (**Pseudomonadota**). *Sphingomonas* is tolerant of low temperatures and produces growth-promoting substances. *Pseudonocardia* has antibacterial activity. *Acidiphilium* is able to solubilize rock phosphates. *Roseateles* can degrade aliphatic and aliphatic-aromatic copolyesters. The researchers speculated that this bacterial community might be important in community dynamics in the organic matter associated with the *Entodon compressus*. Associated with *Grimmia montana* (Figure 48) they found *Rheinheimera* (**Pseudomonadota**; Figure 51), a genus that might be useful for the growth of this species on exposed rock with very little matrix by inhibiting the production of other microbes. This genus occurred in multiple locations and has antibiotic properties that might inhibit other bacteria.

Figure 50. *Pseudonocardia* on *Acromyrmex* worker, a bacterium cultured by the ant to protect fungus farms. This bacterium occurs on the moss *Entodon compressus*. Photo by João Pedro Sá Medeiros, through Creative Commons.

Figure 51. *Rheinheimera baltica* SEM; some members of this genus grow in association with *Grimmia montana* on bare rocks, where they are suspected of enhancing the moss growth by inhibiting other microbes. Photo by Manfred Rohde, through Creative Commons.

Saha *et al.* (2021) investigated the bacteria associated with the moss *Plagiomnium rostratum* (Figure 52). They found that the predominant bacterial species were members of the families **Bacillaceae** (**Bacillota**), **Enterobacteriaceae** (**Pseudomonadota**; Figure 14), **Lactobacillaceae** (**Bacillota**), **Moraxellaceae** (**Pseudomonadota**), and **Pseudomonadaceae** (**Pseudomonadota**). Many of the bacteria isolated were able to solubilize phosphates and scavenge nitrogen efficiently, as well as degrade starch, cellulose, and casein. They found that variation in the bacterial association was significantly correlated with total carbohydrate and phosphorus contents of the moss gametophytes.

Figure 52. *Plagiomnium rostratum*, a moss colonized mostly by members of the **Bacillota** and **Pseudomonadota**. Photo by Hermann Schachner, through Creative Commons.

Effects on Bryophytes

The relationships between bacteria and bryophytes has been almost totally neglected (Jessica M. Nelson, Bryonet 22 April 2021). Recently a few researchers have begun to uncover exciting roles that these might play in the physiology of bryophytes. In sharp contrast, we are now learning about exciting interactions between these two groups of organisms.

Carella and Schornack (2018) described the relationship between bacteria and bryophytes as an association "with a strong and directed effort [by bacteria] to reprogram host cells [of bryophytes] in order to permit, promote and sustain microbial growth. In response to colonization, hosts accommodate or sequester invading microbes by activating a set of complex regulatory programs that initiate symbioses or bolster defenses."

Alvarez *et al.* (2016) found that the level of expression of antibacterial genes by the mosses were dependent on the developmental stage of the mosses. There was greater expression by the gametophore tissue than by the protonema tissue. Could these relate to habitat conditions at the time of development? Or is there an energy limitation on the protonema? Production of secondary compounds used for defense requires resources that compete with resources needed for growth and reproduction. Therefore, there is most likely a tradeoff, with the bryophyte optimizing its production of secondary compounds by producing them when they are needed most for the continuation of the species. On the other hand, having bacteria that produce defenses against the pathogenic bacteria in the association would be an important savings of resources.

Symbiosis

There is limited direct evidence of symbiotic relationships between bryophytes and bacteria. The evidence that exists suggests that this is an area that warrants our attention. At the very least, the relationship does not seem to be neutral, with cases of protocoeperation, commensalism, and antagonism, as well as symbiosis.

Nitrogen Fixation

The nitrogen-fixing bacterial genus *Bradyrhizobium* (*Pseudomonadota*; Figure 1, Figure 53) forms a symbiotic connection with the adventitious roots of its host, *Acacia koa* (Figure 54) in Hawai'ian mesic forests. Leary *et al.* (2004) discovered that when these symbioses occur in mosses growing in the canopy, they form more and larger nodules than when associated with roots in soil.

Figure 53. *Bradyrhizobium* nodules with moss on *Acacia koa*. Photo courtesy of James Leary.

Figure 54. *Acacia koa*, a tree that benefits from mosses associated with its nitrogen-fixing *Bradyrhizobium* nodules. Photo by Forest and Kim Starr, through Creative Commons.

Methylobacteria

The **methylobacteria** are a group of bacteria that are able to use methanol as their sole source of carbon and energy (Corpe & Basile 1982). They have been isolated from the surfaces of bryophytes. There is evidence that these pink, facultative methylotrophs are beneficial to the plants on which they grow. Evidence suggests this includes bryophytes.

Alcalde *et al.* (1996) demonstrated a little-known interaction between the moss *Bartramia* (Figure 55) and the genus *Methylobacterium* (Figure 6) in Spain, a relationship discussed elsewhere in this chapter for peatland habitats. Bryophytes and tracheophytes have

pectin in their cells walls, causing them to emit methanol. The pink-pigmented *Methylobacterium* (Figure 6) species are able to colonize leaf surfaces and use the methanol as their only source of carbon and energy (see also Raghoebarsing *et al.* 2005; Liu *et al.* 2014).

Kutschera (2007) found that the tracheophytes failed to respond to the relationship. However, development of both the mosses and liverworts in the study was affected. Organ development in moss protonemata and in liverwort thalli was "considerably" enhanced. *Methylobacterium* secretes both cytokinins and auxins that can initiate or control developmental stages. This seems only to affect haploid stages (gametophytes) and the interaction has been lost in tracheophytes that are apparently able to sufficiently produce and control their own growth hormones.

Figure 55. *Bartramia stricta* with capsules; a species of *Methylobacterium* in Spain uses methanol as its only source of carbon and energy. This is emitted by the moss and provides needed carbon for the *Methylobacterium*, which in turn releases CO₂ used by the moss. Photo by John Game, through Creative Commons.

In bryophytes, *Methylobacterium* (Figure 6) enhances cell growth (Kutschera *et al.* 2007). Bacteria isolated from the upper surface of the thalli of *Marchantia polymorpha* (Figure 37) proved to be an undescribed species of *Methylobacterium*, now known as *Methylobacterium marchantiae* (Schauer *et al.* 2011; see Figure 6). This bacterium stimulates the surface expansion of isolated gemmae (Figure 37, Figure 56) from *M. polymorpha* by about 350% (Kutschera *et al.* 2007)! In water suspension, the *Methylobacterium marchantiae* from the liverwort forms dense clusters of up to 600 cells. But when *Methylobacterium mesophilicum*, a tracheophyte associate, is cultured in water, only single cells are formed. Kutschera and coworkers suggested that the clusters on the liverwort inhabitant were an adaptation to surviving on the liverwort when it underwent desiccation in its natural habitat.

Figure 56. *Marchantia polymorpha* gemma. The bacterium *Methylobacterium marchantiae* stimulates the surface expansion of such isolated gemmae. Photo by Des Callaghan, through Creative Commons.

Kutschera and Koopmann (2005) discovered that the thallose liverworts *Marchantia polymorpha* (Figure 37) and *Lunularia cruciata* (Figure 57) serve as host plants for the genus *Methylobacterium* (Figure 6) that secretes phytohormones on the surfaces of the thalli. These hormones promote the growth of isolated gemmae (Figure 56) on agar and appear to be a necessary component for the completion of the life cycle. When bryophytes first evolved, it appears that they depended on external sources such as bacteria for critical factors in their life cycles. They spent their evolutionary capital developing numerous secondary compounds so that they could survive the bacteria fungi, protozoa, and herbivores that threatened their existence.

Figure 57. *Lunularia cruciata* showing gemmae that respond to hormones secreted by *Methylobacterium*. Photo by Hermann Schachner, through Creative Commons.

Tian and Li (2017) identified the dominant methylamine-utilizing bacteria from *Hygroamblystegium noterophilum* (Figure 49) as *Methylothena*, *Methyloversatilis*, and *Tepidimonas*. These genera contribute primarily to denitrification and methanol metabolism.

Hornschuh *et al.* (2002) found that bacteria were numerous on the leaf surfaces of moss *Funaria hygrometrica* (Figure 29). In particular, they occurred in

the grooves between adjacent lamina cells (Figure 58). Isolated strains of *Methylobacterium mesophilicum* (see Figure 6) and *Methylobacterium* sp. elicited the same response as cytokinin application on protonemal bud formation (Figure 59) and promoted growth of the protonemal filaments. This suggests that these bacteria have an important role in the development of *Funaria hygrometrica*.

Figure 59. *Funaria hygrometrica* cultures with young gametophores and gametophore buds near the ends of the protonemata. *Methylobacterium* elicits a cytokinin type of response in the growth and bud formation of the protonema. Photo by Janice Glime.

Schauer and Kutschera (2011) further investigated the bacterium now known as *Methylobacterium funariae* (see Figure 6) isolated from *Funaria hygrometrica* (Figure 29). These bacteria provide cytokinins and auxins to the moss associates. In the association, methanol is emitted by the mosses and used by the bacteria as their carbon source. Schauer and Kutschera suggested that amino acids leached from the bryophytes might be important as sources of carbon and nitrogen for the bacteria.

CO₂ Source

One of the first considerations regarding bryophyte interactions with bacteria was that bacteria provide a source

of CO₂ for the bryophytes, particularly in aquatic habitats. Wetzel *et al.* (1985) noted that algae and aquatic plants are rapidly limited by low availability of CO₂ even at low pH in the range of 4-6. They found that 25-40% of the carbon fixed by leaves can originate from the sediments. When more CO₂ becomes available in the rhizosphere sediments, the reliance on CO₂ diminishes.

In the remote location of Antarctica, Tarnawski *et al.* (1992) noticed differences in growth of the moss *Schistidium chrysoneurum* (Figure 60). This moss grows as turf in wet locations and as cushions at relatively dry sites. Tarnawski and coworkers discovered that the CO₂ concentrations within these two communities differed "substantially." At the beginning of the growing season, both communities had the same CO₂ concentrations of about 350 ppm. But in the turf, the CO₂ levels rose tenfold during the growing season while those in the cushions changed little. This provided ideal growing conditions in the turf. The researchers attributed the higher CO₂ levels to respiration of rhizoids and heterotrophic communities, including the bacterial component.

Figure 60. *Schistidium chrysoneurum* in Antarctica, a species that benefits from the CO₂ produced by bacteria. Photo by Sharon Robinson, with permission.

In another example a surprisingly large colony of *Fontinalis cf. novae-angliae* (Figure 61-Figure 62) was discovered on the floor of Yellowstone Lake, a 119-m-deep lake in Yellowstone National Park, USA, at 2,357 m asl (Lovalvo *et al.* 2010). Due to its elevation and location, the lake averages a temperature of 5°C. We would expect that the attenuation of light and the cold temperatures at that depth would discourage the growth of any photosynthetic organism other than some highly adapted algae. In the lake, the mosses were associated with geothermal vents where the water was supersaturated with CO₂. This situation illustrates the ability of high CO₂ levels to enhance photosynthesis in otherwise limiting conditions. Thus, we should look for aquatic mosses at depths where heterotrophic bacteria benefit from organic sediments and release respiratory CO₂ that is available to the aquatic bryophytes.

Figure 61. *Fontinalis cf. novae-angliae* from Yellowstone Lake geothermal vent, where bacterial respiration most likely contributes to its needed CO₂. Photo from Lovalvo *et al.* 2010.

Figure 62. *Fontinalis novae-angliae* habitat in a stream; bacteria associated with the moss most likely contribute CO₂ for photosynthesis by the moss. Photo by Janice Glime.

Gimeno *et al.* (2017) suggested that bacterial partners could contribute to carbonyl sulphide production (COS) in bryophytes. Uptake of COS, a surrogate for measuring photosynthesis, could be significant in bryophyte cells at night, as suggested by their experiments, because bryophytes are able to take in COS in the dark, using the light-independent carbonic anhydrase, not relying on light to open stomata as is the case for tracheophytes. Carbonyl sulfide is an intermediate between carbon dioxide and carbon disulfide (Wikipedia 2022). With sufficient humidity or water in association with bases, carbonyl sulfide decomposes to carbon dioxide and hydrogen sulfide. Could this help to account for the bryophytes that occur in highly alkaline waters? It is unclear if the bryophytes can benefit the bacteria at night, but in the daytime they could provide O₂.

Growth Hormones

One of the important discoveries in the bryophyte-bacteria relationship is that bacteria can provide hormones that are necessary for the development of bryophytes through the life cycle. Researchers have discovered that optimal growth conditions, including development and reproduction, often require interactions with

microorganisms in a parasitic, mutualistic, or protocoeperative relationship (Spiess *et al.* 1984a, 2019).

Bud Induction

I suspected such a relationship between bacteria and protonemal development in the 1980's when I cultured *Fontinalis squamosa* (Figure 63-Figure 64) from spores (Glime & Knoop 1986). I cultured these in the lab of Martin Bopp in Germany and had to abandon them to return to my responsibilities in the USA. My colleague, Bernd Knoop, continued to watch the cultures until they became contaminated, at which time they were discarded. But he reported to me that the only buds (see Figure 65) on my cultures were on the contaminated cultures. That suggested to me that my sterile cultures needed something that was produced by partner organisms in nature. Ares *et al.* likewise concluded that the developmental differences between the axenic cultures of *Fontinalis antipyretica* (Figure 66) and those contaminated with bacteria (or fungi) were likely to be due to interaction with the contaminants.

Figure 63. *Fontinalis squamosa* in stream at Cwm Idwal National Nature Reserve, Wales. This species seems to require bacterial hormones to complete its development. Photo by Janice Glime.

Figure 66. *Fontinalis antipyretica*, a species that seems to gain developmental benefits from microbes. Photo by Misha Ignatov, with permission.

As we now have observed in many other axenic cultures of bryophytes, the protonemata of *Hyophila involuta* (Figure 34) failed to produce buds on basal Knop's + Nitsch's minor salts (Rahbar & Chopra 1982). Furthermore, addition of auxins, gibberellic acid, abscisic acid, chelates, vitamin B₁₂, activated charcoal, coconut milk, and altered hydration, pH, temperature, light intensity and duration all failed to stimulate bud formation. Cytokinins could initiate multicellular gemmae on the protonemata, but failed to initiate buds. Only the interaction of IAA with either kinetin or DMAAP stimulated formation of buds and normal gametophore development. Such observations suggest that in nature some exogenous source, perhaps from bacteria or fungi, contributes the hormones necessary to initiate the next developmental stage.

Reutter *et al.* (1998) found that application of cytokinins to *Physcomitrium patens* (syn. = *Physcomitrella patens*; Figure 67) cultures enhances bud formation but fails to stimulate the subsequent gametophore development. Most of the cytokinin and auxin occur in extracellular pools and appear to be involved in hormone transport in mosses. Gonneau *et al.* (2001)

further demonstrated that development in *Physcomitrium patens* is regulated by environmental signals and hormones. Cytokinins are required to give rise to the leafy gametophore, but it appears to be regulated to different concentrations in the bud stage compared to elongation of the gametophore.

Figure 67. *Physcomitrium patens*; AHLs from bacteria promote spore germination in this moss. Photo by Hugues Tinguy, with permission.

My suspicion of bacterial hormone contributions was influenced by the early research of Loretta Spiess and her coworkers. They were able to demonstrate that the bacterium *Agrobacterium tumefaciens* (Figure 68) influenced the development of the epiphytic moss *Pylaisiella selwynii* (Figure 69), including initiation of gametophore buds more quickly (Spiess *et al.* 1971). After 35 days, mosses cultured axenically exhibited only 0-24% gametophore formation, whereas those inoculated with *A. tumefaciens* had at least 96% gametophore formation. Bacterial-assisted cultures also produced 4-6 gametophores per culture, compared to 1 in the absence of the bacteria. The supernatant from the cultures did not cause any changes in bud production.

Figure 68. *Agrobacterium tumefaciens*, a species that provides hormones needed for the development of *Pylaisiella selwynii*. Photo by Martha Hawes, University of Arizona through NSF public domain.

Figure 69. *Pylaisiella selwynii*, a moss that has a hormonal benefit from the bacterium *Agrobacterium tumefaciens*. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Spiess *et al.* (1972) explored the possible influence of bacteria by testing the effects of various hormones on *Pylaisiella selwynii* (Figure 69). They found that indoleacetic acid (IAA) and ethrel increased bud formation at a narrow concentration range. But bud formation responded well at various concentrations of cytokinins. Nevertheless, the cytokinin-induced buds failed to develop into normal gametophores. This is not surprising because Bopp and Jacob (1986) later found that in the moss *Funaria hygrometrica* (Figure 29) the concentration of cytokinin that effects branching of caulonemata requires pico-molar concentrations, whereas bud formation requires micro-molar concentrations.

More encouraging for Spiess *et al.* (1972) was the fact that octopine, lysopine, and octopinic acid from crown-gall tumors increased *Pylaisiella selwynii* (Figure 69) bud formation at 10^{-3} M. In particular, lysopine stimulated the formation of buds that developed into typical gametophores. However, octopine initiated the formation of gemma-like structures, but no gametophores. Culturing with l-arginine from octopine and l-lysine from lysopine failed to induce gametophore formation. γ -guanidinobutyric acid induced bud formation at 10^{-3} M concentrations; the buds produced highly abnormal gametophores. Reminiscent of the ineffectual influence of the supernatant, Spiess *et al.* (1976) found that physical contact was necessary for the bacteria to be effective in production of gametophores.

Whately and Spiess (1977) demonstrated that LPS (lipopolysaccharide) from *Agrobacterium tumefaciens* (*Pseudomonadota*; Figure 68) inhibited gametophore development by preventing the bacterium from binding, providing further evidence that direct contact was needed between the moss and the bacterium. This effect is apparently only effective for a short time; if the LPS was added 24 hours after the addition of the bacterial cells, it had no effect in reducing the development of the gametophore.

Protonemal growth of *Pylaisiella selwynii* (Figure 69) was slightly accelerated by cAMP (Spiess 1979). IAA (10^{-6} M) alone, or with cAMP, inhibited protonemal elongation but when added at 10^{-12} M it increased filament growth, demonstrating the importance of the concentration. When adenosine and guanosine were added together (depending on the ratio), they caused a marked increase in rapidly elongating normal gametophores.

After ten years of study with *Agrobacterium* (Figure 68), Spiess *et al.* (1981a) still could not assign the bacterial isolates from three other species of mosses and *Pylaisiella selwynii* (Figure 69) from another location to the genus *Agrobacterium*. Many of these isolates elicited developmental changes in the protonemata of *Pylaisiella selwynii* (Figure 69) that were similar to those of the *Agrobacterium*. In any case, it was becoming clear that in nature bacteria can influence the developmental stages of mosses.

Spiess *et al.* (1981b) again pursued the effects of octopine and cytokinin on the growth and gametophore formation of *Pylaisiella selwynii* (Figure 69). Octopine is an unusual amino acid, but it occurs in crown gall tumors. In combination with cytokinin it increased the number of gametophores and decreased the time required for them to develop. This effect was similar to that seen with *Agrobacterium* (Figure 68) in *Pylaisiella selwynii* cultures. But concentration was important. More common amino acids alone or in combination with auxins or cytokinins generally had a neutral effect on the moss development.

There is an interesting inhibitory action by the cell walls of *Pylaisiella selwynii* (Figure 69). Cell walls of several dicots, but not of tested monocots, inhibited the induction of buds and gametophore development by *Agrobacterium tumefaciens* (Figure 68) (Spiess *et al.* 1984b). Both pectin and polygalacturonate were inhibitory. Protonemal cell walls inhibited gametophore induction; gametophores were less inhibitory. But cell walls from the moss *Polytrichum commune* (Figure 24) protonema and gametophores caused little inhibition. On the other hand, *Agrobacterium* is ineffective in increasing bud formation in *Polytrichum commune*. If the *Polytrichum* protonemata or gametophore cell walls are treated with pectinesterase, they do inhibit the developmental stimulation of *Agrobacterium* on *Pylaisiella selwynii* and pectinesterase increases the inhibitory effect by *Pylaisiella* gametophore cell walls. Conversely, pectinesterase treatment of the *Polytrichum* protonema makes it more sensitive to the *Agrobacterium*, causing increased bud and gametophore formation. Spiess and coworkers reasoned that the bacteria require suitable adherence sites and that the addition of the pectinesterase made these sites available in *Polytrichum*.

One effect of at least some bryophytes on *Agrobacterium tumefaciens* (Figure 68) is the ability to induce the expression of its virulence gene (Primich-Zachwieja & Minocha 1991). This was evident by the β -galactosidase activity in the bacteria.

While Spiess and coworkers were attempting to understand the relationships of bacteria with *Pylaisiella selwynii* (Figure 69), Chopra and Vashistha (1990) explored the effect of auxins and antiauxins on the shoot bud induction and growth form of the moss *Bryum atrovirens* (Figure 70). In culture, various auxins induced buds on the protonemata, whereas without these added

hormones the sterile culture conditions were not conducive to bud formation. Again, concentration was important, with higher levels causing adverse effects on the morphology.

Figure 70. *Bryum atrovirens*; various auxins induced buds on the protonemata, whereas without these added hormones buds were absent; bacteria most likely supply these auxins in nature. Photo by Jan-Peter Frahm, with permission.

The study of hormones and their effects on bryophytes has been largely confined to auxins and cytokinins (Sabovljević *et al.* 2014). Gibberellic acid (GA) has been mostly ignored, with investigations suggesting that it did not evolve its interaction with GID1-DELLA until after bryophytes diverged from other land plants (Yasumura *et al.* 2007). ABA and its sister compound lunularic acid have been studied somewhat extensively (Decker *et al.* 2006).

Chopra and Dhingra-Babbar (1984) also found that indoleacetic acid (IAA), gibberellic acid, abscisic acid, chelates, salicylic acid, and altered temperature, pH, agar, sucrose levels, light levels, and photoperiod do not induce buds in the moss *Trematodon brevicalyx* (see Figure 71). Only cytokinins elicited a bud response in sterile cultures. In fact, even at concentrations of cytokinins that induced buds, varying concentrations of IAA reduced the number of buds considerably.

Figure 71. *Trematodon longicollis* on a wet roadside bank; *Trematodon brevicalyx* requires cytokinins to induce bud formation in culture, hormones most likely supplied by bacteria in nature. Photo by Michael Lüth, with permission.

Yasumura *et al.* (2007) demonstrated a lack of GA production in *Physcomitrium patens* and suggested the pathway to its production arose after the bryophyte lineage. Nevertheless, gibberellic acid, a known product of bacteria (MacMillan 2002; Yamaguchi 2008) has a positive effect on morphogenesis in *Bryum argenteum* (Figure 72) (Sabovljević *et al.* 2010) and interferes with gravitropism in *Ceratodon purpureus* (Figure 73) (Chaban *et al.* 1999). Since bacteria that inhabit plants are able to produce gibberellic acid (Katznelson & Cole 1965; MacMillan 2002; Karakoç & Aksöz 2006; Zhang *et al.* 2012; Ambawade & Pathade 2015; Desai 2017), this interaction should be explored with bryophytes *in situ* and in the lab.

If mosses respond to different concentrations in different ways, how do bacterial levels coordinate the developmental stages? Do the bacteria respond to environmental signals so that protonemata branch while the bacteria are at low numbers (that would give bacteria more cover and hold moisture better), then the bryophytes

develop gametophores when the bacterial numbers increase (that would ensure a large colony of mosses that can help to conserve moisture within the colony)? Do differences in developmental responses occur among bryophyte species? If so, how important are the bacteria species in determining the success of specific bryophyte species in particular habitats?

Growth

The moisture-loving leafy liverwort *Scapania nemorea* (Figure 74) has a regular association with the bacterium *Pseudomonas extorquens* (see Figure 10) (Basile *et al.* 1969). When *S. nemorea* gametophytes were inoculated with this bacterium in culture, they grew larger and reached reproductive maturity more quickly than those cultures without the bacteria. It is likely that this stimulus occurs in nature as well.

Figure 74. *Scapania nemorea* with gemmae, a species with a regular positive association with the bacterium *Pseudomonas extorquens*. Photo by Blanka Aguero, through Creative Commons.

Tani *et al.* (2011) explored *Racomitrium japonicum* (Figure 75) with the intent of increasing its growth rate for culture as a green-roof plant. They isolated *Pseudomonas* (Figure 10), *Rhodococcus* (Actinomycetota; Figure 76), and *Duganella* (Pseudomonadota) species from hydroponic culture of the moss. The researchers characterized these bacteria by their plant interactions such as auxin production, siderophores (molecules that bind and transport iron in microorganisms), or hydrogen cyanate, growth in absence of added nitrogen source, calcium phosphate solubilization, utilization of sugars, polymers, or aliphatic compounds, and antifungal activity. Such activities cause the bacteria to stabilize production and enhance the growth of *Racomitrium japonicum*.

Rhizoids

Sheldrake (1971) determined that the concentrations of auxins in the soil were in the same range as those known to stimulate the formation of rhizoids in liverworts. Sheldrake further considered that the greatest concentration of auxins would occur in areas with the highest nutrient levels. This mechanism would cause the bryophytes to produce the most rhizoids in microhabitats with the highest concentrations of nutrients. Sheldrake concluded that the bryophytes did not produce auxins and that they depended on the environment to supply them. Hence, the bacteria could provide an important role in signalling environmental conditions to the bryophytes. This increased production of bryophyte rhizoids could be beneficial in high-nutrient environments that would also increase competition from other plant species.

Khan *et al.* (1997) found that rhizoids of mosses could also stimulate the growth of bacteria. This was particularly

true for the bacterium *Bacillus* (Figure 9). Where do these mutual stimulation partnerships end?

Quorum Sensing

It is important to realize that bacteria do not live as solitary cells, but that they require the coordination of a colony with intercellular communication that permits them to adjust to changing environmental conditions (Whitehead *et al.* 2001). This communication, as we might expect, is through chemical signals. These signals are dependent on cell density and growth phase.

Bacteria use **quorum sensing** as a way of monitoring their population density and interacting with their environment (Vesty *et al.* 2020). Quorum sensing requires intercellular signalling mechanisms (ISMs) that serve as a means of recognizing cell density (Whitehead *et al.* 2001). In the environment, the expression of virulence depends on the synthesis of and response to diffusible signalling metabolites (Manefield & Turner 2002). Thus far, only the **Pseudomonadota** are known to produce the necessary AHL (N-acyl-L-homoserine lactone) compounds used for signalling, thus limiting the availability of such signalling. This may account for the preponderance of the **Pseudomonadota** in association with bryophytes. However, widespread testing of signalling among bacteria and to bryophytes is lacking. For example, <1% of all bacteria that are present in any environment can be cultured in the lab using standard media, so many more AHL-producing bacteria are possible (Vesty *et al.* 2020). Recent DNA techniques may help us to elucidate these bacteria.

As Whitehead *et al.* 2001 suggested, Williams *et al.* (2007) found that bacteria associated with bryophytes, instead of being the passive autonomous organisms we thought, are highly communicative. As the population density increases, the production of quorum sensing molecules also increases, increasing their presence in the external environment. Quorum sensing enables a bacterial population to achieve a co-operative response that improves access to nutrients or specific environmental niches, promotes collective defense against other competitor prokaryotic or eukaryotic defense mechanisms, and facilitates differentiation into forms that promote survival by making the cells better able to combat environmental threats. Quorum sensing can be exploited or inactivated by both plants and mammals, and it appears that bryophytes are among the users of this phenomenon.

Spore Germination

Among the Gram-negative bacteria, the quorum sensing molecules are N-acylhomoserine lactones (AHLs) (Vesty *et al.* 2020). These AHLs can affect the spore germination of the moss *Physcomitrium patens* (Figure 67). AHLs promote this spore germination at sub-micromolar concentrations but inhibit spore germination at concentrations above 1 μM . Even the sporophytes of some wild isolates of *Physcomitrium patens* are associated with AHL-producing bacteria. Many of the *Pseudomonas* (Figure 10) isolates, most of the *Serratia* (Figure 8) isolates, and one of the *Aeromonas* (Figure 77) isolates, all known from bryophytes, produced AHLs in their study. Furthermore, there are many bacteria that thus far have not been cultured, so there could be many additional sources of AHL's in the bryophyte habitats.

Figure 77. *Aeromonas hydrophila*, a bacterium that produces AHLs as signalling compounds. Photo by W. A. Clark, CDC, through public domain.

Vesty *et al.* (2016) concluded that endogenous hormone signalling networks that control germination of spores and seeds as environmental responses may have evolved independently in spores and seeds. Such parallel evolution is a testimony to the importance of the relationship.

Vitamins

Algae use **vitamin B₁₂** that is manufactured by bacteria, a symbiotic need generated by the lack of B₁₂-dependent enzymes in algae (Croft *et al.* 2005). Bryophytes likewise obtain vitamin B₁₂ from bacteria (Basile *et al.* 1985), although it does not seem to have a direct role. Its presence in bryophyte-associated bacteria, however, could be important for animals feeding there, particularly large herbivores that use bryophytes as emergency food. Growth of *Lioclaena lanceolata* (Figure 78) and *Gymnocolea inflata* (Figure 79) was significantly stimulated by the pink facultative methylotrophic bacteria that both synthesize and accumulate vitamin B₁₂. These bacteria commonly associate with bryophytes, but the physiological role of vitamin B₁₂ is elusive (Marsten 1952).

Water Relations

Could bacteria help bryophytes in their recovery from desiccation? Or are they a threat to be reckoned with?

Minibayeva and Beckett (2001) suggested that the oxidative burst seen upon rehydration in a hornwort (*Anthoceros natalensis* – Figure 80) and two thalloid liverworts [*Dumortiera hirsuta* (Figure 81), *Pellia epiphylla* (Figure 82)] is actually a defense mechanism against pathogenic fungi and bacteria. Li *et al.* (2010) found a similar response to both biotic and abiotic stresses in *Dumortiera hirsuta*. When bryophytes desiccate, their membranes become leaky. When they rehydrate, bacteria and fungi can enter the leaky cells as the water rehydrates them (Minibayeva & Beckett 2001). Hence the oxidative burst can help to prevent those pathogens from damaging the cells of the bryophyte. It is interesting that mosses and at least some leafy liverworts tested lacked the oxidative burst and its absence may be related to their desiccation tolerance. We need experiments and observations to determine how well the oxidative burst correlates with desiccation tolerance, and is it needed more in those with higher moisture requirements?

Bacteria can confound measurements of productivity in bryophytes. From an ecosystem point of view, it may be legitimate to express the productivity of the bryophyte-periphyton association, but from a physiological perspective of the bryophyte alone, this is not acceptable. Gupta (1977) noted that following desiccation in the mosses *Dicranella palustris* (Figure 83), *Mnium hornum* (Figure 84), and *Syntrichia ruralis* (Figure 85), and the liverworts *Porella platyphylla* (Figure 82) and *Scapania undulata* (Figure 86) the external water collected from them after 22 hours had large numbers of microorganisms. The burst of respiration following rehydration was due to these microorganisms. But does this respiratory activity indicate damage to the bryophytes, providing leaked carbohydrates to the bacteria, or could it be a benefit by providing additional CO₂ for photosynthesis?

Do bacteria help in the uptake of nutrients in bryophytes? For the bean, *Phaseolus vulgaris*, 42 hours after 10 nM homoserine lactone (HL) was supplied to roots the transpiration and stomatal conductance increased significantly. Although the experiments were done with tracheophytes, the same effect could occur with bryophytes, especially those that form cushions. They lack

stomata, but transpiration still occurs from the cushion. Joseph and Phillips (2003) considered the bacteria in the soil to have a role in plant water and nutrient relations. As water diffuses from the plant to the atmosphere, the action helps to move diffusion-limited nutrients such as phosphorus from the soil to the plant and also to the microbes.

Figure 86. *Scapania undulata*, a liverwort species that has large numbers of microorganisms in its external water, causing a burst of respiration upon rehydration. Photo by Hermann Schachner, through Creative Commons.

By contrast, Krochko *et al.* (1978) found that respiration in the semiaquatic moss *Cratoneuron filicinum* (Figure 87) does not occur upon rehydration following rapid drying. They, too, cautioned that contamination by bacteria could cause false readings of the respiration by the moss.

Figure 87. *Cratoneuron filicinum*, a moss that does not exhibit a rapid respiration following rehydration. Photo by Claire Halpin, with permission.

Freezing Protection

Liquid pure water does not freeze at 0°C, but requires the temperature to drop to -38°C before it freezes, and even lower in very small samples (Moffett 2015). But water does not occur in the ecosystem in its pure state. Instead it has many nucleating materials, including bacteria, that permit it to crystallize at a temperature near 0°C. In fact, it is the bacteria that permit it to freeze at the highest temperatures. The **ice nucleation** bacteria seem to be limited to a small number of plant pathogens that use specific proteins to cause freezing. The resulting damage permits them to gain nutrients from the plants. Moffett showed that ice nucleation is likewise an active process in both mosses and liverworts. In fact, those tested harbor 106-107 g L⁻¹, an order of magnitude greater than that

known for lichens. But Moffett failed to find more than a few bacteria on the surfaces of mosses cultured on selective media, thus concluding that ice nucleation activity is unlikely to be caused by surface bacteria. But there seem to be many bacteria that have never been cultured because we don't know their requirements (Vesty *et al.* 2020). Could it be that tiny nucleating bacteria are present, but not yet detected by traditional methodology?

When ice forms on bryophytes, it grows at the expense of the bryophyte by pulling water from the cells or scavenging it from the surface. This is a particular problem for those species that are dependent on fog, dew, and cloudwater. Moffett *et al.* (2009a, b) suggested that mosses produce ice nuclei that are very different from those produced by bacteria. Instead, they are proteins that show only distant relationship to the classical bacterial ice nuclei. Moffett *et al.* suggest that these ice nuclei are used as a water harvesting mechanism by the bryophytes, removing it from atmospheric moisture rather than from the bryophyte cells.

On the other hand, some bacteria do have a sneaky trick to gain entry into plant cells. These are a small number of ice-nucleating bacteria (Moffett 2015). The bacteria use certain proteins to induce freezing that damages the plants, permitting the bacteria to gain nutrients (Lindow 1983). But for bryophytes, it is possible that they help the plants gain water (Moffett 2015). Ice crystals are hygroscopic, gathering water from the atmosphere. This could be an advantage following the desiccating effects of freezing. Size matters, and smaller ice nucleating bacteria could prevent large crystal formation by out-competing the larger bacteria, a phenomenon used by Florida orange growers to prevent ice damage to the oranges on cold nights. Moffett found that all mosses and liverworts tested have active ice nucleation. This benefit for bryophytes survived as a water-gathering mechanism. Moffett suggested a number of hypotheses:

1. Ice nucleation is a ubiquitous feature of bryophytes.
2. Ice nucleation is used as a water-gathering mechanism.
3. Ice nucleation is of greater selective advantages to bryophytes growing in habitats such as rock and tree surfaces.
4. Ice nucleation in bryophytes is due to a surface expressed protein.
5. Ice nuclei from bryophytes become airborne and influence atmospheric processes.

All of these hypotheses need to be tested. Could the finding of a protein on the surface of the liverwort be a product of some unknown bacterium that didn't have the right conditions to appear in culture, rather than of the liverwort (see Kazda *et al.* 1980; Vesty *et al.* 2020)?

Weber (2016) provided evidence that spores (Figure 88) of *Polytrichum commune* (Figure 24) in the atmosphere are ice nucleators. This nucleation ability was active at -7°C when the spores were contaminated with bacteria, compared to -12°C for spores contaminated with microorganisms. Hence, moss spores can affect precipitation patterns, with the more common contaminated spores having the greater effect by causing freezing at a higher temperature.

Figure 88. *Polytrichum commune* spores; these serve as ice nucleators in the atmosphere and are active at even higher temperatures when they have bacteria. Photo by Global Pollen Project, through Creative Commons.

Nutrients

Šoltés *et al.* (2015) attempted to understand the seasonal variation of bryophytes in a calcareous mire in Slovakia. In a detailed examination of *Campylium stellatum* (Figure 89) and *Drepanocladus cossonii* (Figure 90), they found that distribution of these two mosses was limited primarily by decreasing concentrations of NH_4^+ and increasing concentrations of NO_3^+ . They determined that this seasonal variation in bryophyte cover was the result of the synergistic relationship with the nitrifying bacteria and by the unstable water table. The bacteria were instrumental in the decomposition of the organic substances in the soils, thus returning nutrients that benefitted the bryophytes.

Figure 89. *Campylium stellatum*, a species limited primarily by decreasing concentrations of NH_4^+ and increasing concentrations of NO_3^+ . Seasonal variation in this bryophyte cover resulted from a synergism with nitrifying bacteria and by an unstable water table. Photo from Dale A. Some plants, especially graminoids, require silica (Si). It increases resistance to various forms of stress. But Si has limited availability to plants because of its insolubility. Bryophytes grow in locations where high levels of silica are present in rocks, so Hu *et al.* (2019) investigated the associated bacteria in the widespread moss *Hypnum plumaeforme* (Figure 91). They did indeed find that a strain in the bacterial genus *Kosakonia* was able to release Si from feldspar and quartz. These bacteria significantly increased the water-extractable Si in the soil, improved Si uptake by *Zea mays*, and promoted seedling growth. Hence the bryophyte rhizoids can provide the environment needed for the bacteria that release needed Si. We need research on this partnership role in habitats where both grasses and bryophytes grow. And do any of the bryophytes use silica?

Figure 91. *Hypnum plumaeforme*; the bacterium *Kosakonia* lives in the moisture provided by rhizoids of this moss and is able to release Si from feldspar and quartz. Photo by Janice Glime.

Epiphyllous liverworts can benefit nitrogen-fixing bacteria and *Cyanobacteria* by maintaining leaf moisture for a longer period of time, thus improving the usable N content in the canopy (Bentley & Carpenter 1980).

Decomposition

When one thinks of bacteria in natural habitats, decomposition usually comes to mind. Nevertheless, we know that decomposition of bryophytes is notoriously slow (Fenton *et al.* 2010). Instead, the bryophytes retain high levels of soil carbon, retain excessively high soil water content, cool the soil, and slow nutrient cycles.

Sphagnum (Figure 12) decomposition can require specialized bacteria, with the abiotic environmental conditions having more importance than in other systems because of this bacterial specialization (Kulichevskaya *et al.* 2007). These bacteria are primarily members of the phyla **Actinomycetota**, **Planctomycetota**, and **Pseudomonadota** (Alphaproteobacteria). Kulichevskaya *et al.* found that the numbers of **Bacillota** and **Bacteroidota**, which are believed to be the primary decomposers in eutrophic wetlands, are low. As the decomposition reached its final stage, the numbers of **Planctomycetota** increased. Representatives of the **Pseudomonadota** were able to utilize galacturonic acid, the only low-molecular-weight organic compound detected in the water samples of the decomposing peat. The bacterial community involved in *Sphagnum* decomposition appears to be fundamentally different from that which decomposes the dead plant parts in eutrophic ecosystems at neutral pH. Even where *Sphagnum* is present, decomposition of the other bryophytes is significantly higher than that of the *Sphagnum* (Lang *et al.* (2009). The loss of mass in these other species correlates with the initial nitrogen, without influence of incubation conditions.

Kulichevskaya *et al.* (2010) named a new genus and species [*Bryobacter aggregatus* (Figure 39) in **Acidobacteriota**] for three strains of chemo-organotrophic bacteria isolated from acidic *Sphagnum* bogs (Figure 12). These bacteria preferred substrates of sugars (heteropolysaccharides, galacturonic acid, and glucuronic acids) – substances released during *Sphagnum* decomposition. These grew at pH 4.5-7.2 and 4-33°C.

Again in 2014 Kulichevskaya *et al.* described a new species, genus, and family of bacteria from *Sphagnum*. The species, *Roseiarcus fermentans*, is a microaerophilic fermentative bacterium in the **Pseudomonadota**.

Bamforth (2007) noted that protozoa are important in stimulating bacterial activity for decomposition. In a tropical forest in Puerto Rico, he found that the high moisture content of the tropical rainforest litter (including bryophytes) and soils provided the connected soil water needed for protozoan transport. Often there needs to be consideration of protozoan potential because of their dormancy status. Nevertheless, the large numbers of protozoa suggest that a major proportion of these contribute to stimulation of the bacterial decomposition for this organic matter.

Mikola and Hintikka (1956) experimented with decomposition of five forest litter types. One of these was the moss *Pleurozium schreberi* (Figure 92). Others were the grass *Deschampsia flexuosa* (Figure 93), shrub *Alnus incana* (Figure 94), deciduous tree *Populus tremula* (Figure 95), and conifer tree *Pinus sylvestris* (Figure 96). Of these, the *Pleurozium schreberi* litter had the lowest bacterial number and highest fungal count. The researchers noted that the related moss *Hylocomium splendens* (Figure 97) is very acid and decomposes differently from tracheophyte

leaves (Mikola 1954). Since these mosses are closely related species and occur in overlapping acidic habitats, it is possible that the acid conditions are unfavorable to bacteria while being favorable to the fungi.

Relative to lichen-dominated sites, bryophytes are associated with higher soil nutrient concentrations and a greater production of easily decomposable substrates that provide better maintenance of microbial activities (Ohtonen & Vare 1998). Do the bryophytes contribute to these better conditions, or are they simply indicators of the better conditions?

Bastardo (1979) experimented with decomposition in *Fontinalis antipyretica* (Figure 98). Satake and Miyasaka (1984) found, by using TEM, that the leaves of the aquatic liverwort *Solenostoma vulcanicola* (Figure 99) exhibit rod-shaped bacteria and numerous holes in the liverwort cell walls. They suggested that these bacteria contribute to the decomposition of this liverwort.

Van Tooren *et al.* (1988) found that nutrients released by decomposing bryophytes in spring and summer are incorporated by the tracheophytes, thus ensuring their retention in the system. In ecosystems where they are associated with nitrogen-fixing bacteria, such as mires and grasslands, they enhance the N in the ecosystem (Oechel & van Cleve 1986). Hence the nutrient content of the bryophytes affects the nutrient cycle of the whole ecosystem.

Fauna and Bryophagy

Bacteria often play a role in feeding the animals that live among the bryophytes. In peatlands, *Sphagnum* is often a suitable substrate for a number of Protozoa (Mieczan 2006). The bacterivorous Protozoa were in the highest numbers in all the moss samples, whereas the algivorous ones were the lowest.

Nematodes are common among bryophytes in some habitats. Among these, members of the genus *Panagrolaimus* (Figure 100) are bacterial feeders that are known from terrestrial mosses in both the Antarctic and temperate ecosystems (Shannon *et al.* 2005). In a Balkan oak forest, Lazarova *et al.* (2000) found a similar relationship, with bacterial feeders being the most abundant group of nematodes on the moss *Hypnum cupressiforme* (Figure 101). Merrifield (1992) likewise found that the moss-dwelling nematode *Plectus* sp. (Figure 102) is a bacteria feeder.

Figure 100. *Panagrolaimus davidi*, in a nematode genus that has bacterial feeders that live among bryophytes. Photo from Smithsonian, through Creative Commons.

Many tardigrades are well adapted to living among mosses. They have the ability to dry out and rehydrate under the same water regimes as their moss hosts. Although one group of tardigrades has a stylet that permits them to feed on mosses, some of the tardigrades, particularly smaller ones, feed on bacteria that they find among the mosses (Tardigrada 2005; Schill *et al.* 2011).

Bryophyte communities often have associated arthropods. There is a body of evidence that many of these arthropods feed on the associated bacteria (Varga 1992).

Although we often think of isopods as scavengers, they can be quite common among and under bryophytes. *Porcellio scaber* can come to the surface to feed on the softer apical tissues at night (Hribljan & Glime, in prep.). Because bryophytes have many substances that are difficult to digest, it is likely that they need some help. Zimmer (1999) found that oxidation of phenolics, common in many bryophytes, is primarily due to endosymbiotic bacteria. Furthermore, the gut has oxygen zones such that the outer, peripheral portion is anaerobic while the inner portion is aerobic. This range of conditions permits both aerobic and anaerobic bacteria to survive in the gut. Furthermore, the beginning of the gut is acidic, whereas the hindgut is neutral. It is not clear if these bacteria are gained from the bryophytes, but their presence could make bryophytes a good source of food.

Isopods also have bacteria in the gut that help them break down complex carbohydrates (Zimmer & Brune

2005). On the other hand, phenolics such as those present in mosses can reduce the gut flora needed for breaking down lignocelluloses (Zimmer 1999; Zimmer & Brune 2005). When the gut flora was reduced they were unable to hydrolyze gallotannins. When they ingested gallic acid, it reduced both the palatable fungi and the bacteria, but at the same time it increased the gut microflora. Thus, it would appear they cannot benefit from eating tracheophyte litter and bryophytes at the same time. This suggests that eating foods with hydrolyzable tannins, as found in some mosses, can inhibit the digestion of other foods in the diet of this species.

Pyszko *et al.* (2019) pointed out that we still lack an understanding of the gut bacterial flora of the moss-eating insects. Among the true bugs, the moss bugs (**Peloridiidae**; Figure 103) are obligately associated with endosymbiotic bacteria (Kuechler *et al.* 2013). The Malpighian tubules (part of the excretory system) have most of their nuclei infected by **Pseudomonadota** in the genus **Rickettsia** (Figure 104). The connection to bryophytes as food is not clear. Could the bugs subsequently eat the excreted uric acid complex? Or might the feces benefit from these bacteria, permitting the bugs to reingest them and benefit from them?

Figure 103. *Hemiodoecellus fidelis* (**Peloridiidae**) on *Sphagnum*, a moss bug that cultures *Rickettsia* bacteria in its Malpighian tubules. Photo by Simon Grove, through Creative Commons.

Using two bryophagous species of beetles in the **Byrrhidae** [*Simplocaria semistriata* (Figure 105) and *Curimopsis paleata* (Figure 106)], Pyszko *et al.* (2019) found that the gut flora differed considerably from the abdominal flora in the same individual beetle (Figure 107). Furthermore, both differed substantially from the substrate surface bacterial flora. The dominant bacteria in the guts and abdomens were all **Pseudomonadota**: *Novosphingobium* (Figure 28), *Bradyrhizobium* (Figure 1, Figure 53), *Ralstonia* (Figure 108), and *Caulobacter* (Figure 109). These bacteria are involved in detoxification of secondary metabolites or in nitrogen fixation. Since these genera are less common in the substrate surface samples, it is likely that they are associated with the specific ability of bryophages to feed on mosses.

Some of the bacteria found in the **Byrrhidae** (pill beetles) guts are nitrogen fixers, *e.g.* *Bradyrhizobium* (Figure 1, Figure 53) (Pyszko *et al.* 2020). Since nitrogen is typically deficient in plants (Benemann 1973), the ability to extract more of it from food items may be especially beneficial. Rapid travel through the gut reduces this ability (Pyszko *et al.* 2020). Therefore, having nitrogen fixers in the guts of bryophyte eaters may be useful. Other benefits may include detoxification, such as the ability of the bacteria *Novosphingobium* (Figure 28) and *Ralstonia* (Figure 108) to degrade phenols and aromatics.

In bryophyte-dwelling *Cytilus sericeus* (Byrrhidae; Figure 110) treated with bactericides and fungicides, the bactericides actually had a positive effect on egg hatching and larval development, whereas the fungicides were detrimental to their fitness, particularly during hatching (Pyszko *et al.* 2020). When the larvae were supplied with adult feces, the feces did not improve fitness. Hence, the beneficial fungi are associated with the eggs, but are not transmitted in the feces. Could the bryophytes be providing bactericides that make the environment favorable to the developing eggs and larvae?

Figure 110. *Cytilus sericeus* on moss; bactericides actually had a positive effect on egg hatching and larval development. Bryophytes are likely to provide these bactericides in nature. Photo by James K. Lindsey, with permission.

Wolf and Rockett (1984) assessed the bacteria in the alimentary canals of two oribatid mites (*Rhysotritia* sp. (Figure 111) and *Pergalumna* sp.). These included *Acinetobacter* (Figure 112), *Actinomycetota*, *Alcaligenes* (Figure 113), *Bacillus* (Figure 9), *Citrobacter* (Figure 18), *Corynebacterium* (Figure 114), *Flavobacterium* (Figure 115), *Mycobacterium* (Figure 116), and *Pseudomonas* (Figure 10). The frequency of *Bacillus* and *Pseudomonas* was considerably lower in mites taken directly from natural habitats than from those found in moss-soil habitats. Both of these bacterial genera are common on mosses, so it is possible that the moss was the source of the bacteria. After being cultured in the lab (with no moss), both mite species showed dramatic shifts in their gut flora.

Moquin *et al.* (2012) found that for both **soil crusts** and mites the dominant phyla of bacteria were **Bacteroidota**, **Acidobacteriota**, and **Pseudomonadota**. The bacterial community and prevalence of **Bacteroidota** in the bryophytic crusts appear to be affected by high carbon availability. The bacterial communities associated with the bryophytic crusts are distinctly different from those of the cyanobacterial crusts and soils. **Acidobacteriota** prevailed in the mites, and the bacteria present in the gut are the same as those known as symbionts in *Tetraponera* (Figure 117) ants.

Figure 117. *Tetraponera punctulata*, an ant that has **Acidobacteria** as gut bacteria symbionts. Photo by Farhan Bokhari, through Creative Commons.

Mammals also may benefit from bacteria by getting more energy from bryophytes than would be possible otherwise. Pikas (*Ochotona princeps*, Figure 118) store plant foods for winter. They manipulate the decomposition of their food by storing with them plants with a high content of secondary compounds, including bryophytes (Dearing 1997). This permits them to store the plants for longer periods and to maintain higher levels of biomass and nutrients until they are eaten. Eating plants with high phenolic compounds is delayed until the phenolic content has decreased due to the microbial activity.

Bjorkvoll *et al.* (2009) suggested that the Svalbard reindeer (*Rangifer tarandus platyrhynchus*, Figure 119) may be a specialist in consuming mosses. The fermentation chambers of the rumen are increased in size and have a very high number of fiber-digesting rumen bacteria. *Polytrichum* (Figure 24) was the most frequent moss consumed.

Figure 119. *Rangifer tarandus platyrhynchus* (Svalbard reindeer), apparently a specialist in moss consumption, probably due to the large number of bacteria in the rumen. Photo by Buiobuione, through Creative Commons.

Pathogens

Not all bacteria are friendly symbionts among their bryophyte neighbors. Lawton and Saidasan (2009) showed that *Physcomitrium patens* (Figure 67) is susceptible to a range of bacterial pathogens that can infect and multiply on the moss. In defense against these pathogens, it uses a variety of mechanisms: production of reactive oxygen species, synthesis of secondary metabolites, changes in gene expression, and activation of the programmed cell death pathway. These responses can be elicited by toxins as well as directly by the bacteria and are under genetic control.

The lab rat of mosses, *Physcomitrium patens* (Figure 67), is susceptible to a range of bacterial pathogens that can infect and multiply on the moss plants (Lawton & Saidasan 2009). One of the responses of the moss is to produce **reactive oxygen species**, as well as synthesis of secondary metabolites, changes in gene expression, and activation of the programmed cell death pathway.

One of the common bacteria on bryophytes is *Bacillus cereus* (Figure 9) (Sabovljević *et al.* 2010). On the other hand, the leafy liverwort *Lophocolea heterophylla* (Figure 120) and moss *Polytrichum commune* (Figure 24) produce antibiotics that are effective against this bacterium species (Nikolajeva *et al.* 2012) and in another study extracts of *Atrichum undulatum* were the most effective against *B. cereus* (Sabovljević *et al.* 2010).

Figure 120. *Lophocolea heterophylla*, a species that produces antibiotics against *Bacillus cereus*, a bacterial species that is antagonistic toward bryophytes. Photo by Kristian Peters, with permission.

In many of these studies, it is likely that more bacteria exist that are not stimulated to grow on the media being used. Kazda *et al.* (1980) cultured bacteria from 122 samples of *Sphagnum* (Figure 12) and other moss vegetation using foot pad inoculation. They found that of the 759 foot pads examined 20% had noncultivable acid-fast *Bacillus* (Figure 9). The frequency was significantly higher in the *Sphagnum cuspidatum* habitat (Figure 121).

Figure 121. *Sphagnum cuspidatum*, a habitat where *Bacillus* has a high frequency. Photo by Rob Routledge, through Creative Commons.

This suggests that bryophytes could be reservoirs of bacteria that are pathogenic to other organisms. D'aoust *et al.* (1990) found that *Salmonella poona* (see Figure 16) and *S. arizonae* (see Figure 16) are frequently encountered in fertile eggs of pet turtles (*Trachemys scripta elegans*, Figure 122) and in the mosses used for packing the turtles. Since these species of bacteria became resistant to the antibiotics, the turtles were taken off the market to protect the children who would otherwise choose them as pets and possibly get infected by the bacteria.

Bacterial Source of Antibiotics Useful to Bryophytes

Pantoea agglomerans (Figure 7) is known from bryophytes, in particular *Sphagnum fallax* (Figure 123- Figure 124) (Opelt *et al.* 2007). This bacterial species is an active producer of antibiotics that are effective against many plant pathogens among the bacteria and fungi (Dutkiewicz *et al.* 2016). This species of *Pantoea* does this by competition, releasing antibiotics, and induction of plant resistance. Bryophytes such as *Sphagnum fallax* can serve as a reservoir for the bacteria so that they become available to animals and annual plants and plant parts (Opelt *et al.* 2007). It is further useful, especially to rooted plants, by preventing the penetration of harmful industrial contaminants. But how does this latter feature affect bryophytes? Could it hold high concentrations near the soil surface where they may be harmful to bryophytes?

Figure 123. *Sphagnum fallax*, a species that can serve as a reservoir of bacteria needed by other plants and animals. Photo by Hugues Tinguy, with permission.

Figure 124. *Sphagnum fallax* hyaline cells with bacteria. Photo by Gabi Berg, with permission.

Opelt and Berg (2004) used *Syntrichia ruralis* (patches on sand dunes; Figure 85), *Aulacomnium palustre* (edge of non-calcareous mire; Figure 13), and *Sphagnum rubellum* (open part of mire; Figure 125) to represent typical moss species of nutrient-poor communities on the Baltic Sea coast of Germany and examine the antagonistic potential of bacteria associated with them. They found a high degree of specificity of the bacteria for the particular moss. This specificity was also manifest in the bacterial antagonistic behavior. For example, the antagonistic activity against the fungus *Verticillium dahliae* (Figure 126) ranged from 31% for *Sphagnum rubellum*, to 17% for *Aulacomnium palustre*, to 5% for *Syntrichia ruralis*. The antifungal role of the antagonistic bacteria is remarkable – 99% of those associated with mosses produced antifungal compounds.

Figure 125. *Sphagnum rubellum*, a strong antagonist against *Verticillium dahliae*. Photo by J. C. Schou, through Creative Commons.

Figure 126. *Verticillium dahliae* showing wilt disease. Photo by Howard F. Schwartz, through Creative Commons.

Out of the 52 species of bryophytes tested with 12 species of microorganisms, 29 (56%) were active against at least one of the test bacteria, but none exhibited any antifungal property (Banerjee & Sen 1979). Anyone who has tried to grow mosses in a closed space with a high humidity recognizes that fungi can be a threat to the moss health, so these antifungal roles of bacteria could be exceedingly important.

After searching through many papers on bacteria and bryophytes, it is unclear to me in many cases which bacteria can serve as pathogens to the bryophytes and which are either neutral or offer some antagonistic advantage to the bryophytes by inhibiting other bacteria or fungi. And some bryophytes produce antibiotics against specific antagonistic bacteria whereas others do not. This is a huge field of bryological interaction where we have just begun to scratch the surface in our understanding.

Speculation

What a fantastic world of interaction! The bacteria got here first and developed all sorts of signals. Bryophytes took advantage of all those signals and developed quorum sensing. This made a close dependence possible and beneficial. So what might remain that we haven't even considered?

Could it be that the inhibition of gemmae germination on the thallus of *Marchantia* species (Figure 37, Figure 38) is due to a lack of germination signals from bacteria? The *Marchantia* produces secondary compounds that inhibit bacteria. Thus, germination might be prevented because the gemmae need hormones from the bacteria. On the other hand, *Methylobacterium marchantiae* (see Figure 6) isolated from *Marchantia polymorpha* (Figure 37) stimulates the surface expansion of isolated gemmae. But what is the timing? Under what environmental conditions? Does this only work if the thallus is dying? Do the numbers of bacteria signal the right season to germinate?

Spore germination signals are another potential role for bacteria. Some desert seeds have chemical inhibitors that prevent their germination. When there is a heavy rain, the inhibitors are washed away and the seeds germinate. This prevents them from germinating in a light shower or dew that provides insufficient water for continued survival of the germinated seedling. Do spores use bacteria as a similar signal? AHLs inhibit spore germination at high concentrations, but stimulate it at low concentrations.

Could the rain wash away the AHLs and permit the spores to germinate only when there is enough water for successful protonemal survival?

Summary

The predominant members of the bryophyte bacterial communities belong to the **Pseudomonadota**. The **Bacillota** are common in some habitats, and a number of other bacterial phyla are less common.

I found it fascinating that the bryophytes have in many cases relied on bacteria to provide them with needed hormones for their growth and development. In such small plants, economy of resources is an important survival mechanism, so using products of reliably associated organisms is an adaptive advantage. These hormones were most likely available before the bryophytes originated, making the production of these substances by the bryophytes unnecessary.

A number of unrelated bryophytes require bacterially produced hormones to change stages in their life cycle. This is best known in producing buds on the protonema and in development of the buds into gametophores, explaining why some mosses won't develop in sterile culture with no added hormones.

The **Methanobacteria** typically are able both to break down methane to form CO₂ (then available to bryophytes for photosynthesis) and to fix atmospheric nitrogen (also used by bryophytes). This implies that these bacteria somehow provide anaerobic conditions within the cells to permit nitrogen fixation to occur.

At least some, perhaps all, bryophytes obtain vitamin B₁₂ from bacteria, but the physiological roll seems to be unknown – it does enhance growth and development in culture. The oxidative burst seen on rehydration of bryophytes can be a defense against pathogenic fungi and bacteria. Bacteria interfere with measurements of primary productivity of bryophytes, especially aquatic ones. They may help in the movement of water and nutrients up the bryophyte stems as water evaporates from the tips. Some bacteria provide freezing protection through ice nucleation. Others gain entry by causing freezing damage to bryophyte cell membranes. They can contribute to release of elements from rock, making them available to the community of plants. Bryophytes benefit bacteria by maintaining moisture for a longer period of time.

Some bacteria are pathogens to bryophytes, whereas others produce antibiotic compounds that protect the bryophytes from these pathogens. Bacteria are particularly important in producing antifungal compounds used by bryophytes, particularly liverworts. Bryophytes themselves produce many antibiotic compounds against bacteria. When the bacteria multiply, the bryophytes can respond to increased numbers (**quorum sensing**) to produce antibiotics needed for protection.

Many of the invertebrates that live among the bryophytes consume the bacteria or depend on them in other ways. Some bryophagous insects incorporate nitrogen-fixing bacteria in their gut to permit them to gain usable nitrogen from consumed bryophytes.

Bacteria associated with some bryophytes might prepare them for consumption by giving access to nutrients that were bound in recalcitrant tissues.

As a newly explored habitat, bryophytes have revealed new species and even new families of bacteria. Furthermore, many bacteria remain as unculturable, likely comprising a large number of new species. Their roles could be important to both the bryophytes and the larger plant community.

CHAPTER 19-2

BRYOPHYTE BACTERIA EFFECTS ON COMMUNITIES

Figure 1. *Fontinalis dalecarlica* showing collection of sediments that harbor many bacteria, including *Methylocystis* that oxidizes CH_4 , releasing CO_2 . Photo by Jean Faubert, with permission.

Community Effects

During and van Tooren (1990) noted that bryophytes occur in microhabitats that are formed by the physical environment and typically modified by the tracheophyte vegetation occurring with them, but the bryophytes are typically treated as if they are isolated from other plants and other organisms in the environment. More realistically, we are now beginning to realize the importance of the interactions between bryophytes and other organisms. These interactions are involved in competitive, parasitic, symbiotic, and mutualistic relationships. During and van Tooren pointed out that information regarding the relationships of bryophytes with other organisms, including bacteria, is essential for understanding mineral nutrition, carbon economy, herbivory, growth, development, and the overall ecological role of the bryophytes.

Reboledo and León (2021) again pointed out the importance of bryophyte-microorganism interactions. They pointed out that these interactions had developed during coevolution of the bryophytes with microorganisms. Some of the interactions took the place of substances the bryophytes would otherwise have needed to produce themselves, thus saving them energy. They also avoided complex pathways that responded to environmental differences and changes such as seasons.

Sun *et al.* (2017) used bryophyte removal experiments to learn that absence of bryophytes caused a change in the soil microbial community in the conifer-dominated forest and an ericaceous shrubland of the alpine Tibetan Plateau. Frahm *et al.* (2012) suggested that bacterial contamination may affect the antibiotic effect of bryophytes on seed germination.

Ma *et al.* (2017a) examined the bacterial communities on four moss species [*Campyliadelphus polygamus* (Figure 2), *Cratoneuron filicinum* (Figure 3), *Grimmia pilifera* (Figure 4), *Pylaisia polyantha* (Figure 5)]. They found a total of 279 genera comprised of 558 OTU's (operational taxonomic units). Of the 16 bacterial phyla found, the **Pseudomonadota** and **Actinomycetota** were the two most abundant phyla. The most common bacterial genera were *Bosea*, *Cellvibrio*, *Friedmanniella*, *Jatrophihabitans*, *Lapillicoccus*, and *Oligoflexus*. The two wet-habitat mosses (*Campyliadelphus polygamus*, *Cratoneuron filicinum*) had similar bacterial communities, differing from those of the two relatively dry habitat species (*Grimmia pilifera*, *Pylaisia polyantha*) that also had similar bacterial communities. The bacterial communities in the summer and autumn were most similar on each moss species. However the season was not the most important factor in causing community differences.

Tang *et al.* (2016) were curious about the specificity of the bacteria on the bryophytes. They investigated ten liverworts and ten mosses from Tibet, China, using sequencing techniques. Six of the mosses had bacterial communities with a higher community similarity, but the remaining four mosses had communities that were more similar to those of the ten liverworts. Tang and coworkers concluded that the phylogeny of hosts has a strong influence on the associated bacterial community and that niche also plays important roles when the hosts are phylogenetically more similar.

Harris and Tibbles (1997) compared bacterial productivity in four Antarctic habitats. These included soils from four different habitats: beneath moss beds, from nests of snow petrel (*Pagodroma nivea*), exposed unvegetated soil (polygon soil) 5 m away from nests, and exposed polygon soil on nunataks without nests of breeding birds. The moisture levels from nest entrances and beneath mosses were much higher than in those from unvegetated exposed polygons. Mosses also modify temperatures, providing much cooler summer temperatures than exposed polygons on continental Antarctica, which are greater than 20°C at midday, and exhibited less temperature fluctuation. Harris and Tibbles considered these moss beds to be bacterial "hotspots," although based on temperature "coolspots" might be more appropriate. They considered that bacterial productivity in moss soils was typically nutrient limited, whereas in the polygons moisture was a more important factor.

Opelt and Berg (2004) considered the bryophytes to serve as a diverse community reservoir of bacteria that provided antibiotics against plant pathogens. Koua *et al.* (2015), in Japan, found that many of the bacteria associated with bryophytes played critical roles in soil nutrient enrichment, especially in nitrogen fixation. They seem to be especially important as hosts of nitrogen-fixing bacteria, contributing to biogeochemical cycling (Cornelissen *et al.* 2007).

Vollár *et al.* (2018) found that among the 42 bryophyte species in their study, the families *Brachytheciaceae* and *Amblystegiaceae* produced the greatest numbers of antiproliferative extracts – extracts that worked against the proliferation of cancer cells. *Plagiomnium cuspidatum* (Figure 6) seemed to be the most active, affecting 8 bacterial strains. As in several other bryophyte studies (*e.g.*

Bodade *et al.* 2008; Liu & Wang 2010; Liyanage *et al.* 2015; Sabovljević *et al.* 2010), *Staphylococcus aureus* (Figure 7) was the most susceptible to the antiproliferation activity. *Paraleucobryum longifolium* (Figure 8) exhibited the highest activity.

Koua *et al.* (2015) reiterated that little is known about the bryophyte-associated microbial diversity or their role in

soil enrichment and nitrogen fixation. As community members, the bacteria associated with bryophytes have the potential to infect other members of the community. This is especially true for plant pathogens, but the bryophytes can also serve as a refuge for bacteria that affect animals and fungi.

Zhu *et al.* (2006) assayed 60 bryophyte species for their antibacterial activity and found that 93.3% of the species demonstrated antibacterial activity against at least two of the seven tested bacterial species [*Priestia megaterium* (Figure 9) – syn. = *Bacillus megaterium*, *Bacillus subtilis* (Figure 10), *Bacillus thuringiensis* (Figure 11), *Escherichia coli* (Figure 12), *Pseudomonas aeruginosa* (Figure 13), *Pseudomonas putida* (see Figure 13), and *Staphylococcus aureus* (Figure 7)]. This activity was particularly strong in the liverwort genera *Conocephalum* (Figure 14), *Frullania* (Figure 15), *Herbertus* (Figure 16), *Marchantia* (Figure 17), *Mastigophora* (Figure 18), and *Porella* (Figure 19). But what does this activity against human tracheophyte pathogens mean for the communities where these bryophytes live?

In one study *Pseudomonas putida* (see Figure 13) is most sensitive to the extracts of mosses, and *Bacillus subtilis* (Figure 10) is most sensitive to the extracts of liverworts (Zhu *et al.* 2006). *Staphylococcus aureus* (Figure 7) is the most resistant of the seven tested bacteria to the extracts of both liverworts and mosses, contrasting

with its widespread susceptibility to bryophyte extracts in a number of other studies (*e.g.* Bodade *et al.* 2008; Liu & Wang 2010; Liyanage *et al.* 2015; Sabovljević *et al.* 2010). This suggests that some bryophytes could serve as a refuge for the *Staphylococcus aureus*, but there is evidence that suggests that the antibiotics against *S. aureus* from some of the bryophytes are only produced when the bacteria are present (Sabovljević *et al.* 2010).

The importance of this inducible response to the community has not been investigated. If the antibiotics manufactured by bryophytes are effective against these bacteria that are not known to be pathogenic to bryophytes, how might these antibiotics affect other bacteria in the ecosystem? What selection pressures kept these antibiotic properties in the library of secondary compounds produced by bryophytes that weren't harmed by them? How can we explain that *Bacillus subtilis* is the most sensitive of the seven tested bacteria to liverwort extracts and that *Pseudomonas putida* is the most sensitive to moss extracts (Zhu *et al.* 2006)? And why do 99% of the bacteria found with mosses produce antifungal compounds (Opelt and Berg 2004)? Why are there no compounds produced by any liverwort as protection against fungi (Banerjee & Sen 1979)? Why should bryophytes produce so many compounds that protect other organisms, but at the same time depend on bacteria to produce some compounds that protect the bryophytes?

Many of the bacteria associated with bryophytes appear to be unknown because they do not grow on standard media (see Vesty *et al.* 2020).

Are some of these undetected bacteria the sources of any of the antibiotic compounds that we attribute to the bryophytes? Are we missing some antibiotic compounds when we culture the bryophytes axenically before testing them, thus failing to elicit any inducible responses (see Sabovljević *et al.* 2010)? Among these bacteria, how important are they to soil nutrient cycling? Are they nucleators that affect our weather? Are the bryophytes a reservoir for ice-nucleators that may be beneficial or detrimental to other kinds of plants? What sorts of selection pressures exist for these less known or unknown bacteria?

Using DNA and RNA techniques we are able to assess such differences without the need to name the bacteria involved. In China, Wang *et al.* (2018) found abundant bacteria associated with all the mosses they sampled and identified in this manner. These were mostly in the phyla **Pseudomonadota** and **Actinomycetota**. Their OTU level hierarchy separated the bacteria into two main branches of aquatic vs terrestrial. The aquatic habitat showed larger differences in the bacterial community composition than did the terrestrial habitat. Thus, the habitat of the host bryophyte is an important factor in determining the community.

Streams and Rivers

Bryophytes in streams typically are covered with bacteria, making it difficult to assess productivity of the bryophytes alone (Arscott *et al.* 1998). These are difficult to remove, and the role of the bacteria in producing CO₂ that bryophytes can use in photosynthesis needs to be assessed. Furthermore, the bryophytes trap silt and organic

matter (Figure 20) that flows in the stream or river, making them an important habitat for some kinds of bacteria.

Figure 20. *Fontinalis antipyretica* with detritus that can serve as food for bacteria and macroinvertebrate scrapers. Photo by J. C. Schou, with permission.

In their study of carbon sources used by primary consumers in two oligotrophic rivers, McWilliams-Hughes *et al.* (2009) found that tracheophyte macrophytes and **Cyanobacteria** were unimportant as food sources for insect scrapers. Rather, 98% of the scrapers exhibited $\delta^{13}\text{C}$ values that were enriched with bryophyte $\delta^{13}\text{C}$ values, especially when slow-flowing habitats were excluded from the analysis. *Fontinalis* sp. (Figure 21) was abundant in headwater (low order) streams, where it exhibited more dependence by scrapers than the dependence by scrapers associated with the *Drepanocladus* (Figure 22) sp. of the high-order streams (with higher order streams having more combining tributaries). This is consistent with the greater cover by bryophytes in the headwater streams. They suggested that scrapers might switch to marginal food sources such as bryophytes in the headwaters where productivity and nutrients are low. But what is really providing their food? Might it be the bacteria and other periphyton that are always associated with the mosses? I have seen a Dipteran larva eat "dirty" mosses (Figure 20) and watched the feces come out as clean moss fragments.

Figure 22. *Drepanocladus aduncus*, in a genus in slower water in streams than that of *Fontinalis* and where scrapers are less dependent on it for food. Photo by Hermann Schachner, through Creative Commons.

Špoljar *et al.* (2012) found that when the bryophyte coverage was scattered the diversity of algae, protozoa, and meiofauna was governed by the amount of suspended organic matter and epiphytes. They concluded that this was the result of enrichment by seston travelling downstream. One can assume that bacteria are associated with this seston (Bowden *et al.* 2017), but what is their role? Are the bacteria food themselves, or are they only important in releasing nutrients from the seston?

Heino *et al.* (2015) examined the metacommunity structure by surveying the diatoms, bacteria, bryophytes, and invertebrates in three drainage basins in Finland. The species were mostly distributed independently of one another in the southernmost drainage basin, but in the northernmost drainage basin there were discrete community types. These relationships seem only to be related to geography and not to environmental heterogeneity. They suggested that environmental variables may vary between organismal groups.

Stream conditions would seem to be ideal for many kinds of bacteria. The constant supply of sediments that get carried during times of rapid flow are trapped by the bryophytes, where these sediments can accumulate. But what protections do the stream bryophytes have against this potential associated bacterial onslaught? Basile *et al.* (1998) used an acetone extract to assess the bacterial activity of the stream moss *Platyhypnidium riparioides* (Figure 23) against 11 strains of bacteria. They found that this extract was active against some Gram-negative strains. Are these antibacterial properties effective against the bacteria that normally inhabit this moss? Most of the testing has been with human pathogens, but early assessments did not determine the natural bacterial flora of the mosses.

What quickly becomes evident by these studies is that we know little about the bryophyte bacteria and their role in the stream ecosystems. Meyer *et al.* (2007) commented that whereas we have an understanding of stream fungal diversity and know that fungi are critical to the organic matter dynamics and food webs in headwater streams, we know little about bacterial diversity.

Figure 23. *Platyhypnidium riparioides*, a stream moss with antibacterial activity against 11 strains. Photo by J. C. Schou, with permission.

Demars *et al.* (2020) showed that addition of carbon caused a rapid increase in both photosynthesis and heterotrophic respiration in a stream. In the control stream, with no added carbon, the carbon exchange between the autotrophs and bacteria accounted for ~49% of the bacterial production and 37% of the net primary production during periods of stable flow. The researchers considered the bryophyte contribution to primary productivity to be negligible, so they did not include them in their food flow calculations. Furthermore, the added sucrose (carbon) in the experiment did not end up in the bryophytes. It is likely that such carbon exchange between the bacteria and bryophytes in an important occurrence when the predominant autotrophs are bryophytes.

Yakubik *et al.* (2000) noted that some bacteria in bryophyte mats contribute to denitrification. This can be accentuated in lower reaches of a stream where the water is slower. This lower flow rate results in less mixing and permits the bacteria to colonize the mosses more easily, and provides a longer residence time for the denitrification to occur.

On the other hand, Leppänen (2013) demonstrated that N_2 fixation can occur in association with *Fontinalis dalecarlica* (Figure 1), although the rates are low. The highest activity was in the upper, green portion, compared to the lower, brown portion of the plants. In boreal forest streams in Finland, it oxidized CH_4 at the highest rate among the boreal mosses investigated, which included peatland and feather mosses. It seems certain that the N_2 fixation is dependent on an external energy source and is closely connected with the oxidation of CH_4 . But N fixation must take place in an oxygen-free environment. As much as 74% of this fixation is tied to the *nifH* sequences best identified as the bacterium *Methylocystis* (Figure 24). This evidence, coupled with the high CH_4 rates, suggests that *Fontinalis dalecarlica* is important in the CH_4 of boreal rivers. The bacteria are located on the leaf, in the cavity between the leaf and stem, but can also occur inside the outer stem cells. There is a mucous-like substance in the cells of the moss that may be important in the relationship. Solheim *et al.* (2004) suggested that the mucous might result from or contribute to a symbiotic relationship between the bacteria and moss. On the other hand, Postgate (1998) suggested that it could be a protective strategy to create an anaerobic environment for the nitrogenase to work.

Figure 24. *Methylocystis bryophila* extracted from peat. **a.** Phase-contrast micrograph of cells. **b.** Electron micrograph of an ultrathin section of a cell. From Belova *et al.* 2013, with permission from Svetlana Dedys.

Martinez-Abaigar *et al.* (1993) evaluated the effects of organic pollution on the mosses *Fontinalis antipyretica* (Figure 20, Figure 21) and *Brachythecium rivulare* (Figure 25) and the leafy liverwort *Jungermannia exsertifolia* subsp. *cordifolia* (Figure 26) in rivers in Spain. They suggested that the morphology of the bryophytes influenced the sensitivity to the pollution, resulting from differences in their ability to capture suspended organic materials (Figure 20). This organic matter promotes the growth of bacteria and their ability to degrade and cause senescence in the bryophytes.

Faunal Connections

Bryophytes can play a key role in food for stream nematodes (Dražina *et al.* 2014). Dražina *et al.* (2013) found that it is the suction-feeding nematodes that dominate among the stream bryophytes, the same group that is common among terrestrial mosses in Europe (Barbuto & Zullini 2006). The nematodes use their stylets to pierce the bryophyte cells and suck out the contents (Traunspurger 2002; Dražina *et al.* 2013). Other nematodes feed on the epiphyton and deposits associated with the bryophytes (Suren 1992; Majdi *et al.* 2011). Thus, not only do some stylet-feeding nematodes eat bryophytes, but bryophytes provide the substrate for detrital pathways for nematode food. Furthermore, uptake of bacterial-respired CO₂ by the bryophytes (and algae) finds its way into these photosynthetic bryophytes, thus increasing the food available to both stylet bryophyte-feeding nematodes and other invertebrates (Demars *et al.* 2021).

In contrast to many earlier studies, Demars *et al.* (2021) suggested that the aquatic bryophytes covered by periphyton might contribute to the macroinvertebrate diet, a suggestion already supported by some earlier researchers (Jones 1949; Dangles 2002; Parker & Huryn 2006; Carroll *et al.* 2016). This also contrasts with their earlier conclusion (Demars *et al.* 2020) that this bryophyte-periphyton association does not contribute much to primary productivity. Stream ecologists are beginning to rethink the role of bryophytes in streams.

Antarctic

Christie (1987) contrasted the nitrogen in a wet carpet and dry peat in the Antarctic. The numbers of sulphate-reducing bacteria [*Desulfovibrio* (Figure 28) and *Desulfotomaculum* (Figure 29) and of *Clostridium* (Figure 30) were very low, even in the wet carpet. The low acetylene reduction activity of these bacteria and absence of *Azotobacter* (Figure 31) suggest that nitrogen fixation was not an important contributor to nitrogen present. There

furthermore were no nitrifying bacteria. However, there were substantial numbers of proteolytic and nitrate-respiring bacteria as well as a small number of denitrifying bacteria. The heterotrophic groups were more abundant in the wet carpet than in the dry turf.

Figure 31. *Azotobacter*, a nitrogen-fixing bacterium that is absent in the Antarctic peat. Photo by Dan H. Jones, through public domain.

Park *et al.* (2013) investigated the neglected bacterial relationships among Antarctic bryophytes, using the moss *Sanionia uncinata* (Figure 32). They found that the **Pseudomonadota** was the dominant phylum, comprising 65.5% of the associated bacteria. The **Bacteroidota** (29.1%) and **Actinomycetota** (11.7%) were also important. The bacteria on the mosses exhibited zonation, with the **Alphaproteobacteria** comprising only 2% of the bacterial flora in the upper green parts, but were in significantly greater proportion at 22.2% in the lower brown portions. Park and coworkers considered it likely that there were specific relationships between these endophytes and the host moss.

Figure 32. *Sanionia uncinata*, a species with **Proteobacteria** comprising 65.5% of the associated bacteria in an Antarctic study. Photo by Hermann Schachner, through Creative Commons.

Raymond (2016) answered a question I raised earlier, before reading this – Is it the bryophyte or the bacterium that produces the external ice-binding proteins? A strong ice-pitting activity was known in the Antarctic moss *Bryum argenteum* (Figure 33). Raymond realized that this was a sign of ice-binding proteins that protect against freezing damage. He found that this ice-binding activity is the result of ice-binding proteins produced by bacteria living on the moss leaves. These were mostly

Actinomycetota and **Bacteroidota**. He found 42 bacterial ice-binding proteins. These operate in a symbiotic relationship with the moss, with the latter providing the sustaining energy source and the bacteria protecting the moss from freezing damage.

Figure 33. *Bryum argenteum*, an Antarctic moss with a strong ice-pitting activity. Photo by Claire Halpin, with permission.

Arctic Alpine

Löffler *et al.* (2008) found that an increase in the occurrence of bryophytes and shrubs along an arctic-alpine gradient in Scandinavia would also increase the microbial activity. They also found that higher temperatures promoted greater soil microbial activity in the summer. Whereas these temperatures are expected to promote shrub growth as the climate warms, the higher moisture expected with climate change is expected to promote bryophyte growth. Both temperature and moisture increases should increase the microbial activity in the soil in heathlands in Scandinavia. Spruce forests (Figure 34) had the highest bacterial α -diversity, whereas the aspen forests (Figure 35) exhibited greater turnover (β -diversity) and higher γ -diversity.

Boreal Forest

The boreal forest bryophyte bacterial communities have thus far been widely neglected. Only the **Cyanobacteria** (Figure 36) have attracted the attention of researchers. They will be covered in a separate chapter, but their relative role needs to be clarified here.

Figure 36. *Chroococcus*, one of the common **Cyanobacteria** associated with *Sphagnum*. Photo by M. Lorenz, through Creative Commons.

In boreal forests in Finland and elsewhere, the feather mosses *Hylocomium splendens* (Figure 37) and *Pleurozium schreberi* (Figure 38) predominate (Leppänen 2013). The N fixation activity associated with these mosses is well known (Meeks 1998; DeLuca *et al.* 2002; Gundale *et al.* 2012). As in *Fontinalis dalecarlica* (Figure 1), Gavazov *et al.* (2010) found higher nitrogen fixation in the upper portions of *Hylocomium splendens*. This suggests that light has an important role in the fixation (Meeks 1998; Gundale *et al.* 2012), implicating **Cyanobacteria**. But in the boreal forests of Finland, there was no significant amount of methane (CH_4) oxidation activity, a phenomenon that Leppänen (2013) attributed to

the low concentrations of CH_4 in the forest habitats and moisture conditions that are unsuitable for methanotrophs (Larmola *et al.* 2010). Since methane oxidation is often accompanied by nitrogen fixation, this leaves us wondering which organisms are contributing to these higher levels of nitrogen fixation in younger portions of the mosses.

Figure 37. *Hylocomium splendens*, a boreal forest feather moss that is important in hosting bacteria that fix nitrogen. Photo by Clare Halpin, with permission.

Figure 38. *Pleurozium schreberi*, a moss shown to be less important in driving bacterial communities in the boreal forest than the forest type. Photo by Hugues Tinguay, with permission.

DeLuca *et al.* (2002) reported that the **Cyanobacteria** (Figure 36) association with *Pleurozium schreberi* (Figure 38) alone fixes $1.5\text{--}2.0 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ in the mid to late successional forests of northern Scandinavia and Finland. Gavazov *et al.* (2010) found that liverworts did not fix detectable amounts of N_2 in the boreal/sub-Arctic forests. Lichens had the highest rates of fixation, but because of their greater biomass, the mosses served as the nitrogen sink through their nitrogen fixation associations.

Rodríguez-Rodríguez *et al.* (2022) hypothesized that moss species would be the driver in the composition of the ecologically important bacterial communities associated with them. They quantified changes in bacterial communities as a function of host species [mosses *Pleurozium schreberi* (Figure 38) and *Ptilium crista-castrensis* (Figure 39)] and forest type [coniferous black spruce (Figure 34) versus deciduous broadleaf trembling

aspen (Figure 35)] in eastern Canada. But in fact, it was forest type, not moss host species, that was the main factor affecting bacterial community composition on the mosses.

Figure 39. *Ptilium crista-castrensis*, a moss shown to be less important in driving bacterial communities in the boreal forest than the forest type. Photo by M. Porcius Cato, through Creative Commons.

Among these boreal bryophytes, at least some of the nitrogen fixation seems to occur without the activity of **Cyanobacteria** (Figure 36), as for example associations with members of *Dicranum* (Gundale *et al.* 2011). *Pleurozium schreberi* (Figure 38) and *Sanionia uncinata* (Figure 32) exhibited relatively similar mean rates of N_2 -fixation ($46.1 \mu\text{g N g}^{-1} \text{ day}^{-1}$ and $52.4 \mu\text{g N g}^{-1} \text{ day}^{-1}$ respectively), despite a dominance of **Alphaproteobacteria** N_2 -fixers 21.4% vs 6.8% **Cyanobacteria**) on *Pleurozium schreberi* and a dominance of **Cyanobacteria** (79%) on *Sanionia uncinata*, with only 7.2% **Alphaproteobacteria** as N_2 -fixers (Holland-Moritz *et al.* 2018).

Holland-Moritz *et al.* (2018) indicated that the moss microbiome in the boreal forest is highly diverse, includes many undescribed taxa (including an undescribed phylum), and is a major contributor to nitrogen fixation beyond that from the **Cyanobacteria**. The average richness is 924 phylotypes per sample, dominated by 8 bacterial phyla: **Pseudomonadota** (44.8% of reads across all samples), **Acidomycetota** (10.8%), **Verrucomicrobiota** (9.8%), **Bacteroidota** (9.3%), **Cyanobacteria** (6.5%), **Candidate phyla WPS-2** (5.7%), **Planctomycetota** (5.2%), and **Actinomycetota** (4.2%). Cutler *et al.* (2017) found similar relative abundances on *Pleurozium schreberi* (Figure 38). Many of these bacteria are novel and undescribed lineages within the **Alphaproteobacteria** sub-phylum and the **Verrucomicrobiota** phylum (Bragina *et al.* 2015).

But many of the boreal forest phylotypes could not be classified beyond phylum or class (Holland-Moritz *et al.* 2018), emphasizing how little we know about these communities. Contrasting with the study of Rodríguez-Rodríguez *et al.* (2022) in eastern Canada, the identity of the moss species was more important than the site in

determining the composition of the bacterial communities associated with the mosses near Fairbanks, Alaska, USA, with moss species accounting for 63% of the variation in bacterial community composition. The pleurocarpous moss *Sanionia uncinata* (Figure 32) had communities quite distinct from those of the other 6 moss species [*Pleurozium schreberi* (Figure 38), *Tomentypnum nitens* (Figure 40), *Aulacomnium palustre* (Figure 41), *A. turgidum* (Figure 42), *Dicranum elongatum* (Figure 43), and *Sphagnum capillifolium* (Figure 44)]. Of the bacteria on *Sanionia uncinata*, 59% were unique to that moss species. Only 77% of the 30 most abundant phylotypes present on the other mosses were present on *S. uncinata*, whereas 90% of the 30 most abundant phylotypes were found on all the other moss species.

Figure 44. *Sphagnum capillifolium*, a species of fen mosses with bacteria that are similar to those of most of the other dominant fen mosses near Fairbanks, Alaska, USA. Photo by Blanka Aguero, with permission.

The moss-associated bacteria are likely to be anoxygenic phototrophs capable of carbon fixation via Rubisco, with an ability to utilize by-products of photorespiration from hosts via a glyoxylate shunt (Holland-Moritz *et al.* 2018). Furthermore, whereas most of the mosses were dominated by **Acetobacteraceae** (**Alphaproteobacteria**), **Acidobacteriaceae** (**Acidobacteriota**), and **Methylophilales** (**Verrucomicrobiota**), *Sanionia uncinata* (Figure 32) had either a low abundance or total absence of these bacterial taxa. It was dominated instead by **Comamonadaceae** (**Betaproteobacteria**), **Nostocaceae** (**Cyanobacteria**), and **Chitinophagaceae** (**Bacteroidota**). But why are these communities on *Sanionia uncinata* so different? Is it differences in microhabitat, or are the chemical defenders of these mosses different?

In an attempt to predict the effect of climate change on nitrogen fixation in the boreal forest, Gundale *et al.* (2012) assessed the effects of elevated temperatures on the relationship between bacteria and the feather moss substrate. They surmised that *Pleurozium schreberi* (Figure 38) may become a larger source of N in boreal forests relative to *Hylocomium splendens* (Figure 37) as climate warming progresses. Although the feather mosses have been considered to be cyanobacterial hosts, it is quite possible that these are also accompanied by Methanobacteria or other forms of non-cyanobacterial bacteria that are able to fix atmospheric nitrogen.

De Long *et al.* (2016) found that global warming altered the microbial communities in the soil, favoring communities based on bacteria. These, however, were mediated by mosses and shrubs, varying with successional stage. Mosses can serve as a buffer, like a heavy quilt, in modifying the soil temperature, as well as slowing the loss of moisture from the soil.

Peatland Bacterial Flora

Peatlands (Figure 45), often dominated by *Sphagnum* (Figure 46) as the keystone species, contain dead plant material accumulated over thousands of years (Kamal & Varma 2008). This habitat covers ~5-8% of the world's surface and contains ~3-3.5 times the amount of carbon stored by tropical rainforests. Weston *et al.* (2015) noted the importance of *Sphagnum* as a keystone species in a habitat that holds more than one-third of the terrestrial carbon on the planet Earth.

Figure 45. Peatland in Estonia. Photo by Martin Küttim, through Creative Commons.

Figure 46. *Sphagnum* spp. in Estonia. Photo by Martin Küttim, through Creative Commons.

In this role, *Sphagnum* (Figure 46) plays an important role, along with its associated microbiome, in carbon and nitrogen cycling (Kamal & Varma 2008). The combination of high acidity, low temperatures, and extremely low concentrations of nutrients in many *Sphagnum* habitats suggests that we should find unique communities of bacteria associated with these bryophytes.

Kostka *et al.* (2016) noted that *Sphagnum* (Figure 46) displays a diverse community of microorganisms on its surface and within the tissues. The prokaryotes and fungi can act as mutualists, symbionts, or antagonists. In these roles, methanotrophic and nitrogen-fixing bacteria may provide up to 20-30% of *Sphagnum* carbon and nitrogen.

Methane Oxidation

The production of methane (CH₄) in peatlands has become a hot topic recently because of its potential role in global warming. Wetlands, including peatlands, are the largest natural sources of atmospheric methane (Raghoebarsing *et al.* 2005). Nevertheless, most of the methane formed in wetlands stays in wetlands, where it is recycled. *Sphagnum* (Figure 46) species in peatlands use this methane through symbiosis with partly endophytic methanotrophic bacteria. These bacteria occur both on the stem leaves and in the hyaline cells of the *Sphagnum*. The methane is rapidly oxidized by the bacteria to form CO₂ that is then fixed by the *Sphagnum* in photosynthesis and ultimately into plant sterols. The methane, through this pathway, provides 10-15% of the carbon source for *Sphagnum*.

Nevertheless, peatlands are a major source of methane (Larmola *et al.* 2010). But *Sphagnum*-dominated peatlands (Figure 45) have lower methane emissions than those known for other mire types. These researchers found that all 23 species of *Sphagnum* (e.g. Figure 46) in a boreal mire supported methanotrophic bacteria. Furthermore, transplanted *Sphagnum* with no indication of these methanotrophic bacteria exhibited the bacteria in their new

location, showing rapid movement and/or activation of the bacteria among the *Sphagnum*, and the importance of habitat. Water level is important in regulating the methane oxidation. The methanotroph *Methylocystis* (Figure 24) was present with *Sphagnum* plants that exhibited both active and inactive in methane oxidation, suggesting that its activity depended on water availability. Larmola and coworkers concluded that there is a loose symbiosis between the *Sphagnum* species and methanotrophic bacteria that contributes to 10-30% of the *Sphagnum* carbon.

In 2013, Belova *et al.* discovered a new species of *Methylocystis*, *M. bryophila* (Figure 24), that could convert methane to CO₂ and could also fix nitrogen. This species was isolated from an acidic *Sphagnum* (Figure 46) peat-bog lake in Germany and from a peat bog in northern Russia. They attributed the nitrogen-fixing capability to an aerotolerant nitrogenase.

The most abundant methanotrophs in peatlands typically are **Alphaproteobacteria** and **Gammaproteobacteria** (Kip *et al.* 2010). Within the hyaline cells, *Sphagnum* hosts other bacteria that decrease the O₂ concentration and increase the CO₂ concentration in these cells (Granhall & Hofsten 1976), thus favoring photosynthesis in the nearby photosynthetic cells and benefitting the **Cyanobacteria** living in the hyaline cells. These **Cyanobacteria** fix N₂ that could be used by both the moss and the other bacteria (Leppänen 2013). But *Sphagnum* (Figure 46) can also house methanotrophic bacteria in these same cells, and these bacteria are capable of N₂ fixation as well. These methanotrophic bacteria can provide up to 30% of the carbon in the moss (Raghoebarsing *et al.* 2005) because they can fix nitrogen and oxidize CH₄ at the same time (Leppänen 2013). Most of the N₂ is fixed in the dark in aerobic conditions in the peat, indicating activity of heterotrophic bacteria (Kravchenko & Doroshenko 2003).

Nitrogen Sources

Aldous (2002) demonstrated that atmospheric nitrogen deposited among *Sphagnum* (Figure 46) plants was translocated to the capitula, with 11% to >80% in the lower and higher influx sites, respectively. Gerdol *et al.* (2006) noted that *Sphagnum papillosum* (Figure 47-Figure 48) was able to grow more when it had higher capitulum N concentrations. Both research groups noted that high water level favored the movement. Gerdol *et al.* (2006) found that the microbial nitrogen fixers were able to increase the nitrogen in the *Sphagnum* peatland. As with atmospheric nitrogen sources, these bacteria (no **Cyanobacteria** found) that occurred in senescing plant tissues, followed by upward transport of the fixed nitrogen, positively affected the growth of *Sphagnum papillosum*. In dry growing seasons, enhancement of fixed nitrogen in the rhizosphere promoted growth of tracheophytes that subsequently increased their competition against the *Sphagnum*. Experimental additions of nitrogen benefitted the *Sphagnum* only when the growing conditions inhibited the bacterial colonies.

Figure 48. *Sphagnum papillosum*, a species positively affected by increased nitrogen that is often contributed by bacteria. Photo by David T. Holyoak, with permission.

Bragina *et al.* (2013) found that genes for nitrogenase were both high in abundance and diverse among the *Sphagnum* (Figure 46). These were usually specific for each *Sphagnum*. The methanotrophs, on the other hand, exhibited highly similar patterns among species. The sporophyte of the *Sphagnum* had a high proportion of specific **diazotrophs** (organisms able to grow without external sources of fixed nitrogen) (4%) but lacked methanotrophs. The nitrogen-fixing bacteria were highly specific and were transferred with the sporophyte.

Waughman and Bellamy (1980) found that nitrogen fixation rates were lower at the nutrient extremes, with that in bogs being especially low. The highest activity measured was $>100 \text{ nmol C}_2\text{H}_4 \text{ mL peat}^{-1} \text{ d}^{-1}$. Nitrogenase activity had a positive correlation with pH and K and a negative correlation with Ca. Lower latitudes have a greater nitrogenase activity in peat than do higher latitudes, even when temperatures are factored in. In the south German mires the nitrogen fixed annually by the heterotrophic bacteria were 2100 mg N m^{-2} in fens, 530 in poor fens, and 70 in bogs.

Comparisons of *Sphagnum* Species

Bragina *et al.* (2012) compared the communities of bacteria on *Sphagnum fallax* (Figure 49) and *S. angustifolium* (Figure 50), two closely related species with distinct habitat nutrient preferences in weakly acid, mesotrophic situations influenced by minerotrophic groundwater. The two species also produce similar secondary metabolites. The two species exhibited high similarity (minimum of 95.5%) of bacterial colonization patterns. The interior of hyaline cells of the leaves were colonized primarily by **Alphaproteobacteria** (in **Pseudomonadota**). This group of bacteria was represented by a high degree of diversity, including *Acidocella*, *Acidisphaera*, *Phenylobacterium*, and *Rhodopila* as the major bacterial taxa on both species of *Sphagnum*, with no statistically significant differences between the microbial communities of the two *Sphagnum* species. The composition of the subdominant **Caulobacteraceae** did, however, vary between mosses, being more abundant with *S. fallax*. In this group *Phenylobacterium* was detected all over, whereas *Caulobacter* (Figure 51), *Gluconacetobacter* (Figure 52), *Methylocystis* (Figure 24), *Methylosinus*, and *Rhizobium* (Figure 53) occurred only with *S. fallax*. The associated microbial community fulfills functions that can only be accomplished by the cooperation with the *Sphagnum* community. These include nitrogen fixation, solubilizing phosphorus, and providing carbon from peat-derived methane (Raghoebarsing *et al.* 2005; Opelt *et al.* 2007c). Bragina and coworkers considered the moss-bacterial communities to have the same close relationships that are present between *Sphagnum* and the ecology and function of the bog ecosystem.

Bragina *et al.* (2012) also compared the bacterial diversity on *Sphagnum divinum* or *S. medium* (previously considered part of *S. magellanicum*) (Figure 54) and *S. fallax* (Figure 49) in three alpine bogs in Austria. *Sphagnum divinum/medium* characterizes strongly acid habitats with poor nutrients, whereas *S. fallax* inhabits weakly acid mesotrophic habitats. *Sphagnum divinum/medium* was inhabited mainly by **Gammaproteobacteria** (in Phylum **Pseudomonadota**), whereas associates of *S. fallax* (Figure 55) were mainly in the phyla **Verrucomicrobiota** and **Planctomycetota**. Although the bacterial colonies occurred in high abundance in the dead hyaline cells, they were always connected with living photosynthetic cells (Figure 55). Bragina and coworkers found that nutrient richness and pH were the most important determining factors for bacterial communities. They found it interesting that the bacterial diversity was transferred from the sporophyte to the gametophyte, contrasting with the transfer from the soil in tracheophyte communities. Microbial fingerprints showed that bacterial species from different bogs had a high similarity within the same bryophyte species. They considered the plant to plant transfer of bacteria, rather than through a soil intermediary, to be a possible explanation of the high specificity of *Sphagnum*-associated bacteria over long distances.

Shcherbakov *et al.* (2015) isolated bacterial populations from gametophytes of *Sphagnum* (Figure 54) from various geographic regions of Russia. Among the more than 400 strains isolated, ribosomal data indicated that the isolates were in the genera *Pseudomonas* (Figure 13) (20-57%), *Collimonas* (7-10%), *Flavobacterium* (Figure 56) (6-8%), *Burkholderia* (Figure 57) (5-6%), and *Serratia* (Figure 58) (3%). These are similar to the bacteria taxa reported for *Sphagnum* from the Austrian Alps (Bragina *et al.* 2015).

Tian *et al.* (2019) compared the microbial community associated with the brown (lower) and green portions of *Sphagnum palustre* (Figure 59) peat. Alphaproteobacteria (in phylum Pseudomonadota) were dominant in all samples. Members of the phylum Acidobacteriota were abundant in the *S. palustre* peat, whereas Gammaproteobacteria (in phylum Pseudomonadota) dominated the brown layer. Cyanobacteria dominated the green portion. They considered the structural differences in the microbiome to be mainly due to microhabitat differences. The microbial communities of the *Sphagnum palustre* peat was significantly influenced by the water table and the total nitrogen content.

Figure 59. *Sphagnum palustre*, a species where **Alphaproteobacteria** is very frequent; **Gammaproteobacteria** dominates in the lower brown layer. Photo by Hugues Tinguy, with permission.

Opelt *et al.* (2007a, b) explored the bacterial relationships with *Sphagnum divinum/medium* (Figure 54) and *S. fallax* (Figure 49) from three locations in Germany and three in Norway. They particularly looked for bacteria that exhibited antagonistic activity against fungal pathogens; these comprised 48% of the isolates. *Sphagnum divinum/medium* housed 24% of the antagonists compared to only 19% for *S. fallax*. Nevertheless, *S. fallax* bacterial communities exhibited a significantly higher diversity $\{H' = -\sum_{i=1}^s [(n_i/N)\ln(n_i/N)]\}$ than did the *S. divinum/medium* associates. More of the inhabitants of *S. divinum/medium* were specific to that species. The researchers suggested that the higher nutrient levels in the *S. fallax* habitat could explain the higher bacterial diversity.

Most of the antagonists in the Germany/Norway study were in the genera *Serratia* (Figure 58) (15%), *Burkholderia* (Figure 57) (13.5%), *Staphylococcus* (Figure 7) (13.5%), and *Pseudomonas* (Figure 13) (10%) (Opelt *et al.* 2007a). Whereas most of the antagonist strains had a high moss specificity, *Burkholderia* and *Serratia* had similar molecular fingerprints on both *Sphagnum* (Figure 49, Figure 54) species. A high proportion of the antagonist strains [*Hafnia* (Figure 60), *Pantoea* (Figure 61), *Staphylococcus*, and *Yersinia* (Figure 62)] are known as facultative pathogens of humans.

Antibiotic Role

Bacteria associated with bryophytes often serve as protectors, providing the antibacterial or antifungal compounds needed to protect the bryophytes. Whereas Opelt *et al.* (2007c) found a high proportion (26%) of antifungal bacteria, they found only 0.4% antibacterial strains. Among these antagonists, there was a high diversity of *Burkholderia* (Figure 57) isolates in the **endophytic** (living within cell) and **ectophytic** (living on plant surface) habitats of *Sphagnum* (Figure 49, Figure 54). The researchers suggested that these antagonistic bacteria could account for the high level of antimicrobial activity of *Sphagnum*. It seems likely that the high level of antimicrobial compounds in at least some *Sphagnum* species could account for the specificity of the bacteria that grow there. The researchers also found a high diversity of nitrogen-fixing bacteria, especially inside *Sphagnum*.

Because of these antagonistic properties, Sarolta *et al.* (2010) sought new types of medically useful antagonists in the Borsáros Raised Bog in Romania. They explored the communication forms that make the bacterial antagonism successful, analyzing the biofilm formation of single strains and co-cultures.

Szentes *et al.* (2011) found that rhizobacteria produced plant-growth-promoting substances that interacted in various ways, including competing with pathogens for nutrients. This research team found *Bacillus* (Figure 10-Figure 11), *Cedecea*, *Delftia* (Figure 63), *Lysinibacillus* (Figure 64), *Pseudomonas* (Figure 13), *Serratia* (Figure 58), *Stenotrophomonas* (Figure 65), and *Viridibacillus*. *Bacillus*, *Pseudomonas*, and *Serratia* were the dominant bacterial genera associated with bryophytes. *In vitro* cultures showed that a high number of the isolates inhibited the growth of fungal and bacterial plant pathogens such as *Pectobacterium carotovorum* (Figure 66) or produced secondary metabolic substances with biocontrol properties. *Serratia fonticola* BB17 (see Figure 58) and *Pseudomonas fluorescens* (Figure 67) BE8 were the most efficient against plant pathogens, with effectiveness up to 48.28% and 55.17% respectively.

Ecosystem Roles

Robroek *et al.* (2021) approached the "rewiring" of peatland plant-microbe interactions and communities using a network approach. They found that the prokaryotic communities differed between sites. This was manifest in a more rapid turnover in the plant-microbial interactions than in the communities they inhabited. They found that the turnover in the bacterial network composition was driven mostly by the establishment of new interactions between the plant community and that of the microorganisms, a phenomenon that was shared among all the sites.

Wicaksono *et al.* (2021a, b) produced evidence that the tracheophytes tended to have specific bacteria, whereas the bryophytes presented greater bacterial species richness and diversity. Nevertheless, Bragina *et al.* (2015) was able to demonstrate that the plants and lichens of bogs shared a core microbiome over the entire ecosystem, forming a transkingdom metacommunity. All of these bog organisms are connected to the keystone *Sphagnum* (Figure 49, Figure 54) species through the microbial species such as *Burkholderia bryophila* (see Figure 57). This bacterial species was associated with a wide array of host plants and provides a beneficial plant-microbe interaction.

Bragina *et al.* (2014) were among the early researchers attempting to unravel the roles of the symbiotic and protocoeoperation effects of the *Sphagnum* (Figure 49, Figure 54) microbiome. It appears that the microbiome is important in facilitating survival in the extreme conditions found in the *Sphagnum* habitats. The microbiome provides abundant subsystems that facilitate coping with oxidative and drought stresses, resistance to detrimental environmental factors, repair, and self-controlling mechanisms. Microbe-microbe and plant-microbe interactions are important in biofilm formation, interaction via quorum sensing (see Chapter 19-1 of this volume), and nutrient exchange. Their involvement in the nitrogen cycle and recycling of organic material are important contributions to the nutrient supply.

In addition to the products produced by the bacteria that are associated with *Sphagnum* (Figure 49, Figure 54), the bacteria can alter the response to a change in physical growth conditions as well. With the threat of global warming looming over the cold-climate peatlands, the ability of bacteria to rapidly acclimatize may promote the survival of *Sphagnum* through host-microbiome acquired thermotolerance (Carrell *et al.* 2021). First the researchers showed that elevated temperatures decreased the growth of sterile *Sphagnum* without addition of microbes. The addition of a microbiome from a thermal habitat matching the experimental temperatures returned the *Sphagnum* to its pre-warming growth rates. Warming changed the structure of the microbiome and induced a plant heat shock response. They suggested that the thermally conditioned microbiomes provided thermal conditioning to the *Sphagnum* host. The same results occurred when the microbiomes were isolated from *Sphagnum* warming experiments in Iceland, Sweden, and France.

But we may have barely scratched the surface of the interactions in the peatland community. As reported by Dedysh (2011) in her review, these uncultivated and unidentified bacteria form a large proportion of the microbial communities in acidic, cold, nutrient-poor, and water-saturated peatlands, hiding from us unknown physiologies and roles in the peatland ecology. New genetic techniques are permitting us to enumerate the number of strains present, and our culturing techniques are improving for these more elusive organisms.

Decomposition

Sphagnum litter has a very slow decomposition, with first year loss of mass ranging 0.1-25% (Clymo 1965; Aerts *et al.* 2001; Scheffer *et al.* 2001; Dedysh 2011). This has been attributed to acidity (that favors fungi more than bacteria), phenolic compounds and waxes (mostly from shrubs) that are highly resistant to decay (Verhoeven & Liefveld 1997; Dedysh 2011), low nutrient content, especially N and P in *Sphagnum*, low temperatures, and anoxic conditions (Dedysh 2011). When decay occurs, the end-products are transferred into methane. This methane diffuses into the living, aerobic parts of the peat where Methanobacteria oxidize it and release CO₂.

Bacteria affect the decay of *Sphagnum* (Figure 49, Figure 54), or more accurately, its near absence. Using *Sphagnum fallax* (Figure 49) from a fen woodland, Brock and Bregman (1989) found that after 12 months, the original N and P content associated with the moss had diminished little. Furthermore, the cells lacked much damage and had poor colonization by bacteria.

Patra (2020) reminded us of the role of *Sphagnum* (Figure 49, Figure 54) in secreting acids, making acid conditions that are unfavorable for the growth of most decomposing bacteria. The decomposition is further slowed by the absence of oxygen in the lower peat layers, causing an accumulation of dead material we know as peat.

Xeric

Liu *et al.* (2014) investigated the endophytic bacterial community in the xerophytic moss *Grimmia montana* (Figure 68). Using a 212 sequence library, they identified 54 genera of bacteria in 4 phyla (*Pseudomonadota*, *Bacillota*, *Actinomycetota*, and *Cytophaga/Flexibacter/Bacteroids*). As in many other bryophyte bacterial communities, the *Pseudomonadota* were dominant (45.9%), with *Bacillota* being second (27.6%). The most abundant genera included *Acinetobacter* (Figure 69), *Aeromonas* (Figure 70), *Enterobacter* (Figure 71), *Leclercia*, *Microvirga*, *Paenisporosarcina*, *Planococcus*, *Planomicrobium*, *Pseudomonas* (Figure 13), and *Rhizobium* (Figure 53). They did not determine the role of the bacteria in the association, but some were known to have beneficial effects on their hosts. Some of the genera isolated differed from those detected by the molecular method, thus emphasizing that our methods may often miss important genera and species due to inappropriate culture conditions. At the same time, some taxa may not be in the molecular library.

Soil Crusts

Soil crusts are a community of organisms that together colonize and stabilize soil surfaces. These are most common in dry areas where their ability to survive long periods of drought permit them to survive with little competition (Weber *et al.* 2019). These crusts occupy approximately ~12% of the terrestrial surface of the planet Earth (Weber *et al.* 2019). It is important that we understand these processes as they relate to ecosystem processes, especially in cryptogamic soil crusts (Deane-Coe & Stanton 2017), as our Earth remains in a state of continuous change.

The biocrusts may be dominated by **Cyanobacteria**, lichens, or bryophytes (Warren *et al.* 2019; Weber *et al.* 2019). The communities differ significantly from each other (Maier *et al.* 2018). Their organisms include free living, lichenized, and mycorrhizal fungi, **Cyanobacteria**, chemoheterotrophic bacteria, diazotrophic bacteria and archaea, eukaryotic algae, and bryophytes (Warren *et al.* 2019; Weber *et al.* 2019). The organisms are characterized by desiccation and extreme temperature tolerance, production of various soil-binding chemistries, almost exclusive dependency on asexual reproduction, pattern of aerial dispersal over impressive distances, and universal vulnerability to a wide range of human-related perturbations (Warren *et al.* 2019).

The role of bacteria in the bryophyte-lichen matrix of soil crusts remains poorly known. Weber *et al.* (2019) found that bacterial community composition changed in a stepwise manner along with biocrust succession, while bare soil communities were completely different. As the climate changes and land use destroys these communities, it is important that we understand the role of interactions, including those between the bacteria and bryophytes.

Weber *et al.* (2012) explored the soil crusts in the succulent Karoo of South Africa. They found that leaching from mosses may cause the high rates of soil respiration. The leaching creates microsites with high nutrient levels, favoring the growth of the microorganisms.

Moquin *et al.* (2012) examined the bacterial diversity in bryophyte-dominated soil crusts. They found the dominant phyla to be **Acidobacteriota**, **Bacteroidota**, and **Pseudomonadota**. Although tracheophytes are not a common member of the crusts, they found bacterial root associates, especially in the family **Oxalobacteraceae**. The presence of **Bacteroidota** suggests that the bacterial community in these crusts is affected by high carbon availability. The bacterial communities of soils and the **Cyanobacteria**-dominant crusts differed from those of the bryophyte-dominated ones. Bamforth (2008) noted that the microorganisms are important in the nutrient cycling of the crust community and subsequently contribute nutrients to the underlying soils.

In southwestern China, Cao *et al.* (2020) found that not only moss species, but also the types of karst rocky desertification, affect the microbial communities. Mosses were by far the more impacting factor, with changes in moss species bringing drought-resistant factors that affected the bacterial community, or *vice-versa*. The bacteria were able to provide proline content, superoxide dismutase activity, and peroxidase activity. These compounds are closely related to the drought adaptability of mosses.

Maier *et al.* (2018) found that alpha diversity of the crust community increases as succession progresses, with a concomitant shift from more generalized to more specialized organisms. At the same time, the CO₂ gas exchange exhibits significantly larger respiration rates in later successional stages. The NO and HONO emission patterns also change during succession. Thus, as the photosynthetic organisms change, they facilitate specific microbial communities, and these microbial changes in turn influence the physiological properties of the biocrusts and their contributions to both local and global nutrient cycles. The three dominance types of biocrusts have significantly different communities.

In the *Didymodon rigidulus* (Figure 72) community, there are endophytic bacteria, including *Bacillus cereus* (Figure 73), *Bacillus pumilus*, *B. subtilis* (Figure 10), *Bacillus* sp., *Neobacillus niacini*, *Peribacillus simplex* (see Figure 74), and *Priestia aryabhatai* (all previously in *Bacillus*; see Figure 9) (Ma *et al.* 2017b). The dominant species was *B. subtilis*. They found that at the test concentrations of petroleum ether, ethyl acetate, and n-butyl alcohol extracts, *B. cereus* and *B. subtilis* did not significantly alter the bryophyte spore germination. On the other hand, the protonema growth was inhibited to varying degrees by the same extracts. Hence, we know that bacteria can use their secondary metabolites to affect the development of bryophytes and alter the community composition.

Honeybees

Honeybees can benefit from the antibacterial activity of bryophytes against bacteria. And without honeybees, the plant community can suffer due to absence of pollination. Gahtori *et al.* (2011) identified the bacterium *Medisaccoccus plutonius* as the cause of the European foulbrood disease in honeybees (Figure 75). They extracted antibacterial compounds from three different bryophytes and tested them against this bacterium. All of the tested extracts exhibited good antibacterial activity against the foulbrood bacteria. The maximum activity derived from *Dicranum undulatum* (Figure 76) and *Marchantia polymorpha* (Figure 17) and was comparable to that of the standard drug in use against these bacteria.

Figure 76. *Dicranum undulatum*, a species that has compounds that are antibacterial against the foulbrood bacteria in honeybees. Photo by Robin Bovey, with permission through Dale Vitt.

Sevim *et al.* (2017) tested the antibacterial activity of 23 bryophyte species in Turkey against *Paenibacillus larvae* (Figure 77) isolates from honeybee larvae; these bacteria are responsible for the American foulbrood diseases in the honeybee larvae. Of the 23 bryophytes sampled, they found 10 [liverwort *Metzgeria conjugata* (Figure 78); mosses *Calliergonella cuspidata* (Figure 79), *Calliergonella lindbergii* (Figure 80), *Grimmia alpestris* (Figure 81), *Isoetecium alopecuroides* (Figure 82),

Polytrichastrum formosum (Figure 83), *Polytrichum commune* (Figure 84), *Syntrichia calcicola* (Figure 85), *Syntrichia intermedia* (Figure 86), *Tortella densa* (Figure 87)] that exhibited good antimicrobial activity against *P. larvae* isolates.

But does this protection work in nature? Are honeybees able to bring mosses to the hive to prevent the growth of the bacteria? Do they have behavioral adaptations that cause them to move about among the mosses to sanitize themselves? What an interesting relationship it would be if such activities were true. But we don't know; perhaps nature was simply waiting for humans to do the sanitizing job.

Pollution Relationships

Meyer *et al.* (2010a) compared bryophyte microbial communities in rural, urban, and industrialized communities. The particulate atmospheric pollution affects the bryophyte-microorganism complexes. They found that microalgae, bacteria, rotifers, and testate amoebae biomasses were significantly higher in the rural site. The physico-chemical variables (NO_2 , relative humidity,

temperature, site) and the trace elements accumulated in bryophytes (copper, strontium, lead) explained 69.3% of the variance in the microbial community. These numbers suggest that bacteria in a community are potential biomonitors of atmospheric pollution.

Rojas *et al.* (2016) reported that bryophytes dominated control precipitates, whereas the **Basidiomycota** fungi were most abundant under reclaimed precipitates at an acid mine drainage reclamation site in central Pennsylvania, USA. Furthermore the reclaimed precipitates had more bacterial diversity than did the controls. Bacteria under bryophytes were more common under unreclaimed (control) soils.

Meyer *et al.* (2010b) found that the bryophytes did not accumulate the low concentrations of metallic trace elements. However, the **Cyanobacteria**, testate amoebae, and fungi all decreased in the microbial community in response to the particle deposition. Thus, the composition of the microbe community could serve as a useful indicator of pollution effects.

Reclamation Communities

Bryophytes can help to reclaim despoiled areas in a number of ways. Kyyak *et al.* (2020) found that they could colonize saline substrates of tailings storage, where they provide extended surface area for the accumulation of organic matter. The organic carbon under moss turfs increased 2.2-5.0 times compared to areas with no bryophytes. The dense-turf mosses *Didymodon rigidulus* (Figure 72) and *Ptychostomum pseudotriquetrum* var. *bimum* (Figure 88) accumulated the most organic matter, compared with loose turf formed by *Barbula unguiculata* (Figure 89) and *Funaria hygrometrica* (Figure 90). The moss turfs facilitate a 0.2-0.5 unit increase in acidity of the aqueous solutions of the tailings. Bacterial quantity increased significantly under mosses in reclaimed mine tailings, achieving a biomass under the moss turfs of *Didymodon rigidulus* and *Funaria hygrometrica* of 5.09-6.10 $\mu\text{g C g}^{-1}$ dry weight soil. Without mosses, bacteria reached only 3.19-11.27 $\mu\text{g C g}^{-1}$ dry weight soil.

Figure 88. *Ptychostomum pseudotriquetrum* var. *bimum* where organic matter accumulates in greater amounts than in the tailings beneath the loose moss turfs. Photo by Hugues Tinguy, with permission.

Figure 89. *Barbula unguiculata* dry, where less organic matter accumulates in the tailings beneath the moss loose turfs than in dense turf areas. Photo by Bob Klips, with permission.

Figure 90. *Funaria hygrometrica* where less organic matter accumulates in the tailings beneath the moss loose turfs than in the dense turf areas. Photo by Kurt Stueber, through Creative Commons.

The microbial biomass in the tailings beneath the moss turfs depended on the species characteristics of the mosses (Kyyak *et al.* 2020). The microbial biomass index almost doubled with the high level of salinization under turfs of *Didymodon rigidulus* (Figure 72) and *Funaria hygrometrica* (Figure 90). The moss cover also promoted a significant increase in the primary ecological and trophic groups of microorganisms (saprophytes, cellulose-degrading bacteria, oligonitrophils, and nitrogen fixers). Thus the pioneer bryophytes are important in the accumulation of organic matter, increase in acidity, improvement of the redox regime of the substrate, and promotion of development of the important soil microbiota (DeLuca *et al.* 2002; Gavazov *et al.* 2010; Stewart *et al.* 2011; Kyyak *et al.* 2020). In particular, they increased the productivity of cellulose-degrading bacteria.

Summary

It is only in the 21st century that much research has addressed the bacterial communities associated with bryophytes. It appears that these communities have important roles in the ecosystems they inhabit.

Bryophytes in rivers and streams trap organic sediments. These provide rich habitats for bacteria, which in turn provide food for invertebrates both large and small. We now know that they can cause denitrification, whereas others are important in nitrogen fixation, while at the same time converting methane to free CO₂ that is used by the bryophytes. Their role in nitrogen fixation in peatlands, the boreal forest, cryptogamic crusts, and other low-nutrient habitats is significant. They are also, at least in part, responsible for degradation, senescence, and decomposition of the bryophytes, thus contributing to nutrient cycling. However, in acidic peatlands, the decomposition is slow.

Some bacteria produce ice-binding proteins that help bryophytes, especially in the polar and alpine regions, to survive freezing by preventing large crystals from forming in the bryophyte cells.

Some communities are very similar on a number of bryophyte species in an area, while at the same time some bryophytes can have unique communities. But we do not understand what causes the bacterial community differences with bryophyte species – microhabitat needs, bryophyte secondary compounds, bryophyte structure, bacteria-bacteria interactions?

There are many habitats where the bacterial associates of bryophytes have not been assessed. Their roles in these communities could be critical for some of the vital ecosystem functions. It is likely that there are multiple connections for some of these roles and that the community composition will change with climate change, probably before we begin to understand these connections.

CHAPTER 19-3

BRYOPHYTE DEFENSES AGAINST BACTERIA

Figure 1. *Salmonella typhi*, a human pathogen that is very sensitive to bryophyte extracts. Photo from CDC, through public domain.

Defenses Against Bacteria

Bryophytes generally seem to lack damage by bacteria and other pathogens. Although some bacteria can be pathogens on bryophytes, others actually help to protect the bryophytes.

Martínez-Abaigar and Núñez-Olivera (2021) referred to bryophyte defenses as "the outstanding capacity of bryophytes to produce bioactive compounds with diverse biological functions." In addition to the great variety of terpenoids produced by liverworts, all three bryophyte lineages can produce phenolic derivatives (from simple cinnamic acids to complex flavonoids), alkaloids, and lipids. Among these defenses, the liverwort bisbibenzyls and sesquiterpenoid derivatives and the moss diterpenoid derivatives momilactones are the most important compounds.

We now know that bryophyte defenses include phenylquinone, aromatic and phenolic substances, oligosaccharides, polysaccharides, sugar alcohols, amino acids, fatty acids, and aliphatic compounds (Alam *et al.*

2012). Bryophytes also produce polyunsaturated C₂₀ fatty acids. These include arachidonic acid and eicosapentaenoic acid (Ponce de León *et al.* 2015). These can be oxidized and transformed into bioactive compounds.

More than 1600 terpenoids have been identified from bryophytes (Chen *et al.* 2018). Some of these are unique to bryophytes. These terpenoids have a variety of functions, but they are particularly useful as defenses against both biotic and abiotic stresses.

Until 2016 momilactones were known only from rice and the moss *Hypnum plumaeforme* (Figure 2) (Okada *et al.* 2016). These compounds are diterpenoid phytoalexins with antimicrobial and allelopathic functions. A similar transcription response to stresses was identified in *Physcomitrium patens* (Figure 3), suggesting a similarity between mosses and tracheophytes in response to stresses, including pathogens. On the other hand, jasmonic acid seems to be absent in bryophytes, whereas it is a signalling mechanism in tracheophytes, initiating plant defenses (Ponce de León *et al.* 2015; Okada *et al.* 2016).

Figure 3. *Physcomitrium patens*, a new source of momilactones. Photo by Michael Lüth, with permission.

Liverworts seem to have the most diverse array of secondary compounds with antibiotic properties (Russell 2010). Among the 14 species tested, 88% had antibiotic activity, whereas only 33% of the moss species exhibited any activity against the three bacterial strains tested. The liverwort *Lunularia cruciata* (Figure 4) presented the greatest activity against the three bacteria tested. But this is only a small sampling of bacteria and bryophytes. A wider array of bacterial species would most likely reveal even more kinds of activity.

The liverworts are known for their often distinctive odors. They also have distinctive **oil bodies** in the cells, and these are unique enough that they are often of taxonomic value. We now know that these oil bodies are the sites of many defense compounds – secondary compounds that seem to have no other metabolic functions (Asakawa 2011). The oil bodies are known only from the liverworts and are the site for storing terpenoids (He *et al.* 2013). These include the mono-, sesqui- and di-terpenoids, aromatic compounds like bibenzyl, bis-bibenzyls, and acetogenins (Asakawa *et al.* 2013) – compounds that serve

to protect the liverworts against both herbivory and pathogens (antimicrobial, antifungal, and antiviral). On the other hand, mosses and hornworts produce primarily di- and triterpenes (Zhan *et al.* 2015). Among the liverworts, more than 40 new carbon skeletons of terpenoids and aromatic compounds have been found (Asakawa & Ludwiczuk 2017).

Figure 4. *Lunularia cruciata*, a species with the greatest antibacterial activity among species in one test. Photo from Botany Website, UBC, with permission.

Wang *et al.* (2006) suggested that the lower inhibitory activity of *Cylindrocolea recurvifolia* (Figure 5) compared to that of *Pleurozia subinflata* (Figure 6), both leafy liverworts, could be due to the lower contents of oil bodies in the former, where they are both smaller and fewer. On the other hand, Zhu *et al.* (2006) found that there was no correlation between antibacterial activity and size or number of oil bodies in 38 liverwort species.

Figure 5. *Cylindrocolea recurvifolia*, a leafy liverwort with small and few oil bodies and less antibiotic activity than that of *Pleurozia subinflata*. Photo from Museum of Hiroshima University, with permission.

Figure 6. *Pleurozia subinflata*, a leafy liverwort with larger and more numerous oil bodies than those of *Cylindrocolea recurvifolia* and with greater antibiotic activity. Photo by Jan-Peter Frahm, with permission.

Mosses and liverworts seem to lack tissue-specific antibody binding against the lignin-like polymers homoguaiacyl (G) and guaiacyl/syringyl (GS) (Ligrone *et al.* 2008). On the other hand, the hornworts *Megaceros pellucidus* (Figure 7) and *Nothoceros fuegiensis* (see Figure 8) exhibited more intense labelling with the GS antibody of the pseudoelaters and spores than in the other cell types.

Figure 7. *Megaceros pellucidus*, a species in which GS antibody labelling of the pseudoelaters and spores was greater than for other cell types. Photo by Ashley Bradford, through Creative Commons.

Antibiotic Response by Bryophytes

Banerjee and Sen (1979) reported that 56% of the bryophytes they tested were active against at least one bacterial species. Our knowledge of moss antibiotic properties is much less than that of liverworts (Provenzano *et al.* 2019). Only 3.2% of the mosses and 8.8 of the hornworts have been characterized. This is probably because the liverworts seem to a more promising variety of interesting secondary compounds that could be useful to humans.

Van Hoof *et al.* (2013) found that the moss *Hypnum cupressiforme* (Figure 9) had strong antimicrobial effects. In this case, at least, the activity was greater against plant bacteria than it was against human bacteria.

Figure 9. *Hypnum cupressiforme*, a species with strong antibacterial effects against plant bacteria. Photo by J. C. Schou, with permission.

Sawant and Karadge (2010) found that extracts of the cave liverwort *Cyathodium cavernarum* (Figure 10) were mostly inactive against the bacteria tested, whereas other liverworts [*Plagiochasma intermedium* (Figure 11), *Asterella wallichiana* (Figure 12), *Targionia hypophylla* (Figure 13)] in these tests exhibited good antimicrobial activity. Chavhan (2017) likewise found that *Targionia hypophylla* exhibited a high level of antibiotic activity against two bacterial strains. And *Cyathodium tuberosum* (Figure 14) exhibited the least. Is there a pattern to the absence of antimicrobial properties in cave mosses? This would seemingly save energy in these low-energy systems.

Figure 14. *Cyathodium tuberosum* a liverwort with the weakest antibiotic activity among those tested. Photo by Silvia Pressel and Jeff Duckett, with permission.

Zhu *et al.* (2006) found that 93% of the 60 tested bryophytes exhibited antibacterial activity. All liverworts tested (38) had activity against at least two bacterial species tested. Of the 60 bryophyte species, 17 were active against all seven of the tested bacterial species (Gram positive: *Bacillus megaterium* (Figure 15), *Bacillus subtilis* (Figure 16), *Bacillus thuringiensis* (Figure 17), *Staphylococcus aureus* (Figure 18); Gram negative: *Escherichia coli* (Figure 19), *Pseudomonas aeruginosa* (Figure 20), *Pseudomonas putida*). The activity was especially high in the liverwort genera *Conocephalum* (Figure 21), *Frullania* (Figure 22), *Herbertus* (Figure 23), *Marchantia* (Figure 24), *Mastigophora* (Figure 25), and *Porella* (Figure 26). Among these, *Staphylococcus aureus* was the most resistant to bryophyte extracts from both mosses and liverworts, in sharp contrast to a number of other studies in which it was the most susceptible to bryophyte extracts (*e.g.* Bodade *et al.* 2008; Liu & Wang 2010; Liyanage *et al.* 2015; Sabovljević *et al.* 2010). The most sensitive bacterial species to moss extracts was *Pseudomonas putida*; sensitivity to liverwort extracts was greatest in *Bacillus subtilis*. When negative results are found, it is possible that the bryophyte had not received the proper signals to make the antibiotic compounds. This would be particularly true in sterile cultures.

Figure 24. *Marchantia polymorpha*, a species that responds to the bacterium *Pseudomonas syringae* by producing antibacterial compounds. Image copyright Stuart Dunlop <www.donegal-wildlife.blogspot.com>, with permission.

When Shirzadian and Afshari Azad (2010) tested the activity of 11 Iranian bryophytes, they found that only *Xanthomonas citri* pv. *malvacearum* (pv. = pathovar; Figure 27) failed to show any response to extracts from the bryophytes. The other bacteria [*Erwinia amylovora* (Figure 28), *Pectobacterium carotovora* (Figure 29), *Ralstonia solanacearum* (Figure 30), *Agrobacterium tumefaciens* (Figure 31)] responded to the extracts.

It is interesting that the α -DOX (α -dioxygenase) in the moss *Physcomitrium patens* (Figure 3) is both part of the defense system and a controlling agent in development (Machado *et al.* 2015). α -DOX contributes to the synthesis of **oxylipins**, permitting plant signaling against both biotic and abiotic stresses. On the other hand, Bressendorff *et al.* (2016) found that the moss *Physcomitrium patens*, unlike tracheophytes, uses a different signalling pathway for immunity than the one used to respond to osmotic stress.

The evolution in bacteria only got part way to having a successful jasmonic acid defense (Monte *et al.* 2018). They have the genes for the JA-Ile (jasmonoyl-isoleucine) signalling pathway, but they do not produce JA-Ile.

Habitat Differences?

It seems reasonable to hypothesize that bryophytes from damp habitats are more likely to provide a suitable habitat for bacteria and fungi. Therefore, we can also hypothesize that bryophytes of moist habitats should have more defense compounds than those from dry habitats. Or could these be obtained through partnerships?

Liu and Wang (2010) noted that the moss *Ditrichum pallidum* (Figure 32) was able to defend against the bacteria *Staphylococcus aureus* (Figure 18), *Escherichia coli* (Figure 19), and *Proteus vulgaris* (Figure 33) to different degrees. Could this indicate differences in abundance of these three bacteria in the habitat of the

Ditrichum pallidum used in the tests? Or is it just specificity to the individual species and their relative abundance in bryophyte habitats?

Figure 32. *Ditrichum pallidum*, a moss that has different degrees of response to bacteria, depending on the bacterial species. Photo by Hugues Tinguy, with permission.

Figure 33. *Proteus vulgaris* drawing, the species that suffered the least effect by *Ditrichum pallidum* extracts in tests by Liu and Wang (2010). Image from Project Gutenberg Distributed Proofreaders, Encyclopædia Britannica, 1911, through public domain.

Bodade *et al.* (2008) similarly found that the dry habitat moss *Racomitrium crispulum* (Figure 34) did not provide any effective antibacterial compounds against the bacteria tested [including *Escherichia coli* (Figure 19) and *Staphylococcus aureus* (Figure 18)], whereas other bryophyte species in the test were all effective at least some of the time.

Dulger *et al.* (2005) tested 8 mosses from relatively dry habitats of rocks, soil, and tree trunks in Turkey and found that they inhibited 11 species of bacteria. The most susceptible bacteria among these were *Bacillus subtilis* (Figure 16) and *Pseudomonas aeruginosa* (Figure 20). The antiyeast activity was weak.

Figure 34. *Racomitrium crispulum* with capsules, an exposed-rock moss that was ineffective against the tested bacteria. Photo by Larry Jensen, with permission.

Leptodictyum riparium (Figure 35), a moss of wet habitats, had the best inhibitory power against all eight bacteria tested when compared to that of the thallose liverwort *Conocephalum conicum* (Figure 21) and the moss *Plagiomnium undulatum* (Figure 36) (Castaldo-Cobianchi *et al.* 1988). They commented there is competition between species growing in the water where one might find *L. riparium*.

Figure 35. *Leptodictyum riparium*, a moss that is even more inhibitory toward eight bacteria than the strongly inhibitory *Conocephalum conicum*. Photo by Hermann Schachner, through Creative Commons.

Figure 36. *Plagiomnium undulatum*, a moss that is less inhibitory toward eight bacteria than the strongly inhibitory *Leptodictyum riparium*. Photo by Hermann Schachner, through Creative Commons.

Altuner *et al.* (2014) found that the antibacterial activity of the forest floor species *Dicranum polysetum* (Figure 37) was especially strong against *Staphylococcus carnosus* (see Figure 18). It is interesting that such a strong activity against *Staphylococcus carnosus* exists when this bacterial species is not known from any natural habitat **and** it has no known pathogenicity (Löfblom *et al.* 2017)! Furthermore, it lacks any pathogenicity genes. Altuner *et al.* (2014) found that all three mosses in their study [*Calliergonella cuspidata* (Figure 38), *Dicranum polysetum*, and *Hypnum cupressiforme* (Figure 9)] were active against several species of Gram positive and Gram negative pathogenic bacteria.

Figure 37. *Dicranum polysetum*, a species with especially strong antibacterial activity against the non-pathogenic *Staphylococcus carnosus*. Photo by Kristian Peters, through Creative Commons.

Figure 38. *Calliergonella cuspidata*, a species active against several Gram positive and Gram negative pathogenic bacteria. Photo by Claire Halpin, with permission.

Dey *et al.* (2015) found that elevation made a difference in antibacterial activity of *Pellia endiviifolia* (Figure 39) from the eastern Himalayas. Those collected at

higher elevations had significantly higher antimicrobial activity. They suggested this might be due to differences in UV light levels, with the intensity increasing at higher elevations.

Figure 39. *Pellia endiviifolia*, a species with significantly higher antibacterial activity at higher altitudes. Photo by David T. Holyoak, with permission.

By contrast, Mukherjee *et al.* (2012) found that in the thallose liverwort *Dumortiera hirsuta* (Figure 40) those specimens from a higher elevation had slightly lower antibacterial activity than those from lower elevations. Clearly more detailed information is needed about the habitats to determine the differences in antibacterial activity.

Figure 40. *Dumortiera hirsuta*, a species with slightly lower antibacterial properties at higher elevations. Photo by Mutolisip, through Creative Commons.

Out of 29 species of bryophytes from Sri Lanka, only *Pogonatum marginatum* (a species of wet soil and shady banks; Figure 41) failed to respond with antibiotics against any of the test bacteria [*Lysinibacillus sphaericus* (MTCC511), *Staphylococcus aureus* (Figure 18) (ATCC25923), *Klebsiella pneumoniae* (Figure 42) (ATCC700603), *Pseudomonas aeruginosa* (Figure 20) (ATCC27853)] (Liyanage *et al.* 2015).

Bacterial Defense Partners

Bacteria themselves can often be of antibiotic benefit to the bryophytes. They can provide antagonistic compounds that serve as defense compounds against other bacteria and fungi. I wonder if the bacteria ever serve as deterrents to larger herbivores such as insects, birds, and rodents. One would expect the insects to avoid some of the bryophytes because they produce insect repellent (Ludwiczuk & Asakawa 2019), but it seems that the bacteria could also serve this role.

Mechanisms of control of microorganisms by bryophyte-associated bacteria include secretion of metabolic substances (e.g. antibiotics, **siderophores** - small, high-affinity iron-chelating compounds secreted by microorganism), controlling proliferation, and competitive exclusion of plant pathogens (Glick & Bashan 1997; Muleta *et al.* 2007; Szentes *et al.* 2010). Among these antagonistic bacteria Szentes *et al.* (2010) found the genera *Azospirillum* (Figure 43), *Bacillus* (Figure 15, Figure 16, Figure 17, Figure 74), *Burkholderia* (Figure 44), *Enterobacter* (Figure 45), *Pseudomonas* (Figure 20), and *Rhodococcus* (Figure 46).

Banerjee and Sen (1979) found that the liverwort family **Reboulia** (Figure 47) had especially good antibiotic activity in all 5 tested species. The moss *Brachythecium procumbens* and the liverworts *Asterella wallichiana* (Figure 48) and *Marchantia paleacea* (Figure 49) showed the widest range of antibiotic activity. *Salmonella typhi* (Figure 1) was the most sensitive of the microorganisms used in the tests.

Figure 49. *Marchantia paleacea*, among the bryophyte species with the widest range of antibiotic activity. Photo by Des Callaghan, with permission.

It is interesting that some newly recognized strains of bacteria present among the bryophytes have toxicity to things that presumably never affect the bryophytes. For

example, 12 new strains of *Bacillus thuringiensis* (Figure 17) were isolated from among 76 bryophyte species (Zhang *et al.* 2007). A strain of this bacterium harbored a new gene that exhibited activity against the Asian tiger mosquito *Aedes albopictus* (Figure 50). This mosquito species is a vector of chikungunya virus, dengue virus, and dirofilariasis, and is rapidly expanding its range due to human activity. But perhaps it is more likely that this strain and others of the species *Bacillus thuringiensis* are active against multiple pathogens, some of which do affect bryophytes. The bryophytes may also provide a service to the community by maintaining a reservoir of these bacteria that are available to the other plant species and able to render their antagonistic effects there.

Figure 50. *Aedes albopictus*, a species of mosquito that is sensitive to a bryophyte-inhabiting strain of the bacterium *Bacillus thuringiensis*. Photo by James Gathany, CDC, through public domain.

Inducible Defenses

Bodade *et al.* (2008) provided indirect evidence that an inducible reservoir of defense compounds might be the case in the bryophytes they tested. They found that the antibacterial extracts were not always effective against the same bacterium, nor was the magnitude of inhibition consistent. This suggests the possibility of environmental stimulation by the bacteria themselves or by the environmental conditions with the possibility of seasonal changes. The interactions of bacteria with their bryophyte substrates are a new field of study with many questions needing answers.

Gimenez-Ibanez *et al.* (2019) noted that to that date no bacterial pathogens had been discovered in association with the widespread liverwort *Marchantia polymorpha* (Figure 24). In addition to this lack of evidence of bacterial pathogens, the researchers discovered an ancient immune system that governs plant-microbe interactions between *M. polymorpha* and the plant pathogenic bacterium *Pseudomonas syringae* (Figure 51). The presence of this bacterium on the liverwort activates the immune response, including effector activities inside the liverwort cells. This response also appears to be very specific and differs among the strains of *Pseudomonas syringae*.

Figure 51. *Pseudomonas syringae* on lilac leaf. This bacterium also induces *Marchantia polymorpha* to produce antibiotics. Photo by Jerzy Opiola, through Creative Commons.

Thus, it appears that at least some of the defenses are inducible. This saves energy and permits the bryophyte to maintain a larger library of defenses. Sabovljević *et al.* (2010) found that all extracts (in DMSO) from their investigated bryophytes [*Atrichum undulatum* (Figure 52), *Marchantia polymorpha* ssp. *ruderalis* (Figure 53), *Physcomitrium patens* (Figure 3)] produced antibacterial compounds against the bacteria *Escherichia coli* (Figure 19) ATCC 35210, *Pseudomonas aeruginosa* (Figure 20) ATCC 27853, *Salmonella typhimurium* (Figure 54) ATCC 13311, *Enterobacter cloacae* (human isolate; Figure 45), *Listeria monocytogenes* (Figure 55) NCTC 7973, *Bacillus cereus* (human isolate; Figure 56), *Micrococcus flavus* (Figure 57) ATCC 10240 and *Staphylococcus aureus* (Figure 18) ATCC 6538). Extracts from naturally grown bryophytes demonstrated better antibacterial activity than did those from laboratory-grown bacteria, suggesting that the presence of bacteria in the environment could stimulate production of defense compounds.

Ponce de León and Montesano (2017) noted that early bryophytes needed adaptations to combat both abiotic stresses and pathogenic microorganisms. They reported that several of the defense mechanisms against microbial pathogens were retained in the evolution of flowering plants and they provided evidence that defense compounds can, in fact, be induced. The moss *Physcomitrium patens* (Figure 3) uses plasma membrane receptor(s) to sense the pathogen. It then transduces the signal through a MAP kinase cascade that leads to activation of defenses associated with the cell wall and expression of genes encoding for proteins with various roles in plant resistance. Other responses include activation of the production of reactive oxygen species (ROS), induction of an HR-like reaction, and an increase in some hormone levels.

Alvarez *et al.* (2016) noted that the shikimate, phenylpropanoid, oxylipins, and auxin pathways were all activated by introducing the bacterium *Pectobacterium carotovorum* (Figure 29) to the moss *Physcomitrium patens* (Figure 3). The **shikimate pathway** leads to the production of phenolic compounds, which are known inhibitors of bacteria (Santos-Sánchez *et al.* 2019). **Phenylpropanoids** can work synergistically with most antibiotics and provide enhanced antibacterial activity (Hemaiswarya & Doble 2010). **Oxylipins** signal the regulation of plant growth and development, senescence,

sex determination of reproductive organs, and of importance here, the defense against biotic and abiotic stress and programmed cell death (Christensen & Kolomiets 2011). **Auxin** is a growth hormone for which concentrations, and relative concentrations, matter (Leyser 2017).

In experiments with *Physcomitrium patens* (Figure 3), Ponce de León *et al.* (2007) clearly demonstrated induction. This was achieved with the pathogenic bacterium *Pectobacterium carotovorum* ssp. *carotovorum* (Figure 29). Infection with this bacterium caused severe maceration, whereas *carotovorum* caused only mild symptoms. Both the species and subspecies induce a defense response in the moss, as evidenced by enhanced expression of conserved plant defense-related genes.

Inducible defense mechanisms in *Physcomitrium patens* (Figure 3) include reinforcement of the cell wall, production of reactive oxygen species, programmed cell death, activation of defense genes, and synthesis of secondary metabolites and defense hormones (Ponce de León & Montesano 2013). These responses are induced by the exposure to the pathogens.

All of this evidence indicates that the defense responses by the bryophytes are inductive, but it is unlikely that they are entirely inductive.

Antioxidants and ROS

The oxidative burst is "a rapid, transient production of huge amounts of reactive oxygen species (ROS)" (Wojtaszek 1997). Changes in cell wall pH are important in controlling this production. H_2O_2 (hydrogen peroxide) is produced and is directly toxic to micro-organisms (Samoilenko *et al.* 1983). The peroxide can disturb the structure and permeability of the bacterial cell wall and the cytoplasmic membrane, as well as inducing ribosomal lesions and rupturing the DNA.

In addition to being an antibacterial phenomenon, the oxidative burst is important in other plant defenses, including oxygen consumption, production of phytoalexins, systemic acquired resistance, immobilization of plant cell wall proteins, changes in membrane permeability and ion fluxes, and an apparent role in hypersensitive cell death (Wojtaszek 1997).

Unlike animal systems, plant cells are able to produce ROS, primarily as H_2O_2 , in significant amounts (Wojtaszek 1997). This production is mostly exocellular and is regulated by such factors as hormones, light, and wounding. Whereas it is generally absent in elongating cells of tracheophytes, it can exhibit significant production in wounded cells or those undergoing mechanical stress. Its half-life of 10^{-9} s makes it difficult to follow the sequence of reactions. In suspension cultures, pathogens such as fungi and bacteria (**elicitors**) usually elicit a response in 1-2 minutes, reaching a maximum response in several minutes (Figure 58). The reaction is completed within 30-60 minutes after initiation. Time intervals for intact plants seem to be much longer. And response time varies with the elicitor and plant species. Furthermore, the specific compound responsible for the elicitation varies among species of elicitor, as does the degree of response. But is all this true in bryophytes?

Figure 58. Oxidative burst of plant cells in response to bacterial elicitation (—) and ROS generation by plants in response to treatment with OGA (oligo-1,4- α -D-galacturonide) (---), a known elicitor of an oxidative burst in many plants. Modified from Wojtaszek 1997.

Minibayeva and Beckett (2001) were among the first to report details on the oxidative burst in bryophytes. They found that among the plants they tested, it was best developed in the cyanobacterial lichens, the hornwort *Anthoceros natalensis*, and two thalloid liverworts [*Dumortiera hirsuta* (Figure 40; Figure 59), *Pellia epiphylla* (Figure 60)]. The four mosses (Figure 59) and leafy liverwort in the test were almost completely unresponsive. Among the responsive species, production of O_2^- was generally higher in species from moist habitats and correlated well with plant water content at full turgor. Unfortunately, at the time of these experiments we were unaware of the importance of rate of drying on the survival success of bryophytes to dehydration. Their drying regime was extended from full hydration to an **RWC** (relative water content) of 0.05-0.10 in only 2.5 hours (Minibayeva & Beckett 2001), a time which usually prevents bryophytes from preparing for desiccation (Stark *et al.* 2013; Greenwood & Stark 2014). Nevertheless, in *Anthoceros natalensis* the rate of oxygen production was more than $1000 \mu\text{mol g}^{-1} \text{ dry mass h}^{-1}$, a rate 100 times that recorded for the roots of wheat (Minibayeva *et al.* 1998)!

Figure 59. Superoxide production (oxidative burst) upon hydration in hydrated (solid squares) and desiccated (solid circles) *Dumortiera hirsuta* (Figure 40), and hydrated (open squares) and desiccated (star) moss *Atrichum androgynum* (Figure 61). Modified from Minibayeva & Beckett 2001.

Figure 60. *Pellia epiphylla*, a thallose liverwort that experiences a high level of oxidative burst when it is rehydrated. Photo by Bernd Haynold, through Creative Commons.

Mayaba *et al.* (2002) found that the moss *Atrichum androgynum* (Figure 61) produced an oxidative burst of hydrogen peroxide during rehydration, an ROS response. They suggested that this oxidative burst might provide protection against bacterial and fungal attempts to invade the cells. As additional support for this hypothesis, Lawton and Saidasan (2009) found that the moss *Physcomitrium patens* (Figure 3) produces reactive oxygen species (ROS) in response to pathogenic bacteria. Mayaba *et al.* found a burst of H_2O_2 (oxidative burst) during rehydration during the first 15 minutes in *Atrichum androgynum*. They found that the production increased as the desiccation time of the moss increased. Light and the hormone ABA (abscisic acid) influenced the rate.

Figure 61. *Atrichum androgynum*, a species that produces an oxidative burst of hydrogen peroxide during rehydration. Photo by Nick Helme, through Creative Commons.

Lyapina *et al.* (2021) found that mosses had a higher number of small secreted peptides (SSPs) in their genomes than did either the liverwort *Marchantia polymorpha* (Figure 24) or the hornwort *Anthoceros* sp. (Figure 62). Synthetic peptide elicitors like those of tracheophytes triggered reactive oxygen species production in the protonema of the moss *Physcomitrium patens* (Figure 3), suggesting that even tracheophytes could elicit the ROS

response in the bryophytes, thus perhaps aiding in their ability to defend against invading bacteria in the protonema stage. This moss also secretes peptides that respond specifically to a chitosan treatment, indicating a possible role in immune signalling. Could these elicitors from tracheophytes be a signal to help the bryophytes determine a suitable place to become established?

Figure 62. *Anthoceros punctatus*; a tested species in this genus has fewer small secreted peptides (SSPs) in its genome than do tested mosses. Photo by Malcolm Storey, <DiscoverLife.org>, with online permission.

But reactive oxygen can be dangerous for cells because it can react in so many ways. Antioxidants can be of valuable protection to bryophytes, particularly during rehydration, scavenging the oxygen quickly before it can do too much damage (Mayaba *et al.* 2002). Seel *et al.* (1992) suggested that the antioxidants may be more important than the levels of H_2O_2 in desiccation survival of bryophytes.

Vats and Alam (2013) evaluated this ROS potential in the moss *Barbula javanica*. The moss had a total phenolic content of 30 ± 0.96 mg GAE/gdw. It exhibited substantial antioxidant behavior against several oxidation agents, with a reducing activity at $1259 \pm 1.56 \mu M L^{-1}$. Vats and Alam suggested that the high phenolic content might account for this activity. The moss *Cryphaea heteromalla* (Figure 63) similarly has a high level of protection against reactive oxygen species (ROS), which can be induced by tert-butyl hydroperoxide (Provenzano *et al.* 2019).

Figure 63. *Cryphaea heteromalla*, a moss with a high level of protection against reactive oxygen species (ROS). Photo by Hermann Schachner, through Creative Commons.

Differences in Plant Parts

One might expect that bryophytes would protect the parts that need protection the most, thus saving energy by not producing secondary compounds where they are not needed. But which tissues are the most vulnerable for the species? Mukherjee *et al.* (2012) compared antibacterial activity in the reproductive thallus to that of the vegetative thallus of *Dumortiera hirsuta* (Figure 40). They found that the reproductive thallus showed the least antibacterial activity of the two. This appears to be an interesting aspect that needs lots more study.

Defending Others?

Bryophytes could accomplish community service by providing antibacterial activity against pathogens that affect roots and seeds. But do they?

We do know that some bryophytes produce antibacterial substances that could protect larvae. Sevim *et al.* (2017) found that 10 [*Calliergonella cuspidata* (Figure 38), *Calliergonella lindbergii* (Figure 64), *Grimmia alpestris* (Figure 65), *Isoetecium alopecuroides* (Figure 66), *Metzgeria conjugata* (Figure 67), *Polytrichastrum formosum* (Figure 68), *Polytrichum commune* (Figure 69), *Syntrichia calcicola* (Figure 70), *Syntrichia montana* (Figure 71), *Tortella inclinata* var. *densa* (Figure 72)] out of 23 tested species of bryophytes were active against *Paenibacillus* (Figure 73) obtained from larvae of the honeybee (*Apis mellifera*). Although it is unlikely that any honeybee larvae will be living among bryophytes, other kinds of larvae do occur there and these antibiotics might protect them against bacteria as well.

Potential Uses

Bryophytes can have a number of functions in the ecosystem resulting from their providing a welcoming habitat for bacteria. For example, *Bacillus thuringiensis* (Figure 17) (*Bt*) is the source of the antibiotics in some

kinds of pesticides (Figure 74), especially against beetles, mosquitoes, black flies, caterpillars, and moths (Perez *et al.* 2015). Zhang *et al.* (2007) found that *Bacillus thuringiensis* occurs naturally on bryophytes. *Bt* is non-toxic to most animals and non-pathogenic to birds, fish, and shrimp (Perez *et al.* 2015). Some of pesticides using *Bt* are even approved for use in organic gardens. Lin *et al.* (2017) found that the bacterium *Bacillus thuringiensis* strains could be isolated from bryophyte populations in Turkey, suggesting that the bryophytes could serve as a reservoir for this important bacterium. These bacteria became established as long-term inhabitants of leaves and stems within 26 days of inoculation.

Figure 74. *Bacillus thuringiensis* damage by larvae (left) and protected by Bt genes (right). Photo from Agricultural Research Service, USDA, through public domain.

Tani *et al.* (2011) cultured bacteria in hydroponic cultures of the moss *Racomitrium japonicum* (a roof-greening moss; Figure 75) and reported that these bacteria had the potential to serve as biofertilizers for production growth of this moss species. They further found that *Methylobacterium* (Figure 76) species formed a mutualistic relationship with the moss (Tani *et al.* 2012). The moss has natural populations of methylotrophic bacteria. And the moss produces methanol. The bacteria use the methanol as a carbon source, converting methanol to CO₂. When these bacteria are present in cultures of *Racomitrium japonicum*, they increase the growth of the moss – a desirable phenomenon for mosses grown in production quantities.

Figure 75. *Racomitrium japonicum*, a species that benefits from the oxidation of methanol by *Methylobacterium* and for which other associated bacteria serve as a "fertilizer" by enhancing growth. Photo by Masaki Shimamura, with permission.

Figure 76. *Methylobacterium symbioticum*, in a bacterium genus that benefits *Racomitrium japonicum* through the oxidation of methanol. Photo by Symborg, through Creative Commons.

Mishra *et al.* (2014) remind us that many bacteria have developed resistance to most of our traditional antibiotics. They suggest the use of bryophyte antibiotic substances as potential replacements (see also Pant 1998). These bryophytes and bacteria have been living together for millions of years, perhaps longer, and the bryophyte antibiotics are still effective.

We have already seen the potential use of bryophyte compounds to inhibit multiplication of *Melissococcus plutonius* (Figure 77), one of the causal bacteria for European foulbrood disease in honeybees. Research in developing culture techniques and enhancing growth are proceeding on *Physcomitrium patens* (Figure 3) and *Marchantia polymorpha* (Figure 24) (Schwartzberg *et al.* 2004; Horn *et al.* 2021).

Figure 77. *Melissococcus plutonius* causing European foulbrood disease. Photo from Georgia Department of Agriculture, <Bugwood.org>, through Creative Commons.

Frahm (2004) reported that experiments at Bonn University in Germany were able to culture the first *in vivo* bryophytes for extraction of biomedical compounds. The products of all 20 tested bryophytes had effects on a variety of crop infections with various fungi. Products from bryophytes are now available commercially in Germany. In addition, successful field experiments have been completed in Peru and Bolivia. These products are

antifungal on human pathogenic fungi. But are these *in vivo* products produced by the bryophytes or by their fungal associates?

Singh *et al.* (2011) found that several bryophytes used by traditional healers were effective in the treatment of burns. The bryophyte extracts are especially effective against *Staphylococcus aureus* (Figure 18).

Mosses harbor **Actinomycetota** that include *Micromonospora chalcea* (Figure 78), a bacterium with growth promoting potential (Insuk *et al.* 2020). This species also codes for genes for phosphate solubilization, permitting the bacteria to survive in the nutrient-limited environment so common where bryophytes thrive. Their production of glycine-betaine and trehalose contribute to tolerance of drought. They have genes for heat shock proteins, cold shock proteins, and oxidative stress.

Figure 79. *Archidium ohioense*, a moss that produces substances that could provide a safer replacement for NSAIDs. Photo by Li Zhang, with permission.

Figure 78. *Micromonospora chalcea*, a bacterium that can promote plant growth and enhance drought tolerance. Photo from Leibniz-Institut DSMZ, through Creative Commons.

Figure 80. *Bryum coronatum* with capsules, a moss that produces substances that could provide a safer replacement for NSAIDs. Photo by Geoffrey Cox, through Creative Commons.

For arthritis sufferers, bryophytes have the potential to support anti-inflammatory functions. *Archidium ohioense* (Figure 79), *Bryum coronatum* (Figure 80), and *Racopilum africanum* (Figure 81) all produced substances that acted against inflammatory agents, but Ayinke *et al.* (2015) found that concentration was important. This includes protection of red blood cells effectively against heat and hypotonic induced lyses. The effects were comparable to those of expensive and somewhat dangerous non-steroidal anti-inflammatory drugs. Should we be looking for use by wild mammals for anti-inflammatory purposes, especially in the Arctic?

Figure 81. *Racopilum africanum*, a moss that produces substances that could provide a safer replacement for NSAIDs. Photo by Jan-Peter Frahm, with permission.

The potential uses of bryophytes and their associated bacteria in the pharmaceutical industry have been reviewed many times by various authors and will not be discussed further in this chapter. But it could be worthwhile to review these for their potential as a pharmaceutical chest for other animals in the wild.

Sterilizing Bryophytes

Sterilizing bryophytes has been a challenge for bryologists. Many of the standard cleaning agents are as dangerous to the bryophytes as they are to the bacteria. Some detergents can even encourage bacterial growth (pers. obs.).

Yet it is often desirable to isolate bryophyte processes from those closely allied bacterial contributions. Hence, the decision to use sterile culture must depend on the purpose of the culture. Is it needed to understand biochemical and physiological pathways of the bryophyte, or is it needed to ascertain potential roles in the ecosystem?

This chapter has revealed that bryophytes often depend on bacteria to carry out normal life functions. On the other hand, Gupta (1977) demonstrated that the large number of bacteria associated with several bryophytes accounted for the respiratory activity measured upon rehydration of the bryophytes. They suggested that this respiration could provide an indication of survival or injury of some bryophytes, but that it presented serious limitations as indication of the cell viability of the bryophytes.

For those conditions where sterile bryophytes are needed, one must establish the conditions for growth and propagation. Schelpe (1953) tried the method of using abscised apical parts of elongated stems of mosses that have been kept in a moist atmosphere and low light intensity. Unfortunately, he had little success in obtaining bacteria-free cuttings. Lack of success in culturing bryophytes is all too common and methods differ among species.

Rowntree (2006) reported on their most successful method to date in preparing bryophytes for the Millennium Seed Bank of threatened UK bryophytes. These are held in sucrose-free $\frac{1}{4}$ or $\frac{1}{2}$ Murashige & Skoog or Knops minimal medium. These were successfully sterilized first (pre-cultured) with 1% (w/v) for 3 min and 0.5% (w/v) for 2 min. Sporophyte cultures were more successful than those of gametophytes due to less contamination (see also Vujičić *et al.* 2011). They found that some sterilizing treatments could cause the bryophytes to develop resistance to the toxic effects of the biocide. Vujičić *et al.* (2011) also suggested the use of sugar-free medium for *Hypnum cupressiforme* (Figure 9). They found that lower temperatures (18-20°C) also helped.

Perhaps Shaw (1986) has a better solution to culturing bryophytes while retaining the necessary interactions with bacteria, as needed for ecological studies. He has successfully cultured them by drying the bryophyte gametophytes, grinding them to a fine powder, and sowing this powder on native soil or other desired substrate. This method has the advantage of producing bryophytes with normal morphology – something that is often missing in sterile culture.

Summary

For whatever reason, bryophytes have many secondary compounds that are antibiotic to many types of human and plant pathogens. In some cases, these are effective against bacteria that could affect the bryophytes. For both types, they are often produced only in response to the presence of certain bacteria or other microorganism. Of greater interest here are the bacteria that protect the bryophytes.

There are some implications that there are differences in quantity of antibacterial substances that depend on habitat. These differences are unclear, with some aquatic species having many such compounds and some cave thallose liverworts, a bryophyte type that usually produces high concentrations of antibacterial compounds, can have none! Part of the problem might relate to sterile culturing, or the bacteria might be unculturable species. In any case, much more must be learned before any generalizations can be made.

Among the protections exhibited by some bryophytes are oxidative bursts upon rehydration. It is suggested that this serves to protect the bryophytes at a time when their membranes are damaged and could provide easy access for the bacteria. To accompany this burst, the bryophytes can accelerate the production of antioxidants, a necessity for the bryophyte to avoid damage by free radicals of oxygen.

Little is known about differences in defense or bacterial numbers among plant parts. In some cases, reproductive parts are less protected.

Some of the bacteria produce compounds such as *Bt* that can protect honeybee larvae from disease. Our knowledge of this is very limited, but the ability of these compounds to serve as antibiotics against multiple organisms suggests that this could be a fertile area for research. The bacteria that live among bryophytes suggest that the bryophytes could serve as a reservoir of these bacteria, and that in turn the bacteria could provide antibiotics for other organisms in the ecosystem, including humans.

Bacteria can present a problem in studying the physiology of bryophytes because they contribute to the measured photosynthesis and respiration. But sterilizing the bryophyte can keep the bryophyte from developing normally or from producing substances that you are trying to measure.

It has become clear that the bacteria associated with a bryophyte can have profound effects on its success, including successful establishment, development, and growth. This is an important consideration for those attempting production levels of moss culturing.

CHAPTER 1-1

FIELD TAXONOMY AND COLLECTION METHODS

Figure 1. Zen Iwatsuki on a collecting trip in Iceland. Photo by Janice Glime.

Collection

Vanderpoorten *et al.* (2010) suggest that to find a high species richness, look for a habitat with lots of bryophyte cover (Figure 1). Species diversity has a high positive correlation with the carpet density. Such a habitat suggests an appropriate moisture level, and the large clumps of bryophytes can create microhabitats where moisture is lost more slowly, permitting smaller species to develop among them.

Stevenson (2005) reminds us that when you focus on one habitat, you begin to ask questions about how and why plants are growing there. These questions form the bases of hypotheses. And when you accept the rigors of recording your habitat observations, these hypotheses are more likely to take form. They are also much more reliable for later descriptions than your memory will be. These notes will help you to formulate better data collection sheets, and you should spend time field-testing these sheets before you begin an actual comprehensive study.

For ecological studies, there are at least two reasons to collect specimens (Vanderpoorten *et al.* 2010). First, you need to collect to verify your field identification and to look for minute species hiding among the more obvious ones. Second, you need to collect **voucher specimens** for

your collections. Collections for quantitative or systematic sampling will be discussed later in a chapter on Sampling. For vouchers, you will probably want some for your own herbarium, but you also need one for your institution or other permanent herbarium that is available to other researchers and one for the person who verifies the species for you. **If you are collecting in another country**, especially a country where the bryophyte flora is poorly known, you should also prepare an identified specimen to give to a national or other public herbarium in that country. By doing this, you help to pay back your debt of collecting there and help the field of bryology progress in that country.

Collection methods have been described many times and in multiple languages (*e.g.* Loeske 1925; Iwatsuki 1970; Kildyushevsky 1973; O'Shea 1989; Buck & Thiers 1996; Gradstein *et al.* 2003). Loeske (1925), interpreted in English by Raup (1926), stressed the importance of a systematic study, rather than a random one. Even at that early date, he opined that a region seldom offers many new or rare mosses. Instead, he espoused the value of studying a bryophyte in relation to its habitat, way of living, and relationship to the rest of the flora.

Bryophytes are the easiest of all plants to collect (Buck & Thiers 1996). They rarely need to be pressed, but rather can be placed in a **paper bag** (Buck & Thiers 1996) or **packet** and permitted to air dry (Smith Merrill 1990). Some bryologists (e.g. Ireland 1982) prefer packets made of newspaper because it allows more rapid water loss than brown paper bags. And very wet specimens may cause the bags to come unglued.

The collection depends somewhat on the substrate of the bryophyte. Buck and Thiers (1996) point out that if plants grow in loose tufts or mats or are pendent, they can be easily picked up by hand. Extra adhering soil can, and should, be removed, provided that does not cause the colony to fall apart. Small plants or those tightly adhering to their substrate will be best served if they are collected with a small portion of their substrate to keep them together and to retain the growth habit. Likewise, epiphytic species should be collected with a shallow strip of the bark. Epiphylls should be collected with their underlying leaf. Those on branches can be collected with clippers.

Some collection methods are unique, permitting collection of difficult specimens. Snider and He (1991) suggest using a **flashlight** to peer into crevices and under cliff overhangs. It should be one that can be locked into the on position rather than requiring continuous pushing of a button switch.

Obtaining the Sample

In most cases, the bryophytes can be sampled by a hand grab. However, bryophytes on bark or those that have grown for decades may require extraction with the help of a knife. As Patricia Eckel put it in Evansia (1996), using a knife can have its hazards: having plants blow away from the blade, getting cut, getting poked by the knife in the pocket, losing one's balance while balancing on a talus slope, and shutting sand in with the blade, making opening and closing more difficult.

The Sposs

After losing all her knives and seemingly suitable tools, Eckel (1996) discovered the "**sposs**" (Figure 2). This is a hybrid form of spoon boss, a tool that doesn't hurt and that catches the loosened bryophyte before the wind can carry it away. Her husband, Richard Zander, invented and named the sposs. The official sposs has its handle bent back so it can be hung over the belt and one can have a firmer grip. Eckel recommends a 30 cm cooking spoon with a 15 cm boss (bowl part) for gathering bryophytes from under cacti and avoiding snakes and other animals enjoying the cool of the same tracheophyte as the bryophyte. This tool works equally well for the bryophytes in a crevice, on a rock ledge, or in the fragile arrangement of sand in the desert. And it is not confiscated from your pack at the airport!

Figure 2. Spoon bent to make a **sposs** for collecting soil bryophytes. Image by Patricia Eckel.

Chisel

If you typically collect bryophytes on rock or bark, especially tiny ones that require bringing the substrate with them, you might want to invest in a good chisel (Schofield 1985). McCune (1994) recommends one available from Miners Inc. (catalog # AO 601). This is currently available for US \$50.80. It has a tungsten carbide cutting edge that makes it strong and durable, and it is lighter in weight than most chisels (Figure 3). On the other hand, a much cheaper putty knife will work well for soil samples and even some bark samples.

Figure 3. Carbide-tipped hand chisel for removing bits of wood or rock. Photo by Miners Inc.

Masking Tape Sampler

Some species are so tiny that the eye cannot discern them even in good light, or they may be within reach but out of view. Once a possible site for tiny bryophytes is located, extraction of the bryophyte can be accomplished with the aid of masking tape (Snider & He 1991). The tape should be at least 5 cm wide (Figure 4). The tapes differ in their ability to adhere, but none adhered well to very wet or dripping rocks. The vinyl packaging tape was least useful because it easily wrinkled, stuck to itself easily, and was unmanageable in the field. Duck tapes, bandaging tapes, and thicker vinyl repair tapes worked well in the field, but weighed more and were difficult to cut or tear; they were also difficult to work with after samples were acquired. Only painter's tape (masking tape) seemed to be adequate for the job. Even if the tape did not adhere well to moist surfaces, it did a good job of removing and holding the bryophytes.

Figure 4. Masking tape bryophyte sampler with masking tape on a strip of plexiglass. Edges of the plexiglass have been sanded to make them smooth. Photo by Janice Glime.

Snider and He (1991) prepared the tapes by cutting them in 5x17 cm strips, then folding over 2 cm at one end (Figure 5). These were attached at one end to a piece of 6 cm x 17 cm x 5 mm plexiglass. The folded end was used to

pull the tape off the plexiglass to take a sample. Once the sample was in place (Figure 6-Figure 7), they attached the sticky side to the other side of the plexiglass and wrote collection data on the non-sticky side of the tape. When the specimen is returned to the lab, it can be removed by moistening the specimen with water or a wetting agent like Pohlstoffe (See Chapter 2-2 in this volume). They used the method to discover such findings as protonemal trumpets of *Diphyscium foliosum*, protonemal flaps of *Tetraphis pellucida* (Figure 8-Figure 9), asexual propagules of various bryophytes, and several minute leafy liverworts such as *Cephaloziella* (Figure 10). These flat samples can even be photographed by a scanner without glares or need for a tripod (Figure 11-Figure 12). They can be enlarged as scanned or later in Photoshop.

Seasons

Some bryophytes are seasonal or annual. Although winter is a good season for epiphytes that don't require capsules for identification, it is often not a good collecting season for other bryophytes that may be buried under snow. Flood plain species are only discernible for a period of time after the water recedes following flooding. Species of arable fields are mostly ephemerals that disappear in a relatively short period and often are present in only either spring or fall. Preston *et al.* (2010) found that autumn, winter, and early spring were suitable times to inventory fields in Great Britain. And capsules are only in a mature state with spores intact for a short time. Most of the sexual structures mature in spring or fall, or when the rainy season occurs. Nevertheless, some mature in winter. Hence, the season most suitable for collection depends on the purpose of the collection, the species, and the location.

What to Sample – the Miniscule

Many different kinds of characters are used to identify bryophytes, and reproductive structures also provide ecological life cycle strategy information. Sporophytes on bryophytes like *Orthotrichum* provide important, and sometimes essential, characters needed for identification. Additional searching can sometimes reveal local hidden capsules from a previous year or young, developing capsules from the current year. Tubers and bulbils are also important for both taxonomic and ecological purposes (Vanderpoorten *et al.* 2010). Unstable habitats such as riverbanks, arable fields, and flood plains are likely to have rhizoidal tubers buried in the soil beneath the bryophytes, so 1-3 cm of soil should be collected with the bryophytes (Whitehouse 1966; Porley 2008). Unfortunately, most countries won't permit soil to come into the country, so these must be cleaned and at least some propagules carefully preserved in a **minipacket** along with the specimen.

Minipackets are useful for a number of rare structures and species (Vanderpoorten *et al.* 2010). These can be made in advance, or as needed, so be sure you have some light-weight paper to use. If small species occur among a clump of larger species, place at least a sample of each of the smaller species in a **minipacket**. These packets can be made like the large packets (see Chapter 3 on Herbarium Methods and Exchanges in this volume). If a small species is left to dry with the larger clump, it can become glued to the larger bryophyte when it dries. It will also be brittle

when dry and easily broken if you try to remove it then. Rewetting to remove it can reduce the ability to extract DNA from the bryophyte. At least some plants of an especially small specimen like *Ephemerum* spp. should also be placed in a minipacket, and if only a few plants have reproductive structures, these, too, should be placed in a minipacket (Rothero & Blackstock 2005). Small species on soil are likely to become invisible if the soil dries and loses its cohesiveness, so extracting a few individuals into a minipacket is again useful.

Sample Size

The amount to collect is an important consideration. An ideal sample is about the size of the palm of your hand (Miller 1988; Smith Merrill 1990; Buck & Thiers 1996; Vanderpoorten *et al.* 2010), but that is not always feasible or wise. Conservation should be a foremost consideration. If you must deposit a sample in an institutional herbarium, send to someone to verify identification, and keep some for yourself, be sure to take enough for all those purposes (Buck & Thiers 1996). Only small samples of suspected rare species should be collected, and then only if absolutely necessary and more than that amount is left intact where you found it. **DO NOT collect rare species** just to add to your personal or institutional herbarium or to use for exchange. Be sure to protect the edges if you take part of a clump, at least for species that seem rare in that location or overall. You can do this by placing a rock against the exposed edge or by packing soil against it to protect against desiccation inside the clump. Even another species of bryophyte might help, but try to avoid ones that might overtake a rare species.

When I joined a field trip with the British Bryological Society (BBS), I was warned not to collect more than a thumbnail (or about a 1.5 cm diameter). On the other hand, if you are collecting for exchange or gifts to herbaria, you usually need at least half a palm size for the herbarium to accept the material. Of course if it is a small species with only small clumps, such size will not be possible, or will require several clumps. The danger of several clumps is that they could turn out to be different species or microspecies, and they should certainly all come from the same small area within a location where it is most likely that they have originated from spores or fragments of the same population.

Mixed Collections

The usefulness of mixed collections depends largely on the use of the collection. These provide us with information and should be treated somewhat differently. If the sample collection contains mixed species (Figure 13), they can be separated partially into minipackets in the field, or separation can occur later in the lab. Each packet can be given a different letter while retaining the original collection number; the species occurring together should be noted on the packets. If these are just small bits among a larger collection, they can be placed in minipackets that are kept with the original collection. It is important that packet labelling makes clear which specimen belongs with which name. This can be clarified with minipackets (David Wagner, Bryonet 20 January 2023).

Figure 13. *Hypnum jutlandicum* (pinnate) + *Hypnum lacunosum* (thick branches) + *Dicranum scoparium* (acrocarpous, bright green) in Denmark, illustrating typical species mixes one might encounter. Photo by Lars Hedenäs.

Mixed populations of closely related species can reveal both genetic differences and ecological information. Both species presumably are exposed to the same conditions, so one might assume that differences in morphology (or physiology) are the result of genetic differences. But Wyatt *et al.* (1985) remind us that the microclimate within a bryophyte clump is not uniform. Young individuals resulting from spores that germinate within the clump will experience different growing conditions than did the spores that germinated to form the original colony.

Thus the question arises as to the usefulness of mixed collections (Wyatt *et al.* 1982, 1985). Consider that whether they are all one species or distinguishable as different species, the multiple morphologies contribute important ecological information about the past history of the clump and its microhabitat conditions.

On the other hand, as common garden information, the mixed collection usually falls short. These will be discussed in more detail in the chapter on bryophyte – bryophyte interactions in the Bryophyte Interactions volume. Isoviita (1985), however, argues that in some cases they can be useful to represent common garden conditions. First of all, bryophytes can be difficult to cultivate, and morphologies of cultured bryophytes are likely to change, being unrepresentative. Secondly, the equipment to conduct common garden experiments is not always available.

To understand when mixed collections might be useful, we can consider the arguments of Wagner and Wagner (1983). "Cohabitation of two or more species without successful interbreeding demonstrates biological discreteness and confirms that the character differences are most likely genetically fixed." They used the technique in their study of the fern genus *Botrychium*. This is a fascinating genus with underground prothalli that depend on mycorrhizal fungi. The sporophyte of some species spends little time above ground. This genus can occur intermixed in ways that have little effect on the environment of each other, thus possibly providing information on niche separation. But their most convincing argument is that most of the species in the genus are endangered, so that this is a means of gaining ecological information with minimal disturbance that could create further endangerment in a species that is difficult to culture.

In Papua, New Guinea, handfuls of *Frullania* often produced two or more species of *Frullania* (Glime *et al.* 1990). Multiple collections of these indicated associations that were rather frequent. Other mixed pairs of species in the same genus (**congeneric**) include *Syntrichia laevigata* and *S. papillosa* (Figure 14) (Robert Klips, pers. comm. 10 August 2012) and *Grimmia anodon* and *G. plagiopodia* growing intermixed on sandstone outcrops in western Montana (Roxanne Hastings, pers. comm. 10 August 2012). Intermixed species will be discussed in detail in the Bryophyte Interactions volume in the chapter on bryophyte – bryophyte interactions.

Figure 14. *Syntrichia laevigata* and *S. papillosa* growing intermixed in Columbus, Ohio, USA. Photo by Robert Klips.

In short, for ecological work intermixed collections can be useful and should not be totally avoided. Rather, for verification purposes, use minipackets to store a small sample of each species, but leave most of the mix intact for whatever use might later be needed, including DNA analysis. All identified species should be listed on the packet.

Epiphytes and Epiphylls

In some habitats, especially the tropics, the greatest diversity and abundance occur in the canopy. These require special collecting (Perry 1978) and preservation techniques. Furthermore, only outer bark should be collected with the bryophyte, keeping enough of the bark on the tree to protect the wood against disease. Nevertheless, at least the outer layer of bark should be collected to maintain the slender species that would otherwise be lost (Buck & Thiers 1996).

Epiphytic bryophytes often have directional, vertical, and bark type preferences, and these need to be noted on the herbarium label. Hence, when collecting these, note the host species, the type of bark (rough, smooth, flaking, fissured), height on the tree, and side/aspect of the tree (N-S-E-W). It is also important to note if the substrate was vertical, on a branch or lean, and whether it was on the top, side or bottom of leaning or horizontal structures.

Some bark bryophytes will come off easily, but for some you will need to make a slice of the underlying bark with a sharp knife or chisel in order to keep the growth form of the bryophyte intact.

Canopy

Bryophytes in the canopy present the greatest challenges. These are typically out of reach, so short of bringing a trained monkey, one needs to develop special

techniques. Several researchers have been successful using a single rope to aid tree climbing (Perry 1978; Ter Steege & Cornelissen 1988; Gradstein *et al.* 1996, 2003) (to be covered in chapter on Sampling in this volume). Smaller branches can be sawed off and lowered by ropes.

But not all of us are so agile. Developing archery skills can help, allowing you to shoot epiphytes from the tree, but not all bryophytes will cooperate, and your arrow may lodge in the canopy without returning the prize. Ropes with a weight or hook on one end can sometimes help; with a little skill you might be able to toss it over a branch to pull the branch down. But this method is limited to lower branches because there is too much congestion to be successful in reaching an adequate number of epiphytes in upper branches. Some studies (for insects and other animals) have used a helium-filled dirigible (Hallé 1990) to reach the canopy, but that has another set of dangers.

You (but not the forest) may get lucky and have the advantage of a hurricane or other wind storm to bring branches down from the canopy, but Gradstein *et al.* (2003) point out that fallen branches are inadequate to sample the canopy diversity. One needs to be careful that these are recent falls and represent canopy colonizations rather than post-fall additions. This should be recognizable by the newness of the break on the branch. This method of collecting has the disadvantage that you don't know the height from which the branch has fallen, and sampling is likely to be biased by size class, position in the canopy, and species of tree. Even the age of the tree can be a factor, especially in heavy wind storms.

Epiphytes with their bark substrate may be subject to squashing, especially if you collect in packets, so you might want to pack paper wads around them to protect against such flattening.

Epiphylls should be collected on their substrate leaves to keep the colonies intact, to help in identification of the substrate leaf, and to recognize patterns of colonization. If the leaf is too large, it can be cut so that your collection includes the base, the middle, and the tip (tip morphology is often important in determining the species that collect there). These should be kept in a plant press or other means of keeping the leaf flat for later examination. These are sites for tiny liverworts, especially those in the **Lejeuneaceae**, and should be explored in the lab with the dissecting microscope. Since there are likely to be fungi and Cyanobacteria as cohabitants, the collected leaves need to be dried quickly. Newspapers are useful absorbent materials, but they or other absorbents must be changed daily, especially in humid climates, to discourage overgrowth by the Cyanobacteria and fungi. Especially wet leaves should be blotted dry before the leaf is put in the plant press.

Aquatic Samples

Aquatic bryophytes tend to be quite "dirty." When the bryophytes dry, this mix of silt, bacteria, fungi, and algae becomes glued to the plants, making it difficult to see cells. Hence, aquatic bryophytes need to be washed in the water of their habitat to remove as much of the adhering material as possible. Once the adhering material is removed as best as practical, the bryophyte should be squeezed or pressed, but not wrung, to remove excess water. Then it should be shaken lightly to loosen up the branches and leaves so they

don't all stick together. It may be helpful to remove a few branches and dry them in a minipacket where they can be spread out singly. Otherwise, you may find leaves hopelessly glued together by the adhering algae and bacteria.

For some of the more delicate species, like *Fontinalis flaccida*, the plants can be floated on a 3"x5" (~7x13 cm) card and branches arranged so that some are clear. This may be especially useful for herbaria that glue specimens to sheets, but the cards can also be put in packets and the specimens are easily removed from the cards.

Conservation Issues

Collecting anywhere that is not slated for another destruction is always a conservation issue. Not only is sampling a potential means of destroying the entire colony by disturbing rhizoids and increasing moisture loss, the trampling involved can also be destructive. Wagner () follows the 1-in-20 rule. That is, don't remove more than 1 plant in 20 or more than 5% of a plant to conserve its life. This same rule has been adopted independently in Australia and at the New York Botanical Garden, suggesting that 1-in-20 is a good rule.

Removal depends partly on the moss species and its growth habit. There are a few "rules" you can follow:

1. If you have permanent plots, sample pieces outside, but adjacent, to the plot when sampling is essential, such as reproductive phenology studies.
2. Don't disturb the cushions and other growth forms that are needed to maintain water relations of the bryophyte.
3. Collect pleurocarpous branches from the edge of the colony.
4. Generally don't remove specimens from the center of a colony, especially of acrocarpous species, because it changes moisture-holding ability.
5. If there is only a small population, avoid removing any, except perhaps a small branch if it is absolutely essential, placing it in a mini packet so it doesn't get lost.
6. Be aware of potentially rare species and take only pictures.
7. Be careful what you tread on and how often. Sometimes a plastic sled can be used for standing or squatting to minimize damage.
8. The objective is to collect in a way that the bryophytes can fill in the vacated space before other species invade.
9. For teaching, I kept a teaching collection (plus photography) that students could use for study without having to collect their own.
10. Some herbaria won't accept specimens smaller than the palm of your hand, but I found that the British get upset if you collect a sample larger than your thumbnail on their forays.
11. Always have permission before collecting.

Collecting Permits

The temptation to pick up a bit of moss anywhere you find it is compelling, especially if it looks new and interesting. And, unfortunately, most land owners don't care about the bryophytes. But in many places, especially parks at any level, a collecting permit is required. At the very least, you need permission of the land-owner. It would be futile to try to list places where one might obtain such a permit, but it is very important. Not only is it embarrassing to be caught "stealing" a specimen, but there may be fines and even sanctions. As a representative of your institution, you can bring bad publicity to that institution and even to your country if you are in another country from your own.

A search of Google for **collecting permit** will get you lots of addresses and websites, but a narrower search for the country, state, or municipality may get just what you need. If you are unable to find anything for that country or state, you can usually get pointed to the right place by contacting a local bryologist. If there is no bryologist, try the Department of Agriculture website to see if it provides any leads – or contact them directly with an explanation of what you want to collect, how much, the purpose of the collection, and a query about who to contact for permission to collect and export. A useful website telling you contact information for various countries and various agencies in the USA is called The Skeptical Moth <<http://skepticalmoth.southernfriedscience.com/techniques/collecting-permits/>>.

One of the most embarrassing things you could do is to take a class collecting somewhere when you don't have permission. And even if you have standing permission, it is often a good idea to notify the owner you are coming so you don't inadvertently enter upon an event where it would be dangerous or awkward.

Don't be surprised if there is a fee for a collecting permit. And that may differ, depending on who you are and where you are from! For example, West Virginia, USA, provides the permits free of charge to academics, students, and researchers from West Virginia, USA, but charges \$25 for the same group out of state. Permits for commercial use are much higher and apply to everyone.

Keep your permit with you in the field. You might want to keep it in a Ziploc bag so it remains legible. When we were in Yellowstone, off trail and out of sight, a ranger approached us and we had to show our permit. Our parked car had attracted his attention.

Bryological Collector Arrested

Collecting without permission is taken seriously, at least in New Zealand. One eager collector in New Zealand was arrested for collecting without a permit. The arrested collector became temporarily famous through journals such as *Commercial Horticulture* (January 1993), with the article titled "US botanist fined for taking native mosses" (Alan Whittemore, Bryonet 29 September 1999). The botanist was collecting material to screen it for natural products, not for herbarium records. In addition to his infamy, he was fined. The mosses had been collected in national parks in quantities for which personnel would not have issued a permit.

In some countries you will be asked to leave your collections behind with a local herbarium or museum and may never see them again (Willem Meijer, Bryonet 28 September 1999). Meijer suggests working with young students from that country who are eager to learn. They may be more willing to send a portion of your specimens from a herbarium just to get them identified.

Record-keeping

When in the field, do fieldwork. Minimal time should be spent doing other record-keeping chores. BUT, do keep complete records. A common way for bryologists to do this is to prepare packets or small paper candy bags in advance (Figure 15). This is done by numbering them consecutively and keeping a small record book (Figure 16). If you keep a life list of numbers, you also have a record of how much collecting you have done. There are numbering machines that use stamp pad ink. These allow you to set the starting number and each time you press it onto a bag or packet, the number advances.

Figure 15. Candy bag collection bags, pre-numbered. Photo by Janice Glime.

When you arrive at a collecting site, record in the notebook the **starting collection number**, **date**, **location**, general features of the **habitat**, **altitude**, and **GPS coordinates** (Figure 17). It is also important to record characters that might change as the specimen dries, including **color**, **growth form**, and **fertility** (Rob Gradstein, pers. comm. 28 July 2012). Be aware that different nationalities abbreviate dates differently, so 3/5/12 means 5 March 2012 in the USA, but means 3 May 2012 in Germany. It is safest to **write out the month**. A good way to be sure your information is not lost due to rain or other mishap is to photograph the beginning page if you have a camera. This also serves to mark the beginning of pictures taken at the site.

Figure 16. Record book showing dates of collection included. Photo by Janice Glime.

Figure 17. Field notebook record of a collection site, including general habitat description and record of collection numbers. GPS was not available. Photo by Janice Glime.

A partial alternative to notebooks or writing on bags is a field packet labelled with habitat characteristics to circle (Figure 18-Figure 19). I was introduced to this in Japan by Zen Iwatsuki. I found I could write just about as fast as I could locate the right word to circle, but I suspect that after one uses the method for awhile it would be faster. It does provide the advantage that the collector is more likely to include more detail about habitat information.

Figure 18. Collecting packet from Zen Iwatsuki, demonstrating a habitat circling system used by some bryologists. Photo by Janice Glime.

Figure 19. Field packet used by Allison Downing and Pina Milne. Photo by Janice Glime.

When collecting the bryophyte, squeeze out excess water and put the bryophyte in the bag or packet. (See chapter on Herbarium Methods and Exchanges to learn one way of folding a packet.) Be sure the numbered packets or bags are kept in order before use. I do this by having an apron with pockets (see Figure 32-Figure 36 below). The pocket is long enough and wide enough for the bags I use to fit easily with an end sticking out for easy grabbing. Always remove the bag or packet from the top of the pile, then record the **elevation, substrate, exposure, indication of moisture, and specific habitat and microhabitat** information that is not included with your general habitat information (Buck & Thiers 1996; Figure 20). It is helpful to put your **best guess name** on the packet, with a question mark if there is any doubt. That can make it easier to find the specimen later when you want a specific one, and it also makes identification easier because you have used the clues provided by growth habit and microhabitat. Try to avoid putting more than one collection or species in the same bag or packet unless they are tightly intermixed or the mix is needed for ecological study.

Figure 20. Bag with sample and tentative name. It is missing substrate information; hopefully that is in the field notebook. Photo by Janice Glime.

When you are ready to leave the site, finish your notebook page by recording the last collection number. Add any further observations that might help. It is also helpful to take another picture of the page to mark the end of that collection site among your pictures. If you take

bryophyte pictures along the way, you might want to photograph the packet or bag with your identification guess to help you recognize your pictures. If you are on an extended collecting trip, it might be awhile before you are able to process them, and bryophytes in pictures are not easy to recognize. And don't forget to include some pictures of the habitat for your collections.

An alternative option for the age of technology is to use a mobile phone app such as EpiCollect (Franks 2013). This app was originally designed for recording epidemiological data, but can be used conveniently for plant field records (Aanensen *et al.* 2009). You can design your own database for a specific project, as Franks has done. Data recorded on your phone can be synched into a Google Cloud that is available through the internet anywhere. The phone GPS system can assign the coordinates, date, and elevation, and you can even link a picture, taken by the same phone, to the data entry. For closer images, a hand lens over the phone's lens can magnify your image considerably. The only drawbacks are carrying extra batteries, risk of getting the phone wet, and having to spend a bit more time entering data while in the field. Thus far, the app cannot duplicate location and habitat from one record to the next, but it is only a matter of time before someone designs a repeat button for that purpose. Franks has created a bryological app that permits you to click on a specific point on Google Maps or Google Earth to see all the data fields for that point and any linked photographs. This application is part of the QBry project at <<http://epicollectserver.appspot.com/project.html?name=QBry>>.

Data Sheets

If consistent habitat information is needed, especially if more than one person is collecting the information, field data sheets can be useful (Shevock 2021; , . For ecological studies, it is best to create a preliminary list of species, allowing plenty of space to add to it as needed. This can be done by a reconnaissance trip and lab identifications prior to a more detailed study, or by a quick reconnaissance on the day of the data collection. In the latter case, the team should combine their lists and discuss possible identification conflicts and annotations for unknown species. At the end of the day, the added species should be coordinated and their temporary names unified to avoid confusion later. Data sheets will be discussed in more detail in the chapter on Sampling in this volume.

Coll. No. _____	Taxon _____
LIGHT: sunny, open, filtered, partial shade, full shade WATER: dry, mesic, moist, seep, wet, saturated, submerged to ___ m TOPOG: ridge, slope, swale, valley, trail, roadside HABITAT: dense/open/cut forest, woodland, savannah, grassland, heath, chaparral, tropical, sub-tropical, temperate, subalpine, alpine, desert, riparian, spring/seep, meadow, bog/fen, swamp, pond, lake, vernal pool, river/stream/creek bank, intermittent streamlet, rivulet, rheophytic SUBSTRATE: igneous (granite, volcanic), metamorphic (slate, shale, marble, limestone), sedimentary (sandstone), other _____ Soil: sand, loam, gravel, clay, rocky, litter, humus, peat Rock: outcrop, cliff, crevice, top/wall of boulder, rock-slab, underhang Tree: base, buttress, trunk, stump, snag, log, fallen/dead/rotten trunk, branch, exposed roots, bark, leaf, shrub, climber, liana, ___ m above ground Type: conifer, podocarp, hardwood, tree fern, palm, bamboo, _____ Dominant plants: _____

Permanent Ink

I (Glime) learned as a graduate student to use a Rapidograph pen with India ink to write labels. This permanence was especially important because I was placing labels into 1 dram vials that housed preserved insects I had removed from stream bryophytes. Since ball point pen ink was readily soluble in the alcohol preservative, and external labels frequently came off the vials, the Rapidograph solved both the permanence problem and the need to write very small on a label small enough to fit in the vial and still be legible.

Zander (2004) pointed out the problems in using Rapidograph pens. The ink easily clogs in the small diameter point, filling them is not easy, and they are expensive. He suggests using a modified ball point pen. In particular, the Beifa "Tank" pen is available in dollar stores and is cheap (Figure 22).

Figure 22. Permanent ink Beifa ball point pen. Photo by Richard Zander.

Although the ink is supposed to be "permanent," Zander replaces it with India ink (Figure 23). To do this, he removes the point stem with its disks using a pair of pliers, then replaces the ink with India ink such as the Rapidograph ink (it comes in a handy squeeze bottle). The stem is then replaced in the pen. Zander has used this modification for a long time without experiencing a point jam.

Figure 23. Permanent ink ball point pen, with original ink replaced with permanent India ink. Photo by Richard Zander.

If your bags and notebooks get wet, not much will work for record-keeping. I keep a felt pen (Sharpie) with me because it has a little more success on wet paper. Pencils just dig up the paper, although they are somewhat more successful on damp paper than most pens. I haven't tried India ink on wet surfaces. Richard Zander (pers. comm. 12 August 2012) recommends a crayon or wax pencil as backup. Zander also suggested waterproof paper such as that from Forestry Suppliers (Rite in the Rain® Field-Flex Notebooks). If you can keep a notebook in a dry place and be able to write in it without getting wet, you can put your notes on a sheet of paper there and put that page into the packet or bag. For this purpose, it helps to have a plastic bag that is large enough for you to write within it. The notebook can be wrapped inside it.

GPS Coordinates

Technology has even improved fieldwork in bryology. A simple hand-held GPS unit permits one to record exact locations, with degree of accuracy depending on the quality of the meter, and of course, its price. And many of the new digital cameras will automatically record GPS coordinates with you pictures. Now even cell phones come with GPS software. Once this information is recorded with the specimen, it is possible to relocate the population much more easily than was possible in most cases before this technology. Furthermore, Jan-Peter Frahm (Bryonet 31 May 2012) reports that he has had a program created that permits him to record a list of species in *.txt format. By clicking on the name, one can record the name with its coordinates, date and hour of collection, and altitude. The records can be transferred to a PC in Excel or a Google file, then imported to the database FLORKART (in German meaning plant map) to produce a map output or to display on Google Earth. This can be used with Android smart phones or with Windows Mobile Smart phones that have a built-in GPS. Unfortunately its website is no longer available.

Voucher Specimens

As noted by Shevock *et al.* (2014), understanding of biodiversity is critical to determining distribution, abundance, rarity, and conservation priorities. To document these, one must place voucher specimens in stable herbaria for later verification and new species concepts. As already mentioned, **every** study, whether it is taxonomic, ecological, physiological, or biochemical, should provide voucher specimens so that later researchers can verify or compare the identifications. This does not imply that you have misidentified the species. Rather, it adds to our comparisons by providing material for species to be checked for possibility of a segregate when they are later split. This will undoubtedly become more common as we increase our DNA knowledge base. And of course if someone studies the same location later, but finds species differences, the voucher specimens will permit checking to be sure the two studies haven't determined different names for the same species. This collection can also be studied by the next researcher before embarking on the field study to learn to recognize the species and prepare the mind for spotting them. Storage of these specimens should take into account that they might be later used for DNA testing,

baseline records of pollutants, or other purposes that require careful treatment.

For voucher specimens to be useful, any publication on the study should clearly state where the specimens are located and how they can be identified as belonging to that study. This is typically done by specifying the **collection numbers** (your field numbers) or **accession numbers** (numbers assigned by the herbarium) in the publication. It also helps to label them as voucher specimens and identification of the study name. This can help to protect them from being discarded or moved without notifying the bryological community. With the digitizing of herbarium records, it should eventually be easier to track such collections.

Field Preservation

Most specimens are easily kept in paper packets or in paper bags until such time as herbarium packets are made, but some require special attention. It is important that the specimens are dried relatively quickly. Schuster (1966) warns that keeping them moist, especially in a confined, warm place, will encourage growth of fungi, and the bryophytes may continue to grow, becoming **etiolated**. **Never** store them in plastic bags as that encourages mold.

It is useful to maintain the growth form, but this will be disturbed when leaves are removed. To facilitate examination, it is helpful to separate a few specimens from the edge of the clump or from a neighboring clump so that these can be used for close observation and leaf removal.

Vanderpoorten *et al.* (2010) advise that material collected for DNA extraction should be cleaned and immediately air-dried, then kept dry. Subsequent moistening can lead to degradation of the DNA so that it cannot be used for molecular analysis.

Liverworts will lose their oil bodies upon drying, so if at all possible they should be kept hydrated until they have been examined. Make drawings or take pictures of the oil bodies, or at least make a detailed description, because these cannot be preserved. In some cases, they will become reestablished after a number of hours of rehydration.

Chris Cargill (Bryonet 12 August 2021) reports using A4 sheets of used photocopy paper to enclose the bryophytes while they dry. This prevents curling in soil specimens as they dry and also reduces or eliminates the effects of light during drying, making the specimens more useful for later study. Wire baskets can be used for faster drying. She further recommends keeping loose soil from the specimens in small Ziploc bags, stored with the specimen. The separate packaging prevents abrasions. Specimens with soil can be wrapped in tissue paper inside the packet to prevent further loss of soil.

Liverworts and other Flat Plants

Although some liverworts, especially *Riccia* species of flood plains, can revive after long periods of desiccation, many thallose liverworts can dry out, break, or become irrevocably distorted when they dry. These are best identified while still fresh and moist, but if this is impossible, add water to rehydrate them. Herbarium specimens should not be preserved in any preservative

because it makes them unusable for DNA or other molecular analysis. If one is concerned about maintaining the natural habit, a small portion of the sample could be preserved (Ohta 1991) or stored in the preservative phenylacetic acid-alcohol (Rob Gradstein, pers. comm. 26 July 2012), with the bulk of the specimen being kept dry and having a cross reference to indicate where the preserved specimen is located.

Liverworts typically need light pressing. This can be done between sheets of a newspaper, or in a phone book, but do not apply pressure, *i.e.*, do not put them in a tight plant press. Buck and Thiers (1996) suggest removing excess soil and debris and placing them between papers or in a folded packet, then placing them in a plant press with light pressure and no heat for 24 hours.

Oil bodies typically disappear upon drying. Flash freezing and other methods that work in the lab might not be available for prolonged fieldwork. Jeff Duckett (Bryonet 5 October 2021) recommends keeping a bottle of 25% glutaraldehyde or formaldehyde on hand and diluting to 1% for use. ETOH should not be used if preservation of oil bodies is desirable.

Tiny Bryophytes

Tiny bryophytes can also be a problem. Richard Zander (pers. comm. 27 July 2012) was kind enough to contribute to dealing with this problem. He suggests that one can use a squirt bottle of water to wash away powdery soil from small plants. In some cases, especially on wet clay, one might be able to put these on a card (3x5" is a good size) and have the clay substrate glue itself to the card. This won't work with dry sand. Using an empty squirt bottle or other type of hand air pump to blow away powdery soil might expose enough of the plant clump that it can be separated from the soil and placed in a minipacket or small envelope so it doesn't get lost. In fact, Zander (pers. comm. 29 July 2012) triple-packets them. He puts the sample (dust and bryophytes) into a large inner packet, then puts each bryophyte species into a small packet inside that.

Keeping a sand-dwelling or clay-dwelling colony intact is a special challenge. Zander (pers. comm. 29 July 2012) tells me he used Elmer's glue once. He says the polyvinyl alcohol available now is soluble in water, so bryophytes can be glued to paper, then removed with water for examination later. I haven't tried it.

Aquatic Species

If wet aquatic species are stored with other bryophytes, they will keep the others from drying. For species like *Sphagnum* and other wet bryophytes, remove as much water as possible by squeezing them (Vanderpoorten *et al.* 2010). If possible, fluff them out again before putting them in their packets or bags. Make their containers triple thick so the water is less likely to cause the container to tear or come apart. If the bryophyte is really wet, put it in a plastic bag, but be sure to take it out as soon as you reach a place where you can dry your collections.

Fornwall (1977) compared three storage methods for the aquatic moss *Fontinalis duriaei*. He found that storage dry at room temperature, and dry packed in coolers with

cold packs both caused the mosses to lose color and appear to be quite unhealthy after being rehydrated and cultured in fresh stream water at 10°C for seven days. However, those mosses that were stored in bags of stream water with cool packs for three weeks (and opened every night to allow gas exchange) exhibited levels of photosynthesis and respiration after storage that did not differ from the measurements prior to storage.

Drying Specimens

Getting specimens dried before they have an opportunity to mold or curl can be a challenge on extended field trips in faraway places. Generally, they can be dried by opening the bags and spreading them around your room or laboratory (Figure 24-Figure 25). If you are travelling by car, bryophytes in their collection bags or packets can be placed in a net or burlap bag and affixed to the top of the car to air dry. It is best not to leave them there when you are not in attendance because it could rain. They also should not be baked in the hot sun.

Figure 24. Jim Shevock in "drying room" with packets on left and specimen bags opened for drying on right. Photo by Blanka Aguero.

Figure 25. Drying bryophytes during Nordic Bryological Society foray. Photo by Michael Lüth.

Croat (1979) addressed this problem in a big way by modifying a truck into a processing lab and modifying a refrigerator by adding a portable propane gas oven to use for field drying. Fortunately, such elaborate equipment is usually not necessary for bryophytes, but in humid warm climates of the tropics, drying can still at times be a challenge.

Frahm and Gradstein (1986) constructed a dryer that is light weight and inexpensive for use in such humid climates (Figure 26). The drying source is a pair of kerosene stoves. The legs of the dryer are made of aluminum, making them light weight. They are about 1 m high and extend above the platform where they support a cotton curtain to hold in the dry heat. The shelf is made of wire screening and packets or open bags can be distributed across it. Of course, these must be protected against wind or your prized collection will escape to freedom! Frahm and Gradstein warn against use of polyester or nylon for the curtains or screen because they are more flammable. Be sure to do a little experimenting so you know just how high to place your shelf and how often the apparatus should be checked or your specimens could turn to charcoal – or worse.

Figure 26. Field drying rack for bryophytes. Note the two kerosene stoves beneath and the inset of the curtained part of the platform above. Image from Frahm & Gradstein 1986, *Bryological Times* 38: 5.

David Wagner (2014), a constant innovator of bryological methods, has devised a simple, rapid, and inexpensive method for drying bryophyte specimens. He uses the spring type of clothespins to attach specimens first to a rod or rope, than to attach additional ones to the specimen above (Figure 27). This method has the advantage of permitting air to reach both sides of the specimens. He devised this method for field packets, but it should work as well for paper bags, provided they are not so wet that they tear under the added weight and pressure of the clothes pins. Bulldog clips (Figure 28) are more compact for travelling and may even be easier to find for purchase. A fan can be used to speed up drying even more. The paper in the packets is kraft paper.

Once the specimens are **thoroughly** dry, they should be packed in sealed plastic bags (unless the air is dry) to avoid having these hygroscopic plants once again take up water. Please note that if they are not completely dry, they are likely to mold inside the plastic bags.

Figure 27. Drying packets clipped together with wooden clothes pins. Photo by David Wagner.

Figure 28. Drying packets clamped together with bulldog clips. Photo by David Wagner.

Once dry, specimens can be kept dry by sealing them in bags containing silica gel ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$) (Greene 1986). Greene reports that the method worked excellently in the southern Chilean rainforest. If the silica gel has absorbed moisture prior to use, it can be dried along with the bryophytes on the drying rack.

If floating species like *Riccia fluitans* (Figure 29) are to be kept, a good way to collect them is to float them on an index card that will fit inside a packet. The algae and other detritus will glue them to the card. Once dry, they can be put in a packet like other bryophytes.

Field Stains

Occasionally you may want to see something more clearly in the field. For ecological studies, being able to identify every individual can sometimes be tedious but necessary. In some cases, field stains can help in this endeavor, such as seeing fimbriate stem leaves on *Sphagnum*. Jan Janssens (Bryonet 4 October 2012) suggested using crystal violet or gentian violet solution. It works well when filled into a rinsed and dried felt-tip pen. He suggests pulling off the *Sphagnum* capitulum and squeezing the *Sphagnum* somewhat dry before applying

stain at the top of the broken stem. This technique also works well in the lab. If no stain is available, you can hold plants up to diffuse skylight to get a somewhat better view.

Figure 29. *Riccia fluitans* that is "floating" on paper. Photo by Kristian Peters, with permission.

Adam Hölzer (Bryonet 4 October 2012) likewise uses **crystal violet** (Merck Art. 1408), enabling him to see pores under the microscope. Dissolve some powder in 50 ml distilled water and add alcohol to preserve. Add new alcohol from time to time as the alcohol evaporates. Use alcohol for cleanup.

Field Gear – Collecting Equipment

If you have the motto "Be prepared" you might want to keep your collecting pack ready to go, or at least keep a checklist. Loeske (1925), interpreted by Raup (1926), suggested that essential equipment consisted of a good lens, paper envelopes, and notebook. I would suggest a bit more to increase efficiency. Here is what I would recommend.

Field Gear Checklist (essentials are in bold)
hand lens on lanyard or string (Figure 40- Figure 43)
indelible pen
pencil
knife with protected point (Figure 36)
prenumbered packets or bags (Figure 15)
bag for collections
Ziploc plastic baggies (Figure 34)
field notebook (Figure 16)
masking tape sampler (Figure 4-Figure 7)
back pack
collecting pockets (Figure 31-Figure 36)
squirt bottle for moistening specimens
cloth measuring tape (Figure 30)
GPS
altimeter
metric ruler
water
sun glasses
hat
pocket raincoat
bug repellent
food (added the day of the trip)
field guide

Figure 30. Cloth measuring tape with metric units on one side and English units on the other. This can be helpful for measuring height on tree, diameter of tree, size of population, and various other distances. Photo by Janice Glime.

Attire

Although attire is mostly dictated by preference and the climate of the collecting location, one might consider a few accessories. Sun protection is important for those working in the open sun, and Eckel (1996) suggests carrying a small, collapsible umbrella to gain some relief from an intense sun. I prefer a wide-brimmed cloth hat that I can fold into a pocket or pack when it isn't needed. Sun glasses that flip up during hand lens use are important for protecting one's eyes.

Collecting Apron

Keeping bags, pens, hand lenses, camera, knife, record book, and other items close at hand but out of the way during a field trip can be a challenge. Back packs can hold a lot, but they are not handy, and sometimes there is no place to set one down. In others, they may throw you off balance, causing a fall and even endangering your life. To solve the problem, I created a set of pockets that I tie around my waist (Figure 31-Figure 34). These can be designed to meet your own needs with pockets to hold your equipment while holding it secure against loss. I recommend a heavy cloth like denim, or even double cloth. Stitching should be in double lines, and ends and corners should be reinforced with criss-cross stitches or other means of reinforcement. Mine are designed to tie, and my last set has the pockets sewn onto the ties. I like my former design better, where the pockets, or at least the front ones, are threaded onto the ties like curtains on a rod. When this is done, don't use loops, as they are easily torn if the pocket gets caught when you are hiking through brush. You could also use a belt, but with some clothing it can be uncomfortable. In either case, try the pockets on before stitching them down to be sure the pockets locate themselves where you want them. The two flank pocket panels provide easiest access when they meet near the middle of the front.

I carry 3x5" cards with me for a variety of uses (Figure 33). They can be helpful for scooping floating bryophytes from the water. They can be used to mount these wet specimens by floating them on the card and letting them

dry there. This permits the specimen to spread out and glue itself to the card instead of the plants gluing themselves together. This may also be useful for some small liverworts that may otherwise get lost in the bag, although minipackets are usually a better way to handle these. Cards can also provide a smooth surface for epiphylls and thallose liverworts and they help create rigidity for packets with thin soil layers.

Figure 31. Janice Glime wearing collecting pockets in geothermal field, Karapiti, NZ. Photo by Zen Iwatsuki.

Figure 32. Set of three pocket panels. Note the bulky middle pocket that hangs over one's rump to hold collected specimens and field guides. The whistle on the tie is for calling missing students or calling for help when you are lost from your companion. Photo by Janice Glime.

Figure 33. Pockets for numbered bags, cards, field notebook. Note the small pockets above the bag pockets. These are suitable for batteries, hand lenses, and other small items. See detailed image of these in Figure 35. Photo by Janice Glime.

Figure 34. Pockets for pens, knives, flash, phone, or camera, or, in this case, plastic bags in case very wet species are collected. Note that the back pocket on the left is gathered at the top to make the inside larger to keep the contents from falling out. Photo by Janice Glime.

It is useful to have small sheets of paper to make mini-packets for small species or small objects such as capsules that might get lost in the collecting bag or among other bryophytes. Pages from the field notebook can serve this purpose, provided that their removal does not cause the remaining pages to come apart.

Small pockets help to keep tools in easy reach and avoid tangling (Figure 35). Long, narrow pockets can hold knives, pens, or pencils (Figure 36).

Figure 35. Small pockets with potential uses shown by the lenses sitting on them. Note the double stitching at the bottom of the pocket. Photo by Janice Glime.

My back pocket is large and is not flat, being larger across the bottom edge (Figure 34). It can hold packets with mosses in them and a field guide. It's a good idea to keep the field guide in a Ziploc bag to protect it from dirt and water.

Some carpenters' aprons may serve your purposes and are made to carry heavy tools, so they are durable. You may have to add your own back pocket and some small pockets if you need them. It depends on your needs – and how ambitious you are.

Figure 36. Long, narrow pockets house pens and knives. Photo by Janice Glime.

Collection Bags

Bryophyte collections can be damp or even soggy. If you are staying in a hotel or have much travelling to do, these must be placed where they won't mold and can begin to dry. In Japan, I was introduced to hand-made collecting bags for holding the paper bags (Figure 37). If you don't go too many places, you can use a separate bag for each collection site. It is usually possible to tie these to your belt or to the collection apron (Figure 38). Bright colors help you to locate a bag you have left on the ground.

Figure 37. Bryophyte collection bag. Photo by Janice Glime.

Figure 38. Zen Iwatsuki warming his hands over a geothermal vent in Iceland. Note the collecting bag hanging from his belt. Photo by Janice Glime.

Eckel (1996) extols the benefits of a Naugahyde (vinyl-coated fabric) flat bag. In the morning it is filled with empty packets that are replaced during the day with filled packets. It can double as a pillow for sitting, a cushion for sliding down a slope, a shield against cacti, and protection for crossing a barbed wire fence.

Hand Lenses (Loupes)

Hand lenses are essential for seeing the details needed for identifying bryophytes. And they also reveal the beauty of the bryophyte world. Lenses come in a variety of magnifications and sizes (Figure 39). The most commonly used is a 10X loupe, but you might even be able to use one up to 30X. The small ones are the most convenient because they weigh less and are often easier to focus, especially if you wear glasses. A reading magnifying glass offers some help but is not nearly as helpful as a 10X hand lens, and it is heavy and bulky.

When using a hand lens, hold it close to your eye and bring the bryophyte toward you until it is in focus (Figure 40). One advantage of the lens is that it permits you to focus on something close to your eye. The exact positioning will depend on the correction in your glasses.

Figure 39. Small 20X and larger 10X hand lens with nylon string. Photo by Janice Glime.

Figure 40. Janice Glime demonstrating the use of a hand lens while wearing eye glasses. Photo by Jill Nissila.

It is a good idea to carry several hand lenses with you. In damp, cold, or rainy weather, the lens can fog up and it may take an hour before it is usable again. And there is always the chance you will lose one. By all means attach your hand lens to something. A lanyard is good, but a heavy string will work well and is flexible and light weight. If your lens is hanging around your neck, you can tuck it inside your coat when it is raining or cold, and it will always be handy without being lost easily.

A few bryophytes have been shown to have fluorescent propagula, and such propagula are often difficult to see in the field. For the taxonomist, the solution is to collect and identify later, but for the ecologist, field identification is important. More importantly, the same species needs to be distinguished from similar species during field studies, even if verification must come later. Zimmermann (2011) introduced us to a 10X hand lens that provides the UV light needed to see this fluorescence in the field Figure 41- Figure 42) (Zimmermann 2012). The lens now is available at 10X, 15X, and 20X with color temperatures of 4500, 600 (neutral), and 8000 K. Norbert Stapper (Bryonet 16 July 2013) recommends the neutral, with cool white not showing the typical yellow color of a the lichen *Flavoparmelia*. Nick Hodgetts (Bryonet 1 December 2011) adds his endorsement to this lens. The lens is a bit costly at 195 Euros plus postage.

Figure 42. Lichen candelaris UV hand lens showing inside. Photo by Erich Zimmermann.

Technical details:

- Cold white light through two laterally shifted LEDs (prevents shadows). LED with low power consumption and high lifespan
- Operation time: 8,000 x 5 sec flashes until low battery indicator lights up, additional 300 flashes to battery empty
- 3V Lithium-batteries (3 pcs. CR 2023 Renata): High energy density and extended shelf life
- Active power source results in constant luminous intensity over the whole battery life cycle and extended temperature range
- Lens system x10, $\text{AE}20\text{mm}$, (triplet, aplanate, achromate, closely glued)
- Submerged key, anodized Alloy-box, water spray proof IP67, your name is laser labelled on special order.
- Weight 76 g
- Swiss made, 1 year warranty
- Included in delivery: 10X magnifying glass, 2 pcs Lanyard, 3 replacement batteries, instruction manual with technical details

Hand lenses have been a popular topic on Bryonet, and members have their own preferences that may help you in your consideration. Werner Pflaum (Bryonet 30 November 2011) recommends the Lichen candelaris despite its high price. He considers the light source to be excellent. Norbert Stapper (Bryonet 30 November 2011) warns that the lens is not waterproof because it lacks an O-ring to seal the electronics and battery compartment. The lens system is a sealed triplet, which eliminates fogging, an important consideration for rainy days or cold weather.

David Wagner (Bryonet 16 July 2013) recommends the 20X hand lens by Iwamoto, claiming it is worth the \$100 or so it costs because of exceptional clarity and wide field of the lens. In USA it can be ordered from Minerox <<http://www.minerox.com>>.

Less expensive lenses lack the light source and generally have only two lenses, not three. David DuMond (Bryonet 28 November 2011) recommends a hand lens with LED source from Miners <https://minerox.com/index.cfm?fuseaction=category.display&category_ID=2>. This 20X lens has a 21 mm diameter and triplet glass (Figure 43). It is only US \$24.95, complete with leather carrying case.

Figure 43. Handlens with LED. Photo by Miners.

The Weinschenk hand lens has excellent optics with sealed triplet lenses, available in 10X and 20X, but no light source. Norbert Stapper (Bryonet 15 July 2013) combines

the 20X Weinschenk hand lens with the Lichen candelaris 10X to obtain 28X magnification. The Weinschenk lens is available through Industrieoptik Fischer, Wetzlar, Germany <<http://www.iof-wetzlar.de>> or from <http://www.kruess.de/shop/Lupen/Weinschenk-Lupe:::21_44.html>. Rune Halvorsen (Bryonet 15 July 2013) considers it "an absolute must for bryologists!" Martin Godfrey (Bryonet 29 November 2011) recommends hand lenses from Quicktest <www.quicktest.co.uk>. This company supplies lenses for the jewelry trade and carries hand lenses that range in cost from £1.50 to £95.00 for a 10X lens. Marshall Crosby (Bryonet 2 February 2012) recommends BioQuip for hand lenses at a range of prices <http://www.bioquip.com/specials/product_special.asp>.

McCune (1994) recommended an illuminated lens by Bausch and Lomb, available through Forestry Suppliers for US \$43.75, but it no longer seems to be available from them. However, they now have one that is 10X instead of the original 7X lens, also by Bausch and Lomb, but for only US \$28.25. It requires two AA batteries and is the size of a fountain pen (if you remember what that is!). McCune found it very useful in the field for examining bryophytes and lichens in a permanent plot when you must get so close you block the daylight.

Jesús Muñoz (Bryonet 15 July 2013) uses both the 14X and 20X Bausch & Lomb Hastings Triplet hand lenses, available from Forestry Suppliers <http://www.forestry-suppliers.com/product_pages/View_Catalog_Page.asp?mi=52491&title=Bausch+%26+Lomb%AE+Hastings+Triplet+Pocket+Magnifiers>.

Sean Edwards (Bryonet 1 August 2013) has found the 10X Ruper triplet lenses from Summerfield Books <www.summerfieldbooks.com> to be excellent for all his uses. These are aplanatic Japanese lenses at a reasonable cost. This company also stocks lanyards. They are also stocking an ultraviolet LED triplet hand lens. Although this is designed for detection of mineral fluorescence, they may be helpful for detecting fluorescent structures such as *Pohlia* bulbils on bryophytes. This is also a triplet lens that corrects for both aplanatic aberrations to improve the field of view (21 mm) and achromatic distortion for true color viewing at the reasonable price of only £21.

Des Callaghan (Bryonet 1 August 2013) advises that one should be sure the lenses are cemented together (usually sold as cemented doublet or cemented triplet). Otherwise, one must seed assurance that the housing is waterproof. And some of the cheaper models have lenses held by a threaded ring that can easily unscrew, causing you to lose the lenses. When lenses are not sealed, they easily steam up inside, especially in cold or wet weather.

Field Microscopes

When you are examining small plots for total bryophyte cover, and you must name every species and determine how much cover it provides, a field microscope can be useful. But when looking with such closeness, it becomes more difficult to avoid missing some parts and overlapping others.

Rod Seppelt (Bryonet 9 February 2012) reports on a field microscope that Gert Steen Mogensen introduced to him many years ago. This microscope was mounted on a miniature train track, maintaining a consistent distance of the lens from the ground and facilitating a consistent

movement. When the train track is on the ground, one can move the microscope along the track. A camera could even be attached to an eyepiece, especially if a trinocular microscope is used. This system provides stability and helps to solve the problem of vibration. It should be adaptable for stacking. I haven't tried it, but the ability to photograph and enlarge the picture later might even permit one to do the cover estimates accurately later in the lab.

You are less likely to need a compound microscope for the field, but you might want to check some things for verification in the evening after a day in the field. Tamás Pócs (Bryonet 10 February 2012) reports great satisfaction with the BioLux NV (Figure 44), made by BRESSER, Meade Instruments Europe Bmbh & Co. KG, Gutenbergstrasse 2, DE-456414 Rhede/Westf. Germany at a price of about 100 Euro. Its magnification ranges 20-128 X. It is lit by LEDs (with transmission and overhead light) and also has a digital camera ocular. It has a movable stage and several built in filters. More information is available at <<http://www.astroshop.eu/monocular-microscopes/bresser-microscope-biolux-nv/p,14667>>.

Figure 44. BioLux NV field microscope, made by BRESSER. Photo modified from Bresser website.

Norbert Stapper (Bryonet 11 February 2012) suggests two good sites for light-weight field microscopes: <http://www.blam-hp.eu/swift_br.pdf> and <<http://dominique.voisin.pagesperso-orange.fr/technique/pyrennee/index.htm>>.

Return at the End of the Day

Rob Gradstein (pers. comm. 28 July 2012) recommends that all information gathered on the specimens should be written in the field notebook. This depends in part on whether legible information with indelible ink is on the collecting packet or bag. Certainly general habitat notes should be in the notebook since that was most likely not repeated on each collection bag. Each specimen should receive a unique collection number, preferably already done in advance. (If the collection contains mixed species

and is separated later, each packet can be given a different letter while retaining the original collection number.) If there wasn't time to clean the specimens in the field, they **should be cleaned as well as possible and excessive substrate removed**. The specimens need to be spread to dry. I have many memories of collecting bags spread around hotel rooms at bryological meetings. It might be a good idea to alert the hotel staff so your specimens don't get tossed or mixed up. Be sure these collections remain in a paper container that won't permit them to escape if someone opens a window or door. If there is such a danger, place the collection packets/bags in a broad weave bag(s) and hang these where they get good air circulation. I still recall bags of mosses blowing around when we opened our hotel room balcony doors to cool the room (no air conditioner) and a storm came up. First the packets were blown around and some where dumped. Then some got soaked when the rain came in. We were scrambling in the middle of the night to move and protect the collections.

Thallose liverworts and epiphylls should be pressed lightly between sheets of absorbent paper (newspaper works well) and the paper changed daily. Place a sample of any liverwort capsules in a small envelope or minipacket with the rest of the sample to help keep some of the capsules unopened (but keep some intact as well). These capsules tend to release when they dry. It is also important to keep part of the liverwort sample alive/moist for later study of **oil bodies** (Rob Gradstein, pers. comm. 28 July 2012). You can accomplish this by keeping them in plastic at a cool (but not freezing) temperature. Examine them as soon as possible with a microscope and carefully describe the oil bodies. If possible, photograph them through a microscope; if not, draw them. Oil bodies will begin to disintegrate within a few days, or hours in a dry climate, and their morphology can change, even if they don't disappear.

Getting your Specimens Home – Customs and Inspection

Transporting your specimens requires a little attention. Some become brittle when they dry, so they should be packed to protect them. The bags or packets help to protect them. They should be tight enough that they will not move around in their shipping or transporting box, but loose enough that they don't crush each other (Buck & Thiers 1996).

Getting your specimens back into your own country can sometimes be problematic. Be sure you know both the import and export requirements for your home country and the country you are sending specimens from. As a courtesy, you should always provide a set of specimens, preferably identified, to the country where you collected them. Ask permission from a national herbarium or other prominent herbarium to give them the specimens. If you are sending them later, follow the protocol for "Sending Specimens for Identification" in Chapter 3 of this volume.

Hedenäs (1993) raised questions about various requirements of some countries. It is important that you understand these. Some countries require deposit of a duplicate set of specimens before you leave the country. This is impractical in most cases, as it is unlikely that you will be able to identify positively all of the specimens in a

country where the flora is poorly known. Nevertheless, if that is the law, it is important that you comply. You can send a list of species and collection numbers later. Instead, if leaving a set is not required, it might be better to send a duplicate set after they have been examined in the lab and identifications verified.

One aspect that can cause import/export problems is rare or protected species (Willem Meijer, Bryonet 28 September 1999). You might need proof that each specimen is not an endangered species. Customs agents are not familiar with mosses and may not even recognize that it is a moss, much less a liverwort.

Frahm (2000) reports on difficulties with specimens mailed to him from other herbaria, requiring him to go to the customs office at the German port of entry. It was no longer sufficient to label the package as "dried specimens" or "dried plants for scientific study." Rather, it is necessary to include a CITES certificate. This requires a declaration of the species enclosed. But bryophytes are not yet on the CITES list. Frahm suggests that the bryophytes be assigned a monetary value below the customs limit. He further suggests that it might help to make the statement that the enclosed bryophytes are not on the CITES list. Therefore Frahm concluded that a customs declaration indicating "Dried herbarium specimens – bryophytes: no CITES required, value \$10" could solve most problems.

When sending collections, divide them into small sets. Large sets (many specimens) may discourage inspectors, causing delays in getting the specimens to you.

Bill Buck (Bryonet 19 July 2012) assures us that there are no restrictions about bringing bryophytes into the United States, nor are any permits required. But importation of soil is problematic. Even a small amount attached to your specimens can result in having your specimens confiscated and destroyed. The process for bringing soil is complex and may include an onsite inspection. Buck showed the customs agents the freezers where new material is placed, and then the herbarium, with its multiple levels of security, where the material will ultimately be stored. But, as Wim Meijer warned, any bryophytes that get on the CITES list will most likely change the whole process. Jim Shevock (Bryonet 19 July 2012) fully agrees that it is best to mail the specimens back, at least to the USA. If you bring specimens into the USA and do not have the needed paperwork, you risk having the entire collection destroyed. In any case, specimens are likely to cause delays at customs at the port of entry and could cause you to miss a connecting flight. It is best if you mail them to yourself in care of the herbarium.

Summary

Collect in individual paper bags or envelopes. Ecological collections should include voucher specimens. Recorded data should include location, date with month written out, GPS coordinates or latitude and longitude, elevation, habitat, substrate, and collection number. Sample size depends on abundance and expected use, with palm-size collections being best for common species. Permission of the owner or a collection permit is important.

A collecting apron can make field equipment orderly and handy without being in your way. Cloth bags for collection bags facilitate drying.

A hand lens is usually essential in the field to permit tentative identification. Care should be taken to obtain one with sealed lenses. A light source (LED or UV) may be useful, depending on expected use. Field dissecting microscopes on a track can also be useful for finding small species and to facilitate consistent and thorough sampling.

If specimens must pass through customs, it is best to mail them to your herbarium. Be aware of customs guidelines for all countries in your travels before collecting.

Acknowledgments

Bryonettors have been invaluable in providing the information used in this chapter. Rob Gradstein provided me his perspectives on field preservation of thallose liverworts. Richard Zander helped with suggestions for tiny bryophytes.

CHAPTER 2-1

LABORATORY TECHNIQUES:

EQUIPMENT

Figure 1. Dries Touw at a microscope in the Hattori Botanical Laboratory, Nichinan, Japan, 1983. Photo by Janice Glime.

Lower Plants

*Moss and lichen – lower plants,
the higher plant people say;
But if you give them half a chance,
they'll really make your day.
Miniature beauty – ecology too,
enough for your interest forever;
You'll need a scope and some chemicals few,
to unlock their secrets most clever.
So get out there – look around,
learn from the lichen and moss;
Treasure the mysteries of lower plants found,
and you'll never be at a loss.*

- Ray Showman

Lab bench Setup

A well stocked lab bench (Figure 1) will save you time and make your work more efficient. Usually this bench will be located near the herbarium specimens for easy checking of your identification and for processing and accessioning specimens (Figure 2).

Figure 2. Working area in the herbarium at the Missouri Botanical Garden. Specimen compactors are on the left and benches with microscopes and other equipment are on the right. Photo by Paul J. Morris through Flickr Creative Commons.

Although making slides seems relatively routine for anyone who has done this often, there are lots of tricks to make it fully effective. Having a set of tools that are in one place is a tremendous time-saver, and it encourages one to

identify that specimen picked up on the way to work rather than tuck it away for later. This can be accomplished easily if you have a workbench reserved for that purpose, but if not, create a sturdy box that holds your needed tools.

This is a **list of supplies** you will probably want to have handy so that you can proceed efficiently:

Desirable Lab Bench Supplies

compound microscope with its own base light source (Figure 5)
 dissecting microscope with top mounted light or lights on each side (Figure 8-Figure 9)
 blue filters for microscope lights
 microscope slides (Figure 33)
 coverslips (Figure 31)
 single-edged razor blades
 microforceps or watchmaker forceps
 a curved one and a straight one are helpful (Figure 25)
 whetstone
 emory board
 dropper bottle with narrow tip and water (Figure 29)
 ocular micrometer
 stage micrometer
 lens paper
 paper towels
 Petri plate(s)
 Syracuse watch glass (Figure 3)
 hot plate for warming water to soften tissues
 jar or beaker of water
 slide labels
 permanent mounting medium
 methylene blue or similar stain

Figure 3. Syracuse watch glass.

Microscopes

As Rockcastle and Barr (1968) pointed out, observing bryophytes requires a "bits made big" technique. Identification of bryophytes usually requires two microscopes, a dissecting/stereo microscope with a zoom (preferred) viewing range of ~3X to 40X and a compound microscope with a viewing range of 40X (or less) to 400X total magnification. Magnification is determined by multiplying the ocular (eyepiece) magnification by that of the objective lens. Higher magnification may be required, depending on your needs.

The dissecting microscope is needed for several purposes. It is usually the first microscope you will want to use to get a clearer view of leaf insertion, paraphyllia, decurrencies, general habit, and other surface features. It is also needed for locating small bryophytes, especially tiny leafy liverworts, from among the dominant bryophytes. It is also needed for locating the fauna. The other important use of this microscope is to guide your hands when you make sections or remove leaves.

The compound microscope is used with microscope slides. It permits you to see cell shape, number of cells wide, borders, costae, and teeth on the leaves. On the sporophyte you can see such details as peristome decorations and imbedded stomata. The compound microscope is also needed for a clear view of your sections of leaves and stems. It will also help you see special structures like gemmae, bulbils, paraphyllia, and reproductive organs.

There is a wide range in quality of microscopes. It is very useful to have trinocular microscopes that can hold a camera (see the two microscopes in Figure 1) or to have a USB connection, or that have a direct image transfer to your computer. Once you have a little experience, you can take pictures that are adequate for identification. This can avoid the need, in some cases, for sending specimens to experts, and it will save them lots of time because you have already made sections and spent the time to get good views of the leaves, insertions, and stem sections. You can also introduce these images on Bryonet <Bryonet-L@mtu.edu> or a web site where you can request help for troublesome species. (Caution: try to keep the total of all image sizes under 2 MB when sending them to an email list such as Bryonet.)

One can usually count on Olympus and Nikon microscopes to be of good quality, but these tend to be rather expensive for a beginner. Tamás Pócs (Bryonet 10 February 2012) reports great satisfaction with the BioLux NV (Figure 5), a compound microscope made by Bresser, Meade Instruments Europe Bmbh & Co. KG, Gutenbergstrasse 2, DE-456414 Rhede/Westf. Germany at a price of about 100 Euro <<http://www.astroshop.eu/monocular-microscopes/bresser-microscope-biolux-nv/p,14667>>. Its magnification ranges 20-128 X. It is lit by LEDs (with transmission and overhead light) and also has a digital camera ocular. It also has a movable stage and several built in filters, as well as a carrying case for field work. An added advantage is that it has a carrying case, making it more convenient for field work.

Figure 4 outlines the principal parts of a **compound** microscope. Since manufacturers vary, the microscope

available to you may differ somewhat. You will note that some microscopes have one eyepiece (**monocular**; Figure

5), whereas others have two (**binocular**; Figure 9). **Ocular** refers to the eyepiece.

Figure 4. Compound microscope showing parts. Drawing by Janice Glime.

Figure 5. BioLux NV compound microscope, made by Bresser. Photo modified from Bresser website.

The **mechanical stage** (not shown) has numbers in both directions that you can move the slides, so that you can note the coordinates on the numerical scales, then remove the slide. When you replace it you can go easily to the same location.

Your microscope should be **parfocal** (having all lenses adjusted to the same focal distance, making it possible to switch objective lenses with minimal refocusing). That means that when you change from one objective to another, the ocular distance is still correct and the object should still be close to being in focus. When you start using a different microscope, it will most likely be somewhat fuzzy for several reasons. You have increased the magnification and it is easier to see that it is not in perfect focus. The oculars may not all be screwed in completely, changing the focal distances. However, in most cases you can adjust this by using the fine adjustment. Different people have different focal distances, and these change with time. Hence, some initial adjustment is needed, with fine-tuning occasionally.

Parfocal Adjustment

Binocular microscopes may require adjustment so that both oculars focus at the same distance. If there is also a camera tube, this also needs to be adjusted.

Procedure

1. Position the objective turret above the subject.
2. Set both eyepiece diopters to "0."
3. Set the microscope near the middle of its focus range.
4. Focus with the microscope on the lowest magnification setting, using first just one ocular (eyepiece). Use the fine adjustment until the image is clear.
5. Focus with the other ocular by turning the diopter ring on the ocular until the image is clear and sharp.

Do not move the fine adjustment. If you can't get the focus clear, put it in the best position, use the fine adjustment, and readjust the other ocular. Repeat until both oculars provide clear focus.

6. Move to the next highest setting and repeat the process.
7. Finally, move to the highest setting and repeat the process. If you will not be using the oil immersion lens, then use the highest magnification below that.
8. Tighten the diopter lock button if there is one and record the setting.
9. Repeat the procedure with the microscope tube.
10. Do this whenever using a microscope that is new to you. As your eyes change, the settings may need adjustment.

Microscope Use

First, it is important that you learn to use the microscope correctly, or you will not be able to see all the things that you should. After you understand how to set up your microscope, make a slide of one of your samples and determine the best way to adjust your microscope.

Adjusting Light and Learning to Focus

1. Start with a **prepared slide**; diatoms are a good choice because of the fine detail of the pores and striations. The diatom *Amphipleura pellucida* is often used. Its striae (lines of pores) have a mean of 0.25 μm distance apart, the theoretical limit of resolution of light optics. If you can see them clearly, it is an indication of a good quality of microscope. If you don't have access to a diatom slide, you can use an onion skin (the thin layer) or other thin, nearly transparent subject in a drop of water with a coverslip.
2. On the slide you can often **locate the organism** by a change in color as you scan, but a more reliable way is to begin by focusing on the edge of the coverslip. This will put your view in the right plane so you can scan the slide.
3. Once you locate the specimen, **focus first with the coarse adjustment**, always starting by focusing upward so you don't run the objective into the slide.
4. Once you have gotten the clearest image possible with coarse adjustment, use the fine adjustment to get and even more distinct image.
5. Using a nearly transparent slide, you can learn to **adjust lighting**. This should be done by adjusting the diaphragm under the condenser. It should **not** be adjusted with the light intensity of the light source because with most microscope lighting systems, lowering the light intensity changes the light quality to the red end. Changing the light intensity by using the rheostat to change the intensity of the light source should only be used to adjust the light for your eye comfort.
6. If the light has a red cast, it can be balanced with a **blue filter** (see Figure 6-Figure 7). This can be especially important for photography. Usually it just requires a blue glass filter over the light or in the condenser housing under the diaphragm, and often one is supplied with the microscope.

Figure 6. Peristome of *Fontinalis squamosa* with tungsten light of microscope and no blue filter. Photo by Janice Glime.

Figure 7. Peristome of *Fontinalis squamosa* with blue filter covering tungsten light of microscope. Photo by Janice Glime.

Adjusting the Focus and Ocular Distance

1. If you are using a binocular microscope, you need to adjust the oculars. If you are right-handed, look through the right ocular with your right eye and get the object into clear focus. Even if you are left-eyed, start with the right ocular, but use your left eye. (If you are right-handed, you are likely to be right-eyed.) You might have to shut the other eye to do this.
2. **Always start with the coarse adjustment and focus upward.** It is safest to adjust the objective downward with the coarse adjustment while watching the slide from the side without using the ocular, bringing the objective as close as possible to the slide without touching it. Then be sure you focus in the opposite direction (upward) **slowly** with the coarse adjustment while watching through the microscope. If you are inexperienced, focus on the edge of the coverslip to get into the right plane.
3. Adjust to the best focus using the **fine adjustment**.
4. Then use your left ocular, still using your right eye, and get it into focus, but this time **turn the left ocular** to adjust the focus. This is usually done by turning a ring at the base of the ocular housing, not the ocular itself.
5. If it is impossible to get a clear image this way, you may have to move the right ocular so it is closer to the middle of its range, then refocus with the fine adjustment before focusing the left ocular. Repeat this until you are able to see clearly with both oculars.

6. Use both eyes, and **move the oculars together and apart slowly** until you can see through both of them. At first, you might see two images; adjust the distance between the oculars carefully until you can see only one image in 3-D.
7. When the images are clear, observe the dial or **vernier scale** between the oculars to see what number is indicated. (Some microscopes, especially dissecting microscopes, might not have this scale.) Then set each of the two oculars at that number. This adjusts the focal distance because you have changed it when you changed the distance between the oculars.
8. **Write that number** on your lab notebook, or on a piece of tape on the microscope if you are the only user. You can always set any microscope at this number and save much time in trying to adjust the ocular distance. You will probably have to set the number on the vernier scale every time you come to lab if different people use the microscope because they will have different distances between their eyes.
9. **Re-focus** with the coarse and fine adjustment until you have the best single clear image.
10. After you are more comfortable using your binocular microscope, try adjusting the ocular distance again and record the new number if you find a better position.

Adjustments for Glasses

1. When you adjust the microscope to see the image clearly, you are also adjusting the focal distance to work best with your eyes. This will compensate for near-sightedness or far-sightedness. However, it will not adjust for astigmatism. Examine the object on the microscope slide to see if it is clearer with or without your glasses. This will require a new adjustment.
2. If you prefer to wear your glasses, then you need to take precautions to prevent scratching them. You can use a bit of masking tape on two sides of the ocular to provide a soft cushion for your glasses. Some microscopes will be equipped with rubber caps that protect glasses. The rubber or plastic extensions that fit around your eyes generally get in the way when you wear glasses.

Dissecting Microscope

In addition to the compound microscope (the one you will use with slides), you will also be using a **dissecting** microscope (microscope with low stage and long focal distance that permits you to dissect an object while viewing). That gives you a large viewing and working space that permits you to work with larger objects that you can dissect while viewing them.

The principles of the dissecting microscope are the same as those for the compound microscope, but this microscope will always have two oculars, and lighting will usually be from above, giving you reflected light. Some microscopes have a light in the base, but I (Glime) find these uncomfortable to work with because they make the stage high (Figure 8) and I cannot rest my hands on the lab bench.

Figure 8. Dissecting microscope with two foam pads and a cork board to permit moving the stage up and down while still working. Photo by David H. Wagner.

Self-focusing Foam Stage for a Dissecting Microscope

David Wagner offers suggestions for working with a dissecting microscope when your plane of focus keeps changing. This can be a problem when searching for propagules or reproductive structures and when sorting for the interesting invertebrate fauna. When you move one hand to the focusing knob, it is easy to lose track of the object of interest. He has created his own vertically movable stage. A foam pad can help (

There are foot-controlled, electric focusing stages, but these are very expensive. Wagner's solution is to place a stack of foam pads such as artificial sponges (must be soft when dry) on the stage of the dissecting microscope and placing a cork board on top to provide a solid surface (Figure 8). Set the focus of the microscope to the surface of the cork board. The specimen will be above this, so you can focus on any part of a specimen by pressing down on the board with the heels of your hand without setting down your tools. It is also easy to tip a specimen from side to side while keeping a particular point of interest in view and in focus (Figure 9), even with magnification set at the highest level. With this system, one seldom needs to touch the focusing knob after the initial focus. Glime thinks you might want to add sponges, pillows, or a box on each side of the stage so that you have something on which to rest

your hands and forearms. They would be steadier that way, and it would be less tiring. Hence, for that reason Glime prefers a microscope that has a low stage. A lower bench or higher seat might help make you more comfortable.

Figure 9. Dissecting microscope showing the ability to tilt a stage with two foam pads and a cork board. Photo by David H. Wagner.

Summary of Microscope Care

1. Always carry the microscope with **two hands**. Do not attempt to carry anything else at the same time.
2. Avoid touching the lenses with your fingers.
3. Always start your examination of a specimen with the **low power objective**. Rotate the nosepiece to a higher objective if greater magnification is desired.
4. **Focus away** from the specimen. Lower the objective only when you are watching from the side.
5. Keep **both eyes open** during microscope use.
6. Remember to keep the **condenser slightly below its highest position** and to adjust the **iris diaphragm** to achieve the best possible image.
7. **Never focus down** with the coarse adjustment when the high power or oil immersion objectives are in place.
8. Use **oil immersion** whenever the numerical aperture marked on an objective is greater than 1.00.
9. Clean the lenses with **lens tissue** and **water** or **saliva** only. Avoid cleaning with powerful solvents like acetone or xylene.
10. When you are done, **rotate the low power objective** into position and **remove the slide**. Turn off the light source and cover the microscope.

Microscope Light Sources

A compound microscope typically has a tungsten light source in its base. This usually causes the image to have a reddish cast, so it is desirable to place a **blue filter** under the condenser or over the light to balance the light. For the dissecting microscope, an even white light makes the best viewing. There are a number of choices for these lights.

For reflected light, I (Glime) have used a dual gooseneck fiber optic light (Figure 10). This provides bright, good quality light and avoids heat of tungsten bulbs, although some of the new LED lights are probably better. Most of them can be focused and the size of the light circle can be adjusted by changing the distance and focus.

Figure 10. Dual gooseneck fiber optic lights. Photo from online advertising.

Regular tungsten microscope lights are hot and are a nuisance to replace when they burn out. **LED lights** last much longer and are cooler. Wagner has marvelled over the amazing products appearing on the market. He has been especially impressed with the intensity of lights now marketed as headlamps for bicyclists. These are intended to be mounted on handlebars or the top of helmets. They are bright enough to serve as truly effective headlights, almost as bright as those for automobiles.

These lights are somewhat expensive, but cost less than a ringlight flash. The 250 lumen Cygolite (Figure 11) is US \$130. Some models in cycling stores have up to a 400 lumen rating, costing about a dollar per lumen. Eventually, as production volume increases, costs should come down.

Figure 11. LED light source for lab or field. Photo by David H. Wagner.

These headlamps are compact (10 cm long, 4 cm diameter) with a rechargeable battery that plugs into either a wall receptacle or a computer's USB port. The latter is very useful because it means you can recharge it on a bench without looking for the wall outlet. Once charged, you can move it from dissecting scope to compound scope easily because no wires tether it (Figure 12). The batteries are rated to have a five-hour working time per charge, making the light useful for extended field work. The light can be directed on a colony of bryophytes in a dark forest. Having a steady light source, an image can be composed in a way not possible with a flash.

Figure 12. LED light source mounted for use with a microscope. Photo by David H. Wagner.

Zander (2006) suggests using a unit with three 1-watt Luxeonwarm-white LED's, which he has attached to his dissecting microscope with duck tape (Figure 13-Figure 16).

Figure 13. Triple 1-watt Luxeonwarm-white LED unit mounted on dissecting microscope with duck tape. Photo by Richard Zander.

When the LED light is bright enough to be mounted some distance from an object, the light doesn't cause the glare of fiber optic sources, yet is as cool as fiber optic

sources. It is useful in adding **reflected light** to images made with a compound microscope, thanks to stacking software. Compare the two images of *Jungermannia atrovirens* androecia (Figure 14), one with transmitted light and the second supplemented by reflected light from an LED headlamp.

Figure 14. Comparison of light sources for microscopy. Note pasted-in scalebars. **Upper:** transmitted light. **Lower:** transmitted + reflected light. Photos by David H. Wagner.

Figure 15. This unit provides an even, warm white light spread over the base of the microscope. Photo by Richard Zander.

Figure 16. The three items needed to provide this LED light system. Photo by Richard Zander.

Three items are needed (Figure 16):

W-15-12 UpLight Power Supply

MR16/MR11 Socket - GX5.3/G40

MR16-WLX3 Warm White LED bulb - Medium 30°

These are available for about US \$51 from:

Super Bright LEDs, Inc.

100 Washington St.

Florissant, MO 63031

314-972-6200

<<http://www.superbrightleds.com/cgi-bin/store/commerce.cgi?product=MR16>>

To set up your light, cut the connector off the end of the line that comes from the transformer. Stuff the copper wires into the holes in the base of the socket, and affix them there with a little duck tape. Plug the transformer into a multi-plug extension cord and use the on-off switch of the extension cord to turn the lamp on and off. For more concentrated light, a narrow-beam 10° bulb is also available.

Differential Interference

Interference microscopy was somewhat popular in the decades from 1940 to 1970. But its complicated design and use caused it to fall into disuse as better microscopes were developed. Its basic principle was to shine two separate beams of light, providing much greater lateral separation than that used in phase contrast microscopy. Gabrys (1978) used it to determine the refractive index of the cell wall of the moss *Funaria hygrometrica*, demonstrating that for both *F. hygrometrica* and the tracheophyte *Lemna trisulca*, the mean refractive index was in the range of 1.41-1.42.

DIC microscopy is one possible way to improve the images. DIC stands for differential interference contrast microscopy and is also known as **Nomarski interference contrast** (NIC) or Nomarski microscopy. This technique enhances contrast in unstained, transparent biological materials. It is the lighting scheme that produces the image, similar to that of phase contrast microscopy, but without producing the diffraction halo that detracts from the latter. This technique has been used for many of the images in the illustrated dictionary produced by Bill and Nancy Malcolm (2006) and in the book *California Mosses* by Malcolm *et al.* (2009).

Ha'penny Optics

Bill and Nancy Malcolm (Bryonet 18 August 2012) have created beautiful images in their well-known *Mosses and Other Bryophytes, an Illustrated Glossary* (second edition). They suggest that to be able to see the delicate details of bryophytes you need differential interference optics. This permits even a transparent specimen to cast a shadow, making it visible (Figure 17). Cheaper microscopes do not have this system, and microscopes from North America and Europe are much more expensive. To solve this cost problem, the Malcolm's recommend a technique called **ha'penny optics**.

Figure 17. *Fissidens pusillus* showing differences in detail in light microscopy (left) and **ha'penny microscopy** (right). Photos by Bill and Nancy Malcolm.

Ha'penny optics cost only about half a cent, hence the name. The Malcolm's suggest placing a whole mount of a moss or liverwort leaf on your microscope and focusing it under the 40X objective. They slide a memo-sized piece of opaque paper across the underside of the condenser lens. When the edge of the paper reaches the midpoint of the condenser lens, the specimen will appear to be lighted from only one side, with the other side appearing to be in a strong shadow. This creates a 3-d look, revealing the structure of the leaf in excellent detail. This technique, if effective on your microscope, is especially useful for leaf margins, cell walls, papillae, and other textural surfaces. Although this technique works better on some microscopes, it will at least improve the effects on most microscopes. If sliding the paper across the condenser doesn't work, then try sliding it across the light source in the base. The effect is usually best with the diaphragm wide open, but experiment with closing it down slightly. Note that some microscopes have a diaphragm on the condenser and another on the light source.

If this technique works for you, you can make a more permanent **ha'penny** shadow source that is easier to use:

1. **Measure** the diameter of the condenser lens of the microscope (or light source if it works better).
2. Draw a **circle** of the same diameter onto a piece of stiff black paper or stiff plastic (Figure 18).
3. Inside that circle, draw a **second circle** that has a diameter 20 mm less, *i.e.*, making a doughnut 10 mm thick.

4. If the underside of the condenser is curved where it attaches to its mount, a circular doughnut won't lie flat. That can sometimes be solved by making the shape be **D** instead of **O** (Figure 18).

Figure 18. Ha'penny differential interference paper of Malcolm and Malcolm. **Left:** O-shaped interference for flat lenses. **Right:** D-shaped interference that may work better on curved lenses. Drawing by Janice Glime.

5. Cut the **O** or **D** using a sharp utility knife or single-edged razor blade.
6. Make a movable **lever** (Figure 19), using the same plastic or black paper, roughly 160 x 20 mm that will partially block the light reaching your specimen.

Figure 19. Ha'penny differential interference paper of Malcolm and Malcolm with lever attached. Drawing by Janice Glime.

7. Use a small **eyelet** to hinge the wide end of the lever to the rim of the doughnut (**O** or **D**).
8. Place the apparatus on the light or condenser with the lever on the upper side of the doughnut so that the edge of the lever is approximately at the center of the doughnut when in use, but it must be possible to pull the **lever** completely out of the light path when you don't need its interference. If you are right-handed, you will probably want the lever to be pointing toward the right.
9. **Tape** the doughnut firmly to the condenser or light with the lever on the upper side of the doughnut. Tape the doughnut in three places, making sure the tape does not interfere with the movement of the lever.

Polarized Light

Polarized light can sometimes make certain structures more visible (Amann 1923, 1931; Kolvoort 1966; Nordhorn-Richter 1988). It requires a special microscope with the right optical system and filters.

Plane polarized light can be used to see lignin and lignin-like compounds in vascular tissue and various other tissues where crystalline structure is suitable. Brilliant colors result from the lignin crystals in the cell walls, where the crystals bend the light rays to give the effect you see.

In bryophytes, this might be a tool to find lignin-like compounds in cell walls. The effect is much like a psychedelic panorama. In tracheophytes the lignin occurs between cells such as parenchyma cells and in the secondary walls of sclerenchyma cells. You can see these bright colors in the xylem, but the phloem and cortex cells will be pale or even disappear under plane polarized light. These bright colors are only seen easily in the cross sections of the stem (Figure 20). Certain dyes might also make tissues become visible in plant polarized light.

Figure 20. *Fargesia* sp. (bamboo) stem cross section in polarized light. Photo by Eckhard Völcker through Flickr.

Polarized light can tell us about the structure of bryophyte cells. That structure cannot be seen directly, but the presence and direction of crystalline structures can be determined by their response to polarized light (Taylor 1959). They can be seen only when examined in a direction perpendicular to their length, becoming dark (invisible) when viewed in the same direction as their length. For example, the crystals can be seen as brilliant colors in xylem when the stem is viewed in cross section, but not when viewed in longitudinal section.

Leaf Borders and Costae

Adams (2009) has devised a cheap Polaroid system for observing the border and costa of moss leaves. For example, in *Fissidens*, it makes it easier to see if the costa joins the border at the tip of the leaf. In this case, and others, the moss cell walls have a regular crystalline nature with the cellulose fibers stacked so tightly and in precisely oriented parallel arrays that they rotate plane polarized light. But when the fibers are dispersed in an amorphous hemicellulose matrix, this effect is minimized.

Adams (2009) recommends making **two Polaroid lenses** from a pair of cheap Polaroid sunglasses. These can be cut to fit the filter holder just beneath the substage condenser and to fit the eyepiece lens. If the eyepiece lens

is cut larger than the lens, it can be taped on its edges to the ocular. The ocular can then be rotated to block the light (when the gel alignment of the two lenses is perpendicular) and only the properly aligned cell walls will be visible, *i.e.* the border and costa.

Fluorescence

Fluorescence is most widely understood in mosses in chlorophyll fluorescence (Figure 21-Figure 22) (*e.g.* Shi *et al.* 1992; Deltoro *et al.* 1998; Proctor & Smirnov 2000; Smith 2002; Heber *et al.* 2006; de Carvalho *et al.* 2011). **Fluorescence** is the emission of light from a substance while it is irradiated by light energy (Nordhorn-Richter 1988). Such cell parts as carotenoids, chlorophyll, and phenolic compounds have the necessary conjugated double bonds to cause fluorescence. In addition to these familiar sources of fluorescence, other fluorescing substances include proteins, flavonoids, oils, and waxes. Fluorochromes can combine with specific cell compounds, making it possible to see very small structures with a microscope because these combinations produce secondary fluorescence.

Figure 21. *Fontinalis squamosa* protonema using tungsten microscope light with blue filter. Photo by Janice Glime.

Figure 22. *Fontinalis squamosa* protonema using fluorescence microscopy and UV light source. Note that the chlorophyll fluoresces red. Photo by Janice Glime.

To view fluorescence, a fluorescence microscope is needed, equipped with a UV light source. An excitation filter (BP 350-410 or BP 450-490) is needed to absorb all wavelengths except the violet light at 350-410 nm or blue

light at 450-490 nm wavelengths (Nordhorn-Richter 1988). The microscope has a light-splitting mirror, which combined with the filtering system provides a light that permits observation and photography of structures that meet the chemical requirements.

When electrons absorb energy, they are elevated to a higher energy level. This is an unstable state that lasts for only about 10^{-15} seconds, during which they emit light as fluorescence (Nordhorn-Richter 1988). For fluorescence to be visible, the substance must be illuminated with UV light or blue light and the fluorescence is seen as yellow, orange, or red. The reaction requires that the energy content of the radiation source corresponds with the energy conditions of the electrons of the excited substance, requiring a broad spectrum of light energy so that the needed wavelength is present.

Details on applications of fluorescence microscopy are in Chapter 2-2 of this volume.

Dark Field Microscopy

Dark field microscopy takes advantage of the differences in light patterns between the specimen and the blank portion of the slide (Figure 23). The specimen will scatter light, whereas the area with no specimen will transmit the light with no scatter. Dark field microscopy uses ? to exclude the part of the image that does not scatter

light. That is, it blocks light from anywhere but the specimen. The result is a greater contrast for the specimen.

Figure 23. Dark field microscopy setup. Illustration modified from Wikimedia Creative Commons.

Phase Contrast Microscopy

The technique of phase contrast microscopy converts phase shifts by the light passing through a somewhat transparent specimen to make changes in the brightness of the image reaching the eye (or camera) (Figure 24).

Figure 24. Comparison of microscopical techniques of *Anthelia juratzkana*. **Left:** light microscopy. **Middle:** phase contrast microscopy. **Right:** dark field microscopy.

Small Equipment

Microforceps

Examining a bryophyte in the lab usually begins with a dissecting microscope and a pair of forceps. And that begins an adventure!

Forceps permit one to widen the spaces between the plants, sometimes revealing an interesting arthropod or gastropod fauna. Rhizoids, gemmae, and other propagules become visible. And it is possible to grasp a single leaf and remove it. **Microforceps** are essential for removing leaves or teasing out tiny liverworts. Standard lab forceps simply are too big.

Do you have leg scars because your forceps fell from your hands and landed point down (Bill Buck, David H. Wagner, Bryonet 5 January 2012)? Some are so expensive that the risk of scars is preferable to buying a new pair. The microforceps, also known as watchmaker forceps, seem to range in price from US \$14.95 for a set of 5 on Amazon to US \$295.00 from an electron microscopy supply company. But why so costly? Bryophyte parts are tiny. Ordinary lab forceps are much too broad to clasp a single leaf. Hence, one needs those fine-pointed forceps used by jewelers and watchmakers (Figure 25). And those hurt both your vulnerable legs and your pocketbook.

Figure 25. Typical steel microforceps used for work with bryophytes. Photo by Janice Glime.

Prices of US \$20-40 are more common for microforceps like the ones in Figure 25. Carolina Biological Supply has extra fine microforceps for US \$10.05 (like those in Figure 26-Figure 27). Terry McIntosh (Bryonet 13 May 2010) has found durable steel needle-nose forceps at Canadian \$1.00 each that work just as well as the expensive ones. These are available at a liquidator place (Midland Liquidators) in Vancouver, Canada. I (Glime) also have found that the cheap ones work as well as the expensive ones, and last as long. The only problem with some forceps, especially for larger male hands, is that these tend to be a bit shorter, giving large hands less control. I (Glime) have used these in botany and bryology labs – they withstood student use.

Figure 26. These forceps are inexpensive but work well. Photo by Janice Glime.

Figure 27. Forceps with points (and people) protected by a short piece of tubing. Photo by Janice Glime.

Bryonettors (January 2012) discussed the pros and cons of a variety of forceps. Wagner recommends BioQuip #4524 for around \$20. Charles Epsey (Bryonet 3 January 2012) and Guy Brassard (Bryonet 3 January 2012) recommend **Dumont** (style 3) in Switzerland for superfine, precisely aligned tips at a reasonable price. I have to agree with the assessment of affordable good quality of the Dumont forceps. They are available at <http://www.finescience.com/Special-Pages/Products.aspx?ProductId=306&CategoryId=29> or <http://www.dumonttweezers.com/>. Richard Zander (Bryonet 3 January 2012) recommends forceps from Micro-Mark. Carl Wishner (Bryonet 3 January 2012) finds ultra-fine and microfine forceps at Fry's Electronics (ER0P5SA stainless, anti magnetic, anti-acid).

Some forceps are "stiff." There is little that can be done, and don't spread your good forceps because they too will become stiff. Once you find a brand you like, stick with it.

For students, cheaper versions of microforceps are sufficient for short-term use, especially if you are supplying them for their use. I recommend keeping one pair of curved microforceps (Figure 25). There are some leaves that are easier to grab with these, and they are good for holding a stem firm with one hand while the other does the pulling. They are also good for removing debris or small arthropods from among the bryophyte stems.

René Schumacker (Bryonet 9 July 2008) suggests also searching for watchmaker tweezers (numbers 4 or 5). Richard Zander and others (Bryonet 8 July 2008) suggest Micromark <http://www.micromark.com/> as a source for inexpensive fine-tipped forceps.

Forceps will last longer if they are kept in a case. Some come in a clear plastic case with a foam sponge to hold them in place so the points don't get knocked around and damaged, but the hinges break easily and you may want a more permanent solution. Cairns (2013) suggests using a pocket reading glasses case for storage (Figure 28). The case should be cushioned at the end where the points go to avoid damaging them. You can cut the tip from a plastic pipette to protect the tips.

Figure 28. Forceps case using a pocket reading glasses case. Note that the upper pair is protected by the tip cut from a pipette. Photo by David Meagher.

Forceps Repair

The inevitable microforceps dropping is likely to require some repair work. They seem to land naturally on their points, blunting and bending them. I have been able to do reasonable straightening on a pair of those cheap student forceps used for ordinary animal dissection. I find that using a curved pair works best – you can stroke the ends of your microforceps like you are milking a cow.

Keep a fine-grain whetstone for needed sharpening or shortening of one side when they are unequal. One approach for restoring the fineness of the tips is to use a

dissecting microscope and whetstone to file the points down to a finer tip (Brian Heitz, Bryonet 3 January 2012). Carl Wishner (Bryonet 3 January 2012) recommends use of a dissecting scope and microfine or fine file "Washita stone." Wagner claims he can upgrade many poorer quality forceps by working with a fine (or extra fine) diamond jeweler's file under a dissecting microscope, but they do not reach the quality of a good pair of Swiss jeweler forceps. Claudio Delgadillo Moya (Bryonet 5 January 2012) suggests putting a final touch on the forceps with fine-grained sandpaper, working under the dissecting microscope. You can also use fine-grained sandpaper to file them, but a whetstone, albeit a more expensive initial investment, is ultimately cheaper because it is usable for a long time.

Ken Kellman (Bryonet 3 January 2012) has some success in bending forceps back into shape by grabbing both arms of the forceps in fine needle-nose pliers. He then uses a diamond double-sided nail file (emery boards are usually too coarse, but better than nothing), and lightly pinches the forceps around the file and files the inside edges of the forceps (Bryonet 20 March 2023). This tends to get rid of the uneven grip of bent forceps. This even filing of both points simultaneously eliminates the little gaps that prevent you from gripping moss leaves and can even improve cheaper new forceps. File until you can no longer see any gaps under the dissecting microscope.

If your forceps have become bowed, you might want to wrap them in a soft cloth or paper towel to prevent scratches and force them together with pliers. For those broken tips, if possible, file down the longer tip to match the shorter length and file the sides to make the narrow width you need. A whetstone might be needed if the break is very far from the end. Ordinary emery boards will work also, but need to be replaced often.

Although dropped forceps with damaged points can be filed to make them sharp again, if you need to do this often, you soon get to wider and thicker portions that cannot be sharpened adequately. To reduce breakage and bending, store them with a tip protector such as seen in Figure 7.

Microdissecting Needles

Microdissecting tools are often needed with tiny leaves (Deguchi & Matsui 1987), such as those of *Cephaloziella* or *Ephemerum*. I (Glime) learned to make a fine tool from entomologist friends. Such a needle can be made by cutting off the head end of an insect pin, leaving about 2-3 cm at the point end, and embedding the dull end into the end of a wooden matchstick. Cut off the flame end of the matchstick with a pair of pliers and you have a microdissecting needle. A slightly larger point can be made with a sewing needle embedded into the handle in place of the needle part of a cheap lab dissecting needle.

Dropper Bottles

Dropper bottles are used to make slides, but can also be used to moisten a portion of the bryophyte sample without making the entire sample wet or removing a portion of the clump for soaking. This also removes the need to dry the sample again if the moisture is confined to a small portion.

Needle Dropper Bottle

A small, ordinary dropper bottle, even one from the pharmacy, will work for most purposes, but sometimes a smaller drop is desirable, especially if you need to add only a tiny bit of water to the edge of a slide. Wagner (Bryonet 11 May 2010) shared a contribution from one of his students who brought a needle dropper bottle to class (Figure 29). These cost US \$3-4 and are made by Gaunt Industries. They are available directly from that company <http://www.gauntindustries.com/2_Ounce_Products-HYPO_25.html> or from plastics fabrication stores such as Tap Plastics <<http://www.tapplastics.com/shop/product.php?pid=409>> or art supply stores. Those with 23 gauge needles are best. An added advantage is that they don't spill if knocked over.

Figure 29. Needle dropper bottle for wetting mosses or adding water to a slide. Photo by David H. Wagner.

Slides

Slides are pretty standard, so little need be said. Occasionally a **depression slide** may be useful so that the bryophyte can maintain its 3-d relationships. Depression slides may be especially useful for observing the fauna in association with the bryophyte.

Coverslips

Plastic or glass? Plastic is cheap and throw away. But plastic is an oil product, so you are using a non-renewable energy resource. That said, there are other issues that are more important for your viewing pleasure. Glass is less likely to get scratched and has different adhesion properties with water. But thin glass coverslips get dirty and break easily. To clean them, get them wet and lay them on a paper towel. Then rub another part or different paper towel over them while they lie flat on a table. Do not try to wipe them between your fingers. They will break most of the time.

Housing for Coverslips

If you have lots of things on your lab bench, It is easy to overturn the coverslips. Zander (1993) suggests gluing the coverslip box to the base of the microscope or to a tray that holds your tools.

Wagner (Bryonet 2011) prefers to keep his coverslips ready for use on a small **polyurethane foam pad** (Figure 30). A small piece, 5 X 10 cm and .5 to 1 cm thick is all that is needed for two or three coverslips. This arrangement makes them easy to pick up by pressing thumb and finger into the foam on either side of the coverslip (Figure 31). The coverslip is then transferred to forceps for careful placement on the slide. But coverslips can be hard to control with forceps because the glass coverslip is slippery. I prefer to hold the coverslip gently by the edges, then with one edge touching the slide, I lower the opposite edge onto the slide with a dissecting needle (See Chapter 2-2 for diagram).

Figure 30. Polyurethane foam for holding microscope slides. Photo by David H. Wagner.

Figure 31. Demonstration of picking up a coverslip from a foam pad. Photo by David H. Wagner.

Standard microscope slides can be placed on a foam pad the same way as coverslips but Wagner prefers to keep them flat on the lab bench. This prevents the drop of water for mounting leaves from getting tipped off. After placing the coverslip on the mount, slip the slide to the edge of the bench to put it on the compound microscope stage. Otherwise, as often as not, the water drop is not added to the slide until it is on the stage of the dissecting microscope and dissections are complete.

Coverslips and Slides in Box

Wagner (Bryonet 2011) keeps his foam pad with coverslips in a wooden box (Figure 32), so that when he's away from the bench for a period of time he can close the lid to keep dust off the coverslips. Cut out a place at one end to store a small stock of coverslips and stack a similar stock of slides at the other end of the box (Figure 33). A reticule for measuring or counting is tucked into a slot in the foam. A fresh razor blade can be stored along the top edge. Wagner's box is not just any old cigar box, it is a box made by a craftsman. It is a way to have an article of beauty on the lab bench, something that can be important to a scientist with an active aesthetic sense.

Figure 32. Storage box used by David H. Wagner for storing slides and coverslips. Photo by David H. Wagner.

Figure 33. Open storage box used by David H. Wagner for storing slides and coverslips. Photo by David H. Wagner.

Other Useful Tools

Annie Martin (Bryonet 13 May 2010) gives us the perspective of an amateur beginner. She tells us that as she entered the world of bryology and started her own closer inspection of mosses, she discovered a couple of "creative"

tools of benefit. First, Paul Davison suggested a **syringe** as a sharp tool for cutting small fragments. She found a package for about \$5 available at a local drug store (but she had to ask the pharmacist to retrieve them from behind the counter).

An idea she claims as her own hillbilly thinking – use a **camping headlight** (cut off the head strap) for a portable light source for microscopes. These head lamps are super bright with several settings, including a spot light. They have a foam backing that keeps them from sliding around on the surface. They actually provide better light than the battery lamps with goosenecks and range in price from US \$5-\$25. The lamps are available in outdoor stores or camping sections of superstores.

Being the daughter of a dentist, Martin found several dental tools with sharp points that work. When you are not affiliated with a university or have access to a research lab, it becomes necessary to find all kinds of creative, cheap solutions.

Photomicrography

Photography has been improving rapidly with the onset of digital cameras (Frahm 2000a, b, 2002) and stacking. But taking pictures through the microscope is still somewhat challenging – and can be expensive to set up. Some suggestions will be discussed here, but more detail will follow later in a chapter on photography in this volume.

There are several ways to get images of microscopic structures: cameras, digital connections to a computer, and scanners.

Scanners

Scanners can sometimes make relatively good images of flat objects and can therefore be used to show larger leaves or whole plants (Figure 34-Figure 35). The only magnification you can get is digital, but it is sometimes adequate when you want to get a quick image at home.

Figure 34. *Plagiomnium* sp. image (drying) from an Epson V500 scanner. Photo by Janice Glime.

Figure 35. *Fissidens* sp. image from an Epson V500 scanner. Photo by Janice Glime.

Experimentation with a scanner demonstrated that one can get reflected images that way, and in the absence of a camera that is able to get close to the subject, it can at least provide a habit image of some bryophytes. But the Epson V500, which is a good flatbed scanner that does an excellent job of transforming 35 mm slides into digital images, is unable to recognize the mosses as an image when using the transmitted light as one would for an image of a 35 mm slide (positive film). I (Glime) was unable to cajole the scanner into making a transmitted light scan of *Fissidens* or *Plagiomnium*. It might be useful for making images of microscope slides of a sufficiently large specimen, or even of larger samples of bryophytes directly on the glass, but that remains to be demonstrated.

Malcolm and Malcolm (2006) describe using a scanner for photographing bryophytes. They recommend using at least **2400 dpi** resolution and then enhancing the image in Photoshop. The white inner lid of the scanner can be replaced with an upside-down tray at least 5 cm deep and spray painted flat black (or some other desirable color), with the spray painting avoiding the brush strokes. Avoid a white background because it can present uneven glares. For light-colored capsules and some bryophytes, use a grey background instead of black to avoid too great a contrast.

The specimen should be well **hydrated**, but not dripping. If condensation occurs, you can warm the platen (glass) of the scanner with a hair dryer. Clean the platen with a cotton cloth between scans to remove dirt, being careful not to scratch it with adhering sand.

Place the specimen upside down on the platen, using one of the upper corners. This will give the appearance of light coming from one side as it would in nature. You might want to test the scanner with a uniform, highly detailed color pattern that covers the platen. That will tell you if the scanner has "sour" areas that do not focus well or render colors well.

Choose **reflective** mode on the scanner and select an area slightly larger than the specimen. Use 100% scale (**original**). **Turn off** sharpening and compression and do all manipulating in Photoshop. The gamma should be set at 1.8.

To improve the image clarity and contrast in Photoshop, experiment using **LEVELS** (and select **PREVIEW**). Adjust colors as needed and sharpen last. Keep your original completed image as a TIFF or PICT file and make a copy before changing to jpg or other lower resolution format. The 2400 dpi resolution will permit you to crop your image while retaining sufficient detail.

Cameras

Michael Lüth (pers. comm.) recommended a Nikon Coolpix 990. This camera can be placed directly onto the ocular of the microscope. A wide field ocular is best to avoid having a circular image. This camera lens is the right size to fit well and exclude stray light. You can look directly at the camera screen to see the microscope image. The camera can be used on both compound and dissecting microscopes, as well as being a general-use camera for close-ups or scenery shots. For both types of microscopes, a third lens dedicated to the camera works best because it is level. It is often necessary to do some adjusting to make its focal plane match that of the other two oculars. But since it

is relatively easy to see the image with the camera, focusing can be done using the camera view.

Many microscopes now are being sold with a digital ocular that connects directly with the computer. Usually you can view the image on the computer screen, making focusing easy. Some of these have excellent quality, but some have very poor quality, being very pixilated due to low resolution. Don't order one unless you can see what it is capable of doing.

If you already have a camera tube on your microscope, or even the right diameter normal ocular, you can make the connection to your computer with an inexpensive attachment such as the one by GeckOOptics (Figure 36-Figure 37) for Australian \$125. The included software package allows you to view, save, and edit images.

Figure 36. Computer screen with USB hookup to microscope. Photo by GeckOOptical. PERMISSION PENDING

Figure 37. USB attachment for microscope from GeckOOptical. Photo by GeckOOptical. PERMISSION PENDING.

Scalebar

For demonstrations of cellular structures or spores, size is important. Hence, providing a scale with the image is important. Rod Seppelt (Bryonet 14 April 2010) suggested taking a picture of a stage micrometer (special microscope slide with a microscopic scale). This should be done for all magnifications that you are likely to use. The image could then be included beside or within all pictures you take at each magnification to provide a reliable scale or even super-imposed on the picture as a scale bar. This can be accomplished with Photoshop or similar program. Once the scale is attached to the original image, the image size can be changed and the scale will change with it. Be sure to label the length of the scale bar on the picture.

An alternative to the Photoshop cut-and-paste approach, suggested by Andrew Spink (Bryonet 16 April 2010) is to use the free software **Combine ZP** <<http://www.hadleyweb.pwp.blueyonder.co.uk/CZP/Installation.htm>>. If you know the actual distance between two points on the photo, this program can add a scale bar (Figure 38). This same program is designed to stack several photos taken at slightly different focus, but it also permits this ability to stack a scale bar.

Figure 38. *Lophocolea heterophylla* with scale bar added using Combine ZP. Photo by Andrew Spink.

Inserting Scales into Images Using Photoshop

David Wagner provides us with a means of making a set of scales to use for various magnifications.

In Photoshop, open three files:

1. page with scales (Figure 39)
2. subject
3. image of stage micrometer at same magnification as subject. (Wagner photographs a stage micrometer at every photo session, at all the magnifications used in that session.)

Figure 39. Scalebars that can be used to label microscope images. Provided by David H. Wagner.

4. Bring file #1 (Figure 39) to the top and select the appropriate scale. (The top one, 100 µm, Wagner uses only with the highest magnification (40X objective), middle ones for 10X objective, and bottom ones for 4X and multi-image mosaics.)
5. Copy the selected scale to the clipboard.
6. Bring file #3 to the top and paste the copied scale onto the micrometer image. (see Picture 1, attached).
7. Use the move tool (in Photoshop CS3 you need also to set the move tool with Edit/Transform/Scale) to adjust the scale to the micrometer.
8. Flatten layers (Layer menu).
9. Select the calibrated scale and paste it onto the subject image (Figure 40). NEVER resize images before the calibrated scale is pasted in!

Figure 40. *Phaeoceros oreganus* spores with image stacking and added scalebar (from Photoshop) using both transmitted and reflected light. Photo by David H. Wagner.

Stacking

Manual stacking, using Photoshop, is also possible, albeit more time-consuming. Stacking in photography is the process of taking multiple images of the same subject, each at a slightly different focus. Software such as Combine ZP is used to put the images together, using the best focus portions of each to make a combined image with outstanding depth of field (Figure 41-Figure 42). This approach is also known as **deep focus** (David H. Wagner, Bryonet 19 April 2010).

Figure 41. Gemma cup of *Marchantia polymorpha* showing all gemmae in focus, a result of stacking 8 images in Photoshop. Note that the 1 mm text is hidden by the dark background. Text on a dark background should be in white or black framed in a white box. Photo by David H. Wagner.

Figure 42. *Phaeoceros pearsonii* spores with image stacking and scalebar, using both transmitted and reflected light. Photo by David H. Wagner.

In creating the images in Figure 41-Figure 42, David H. Wagner (Bryonet 16 April 2010) used this stacking technique to create greater focus for the image of *Marchantia polymorpha* gemmae (Figure 41). This image was created from a stack of eight images, adding one image at a time. The spore image in Figure 42 used stacking with both transmitted and reflected light to make the details clearer.

Norbert Stapper demonstrates the use of stacking to photograph leaves and other parts of a moss under the microscope (Figure 43-Figure 44). He likewise used Combine Z.

Figure 43. Stacked images, using Combine Z, of *Orthotrichum patens*. Photos by Norbert Stapper, with permission.

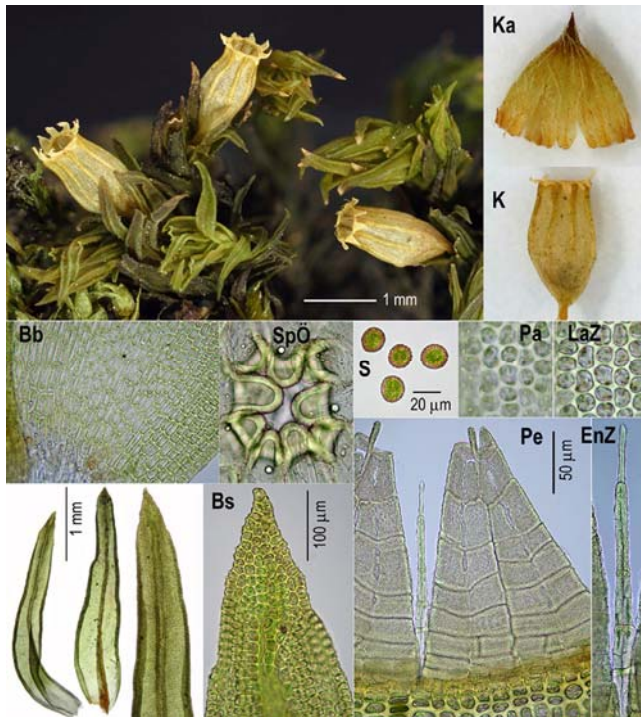

Figure 44. Stacked images, using Combine Z, of *Orthotrichum pulchellum*. Photos by Norbert Stapper.

Standardizing Focus Increments For Image Stacking Photomicrography

Stacking software has reached widespread use in bryology because it makes it possible to greatly increase the depth of field for these small objects. Its principle is to take a series of images, each at a slightly greater focal distance. These are combined using the best focus areas of each with software such as Z or built-in software in the

Olympus Tough camera. Objects such as bryophyte shoots photographed in reflected light with the clear focus of stacking have a three-dimensional appearance that can be very beautiful. This set of instructions is only slightly modified from those of Wagner on Bryonet (19 April 2010).

The stacking software works best if photos are taken in evenly graduated, overlapping focal planes. When the overlap is optimal, usually about 25%, neither too many nor too few pictures need be taken. Precise, expensive equipment is available that performs this process automatically. But obtaining excellent results by careful manual focusing is easily managed. Wagner has installed a handmade metering dial on his microscope that has served well in this regard.

Draw a **circle** on a card and divide it into **10°** segments using a protractor (Figure 45). Draw in the **radii** for each segment (Figure 46). There is nothing special about 10°; it is simply convenient and easy to see for this process.

Cut out the center of this dial, using a hole diameter that will fit around the fine focus knob on one side of the microscope (Figure 46).

Figure 45. Protractor Photo by David H. Wagner.

Figure 46. Card with 10° increments of radii. Photo by David H. Wagner.

Trim the card to fit and tape it to the microscope so that the fine focus knob is centered in the middle of the card's dial (Figure 47). Attach a "needle" firmly to the center of the focusing knob, so that the needle reaches to the edge of the dial. Wagner has used artist's putty to

attach it and for a needle has used a piece of black binding tie that comes with power cords. Plastiline modeling clay and a toothpick or bobby pin would work about as well.

Figure 47. Stacking radii taped to microscope. Photo by David H. Wagner.

Mount a mirror in such a way that the needle and dial are visible as you use the microscope (Figure 48). Although this is not essential, it helps to be able to monitor the view through the microscope, adjusting focus with one hand while taking photographs with the camera's remote shutter release in the other hand.

Figure 48. Mirror mounted so that needle and dial are visible while using the microscope. Photo by David H. Wagner.

For any particular object, first determine how many turns around the dial are necessary for a complete series of images. Focus on the top of the object and note where the needle is on the dial. Then focus down to the lowest focal plane you want to capture to determine the number of revolutions needed. For most slide-mounted objects it usually requires 1-3 complete revolutions around the dial to focus from top to bottom (near to far) focal planes.

Experimentation is necessary to use this system effectively. Wagner has found that with a Nikon Eclipse

E200 microscope and a Nikon Coolpix camera, focus levels that work well are:

4X objective: 6 increments of the dial per image

10X objective: 2 increments of the dial per image

40X objective: 0.5 increments, or even better is to take three images per increment. (Oil-bodies in liverwort cells come into and out of focus with very slight touches of the fine focus knob.)

Practice is needed for consistent results. These guidelines provide about 25% image overlap, which works well with Helicon Focus. Maximum resolution settings on the camera help the stacking program to work optimally.

Once the object is properly staged, keep an eye on the dial and an ear on the shutter sounds. Turn the knob for the pre-determined number of increments with one hand on the fine focus knob, then activate the shutter release with other hand, turn the focus to the next stop, push the shutter release, *etc.*, until you have completed the number of revolutions of the needle on the dial to make a complete set of images from top focus to bottom focus.

For most bryophyte images, 10-30 images are likely to be adequate. Nothing is lost by taking extra images, and some are likely to be discarded. The useful ones are exported to a stacking program such as Combine Z. Once the stacking is completed, you can use Photoshop or other image management software to clean up debris, resize, sharpen, or whatever is needed.

Culture and Viewing Chamber

Paul Davison (2006; pers. comm. 22 February 2012; Davison & Kittle 2004) has made a viewing/photography cell that is useful for viewing aquatic bryophytes and bryophyte inhabitants (Figure 49-Figure 51). This uses two microscope slides with a spacer (foam) between them, temporarily bound together by vice or binder clips. The spacer must leave enough marginal space to squirt silicone between the panes as a sealant. Once the silicone sets, remove the spacer.

Figure 49. Method for constructing a microchamber for observing bryophytes and small invertebrates. This chamber can be used for projecting the images on a screen for teaching purposes. Modified from Davison 2006.

Figure 51. Occupied microchamber (with invertebrates and moss). Image modified from Davison 2006.

Summary

Adjust your microscope for the best possible viewing by adjusting the ocular distance and parfocals. Keep frequently used equipment at the microscope desk in a place that is easy to reach. Protect equipment such as microforceps against damage and sharpen tools as needed. Use a scalebar with the microscope and be sure that images have a scale reference.

Put small inhabitants into small chambers to minimize movement for photography. Use stacking equipment and software for the best images.

CHAPTER 2-2a

LAB TECHNIQUES:

SLIDE PREPARATION AND STAINS

Figure 1. *Polytrichum juniperinum* leaf cross section using a cryostat and displaying natural colors. Photo courtesy of John Hribljan.

Preparing the Specimen

Fresh specimens are the most fun to work with. They are bright green and require little or no hydration before placing them in a drop of water on a slide. Chloroplasts migrate in cyclosis. And tiny invertebrates crawl about to entertain and distract you. But most often we don't have the pleasure to observe fresh material under the microscope. Instead, we have dry, often brittle, specimens collected in great numbers in a day-long or even months-long collecting trip. But don't dismay – the bryophytes will still freshen up to make good slides.

Cleaning Bryophytes

Washing Machine (Jewett 1913)

Jewett (1913) suggests a small "washing machine." The bryophytes are placed on a fine screen – we assume that cloth window screening would work – and sprayed with a nozzle to clean them.

Embroidery Hoop (Mayfield *et al.* 1983)

Mayfield *et al.* (1983) suggested a similar cleaning procedure using a net, but they suggested placing the netting (mosquito or bridal veil netting) tightly in an **embroidery hoop**. This is particularly useful for thallose liverworts. They should be collected with ~3 mm substrate to protect rhizoids and scales. The liverworts are placed on

the hoop netting with a second net placed over them. They are then washed with a stream of water. This may take some practice because too much water will damage the plants whereas a weak stream will not succeed in removing the soil and debris. Mayfield and coworkers suggest that a suitable stream of water can be achieved by attaching an eyedropper to pliable tubing. If the tubing is connected to a tapered laboratory water faucet, water flow can be adequately controlled. Specimens can then be pressed suitably in a telephone book, using folded waxed paper to hold the specimens between the pages of the book. Dried specimens are affixed to a 2x5" (5x12.5 cm) card with water-soluble glue. Specimens can be rehydrated when needed with boiling water. Contemporary workers discourage pressing or gluing specimens.

Wash Bottle (Wagner 2011)

Wagner (2011) suggests having a small **wash bottle** (125 ml) for rinsing the bryophytes and cleaning slides and coverslips for reuse (Figure 2). The water can also be used to wash away the wetting agent. The same ability of a wetting agent (see below) to reduce trapped bubbles also causes the water drop on your slide to lose its cohesion and adhesion, causing the water drop to run all over the place, so start with a small drop.

Figure 2. Water bottle and ceramic washing cup. David Wagner says he likes "to use a pretty, wood-fired stoneware cup, much more pleasing to the eye than the usual beaker." Photo by David Wagner.

HCl (Zander 1993)

Zander (1993) suggests using dilute HCl to clean away limy incrustations. It can also indicate whether the collection was made from a calcareous habitat because, if it is calcareous and bits are present with the sample, it will produce bubbles.

Ultrasound

Jan-Peter Frahm (Bryonet 11 December 2013) suggested using a sonicator to clean bryophytes before making slides, especially when they are used for photography. The bryophyte can be suspended by forceps into the vibrating bath. These are available for cleaning jewelry and watches in small sizes at relatively inexpensive prices. I tried this for cleaning *Fontinalis*, but it disrupted the cell contents without dislodging adhering diatoms like *Cocconeis* (Figure 3-Figure 4). On the other hand, Randal Mindell (pers. comm. 2 January 2022) successfully cleaned ~24,000-year-old bryophyte subfossils.

It might be helpful to add a cleaning agent to the water to facilitate removal. Rod Seppelt (Bryonet 11 December 2013) suggests Tween 80 as a detergent. He dilutes it (lots) with water to clean capillary ink pens.

Aquatic Bryophytes (Landry 1973)

Aquatic bryophytes can be particularly challenging. They typically are covered with epiphytes, some of which (e.g., the diatom *Cocconeis*; Figure 3-Figure 4) embed themselves into the surfaces of the leaves. Landry (1973) experimented with various cleaning techniques on *Fontinalis* (Figure 5). He found that household bleach,

diluted to 0.5%, causes no chlorophyll bleaching, but at 0.10% bleaching appeared in 15 seconds. Solutions diluted to 0.25% caused bleaching in 5 seconds. Bleaching in these cases occurred in the lower (older) leaves and may have been tied to senescence. Unfortunately, these methods did not appear to remove the epiphytes. Ultimately, 5 minutes cleaning with 3% peroxide (H_2O_2) and agitation seemed to remove approximately 85-90% of the epiphytes (Figure 5). Tumbling the moss at 30 revolutions per minute still only removed only about 85% of the epiphytes. Swirling improved the removal. Higher concentrations of peroxide and/or longer time periods caused bleaching of the chlorophyll.

Figure 5. Experiment on cleaning *Fontinalis* sp. with household hydrogen peroxide at various concentrations. Note the bleaching at 70 and 80%. Photo by Janice Glime.

Dealing with Old Specimens

Old samples can be brittle and fragile. Placing them in water to soak can further degrade them so that they fall apart when cut. Adam Hoelzer (Bryonet 11 January 2016) takes from an old sample a single branch and puts it on a slide in a drop of water without soaking. Even if the branch is flattened from storage in a packet, that is helpful. Under a stereo microscope, Hoelzer keeps the branch affixed with his left index finger in position in the drop of water and cuts thin slices of the branch with a single-edged razor blade. You need some experience but that is the quickest and easiest way. Do not soak the parts as they get very soft. There is no need of using *Sambucus* or anything else to hold the moss. After cutting you can heat the sections carefully for swelling for a very short time with the help of a very small amount of KOH under the cover slip.

Sorting the Plants

A classic mistake in identifying bryophytes is looking at the sporophyte of one species and the leaves of another. Sporophytes often originate deep in the clump and may actually belong to a species that achieved sufficient dominance in a previous year to produce a capsule. But another species can easily encroach or simply intermix enough to confuse the unwary. Be sure to track the sporophyte down and locate its attached gametophyte. You might find it belongs to a small pleurocarpous moss that is weaving in and out among your acrocarpous cushion. This sorting should be done with bryophytes that are moist enough to be soft, but not soaked. Dry mosses are likely to break before you can pull the gametophyte out from among its trappings.

Wetting Agents

Assuming your specimens have not been collected in the same day and have gotten dry and brittle, the first step is to re-wet them before attempting to make a slide or even examine them with the dissecting microscope. Dry bryophytes are often brittle and will break easily if you begin manipulating them without wetting them first. However you wet them, we recommend watching them with a dissecting microscope as the water moves through the capillary spaces among the stems. It is a fascinating display and is sure to grab the attention of first-time viewers such as students.

Most bryophytes will wet up adequately by dipping them in water or dropping water or misting on the desired portion of the sample. Once the specimen has regained its wet shape and is pliable, leaves can be removed by holding the tips of the stems with a pair of forceps (can be ordinary lab forceps if the specimen is not tiny) or a dissecting needle (probe) and a second pair of microforceps should be used to pull down on the desired leaf, being careful to hold the leaf in a position close to the stem to get as much of its base as possible. For smaller species, curved microforceps often work best for holding the stems.

But some mosses simply don't wet well. In fact, some bryophytes repel water and may even trap large air bubbles that further keep them from getting wet. Members of the **Mniaceae** (Figure 6) are notorious for this, and **Polytrichaceae** (Figure 7) can be contrary as well if water

cannot reach the leaf bases easily. In particular, wetting agents help to avoid the air bubbles trapped in leaf folds by reducing or eliminating the surface tension of the water. Warm water can sometimes actually increase the bubbles. Soap is a wetting agent, and it doesn't take much. One drop in your dropper bottle is likely to be more than needed. But beware, soap and the other wetting agents, as well as heating, will usually kill the bryophytes and destroy the cell contents.

Figure 6. *Plagiomnium* sp. branch resisting wetting. Photo possibly courtesy of Derek Bewley.

Figure 7. *Pogonatum urnigerum* (Polytrichaceae), a genus where water must enter the leaf bases where there is less wax. Photo by David Holyoak, with permission.

One solution to getting some of these to get wet is to drop them in **hot (not boiling) water** (Jewett 1913; Lucas 2009). I have to wonder if this distorts anything, and it most likely melts waxes such as one might find on the Polytrichaceae. But it does make most of them flexible rather quickly, and lost wax is usually not a problem. Some bryologists actually keep a hot plate nearby with hot water while they work.

Koponen (1974) dips members of **Mniaceae** (Figure 6) into 70-90% ethanol, then into 2% KOH, ultimately washing away the KOH with water. The specimens are ready for examination in one minute and the chloroplasts are destroyed, making other cell contents visible and the cell walls a yellowish to brownish color. This is especially helpful when the corners of the cells must be seen clearly.

A traditional wetting agent is one known by the German word **Pohlstoffe**. This is a non-technical name for a wetting agent (di-octyl sodium sulfosuccinate) available from Fisher Scientific, known as **Aerosol OT** (Wagner 1981; Bryonet 23 July 2008); it is mixed in a 1:24:75 ratio with methanol and water. Wagner suggested omitting the methanol, finding that this modified mix brings leafy bryophytes, dry capsules, and peristomes to turgidity rapidly, virtually everything except thallose liverworts. Schofield (1985) likewise suggested using only Aerosol OT and water with a dilution of 1:100. It is named for Richard Pohl (Diana Horton, Bryonet 19 September 1999) who presented the formula as a softening agent for dried plant parts (Pohl 1954).

Wagner recommends a half dropper of the 10% solution in 50 ml of water in a dropping bottle. The Aerosol OT can be difficult to obtain, especially if you are not affiliated with an institution. A Google search only located sites that sold it in huge quantities at costs of \$500 or more. Wagner (Bryonet 11 May 2010) learned from his students that the critical substance is also known as **docusate sodium**, the active ingredient of stool softener! Hence, it is available at the drugstore for about US \$5.00 for 60 caplets (Figure 8). Wagner determined that one caplet with a liquid center (100 mg docusate sodium), not solid pills, in 25 ml of water works well as Pohlstoffe. The carriers (glycerine, gelatin, propylene glycol, polyethylene glycol) do not appear to leave any noticeable residue.

Figure 8. Examples of stool softeners with docusate sodium. Photos modified by Janice Glime.

Soap (Tom Thekathyl, Bryonet 12 May 2010)

Another solution to wetting bryophytes is to use **soap** or detergent as a wetting agent. Tom Thekathyl (Bryonet 12 May 2010) suggests diluted kitchen detergent. It doesn't take much. One drop in your dropper bottle is likely to be more than needed. **A word of caution:** Soap can destroy the oil bodies of leafy liverworts! Warm water with patience is a better approach, but hot water can destroy the oil bodies.

Agral 600 (Tom Thekathyl, Bryonet 12 May 2010)

Tom Thekathyl also uses **Agral 600** (horticultural wetting agent). The latter kills the animal life that often accompanies the bryophytes but does not seem to affect the plants. This is useful to avoid introducing dermestids and other hungry creatures into the herbarium.

Rehydrating Capsules

DulcoEase

Des Callaghan (Bryonet 28 January 2016) raised the question of rehydrating *Weissia* capsules (Figure 9) that are full of spores. He needed them to regain normal size so he could obtain measurements. He tried the laxative DulcoEase (containing docusate sodium) for rehydrating capsules, but in this case, the interior spores remained dry, presumably insulated from the water by the outer spores. This kept the capsule partially dehydrated and did not permit it to obtain its fresh size as needed for measurements.

Figure 9. *Weissia controversa* capsules. Photo by Michael Lüth, with permission.

Catherine La Farge and Stephen Rae (Bryonet January 2016) both suggested using hot water to rehydrate. David Wagner (Bryonet January 2016) suggested adding docusate to a 50% solution of ethyl alcohol. It can speed the rehydration. A closed capsule can be rehydrated more quickly by putting tiny pricks through the wall using an insect pin.

Terry McIntosh (Bryonet January 2016) suggested a variation on this technique. He puts a complete stem into a shallow glass or plastic dish and sprays them with a fine mist until the leaves open. Then he covers the dish with a tall, clear plastic or glass container and places it outside in a protected area. The next morning the plant appears field-fresh, including capsules.

A mild solution (5-10%) of dish soap (Dawn) in tap water, heated to ~90°C is good for hydrating liverwort capsules (and probably also works on moss capsules). The soap breaks up the surface tension (Scott Schuette, Bryonet January 2016).

Jessica Budke (Bryonet January 2016) had a more sophisticated suggestion. She puts capsules in a low-level vacuum while they are in solution. That is helpful in preparation for TEM. It also helps to cut the capsule lengthwise to excise more tissue. Arno van der Pluijm (Bryonet January 2016), when working with *Orthotrichum*, first punctures the capsule with a minute insect needle into the spore sac. After adding water it then quickly rehydrates and nothing is damaged.

Howard Matcham and Jan Janssens (Bryonet January 2016) both use 2% KOH or stronger to soak capsules. This technique causes the lids to pop, but it is useful for viewing stomata. Matcham suggests a single drop onto a slide, then a 5 minute soak before viewing. Janssens suggests soaking in nearly boiling water before adding KOH.

Rather than KOH, Jurgen Nieuwkoop (Bryonet January 2016) uses a drop of alcohol in water to wet difficult tissues. Norbert Stapper (Bryonet January 2016) suggests using a humidifying air chamber at close to 100% relative humidity. He advises to increase the humidity very slowly to avoid forming condensate on the capsules. This avoids the bubble formation from air expelled from the capsule.

After evaluating the suggestions made by Bryonetters, Des Callaghan (Bryonet 3 February 2016) found that to rehydrate the *Weissia* capsules (Figure 9), this was the method that worked the best:

1. Put the capsules in a drop of 2% KOH on a glass slide
2. Puncture one side of each capsule (I do this with the tip of very fine forceps)
3. Gently heat the KOH solution with a naked flame beneath the slide

This appears to rehydrate most capsules to their original dimensions, though some can be very stubborn.

Clearing Leaves

I (Glime) have never tried clearing leaves – I wish I had known about this for some of those dirty aquatic species! Des Callaghan (Bryonet 30 August 2012) has demonstrated cleared specimens of *Anthelia juratzkana* (Figure 5) in brightfield, phase contrast, and darkfield.

Figure 10. Cleared leaves of *Anthelia juratzkana*. **left:** brightfield, **mid:** phase contrast, **right:** dark field. Photos by Des Callaghan, with permission.

Lactic Acid

The lactic acid clears all the gunk from the cells, making the walls much easier to see (Rod Seppelt, Bryonet 13 May 2010). Rod Seppelt (Bryonet 13 May 2010) uses lactic acid to clear leaves. One drop on a whole mount is

sufficient (particularly if small), or with leaves and sections. The lactic acid may also be added under the cover glass of stems and leaves that have been mounted moist, but not flooded. Gently warm the slide using heat from an incandescent desk lamp. In the lab, if you don't have an incandescent lamp, you can use a hot plate, an alcohol burner, or even a candle, but you will need to clean the carbon off the slide if you wave the slide through the flame or place the slide above the flame. A Bunsen burner is too hot and could result in boiling the solution, a mishap to be avoided!

Unfortunately, lactic acid has its problems. It is somewhat a health hazard if you make contact with it, but less so than phenol, and it is not permanent on the slide. Specimens need to be examined (and drawn if desired) within a few days to weeks.

Water boils more quickly and suddenly than lactic acid, so less water is better. One Bryonetter suggested that a few air bubbles under the cover glass can be a useful **indicator** of imminent danger. When the bubbles begin to expand rapidly, it is time to remove the slide and let it cool so it doesn't boil. If the solution reaches boiling, you will most likely lose most of your dissected leaves and stems as bubbles escape.

KOH or NaOH

Usually these methods will only require a few minutes to clear the specimens. However, for especially dirty ones, you may need to leave the specimen overnight to clear. Potassium hydroxide (KOH) or sodium hydroxide (NaOH) will also clear tissues – particularly if the material is in contact with the air.

Chloral Hydrate

Chloral hydrate works well as a clearing agent, but please read the discussion of its use in Chapter 2-4 of this volume. It is a controlled substance and is dangerous to your health.

If you should choose to use it, the following protocol, developed for clearing parts of the flowering experimental plant *Arabidopsis thaliana*, may be a useful start (Berleth & Jurgens 1993). Substitute solutions for clearing can be tried in place of the chloral hydrate – experiment:

1. Fix plant tissue in 9:1 parts ethanol:acetic acid. Use vacuum infiltration to facilitate penetration of the fix – approximately 2 hours at ambient temperature.
2. Wash tissue twice with 90% ETOH for 30 minutes each wash.
3. Make solution of chloral hydrate or substitute in 30% glycerol. (Note that another substitute might already contain some glycerol.)
4. Add enough clearing agent (chloral hydrate or substitute) to cover the tissue in an Eppendorf tube (ca. 500 mL). Allow tissue to clear several hours.
5. Dissect tissue further if needed, using dissecting microscope. Mount dissected, cleared plant parts in chloral hydrate/glycerol or substitute under coverslip. Seal slide with clear fingernail polish if desired.

Richard Zander (Bryonet 5 March 2017) recommended the use of polyvinyl alcohol-glycerol glue. He originally used a 50:50 mixture, but found it to be too syrupy. He now recommends 70% polyvinyl alcohol glue:30%glycerol. This mix dries to a thick gum. Be generous with this mountant because it is about half water and that will evaporate. Polyvinyl alcohol glue is sold as Elmer's Clear School Glue or Colorations Clear School Glue. The glue also is good for sticking labels to microscope slides. Ready stick on labels dry and fall off in 5-10 years, whereas this glue lasts longer.

Dehydration

Usually specimens are air dried and this is adequate for most species. Some thallose liverworts require preservation, but mosses rarely do. For higher quality specimens, cleaned specimens can be dehydrated with a series of ETOH (70, 90, 100%) (Mayfield *et al.* 1983). Following the dehydration series, specimens are placed in a 1:1 ethyl alcohol:xylene solution, then transferred to 100% xylene. Remove any remaining dislodged soil particles with fine needles. The thalli can then be placed on glass slides in a xylene-soluble mounting medium such as Permunt with coverslips that are weighted down with small weights like nuts (of nuts and bolts) or metal washers.

Stains

For most observations, stains are not necessary. But some things are simply too transparent or lack contrast. The series of images of *Moerckia blyttii* (Figure 11-Figure 14) by David Wagner illustrate what stains can do to aid visibility of the thallus structure.

Figure 11. *Moerckia blyttii* fresh plant. Photo by David Wagner.

Figure 12. *Moerckia blyttii* cleared and stained with methylene blue. Photo by David Wagner.

Figure 13. *Moerckia blyttii* cleared and stained, grey scale. Photo by David Wagner.

Figure 14. *Moerckia blyttii* cleared and stained; gray scale positive image converted to negative. Photo by David Wagner.

Stains can be used for a variety of purposes. They can distinguish cell types, make pores visible, clarify cell walls, make starch visible, and solve other problems in distinguishing special structures. Most stains are readily available, some are toxic, and others are household items.

Tom Thekathyl (Bryonet 13 May 2010) suggests using household chemicals such as those provided by Maier (2012). These include one drop of red or blue **food coloring** in 30 mL of water, or for greater detail and contrast, a mix of one or two drops each of red and blue **food coloring**, five drops water, two to three drops **white vinegar**, and three to five drops **rubbing alcohol**.

Staining Stems

Stems usually have specialized cells, including the epidermis, the cortex, and often a central strand. Others may have hydroids and leptoids and a second distinguishable layer inside the epidermis. In some species, natural colors distinguish the layers, but other specializations may not be easily recognizable.

Triple Stains

Ralf Wagner (pers. comm. 2012) suggests two triple stains that can be used to distinguish cell differences, the Etzold Stain (credited to Dr. Etzold) and W3A. The latter is described (in German) at http://www.mikroskopie-bonn.de/_downloads/Arbeitsplan_W3Asim.pdf.

Etzold Stain

Dissolve in 1L water:

Acetic acid (100 %):	20 ml
Fuchsin (bas.)	0.1 g
Chrysoidin	0.143 g
Astralblue	1.25 g

Color Results

non-ligneous cell walls: blue
ligneous cell walls, sclerenchym and xylem: red
Phloem: blue

Kawai Stem Staining Techniques

Kawai did extensive studies on stem sections using a variety of dyes (Kawai 1971a, b, c, 1974, 1975, 1976, 1977a, b, 1978, 1979, 1980a, b, 1981, 1982, 1989, 1991a, b; Kawai & Ochi 1987; Kawai *et al.* 1985, 1986) (Figure 27-Figure 63). He cut stems in 5 or 10 μm , even 15 μm sections (Isawo Kawai, pers. comm. 5 October 1989). Most of the information we have is the result of personal communication and a set of images he sent to me (Glime) many years ago. The effectiveness and time required varied among species and even within a species, perhaps indicating differences in age of the tissue or habitat where it grew.

For his early studies on mosses [**Hypnaceae**, **Thuidiaceae** (Figure 15)], Kawai (1971c, 1975, 1976) rehydrated the mosses by boiling them for half an hour to an hour in water. He then used a standard technique of ethylalcohol-butylalcohol-parafin for fixation. Sections were usually 5 μm thick.

Figure 15. *Thuidium* stem with leaves and paraphyllia. Photo by Paul Davison, with permission.

As his work progressed, he experimented with various methods of staining. In early studies, he used **acid fuchsin**, **fuchsin**, **fast green**, and **methyl green** (Figure 25-Figure 27) to stain members of **Bartramiaceae**, **Dicranaceae**, **Entodontaceae**, and **Fissidentaceae** (Kawai 1971). In some cases (*Amblystegiaceae sensu lato*, **Dicranaceae**, **Fontinalaceae**, **Hedwigiaceae**, **Lembophyllaceae**, **Leucodontaceae**, **Meteoriaceae**, **Neckeraceae**, **Pterobryaceae**, **Trachypodiaceae**), he used just **gentian violet** and **acid fuchsin** (Kawai 1977b, 1978, 1979). In others (*Amblystegiaceae*, **Bartramiaceae**, **Dicranaceae**, **Hypnaceae**, **Leucobryaceae**) he stained with **gentian violet**, **acid fuchsin**, and **potassium iodide**, using 5 μm sections (Kawai 1980a, b, 1981, 1982). As part of his experimentation with methods, he used 15 μm sections with the **Bryaceae** (Figure 16) (Kawai & Ochi 1987).

Figure 16. *Bryum pseudotriquetrum*, a species Kawai cut in 15 μm sections. Photo by Hermann Schachner, through Creative Commons.

Some mosses were much more resistant to the stains. In particular, members of the **Polytrichaceae** (Figure 7) and **Fontinalaceae** (Figure 17) were difficult to stain so that cell types could be seen clearly (Kawai, pers. comm. 5 October 1989). Kawai *et al.* (1985, 1986) ultimately developed a lengthy and more complex protocol that gave satisfactory results. Even this differed between species within the family.

Figure 17. *Fontinalis antipyretica* shoot, a family in which Kawai found stems difficult to stain. Photo by Kristian Peters, with permission.

For *Polytrichum commune* (Figure 18), Kawai *et al.* (1985) tried three methods. **1) Aniline Blue-Eosin-Methyl Green Method:** They placed the moss in a solution of **aniline blue** and **eosin** for **48 hours**, followed by **washing** and a second solution of just **eosin** for another **48 hours**. Finally, the preparation was **washed** again and placed in a solution of **methyl green** for another **48 hours**. After **washing** the stems were cut in **15 μ m** sections with a cryo-microtome and mounted in **gum arabic**. **2) Janus Green-Eosin-Methyl Green Method:** The specimen was soaked in a solution of **Janus green** and **eosin** for **48 hours**, **washed**, and soaked another **48 hours** in just **eosin**. The specimen was **washed** again and soaked in **methyl green** for **48 hours** before the final **washing**, **sectioning**, and **mounting**. **3) Gentian Violet+Congo Red-Eosin-Methyl Green Method:** The specimen started in a solution of **gentian violet** and **Congo red** for **32 hours**. As in the other procedures, it was **washed** and soaked in **eosin**, this time for **40 hours**. Finally it was **washed** and placed in a solution of **methyl green** for **32 hours**, **washed**, **sectioned**, and **mounted**.

Figure 18. *Polytrichum commune*, a species Kawai used to experiment with stem staining techniques. Photo by Des Callaghan, with permission.

For *Pogonatum contortum* (Figure 19), Method 1 was successful, but specimens were soaked in each solution for **32 hours**, except for **40 hours** for just **eosin** (Kawai *et al.* 1985). For *Rhizogonium* (Figure 20) and *Mnium* (Figure 21), Method 1 was successful, but specimens were soaked in each solution for **72 hours**. For *Fissidens* (Figure 22-Figure 23), Method 2 was successful, but specimens were

soaked in each solution for **36 hours**. In general, Kawai used the following concentrations:

eosin 0.2 g per 100 cc

methyl green 0.005 g per 100 cc

Figure 19. *Pogonatum contortum* with fly taking a drink. Photo from Botany Website, UBC, with permission.

Acid Fuchsin

Acid fuchsin has been used to stain a variety of plant, animal, and fungal tissues. Kawai (1980b) used **acid fuchsin**, along with **I₂KI** and **gentian violet** to distinguish the internal anatomy of stems in the **Leucobryaceae** (Figure 64). Using 5 μ m sections, he was also able to examine the structure in *Atrichum undulatum* (Figure 65), *Bartramia pomiformis* (Figure 66), *Dicranum nipponense* (Figure 67), *Leucobryum neilgherrense*, and *Hypnum plumaeforme* (Figure 68) (Kawai 1981).

Aniline Blue (Kawai & Glime 1988)

Kawai used **aniline blue** to stain several species, including *Fontinalis* spp. (Figure 28-Figure 35; pers. comm. 5 July 1988), *Polytrichum commune* (Figure 18), and *Pogonatum contortum* (Figure 19) (Kawai *et al.* 1985). It stained the epidermal (outermost layers of stem) red and those just inside the red ones were stained blue.

1. Place moss in solution of **aniline blue** and **eosin** for 48 hours. The hydrome cell walls stain violet-brown.
2. After **washing**, place the moss in **eosin** for absorption for 48 hours to stain epidermal cell walls and leptome red.
3. **Wash** again and place moss in solution of **methyl green** for another 48 hours to stain cell walls of cortex blue-green.

Congo Red (Kawai & Glime 1988)

1. Place leafy gametophyte into solution of **gentian violet** and **Congo red** for 48 hours to stain hydrome cell walls violet-brown.
2. **Wash** moss and place in solution of **eosin** for another 48 hours to stain cell walls of epidermis, cytoplasm of leptome, and chloroplasts red.
3. **Wash** again and place moss in solution of **methyl green** for another 48 hours to stain cortex cell walls blue-green.

Eosin

Eosin is a red dye that stains cytoplasm. It is water-soluble and thus can be used to follow water movement through plants. It has been used in the tracheophyte *Arabidopsis* sp. to indicate photodamage to the photosynthetic apparatus (Havaux *et al.* 2000).

Kawai (pers. comm. 8 July 1989) used **eosin** as one of the stains to distinguish cells in *Fontinalis antipyretica*. This stains the outer cells of the stem ("epidermis") (Figure 27) and the cell walls of the cortex red. **Eosin** likewise stained the cytoplasm of the **leptom** and the chloroplasts red. As noted earlier, this stain works well in most bryophytes to stain cell walls and cytoplasm red.

Fast Green

Fast green is the green dye used in food coloring, but it is known to have tumorigenic effects. It is a protein stain and is one of the stains used by Kawai (1971).

Fuchsin

The dye **fuchsin** is a biological stain that is produced by oxidation of a mixture of **aniline** and **toluidine**, producing a brilliant bluish red. Kawai (1971) used it to stain bryophyte stems.

Gentian Violet (=Crystal Violet)

The color of stain by **gentian violet** depends on the acidity. At pH 1.0, the dye is green, but in an alkaline solution it is colorless.

Kawai (1980b) used **gentian violet**, along with **acid fuchsin** and **I₂KI** to distinguish structures within the stems in members of the **Leucobryaceae**.

Janus Green

Janus green is a vital stain that changes color based on the level of oxygen in a cell (Wikipedia 2012). Kawai (pers. comm.) has used it in combination with other stains to stain the **hydrom** of moss stems.

Methyl Green

Isawo Kawai (pers. comm. 8 July 1989) used 0.005 g per 100 cc of **methyl green** for 10 seconds to stain cells in 10 µm sections of the stem of *Fontinalis antipyretica* (Figure 27). This was followed by **eosin** (0.2 g per 100 cc) added to it. This mix was allowed to stand for 50-60 minutes, then **washed** for observation. **Eosin** stained the outer cells of the stem red and **methyl green** stained those just inside the outermost layers a blue-green color (Figure 27). The central tissue did not stain with this combination.

1. Place leafy moss in solution of **Janus green** and **eosin** for 48 hours to stain hydrome cell walls violet-brown.
2. After **washing**, place moss in solution of **eosin** for further 48 hours to stain cell walls of epidermis, cytoplasm of leptome, and chloroplast red.
3. **Wash** again and place moss in solution of **methyl green** for another 48 hours to stain the cortex cell walls blue-green.

Kawai and coworkers (Kawai *et al.* 1985; Kawai, pers. comm. 5 October 1989) found that the leaf cell walls of *Polytrichum* sp. (Figure 54), *Fissidens* sp. (Figure 22), and *Bartramia* sp. (Figure 66; stained blue-green with **methyl green**, but the cell walls of several species of *Fontinalis* (Figure 17) leaves (Kawai, pers. comm. 5 October 1989) would not stain with methyl green.

Leaves

I₂KI – Lugol's Solution (Kruijer & Klazenga 1994)

Kruijer and Klazenga (1994) consider **methylene blue**, a common *Sphagnum* (Figure 69) stain (see chapter on *Sphagnum* Staining in this volume), to be somewhat problematic for other leaves, sometimes staining too darkly. Instead, they recommend staining with a diluted solution of **iodine-potassium iodide** (I₂KI), or Lugol's solution (Johansen 1940). This is the well known stain for starch, causing it to turn blue to purple to nearly black. But it can also stain **cellulose** if tissues are first hydrolyzed with sulfuric acid and **hemicellulose** if hydrolyzed with hydrochloric acid. Kruijer and Klazenga used **I₂KI** successfully on leaves and cross sections of members of the **Hypopterygiaceae** (Figure 70) and the genus *Dicranoloma* (Figure 71). Cell walls became brighter, but remained nearly colorless except for the middle lamella, which sometimes became bright yellow.

KOH (Zander 1989, 1993)

KOH in concentrations from 2% to saturated will stain cell walls of many mosses. It can be used on whole leaf mounts and on sections. In the **Pottiaceae** the resulting colors can be used as diagnostic characters. Zander (1993) uses it to rehydrate mosses as well. The **KOH** should not be kept in glass dropper bottles because it reacts with the glass to form a precipitate. If the specimen will later be mounted with an acidic mountant, add a drop or two of dilute **HCl** to the specimen.

KOH is useful in distinguishing between genera in the **Pottiaceae** (Zander 1993). For example, the lamina color reaction in *Tortula* (Figure 72) and *Ganguleea* is yellow, whereas in *Syntrichia* (Figure 73), *Dolotortula*, *Chenia* (Figure 74), *Hilpertia* (Figure 75), *Sagenotortula* (Figure 76), *Stonea*, and *Hennediella* (Figure 77) it is red, and in *Saitobryum* (Figure 78), deep red (Zander 1989).

Safranin O / Fast Green (Rod Seppelt, Bryonet 15 August 2012)

Rod Seppelt (Bryonet 15 August 2012) considers this a good general stain for plant sections. It works well for bryophytes on specimens that have been fixed and embedded and on sectioned material. Bill and Nancy Malcolm (2006) have used this combination to obtain high-contrast color effects. The technique is somewhat time-consuming, requiring a schedule of dehydration and rehydration. They suggest a quicker option using **toluidine blue**. If it is used simply to clear the cells, then the hydrolyzation step is unnecessary.

Lisa Op den Kamp (Bryonet 4 October 2012) also uses **safranin**. She applies this directly to the leaves or capitula of *Sphagnum* (Figure 79), then washes them in water, all before cutting the *Sphagnum* to make the desired sections. Safranin normally dyes lignin red; although *Sphagnum* doesn't have typical lignin, safranin stains the lignin-like compounds in the tissues. She has kept the solution for 12 years and it still works well.

Figure 79. *Sphagnum auriculatum* capitula, not stained. Photo by Jan-Peter Frahm, with permission.

Sphagnum Stains

In particular, *Sphagnum* (Figure 69) leaves typically need to be stained for the pores to be visible. Rudi Zielman (Bryonet 4 October 2012) considers there to be four *Sphagnum* stains (see Chapter 2b for details):

- aniline blue
- methylene blue
- gentian violet (=crystal violet)
- toluidine blue O

These can be applied in two ways: supply a bit of it directly in a few drops of alcohol or water or make a stock solution based on alcohol or water.

To enhance the pores on *Sphagnum* (Figure 80) leaves, Rod Seppelt (Bryonet 13 May 2010) suggests **toluidine blue**, **aniline blue**, or **methylene blue**. A drop or two in 100 ml of water should be sufficient. Schofield (1985) recommends **methylene blue**, **gentian violet**, or **crystal violet** in a 1-2% aqueous solution. If the stain is very dark, simply dip the moss in quickly and then rinse it in clear water. If it gets too much stain, you will see even less than with no stain. Be careful – these stains also stain fingers and clothing! If you don't have the standard stains, try experimenting. We wonder if beet juice would work. It might need a bit of vinegar to make it colorfast for permanent mounts.

Figure 80. SEM of *Sphagnum* hyaline cells and pores. Photo from Botany Website, UBC, with permission.

Methylene Blue (Kruijer & Klazenga 1994; Wagner, Bryonet 11 May 2010)

When staining *Sphagnum* (Figure 69) pores, it is important not to stain too heavily. Kruijer and Klazenga (1994) use a 1-2% aqueous solution of **methylene blue**. Or, place a drop of full strength dye on a slide or in a Syracuse watch glass. Dip the *Sphagnum* branch quickly into the dye to cover the branch, then dip the branch into clean water to wash the dye off. Don't allow the branch to remain in the dye. After washing, the moss should be ready for viewing.

David Wagner (Bryonet 11 May 2010) brings us a simple solution for staining *Sphagnum* (Figure 69), a contribution from one of his students. Since **methylene blue** is used as an antibiotic for aquarium fish for hatching eggs or getting rid of fungal infections, it is readily available at tropical fish stores. A half ounce bottle (ca 12 ml) of VERY concentrated **methylene blue** is only about US \$4.25 and will be a lifetime supply.

Crystal Violet/Gentian Violet

Crystal violet, also known as gentian violet or methyl violet 10B, is the compound hexamethyl pararosaniline chloride, or pyocyanin(e), and is a triarylmethane dye.

Adam Hölzer (Bryonet 4 October 2012) reports that he can see even the pores of *Sphagnum obtusum* (Figure 81) very well with **crystal violet**. He dissolves some powder in about 50 ml of distilled water with the addition of some alcohol to preserve it. He adds new alcohol occasionally to compensate for evaporation. He puts the moss leaves in a drop of water. Then uses his forceps to dip into the solution and transfer only a small drop into the drop of water. He covers the drop with a cover glass. The color stains the cellulose of the leaves. Excess stain can be removed by adding water to one side and drawing off the solution on the other with tissue paper. The 50 ml of solution will last for several years even if you use it every day. Stains on the desk can be cleaned with alcohol.

Figure 81. *Sphagnum obtusum* stained for pores. Photo by Ralf Wagner.

Crystal violet and gentian violet solutions can be used to fill well-rinsed and dried felt-tip pens (Joannes (Jan) A. Janssens, Bryonet 4 October 2012). These pens can be used in the field to stain *Sphagnum* (Figure 81) that has been squeezed somewhat dry.

Toluidine Blue O (Rod Seppelt, Bryonet 15 August 2012)

Rod Seppelt (Bryonet 15 August 2012) considers this to be the most useful stain for general tissue differentiation in fresh material, but it is not useful for permanent mounts. It can help to distinguish the ventral row of leaves in **liverworts**. It also will reveal the pores and stem leaves in *Sphagnum* (Figure 81).

Simple method:

0.2%-0.25% toluidine blue O in water (be sure it is O), or 1 drop in 10 drops of water

Stain moss in solution for 10-30 seconds, place on slide, apply cover glass, and examine (without washing excess stain away). If too dark, dilute the stain further before use, or wash the moss quickly to remove some of the excess.

In vascular plants, its multiple color responses can indicate tissue type: phloem green, xylem blue, parenchyma purple, lignified tissue of bundle caps pale whitish-green. Similar color distinctions may occur in bryophytes. Unfortunately, the color is not permanent.

More complex recipe:

0.610 g KH_2PO_4
0.970 g K_2HPO_4
0.050 g Toluidine Blue O
In 100 ml distilled water

Des Callaghan (Bryonet 4 October 2012) likewise recommends Toluidine Blue O and Safranin O for *Sphagnum* (Figure 81). Simply dip the branch in the stain and it works almost immediately. You can find the stains on eBay cheaply (e.g. items 261098492176 and 261107216623). But he cautions that for non-aqueous permanent mounts, these stains are not suitable. Instead, Bismark Brown provides a nice stain.

Reproductive Structures

Iron Haematoxylon / Fast Green (Rod Seppelt, Bryonet 15 August 2012)

This stain works very well to show archegonia and spermatogenous cells in antheridia (Rod Seppelt, Bryonet 15 August 2012).

Bulbils and Spores

Fluorescence and Fluorescent Dyes (Nordhorn-Richter 1988)

Gisela Nordhorn-Richter (pers. comm.) discovered the fluorescence of bulbils in *Pohlia* (Figure 82-Figure 83) when a microscope salesman visited her institution. No one was visiting the display and she felt sorry for the salesman, so she took some of her specimens to look at them. She was amazed at the ease of finding bulbils with the fluorescence technique.

Figure 82. *Pohlia bulbifera* with bulbils that can be located by their fluorescence. Photo by Misha Ignatov.

Figure 83. *Pohlia bulbifera* bulbils that can be located by their fluorescence. Photo by Des Callaghan, with permission.

Preparation of bryophytes for fluorescence microscopy is mostly what not to do. They can be prepared on a slide with water or as permanent slides (Nordhorn-Richter 1988). However, some of the embedding materials have phenolic compounds as preservatives or may have a synthetic resin. These produce fluorescence that interferes with seeing the bryophyte structures. Air bubbles are another potential problem because they can scatter the light. Dry plants can only be rewet once because the membranes typically are destroyed by drying. When the plants are rewet, water soluble substances leak from the cell. When they dry once again, the water-soluble fluorescing substances disappear, ending fluorescence.

In the dried condition, fluorescing substances of bryophytes are very stable, with rhizoid bulbils (Figure 84) of *Pohlia* that are more than 100 years old still exhibiting brilliant fluorescence. Chlorophyll, on the other hand, loses its fluorescent ability upon drying.

Figure 84. *Pohlia wilsonii* rhizoidal tubers. Photo by Guillermo M. Suárez, with permission.

To hide the fluorescence of chlorophyll, which can interfere with fluorescence of other substances, a suppression filter of 650 nm can absorb its red fluorescence (Nordhorn-Richter 1984a, b, 1985a, b, 1988). Alternatively, the chlorophyll can be extracted by 80% acetone or DMSO without interfering with other fluorescent substances.

The fluorescence technique for bryophytes permits one to find rhizoid gemmae hiding in a sandy substrate (Nordhorn-Richter 1988). Live spores exhibit red fluorescence, permitting estimation of vitality that can be quantified with a fluorescence spectrophotometer (Figure 85; Ridgway & Larson 1966; Paolillo & Kass 1973; Genkel & Shelamova 1981). Phenolic acids, including *Sphagnum* acid (Tutschek 1975), lignin-like compounds in cell walls (Lal & Chauhan 1982; Nordhorn-Richter 1984a, 1985), peristome structure (Nordhorn-Richter 1985b), and papillae (Nordhorn-Richter 1984b) become visible. Even small bryophytes can be found by using a UV light (366 nm) at night! (Nordhorn-Richter 1983). Gambardella *et al.* (1993) used fluorescence microscopy to examine the cytoskeleton of the columella in *Timmiella barbuloidea* (Figure 86). Animal tissues exhibit only secondary fluorescence, making it possible to distinguish between animal galls and bryophyte propagules (Nordhorn-Richter 1988).

Figure 85. Spores of *Fontinalis squamosa* showing spores in white light on left and fluorescing under UV light on right. Note that the living spores show up as red under fluorescence, whereas dying and dead spores are yellow or invisible. Photos by Janice Glime.

Figure 86. *Timmiella barbuloidea*, the species used by Gambardella and coworkers to examine the cytoskeleton with fluorescence. Photo by Jonathan Sleath, with permission.

Shellhorn *et al.* (1964) demonstrated that both fresh and fossil pollen could be detected with **fluorochromes**, with better results if **acridine orange** was added to enhance detail. Ridgway and Larson (1966) extended the fluorescence technique to provide better viewing of the features of the hornwort *Anthoceros* (Figure 87). The images of spores of *Fontinalis squamosa* demonstrate that the use of fluorescence microscopy can help to distinguish living from dead spores in mosses (Figure 85). The yellow fluorescence in the image suggests that the exine is fluorescing, as it does in pollen (Ridgway & Larson 1966).

Figure 87. *Anthoceros agrestis*, a hornwort in which fluorescence microscopy helps to reveal its structures. Photo by Bernd H through Creative Commons.

Stains can provide one with the ability to see structures using fluorescence microscopy. Brandes (1967) explained the use of **acridine orange** as a vital stain for use with fluorescence microscopy of protonemal pro-buds and buds. The stain moves to the cytoplasm, combining with the RNA. This technique shows the increase of cytoplasmic RNA immediately after the induction of the pro-buds. Hence, kinetin-induced buds, as well as non-induced branches, can be detected ten hours after the beginning of a kinetin treatment.

Fluorescent dyes can have various purposes, including using them as growth markers in the field (Russell 1988). **Fluorochrome** 3,3'-Diethyloxycarbocyanine iodine [DiOC₆(3)] can be used to locate selectively the fungal hyphae among the rhizoids of bryophytes (Duckett & Read 1991). Ascomycetous hyphae are visible when concentrations of 0.01-5 $\mu\text{g ml}^{-1}$ are used, whereas to see Basidiomycetes that form endophytic associations, the concentration needs to be at least 50 $\mu\text{g ml}^{-1}$. Some fungi, such as VA fungi in liverworts, do not stain with **fluorochrome** at any concentration. Others require a much lower concentration than these. One advantage to this method is to recognize the extent of the fungal hyphae in the association.

Staining Liverwort Capsules (Von Konrat *et al.* 1999)

Von Konrat *et al.* (1999) devised a technique to examine the multiple layers of the capsule wall of liverworts. First the layers need to be separated using a **pectinase** preparation. Then the layers need to be cleared and stained to make the details easier to see.

They recommended doing all the treatments on the same slide – results were less satisfactory when the specimen was moved from one reagent to another. Solutions can be removed between treatments by using filter paper cut into strips. The capsule was mounted on a coverslip and the fully stained capsule was mounted between two coverslips so that both surfaces could be examined.

1. Treat with FAA for 24 hours or until decolorized

FAA (Formalin-Acetic-Alcohol) (100 ml)

Ethyl alcohol	50 ml
Glacial acetic acid	5 ml
Formaldehyde (37-40%)	10 ml
Distilled H ₂ O	35 ml

2. **Rinse** in water three times.
3. Clear partially with 80% **lactic acid** at 60°C for 30-60 minutes in container saturated with water vapor.
4. **Wash** again at least three times in water.
5. Add enough 1% (v/v) **pectinase** preparation of *Aspergillus niger* in water to cover specimen. Let stand for a maximum of 1 hour at 37°C with slide in container saturated with water vapor.

Catalog # P-9179

Sigma Chemical Co.

St. Louis, MO, USA

6. At this stage, you should be able to find the cell layers separated or at least tissue fragments from internal layer separated from the epidermal layer, permitting adequate comparisons. Longer digestion causes digestion of the tissue and thus digestion should stop after 1 hour even if tissues are not separated.
7. **Rinse** with water three times.
8. Add 1 drop of water and 3.5% **sodium hypochlorite** (household bleach) for 30-120 sec or until capsule becomes nearly transparent. (Monitor under dissecting microscope.)
9. **Rinse** with water three times for 30-60 sec each time.
10. Add **dye** for 60-120 seconds, depending on dye (see Table 1 below).
11. **Rinse** again for 60 sec in water.
12. Examine capsules in water or **glycerol**. Water can cause surface tension problems and material may scatter, making glycerol preferable (Zander 1997).
13. If necessary, gentle tapping or squashing with a pair of fine forceps may help to separate the internal layer.
14. Mountants may include **Aqueous Mountant** or **glycerol** in **glycerin jelly** (Zander 1997). Hoyer's solution is not suitable because the dye will fade.

Table 1. Von Konrat *et al.* (1999) tested coloration methods on the cell walls of the leafy liverwort *Frullania*.

Stain	Internal Layer		Epidermal Layer	
	Cell walls	Thickening	Cell walls	Thickening
Alcian blue (0.02% w/v in water)	blue +	blue ++	blue +	blue ++
Autofluorescence	blue +	—	blue +	—
Bismark brown Y (1.0% w/v in 5% w/v aqueous phenol soln)	orange/brown +	orange/brown +	orange/brown +	orange/brown +
Calcofluor white (0.01% w/v in water)	blue +	—	blue +	—
Methylene blue (0.05% w/v in water)	blue +	blue +	blue +	blue +
p-Nitrobenzenediazonium tetrafluoroborate (0.5% w/v in 0.1 M sodium phosphate buffer pH 7.0 for 10 min at 4°C)	—	orange +	—	orange +
Ruthenium red (0.02% w/v in 1% w/v aqueous soln ammonium acetate)	—	red ++	—	red ++
Toluidine blue O (0.05% w/v on sodium benzoate buffer pH 4.4)	—	pink–purple +	—	pink–purple +
Nile blue A (0.01% in water)	—	—	—	—
Phloroglucinol-HCl (1 ml 2% w/v in 95% v/v aqueous ethanol + 2 ml 10M HCl)	—	—	—	—
Sudan red 7B (0.1% w/v in 50% v/v polyethylene glycol + 45% v/v glycerol + 5% v/v water)	—	—	—	—

pH Testing (Zander 1980; Long 1982)

Lichenologists are quite familiar with testing pH reactions, but this technique has not been widely used on bryophytes. Zander (1980) used pH responses (acid-base color reactions) to separate *Triquetrella californica* (Figure 89) from *Barbula fallax* var. *reflexa* (Figure 90) and to remove *Bryoerythrophyllum calcareum* and *B. inaequalifolium* (Figure 91) from the genus *Barbula*. Long (1982) similarly tested four species of *Pottiaceae* and was able to distinguish them on the basis of color change. He used concentrated HCl, 10% KOH, concentrated nitric acid, and 2:1 concentrated H₂SO₄, obtaining, respectively, the following results:

Bryoerythrophyllum wallichii (Figure 92) – pale brown, red-brown, red-brown, dark red-brown

Bryoerythrophyllum caledonicum (Figure 93) – pale greenish-brown, red-brown, red-brown, dark red-brown

Leptodontium flexifolium (Figure 94) – green, orange, red, brown & green

Chionoloma recurvifolium (syn. = *Bryoerythrophyllum recurvifolium*; Figure 95) – green, orange, red, dark brownish-green

Weak Alkali (Lane 1978)

Lane (1978) used a saturated solution of sodium bicarbonate (Hill 1976) in distilled water (weak alkali, final pH ~10) to effect color change in red-pigmented *Sphagnum*. The branches or capitula were flooded by pipette, then permitted to stand for 1-2 minutes (Lane 1978). He then permitted the flooded branches to dry overnight, compared them to known specimens again, and flooded them with a weak acid (e.g. vinegar) of pH ~3 to check for color change reversibility. Of the 17 species tested, Lane found that there was no color change in subgenera *Rigida*, *Subsecunda*, or *Cuspidata*, although *Subsecunda* became redder. *Sphagnum magellanicum* (subgenus *Sphagnum*; Figure 96-Figure 97) became dark brown-black. *Sphagnum wulfianum* (subgenus *Polyclada*; Figure 98) became chocolate brown. The nine species in subgenus *Acutifolia* all turned blue or dark blue. The test works equally well on fresh, freshly dried, and herbarium material.

Cleaning Up Stains

Spilled stains are hard to remove. David Wagner's experience testing kitchen cleaning agents for removing stains from floors or bench tops has found "Bar Keepers Friend"™ with oxalic acid is better than most.

Leaf Removal and Making Slides

For identification, cells, margins, costa, and insertion of leaves must be seen clearly. In some cases, especially leafy liverworts, these can be seen by making a slide of the branch or stem intact. But for most mosses, it is too difficult to see everything that is needed. Removing a leaf from a moss is usually a necessity to attain this clarity. It is advisable to mount a number of leaves when leaf and cell characters need to be examined. These will represent various surfaces and positions, and greater numbers of leaves will usually provide more specimens with no interfering air bubbles.

There are a number of publications on preparing slides for viewing bryophytes (Murray 1926). I have extracted from these what works for me:

1. First **moisten the moss** by placing it in a beaker of water.
2. Place a stem on a glass slide and **strip the leaves** by pulling them downward from the tip with a pair of

microforceps while holding the tip of the branch or stem with another pair of forceps. Alternatively, you can run the convex side of a pair of curved microforceps down the stem to break off leaves. Some bryologists remove leaves by running a dissecting needle down the stem while holding the tip with forceps on a glass slide. Still others (Lucas 2009) use a spear point to run down the stem to remove leaves. Lucas points out that the spear tip tends to leave other structures such as paraphyllia on the stem where they are more easily observed.

3. **Remove most of the branches** from the portion of the stem you will observe on the slide (Lucas 2009) so that the coverslip can flatten the stem better for easier viewing. But you will also need to compare branch and stem leaves, which differ in some species.
4. Put a **drop** of water on the leaves and/or stems and spread them out so some are dorsal and others ventral in position.
5. Hold the **coverslip** by its edges and lower one side of the coverslip gently with a needle or forceps to avoid trapping air bubbles (Figure 99). If you drop the coverslip straight down, there will be no chance for bubbles to escape. If the stem is bulky and the leaves small, you might want to put them on separate slides.

Figure 99. Technique for making a slide with minimal air bubbles. Drawing by Janice Glime.

6. If the coverslip is **floating**, remove some of the water by touching a paper towel edge to one coverslip edge. If there is **not enough water**, add water to the edge of the coverslip with a dropper. This should be added where there is adequate water at the edge to avoid trapping air as the water enters. Too much water will allow your images to move about and wiggle, making examination difficult. Too little will cause the water to draw around the specimen and cause distortions of the light.
7. Examine with the **compound microscope**. The magnification depends on the size of the specimen and what you are trying to see. It is usually best to locate the specimen and focus on 40X or 100X, then move to 400X when more detail is needed.
8. To see papillae, decurrencies, projecting costa tips, and perhaps other surface features, you need to see the leaf in side view, so it is best to observe the leaves that remain on the stem for these features. Most other features are best seen on detached leaves that are more or less flattened by the coverslip. Look around and observe several of the leaves.

Ken Kellman (pers. comm. 5 June 2015) provided me with an alternative method:

1. Etch the collection number onto a clean glass slide. I use a carbide scribe for this. I can't tell you how

many times I have gotten confused about what specimen I am looking at before I started doing this.

2. First soak and dissect in a drop of water, then drop 10% glycerol onto the water drop.
3. Set that overnight to evaporate. This leaves the plants moist with most of the water gone.
4. Arrange the specimen and add a small amount of the glycerine jelly. Estimating the amount is very difficult, but you want the jelly to migrate at least to all corners of the cover slip. Too much just makes a mess. Ideally, end up with a small 5mm x 5mm x 1mm thick square.
5. Heat on a hot plate and take it off as soon as the jelly has melted.
6. Put the coverslip on and press it down to make sure the jelly goes out to the perimeter of the slip.
7. Let it cool with a weight on it. (Nuts from nuts and bolts work well).
8. After cooling, scrape the exuded jelly around the edge of the coverslip and use q-tips (cotton swabs) to wipe the perimeter of the coverslip. This has to be clean for the nail polish **lutant** (sealer) to stick. It often takes several wipes. You have to be a little careful as you don't want to keep smearing the jelly that is under the coverslip onto your slide. Keeping the q-tip wrung out helps, also continually changing the q-tip prevents smearing what is on the q-tip from previous wipes.
9. When finally clean, let the slide dry and put a coat of clear nail polish on.
10. Let that dry and put a second coat on so that the nail polish gets just over the top of the coverslip. Note that it is impossible to make this "pretty and neat." The seal is very important since it prevents (or at least drastically slows) the jelly from drying up.
11. Write a stick-on label and store it horizontally in a slide box. The etched number also helps if the label dries up and falls off, you always know what specimen the slide came from.

Avoiding Air Bubbles

Because of the small spaces among the leaves, bryophyte shoots often trap air bubbles that distort the image and make photographs less pleasing. These are hard to coax out. Sometimes it is effective to bounce the coverslip up and down with a dissecting needle or forceps.

Rod Seppelt (Bryonet September 2017) uses a mild vacuum pump attached to a water faucet to extract the air from the tissues. This is made with a Büchner funnel with a rubber bung in the top and. A Tyson of thick rubber tube is attached to the side vent of the funnel on one end and to the side vent of the faucet on the other. When the faucet is turned on, it creates a weak vacuum as it passes the side vent. The plants are put in water in the flask for this weak vacuum to remove the air. A piece of glass tubing is passed through the bung. The vacuum is controlled by the water speed through the faucet and by applying pressure with your fingers on the tube.

Anne Mills (Bryonet September 2017) reports that Bill Buck keeps a beaker full of hot water for dipping moss shoots. The added heat causes the bubbles to dissipate. The same can be accomplished by flaming a prepared slide quickly. Flaming is faster with the coverslip on, but it will sometimes break the coverslip (Dave Kofranek, Bryonet 12 April 2021).

Bubbles often get trapped in the medium when the coverslip is applied. This is especially a problem when the coverslip is dropped straight down. Most of the bubbles can be avoided by using a dissecting needle or fine forceps. With one edge of the coverslip in contact with the slide, use the needle or forceps to slowly lower one edge of the coverslip until it is entirely in contact with the water.

We need to consider a special problem with liverworts. Oil bodies in their cells are especially important in recognizing species of liverworts (David Wagner, Marc Favreau, Bryonet 12 April 2021). However, they are typically absent in dried material in the herbarium. In cases of herbarium material, wetting with hot water or using a wetting agent like Pohlstoffe or detergent that reduces surface tension is useful for combating the bubbles. The advantage of hot water is that it not only has a reduced surface tension, the heating has driven off dissolved gasses so bubbles in the mount will be dissolved. **But** all methods that use reduced surface tension for wetting are hard on liverworts. Fresh, living specimens are necessary for good photographic documentation of oil body character. These should be mounted directly in water. Stacking photography helps to visualize the oil bodies. (See Liverworts and Oil Bodies below.)

Chris Cargill (Bryonet 14 April 2021) found that heating a slide and specimen in water by using a match beneath the slide worked "perfectly" to remove air bubbles in air cavities in fresh sections of *Ricciella*-type *Riccia* plants.

David Wagner (Bryonet 12 April 2021) found that best practice is to submerge the specimen in water, cover, and set aside in a small Petri dish overnight. Squirt each shoot vigorously before the plunge. The swishing helps but he thinks the overnight submersion results in the gas bubbles dissolving in the water. It is not always perfect but usually helps a lot.

Sectioning

Sectioning bryophytes is typically a hit or miss endeavor. For this reason, it is prudent to make a lot of sections (at least 10) so that at least some are likely to show what you need. If you need to see a cross section, the sections need to be thin enough for them to rest on their sides.

It seems that bryologists have developed a number of methods for sectioning bryophytes (e.g. Singh 1942; Foster 1977; Nishimura 1997). Nevertheless, Sean Edwards (Bryonet 30 July 2002) points out that bryologists have tended to avoid cutting sections of moss leaves for several reasons:

1. Microtome sectioning involves some considerable delay owing to the various preparations required (moreover, microtomes are often not available, especially to amateurs, when needed).
2. Pith sectioning is unsatisfactory because of the difficulty in controlling section thickness, and in separating the pith debris without damaging the sections.
3. In both microtome and pith sectioning it is almost impossible to be certain of the exact part of the leaf from which the sections were taken.
4. In both methods of sectioning, considerable care and time are needed to maintain a suitable cutting edge.

Nevertheless, there are several methods used by bryologists for making sections of stems and leaves (e.g. Singh 1942; Frolich 1984; Nishimura 1997). One is to place the stem with leaves on a dry glass slide and chop, like cutting parsley! The idea is that with lots of cuts, some of them will yield a usable section.

Razor Blades

Razor blades are the standard tool for cutting sections. Hutchinson (1954) recommends use of a normal (double-edged) razor blade that is divided into four sections. The blade should be placed between pieces of blotting paper and broken down the center the long way. Each of these pieces is broken again perpendicular to the previous break. She found she could use used blades because only the sharp points are needed. The blades can even be broken again when the points become dull.

Zander (2022) recommends using sharper razor blades – thin blades cut from very hard steel with a narrow bevel on each side. Triple cut bevels are more like a rounded edge and do not cut as well. Comparisons are available on the Refined Shave website <<https://www.refinedshave.com/razor-blade-sharpness-summary/>>. Smith (1980) claims that double-edge blades give better results than single-edge blades for free-hand sectioning, recommending those of the Feather brand.

Cutting Techniques

In the many techniques that create sections, placement of the sections is important. Once the specimen sections are in a drop of water on the slide, Hutchinson (1954) recommends stirring the water to distribute the specimens, while looking through the eyepiece of a dissecting microscope. Be sure the water is not sufficient to exceed the area of the coverslip when it is applied or you will use the smallest, hence the best, specimens. As the slide begins to dry, add 5% glycerine at the edge of the coverslip. If the best specimens need to be moved to another slide, you can use a dental applicator (Figure 100) dipped in a 5% solution of glycerine. When placed over the desired section, this combination will lift it up. The applicator can be dipped into a drop of the same solution on the new slide and the section shaken off.

Figure 100. Dental Disposable Micro-Applicators. White is superfine, yellow is fine. Photo modified from AliExpress.

Hepenstrick (2018) describes a method using a magnet to secure the slide (Figure 101). A second slide is placed across it to provide a guide for cutting (Figure 102). An instructional video is available at <https://doi.org/10.6084/m9.figshare.4781254.v1>. Beginning students who tried the magnet method agreed that it was better than the dissecting microscope with a razor blade, as seen in Figure 103.

Figure 101. A magnetic sectioning aid with fixed *Polytrichum* leaves ready for sectioning. The support plate (A) is a magnetic, rust-free steel sheet with laser cut tongues (B) which are slightly bent upwards, and a non-magnetic strip (C) which helps to align the magnetic slide (D) with its attached neodymium magnets (E) centrally on the lower slide (F) in order to fix the specimen for sectioning. Sections can be cut under a dissecting microscope with a razor blade that is guided with both hands. The semicircle slots (G) help to place and grasp the lower slide. Wax Mounts (Taylor 1957)

Taylor (1957) found a different solution to positioning leaves and stems for cutting. He first coats them with water-soluble wax. These include Carbowax and some kinds of crayons.

Taylor makes two solutions: **Solution A** is 20% aqueous polyethylene glycol 600 with a small quantity of Quaternary amine disinfectant to prevent development of fungi in permanent mounts. **Solution B** consists of polyethylene glycols 1540 and 4000, which can be used alone or in combination. However, 1540 alone may be too soft, and 4000 too crumbly.

1. Place solution B on a slide and melt.
2. Place a piece of stem in molten drop to cover stem. The drop needs to be thick enough to support the blade during cutting.
3. Cool wax for ~1 minute with slide on cool metal surface.
4. Use quarter of razor blade to trim drop at one end to point where sectioning is to start, keeping blade vertical and at right angle to stem.
5. Keep sharp corner of cutting edge on slide with cutting edge slanting upward toward you. This keeps cutting edge sharp.
6. Move blade sideways against squared end of drop, making thinnest section possible while watching through dissecting microscope.
7. If leaves curl, soak in solution A at room temperature until solution reaches consistency of glycerin.
8. Remove leaves and touch to filter paper to remove excess liquid.
9. Transfer blotted moss to molten B and proceed from #1.
10. Transfer cut sections with adhering wax to water with small amount of wetting agent if need to keep from floating. Taylor prefers enough water to cover bottom of Syracuse watch glass.
11. Sections can be transferred by tapping slide on rim of watch glass.
12. Polyethylene glycol is not compatible with gelatin, so sections should stay in water until wax completely dissolves – a few minutes in warm water.
13. Remove sections and put in dilute glycerin onto slide.

Cutting Block (Flowers 1956)

Flowers (1956) used a 2x2x15 cm cutting block made of soft wood. She then made a jellyroll arrangement of the bryophyte in tracing paper (a thin paper):

1. Put bryophyte in boiling water to relax it and select several good, clean shoots.
2. Remove excess water by pressing the bryophyte gently between absorbent paper towels or blotters.
3. Roll a 5-10 x 30-40 mm strips of hard-surfaced, thin transparent tracing paper (such as that used by architects) lengthwise into a tight scroll. The size depends on the size of the strips. Open the roll and place the bryophyte shoots longitudinally into the first coil of the roll, using fine curved forceps.
4. Carefully roll the shoots up in the strip, using thumbs and index fingers of both hands.
5. Hold this roll up to the light to locate the upper ends of the shoots and grasp the roll just above the shoot tip with a pair of forceps.
6. Lay a strip of good quality, smooth, white cardboard (10x40 mm) parallel with the proximal edge of the cutting block.
7. Place the bryophyte roll longitudinally upon the white paper near the proximal edge, holding it down with the left index fingernail at the shoot apex.
8. Using a sharp safety razor blade, cut off the anterior portion of the paper roll and discard.
9. Begin cutting sections of stems and leaves through the tracing paper, using your fingernail as a guide. After each cut, move the blade back slightly before making the next cut.
10. As sections are cut, dip the razor blade in a drop of water on a glass slide to remove the sections.
11. Remove the sections of tracing paper from among the leaves, adding a few drops of water to facilitate the removal.
12. Excess water can be removed by holding the slide over an alcohol lamp, leaving only a thin layer.
13. Large leaves like those of *Polytrichum* (Figure 18) can be treated in the same way as the stems.
6. Make a sandwich by placing other half of pith flat side onto the first flat side of pith, being careful to align edges.
7. Hold sandwich firmly and dip end with moss into water.
8. Place sandwich onto a glass slide without losing grip and make a first cut close to end that holds moss, using sharp, clean safety razor blade, and discard that cut.
9. Dip to wet end of sandwich again.
10. Press firmly down on the pith above the specimen and cut first section as thinly as possible **next to** the end of the pith, taking care not to cut the pith. You may want to do this while watching through a dissecting microscope.
11. After making several cuts, use razor blade or dissecting needle to move cut sections to opposite end of slide and into drop of water or wetting agent.
12. Repeat until you have enough sections.
13. Place coverslip onto cut sections and water.
14. Add extra water at edge of coverslip if needed.
15. To examine, close down the diaphragm that controls the light and examine on low power (40X total).

A modification of this method uses a razorblade instead of a slide on top (Figure 104). This is thinner and makes it easier to work with the bryophyte specimen.

Figure 104. Lüth leaf sectioning. The bryophyte is green, shown at **a** and in the side view at **c**. The cutting position of the double-edge razor blade is at **b**. Photo courtesy of Steve Rae.

Pith Sandwich Cutting Tool (Trotter 1955)

1. Cut a piece of pith from common elder (*Sambucus niger*) 3-4 cm long x 1 cm wide. Make sure ends are cut clean to make a cylinder.
2. Cut cleanly as possible with sharp safety razor blade down the middle to avoid fraying.
3. Put drop of water on clean slide.
4. Lay half of pith on convex side.
5. Place **dry** specimen at end on flat side, slightly extended beyond pith.

Note that sections that are visible to the naked eye are probably too thick to be useful. Note also that stems with oblique leaves, like those of *Fissidens* (Figure 22), may have to be placed with stems in an oblique position so that leaves are perpendicular to the cutting edge. Furthermore, plants with very brittle cells, like *Rhabdoweisia* (Figure 105), may make it difficult to get good sections.

Figure 105. *Rhabdoweisia crispata*, a short species with brittle cell walls. Photo by Amelia Merced, with permission.

Chopping Method

Some bryologists subscribe to a chopping technique. They use a moist, but not flooded, stem with leaves, placed on a glass slide. These are chopped with a razor blade from the apex towards the base. Using some very fine forceps, usually adding a very small amount of water (in addition to that held between the tips by capillary action), they are spread about the water drop where the coverslip will go. After the coverslip is added, this preparation can be cleared, if necessary, by infiltrating it with a drop or two of lactic acid, and warming as discussed under Clearing Spores above. I (Glime) have always felt this chopping method was a waste of time since any chopped bits must be examined afterwards, and often none of them is useful. Most, if not all, of the sections will be wedge-shaped and won't lie on their sides. Perhaps I just gave up too soon before I perfected my skill.

Roll and Chop (Wilson 1990; Zander, Bryonet 8 July 2008)

Wilson (1990) presented a method he calls the "roll and chop" method (Figure 106). He uses a dissecting needle to hold the leaf or stem on a glass slide. After each cut, the needle is rolled back a tiny bit and cut again with the razor blade against the needle. I haven't tried this method, but I do have a concern. If one starts cutting from the bottom of the stem, the leaves become detached after the first cut, reducing the chances they will subsequently be cut in thin sections. If one starts at the tip, rolling the needle will butt into leaf tips and roll under them instead of on top of them. I asked Richard Zander for his advice on this, and he agreed that if you start at the bottom of the plant the leaves fall off. Rather, he always does "one leaf at a time if possible, since results are better. Hold the leaf down, apex away, then chop across the middle of the leaf while rolling. A substitute for rolling the needle (probe) is to hold the leaf down at an angle and slowly chop while dragging the blade down the needle; results are the same. Sometimes one can hold the whole plant down with a needle across the plant apex at an angle perpendicular to the leaves and chop across many leaves. This results in a mess but sometimes cross sections result. Less tedious than doing one leaf at a time, though."

Figure 106. The roll-and-chop method of sectioning bryophytes. This would usually be done while looking through a dissecting microscope. Modified from Wilson (1990).

Richard Zander (Bryonet 8 July 2008) recommends that single-edge razor blades (Figure 107) for sectioning should be discarded after five to ten uses because they become dull. He described his technique, essentially that of Wilson, on Bryonet: "One holds a leaf or stem crosswise with a stiff dissecting needle, then slices the material with a razor blade held longitudinally against the far side of the needle, meanwhile rolling the needle slowly towards oneself to gradually expose uncut portions of the material.

Figure 107. Box of single-edge razor blades. Photo by Micromark.

Practice (and a relatively fresh blade) makes this technique quite effective, even for very small leaves. Remember to scrape off sections (especially stem sections) adhering to the razor blade with a dissecting needle after cutting. The usual pair of compound and dissecting microscopes are needed, but using an additional illuminator with the dissecting microscope for fine dissections rather than just a single lamp will prove surprisingly advantageous for observation of fine features." Zander and others (Bryonet 8 July 2008) suggest Micromark <<http://www.micromark.com/>> as a source for razor blades.

Modified Roll and Chop (Kellman 2005)

Kellman (2005) criticized this roll and chop method because it is difficult and often produces sections that are too thick. The pressure needs to be even and sufficient to prevent the leaf from tearing. He recommended solving the first problem of thick sections by making a special needle using a sewing needle. The needle is cut to the desired length (about 7.5 cm) and inserted into a 4 cm piece of a 1 cm wooden dowel by drilling a 1.6 mm hole into the end to a depth of about 1.2 cm. The large diameter of the dowel provides one with a better grip and makes it easier to roll the needle a shorter distance. Kellman finds that the best needle is a 7.5 cm (3") soft sculpture doll needle 1 mm in diameter (Dritz product #56D). The cut end of the needle should be dipped into a drop of glue and put into the hole in the dowel. The short end of the needle can then be wedged into the hole beside the needle to position it firmly. Kellman warns that cutting the needle often results in having the cut off end flying across the room, so he recommends that it be cut inside a cloth or plastic bag so that it can be retrieved easily. The next step creates the tread that helps the needle grip the leaf. Run an emery board or sandpaper along the length of the needle, rotate the needle and repeat until the entire needle has a tread. Do not run the emery board or paper around the needle because that will not create the lengthwise treads needed.

Kellman solves the tearing and uneven pressure problem by stacking several leaves on top of each other to cut them. This also provides more sections, saving time.

1. To prepare the sections, place the stem on right-hand side of a clean slide and remove leaves under a dissecting microscope.
2. Select the leaves you want to section and move them to the left side of the slide without adding more water.
3. Once you have moved the chosen leaves, stack them together like spoons, stacking at least 3 leaves.
4. When the stack is ready, place the needle over the stack, pressing down lightly.
5. Use a sharp blade to cut along the away side of the needle. Use a chopping type of cut instead of a slice, a method not feasible with a single leaf. The full edge of the blade should reach the slide at one time.
6. Move the cut piece away and roll the needle as little as possible back toward you.
7. Make another cut, making the first section.
8. If sections get stuck to the blade, place a drop of water in the middle and dip the blade in it to remove the sections.
9. Continue this procedure until you have enough sections. Then make a slide as usual. You can place a coverslip on the stem and remaining leaves on the right to view whole leaves and another on the sections, all on one slide.

Dissecting Microscope Hand Sections (Welch 1957; Schofield 1985)

This method works well for leafy stems, branches, and large leaves. Some bryophytes, like *Polytrichum* (Figure 18), require leaf sectioning to view special structures like the lamellae (Figure 1). Because this is a large leaf, it is a

good representative for a beginner to use for practice. Welch (1957; Schofield (1985) published the technique that works best for me (Glime):

1. Place a wet *Polytrichum* (Figure 18) leaf or leafy branch/stem on a dry slide.
2. Put a drop of water on one side of the slide, away from the leaf.
3. Cut away the tip with a sharp razor blade about 1/3 from the tip end of the leaf.
4. Discard your first cut.
5. While viewing through a dissecting microscope, cut as close to the previous cut as possible. Use one hand to cut and the other to guide and steady the cutting hand while holding the specimen with a fingernail or a pair of curved microforceps.
6. Cut 8-10 very thin sections and dip your razor blade in the drop of water to free them.
7. Examine the sections with the dissecting microscope to see if any of them are lying in cross section.
8. Continue cutting until you have about 30-40 sections.
9. If there are satisfactory sections, put a coverslip on the slide and examine the leaves under low and high power on the compound microscope.

With this technique I can usually get 5-8 sections (Figure 108) that will lie on their sides as they should.

Double Slide Sectioning Technique

Sean Edwards (pers. comm. 20 July 2012) has provided us with his double slide sectioning technique, based on his thesis (Edwards 1976 – see Adams 1981; Edwards 2012). The following description is only slightly modified from his description.

This method allows, with very little practice, good clean sections of about 10 μm thickness to be taken from any required part of the moss leaf, with no preparation or specialized equipment, and within a matter of seconds. The equipment required is the normal laboratory dissecting microscope (or good close eyesight), two 7.5 \times 2.5 cm standard glass slides, and a supply of double-edged or single-edged razor blades. As noted by Adams in the Floating Slide Miniblade Technique, throw-away twin-bladed razors are currently in plentiful supply. By carefully prising apart the plastic mounts, two very thin, but easily hand-held ultra-sharp blades can be recovered that are ideal for section cutting (Adams 1981).

Selected moist leaves are arranged parallel with each other on a glass slide, with the parts to be sectioned aligned as shown by the arrows in Figure 109. The second slide is laid (with care) over the leaves, so that its long edge is also aligned with the parts to be sectioned (Figure 110-Figure 111). This may be checked with a dissecting microscope if necessary, and individual leaves adjusted. Firm pressure is applied to the upper slide by the finger of one hand, and half a double-edged razor blade is drawn with the other hand across the leaves, using the upper slide as a guide (Figure 110, Figure 111). Only a corner of the blade is used, but if the 'angle of elevation' of the blade is sufficiently small (about 15° - 20° , perhaps less than that indicated in Figure 110), the cut is perfectly clean.

Sections are made by adjusting the tilt of the razor blade for each successive cut; the first cut is made with the blade leaning somewhat (about 15°) towards the upper slide, and this angle is progressively lessened. The situation is shown diagrammatically in Figure 112, where θ is the angle of tilt and P_1 is the fulcrum. The angle of tilt is surprisingly easy to control, and even a relatively coarse adjustment will give a fine control over the section thickness. After the tilt of the blade has passed 0° (vertical), the fulcrum moves down to P_2 , resulting in an even finer control over the thickness of the last few sections. Although the sections must in theory be slightly wedge-shaped because of 15° angle, this is not noticeable in practice.

Figure 109. Placing specimen on slide in first step of the double slide sectioning technique of Sean Edwards. Drawing by Sean Edwards.

Figure 110. Alignment of slide and specimens in double slide sectioning technique of Sean Edwards. Drawing by Sean Edwards.

Figure 111. Sectioning setup of double slide sectioning technique of Sean Edwards. Photo by Sean Edwards.

Figure 112. Cutting position of the razor blade in the double slide sectioning technique of Sean Edwards. θ is the angle of tilt and P_1 is the fulcrum. P_2 is the position of the fulcrum after the tilt of the blade has passed 0° (vertical). Drawing by Sean Edwards.

Pressure on the blade has to be judged by experience, but it should be no more than is necessary to cut the leaves. One blade corner may provide many series of sections, but such economy is usually not necessary; only with very old and fragile material should a fresh corner be used for each operation. It seems that an 'angle of elevation' of about 15° - 20° enables the pressure to be taken by the less vulnerable curved corner of the blade, while allowing the razor edge unimpeded access to the leaves. It is clearly advantageous to keep this angle constant. If the broken corner of a half-blade immediately above the cutting corner is bent somewhat, just before it is first used, then the unused cutting corners can be recognized without confusion, and a packet of ten blades can be used to section at least forty plants. Particular advantages of this method lie in the degree of control and inspection allowed before and during cutting, by the transparency of the glass cutting-guide, and also in the world-wide availability and cheapness of double-edged razor blades.

Figure 113. Cutting sections along edge of top slide in double slide sectioning technique of Sean Edwards. Note cut sections in water on the lower slide. Photo by Sean Edwards.

Figure 114. Cut sections along edge of top slide in double slide sectioning technique of Sean Edwards. Note the alignment of multiple stem pieces under top slide. Photo by Sean Edwards.

Floating Slide Miniblade Technique (Adams 1981)

This technique is nearly the same as the Double Slide Sectioning Technique of Sean Edwards, but a few modifications may be helpful to some people. The Floating Slide Miniblade Technique likewise involves two microscope slides. However, double-edged razor blades are hard to find and are really too thick to control the sectioning adequately. The second problem with the Edwards Double Slide Sectioning Technique is that the angle of tilt ensures that none of the sections are truly vertical slices with parallel slides.

Use the more readily available twin-bladed razors and pry the plastic mounts apart to obtain two very thin ultra-sharp blades. The second refinement requires the obligate

use of a dissecting microscope (as also recommended by Tony Smith).

1. Mount a clean slide under the center of the low power field at $\sim 45^\circ$ to the left-right plane (near left to away right).
2. Place a large drop of water on the slide, and then mount your selection of leaves etc., in a line across the middle of the slide for sectioning.
3. Finally, add the second slide at right angles as per Edwards' technique, carefully trapping the leaves at the level you need the sections, and most importantly, a film of water between the slides.
4. Then, if you are right-handed use the second (longest) finger of your left hand (N.B. not your thumb as in Edwards' technique) to hold the upper slide down tightly onto the leaves, and using a blade in the right hand, slice away the unwanted projecting leaf segments with a gentle (so as not to blunt the blade) horizontal slice. Hold the blade vertically, but with the cutting edge tilted at $\sim 30^\circ$ towards your right hand, and slide it along the edge of the top slide, gripping the blade between the thumb and second finger, and – doing something you can't do easily with half a double-edged blade – resting your index finger along the top edge to provide that extra control.
5. Now comes the innovative bit. Because you have a film of water trapped between the slides, if you flex your left second finger slightly, you can retract the upper slide (observing all the time under the microscope) and expose new tiny projecting segments of the leaves you wish to slice.
6. Keeping your blade in the vertical plane, but with the sharp edge inclined towards your right hand at $\sim 30^\circ$ as before, you can now slice a beautifully thin section with vertical, parallel sides. With a bit of practice, it is fairly easy to retract the upper slide on its film of water, a potential slice at a time, and go on cutting ultra-thin vertical slices.

You can modify this technique by using a coverslip instead of the top slide:

1. Hold the coverglass in place with your left forefinger, with your left thumb held sideways (nail facing right), pressing down on the slide underneath. The thinness of the glass has the advantage of making it easier to see the projecting leaf segments that you are about to cut, since in the case of a slide, the edge of the glass gives you a double image. It is also easier to trap a film of water under it.
2. If you clean away unwanted bits of leaf you can lift the forward edge of the coverglass slightly with your blade, and pull it forward over the sections all in one operation, the water under it being dragged along with it and serving to suspend the sections.
3. Gripping a bunch of leaves or a shoot between thumb and forefinger, with the soft side of the thumb slightly higher, place a drop of water on the leaves and slice away against your thumb. If you are careful, you can cut a collection of slices, which stick in a film of water at the bottom of the blade, without too much damage to your thumb!
4. On dispersing the sections in a drop of water on a slide, you may find however, that they are not quite

thin enough and insist on lying flat instead of edge on. Don't despair! Pick up the best section with a pair of forceps, and mount it on the edge of a microscope slide in a film of water, as close as possible to the upper face.

5. Now despite the fact that it is lying flat on the edge of the slide, if you look at it under the microscope you will see it edge on. This is usually sufficient to enable you to observe the cell structure of a costa, and whether a margin is bistratose.

Cryostat Sections

If you are fortunate enough to have a cryostat, you can get excellent, consistent sections. I inherited a freezing cryostat that had been obtained as government surplus. The principle is that it freezes your specimen in ice. The specimen is prepared by turning the cold stage to a very cool temperature and building up an ice base with a few drops of water, waiting for each drop to freeze before adding the next. Then the specimen is placed there vertically. If you are cutting small leaves, you may want to position several of them on the ice. Once the specimen is positioned, continue to add drops of water, letting each freeze before adding the next. Once you have covered the portion of the specimen you need, you can cut off any excess with a sharp razor blade. The disk is then clamped into a holder in front of a blade. This blade (or perhaps the holder) can be moved by "winding" much like an old Victrola. Each time the blade comes down, it cuts a narrow slice from the ice and bryophyte. These must be collected on a cold, dry slide placed under the ice ribbon created – something that must be done quickly. A pair of microforceps can help to remove all the ribbon from the blade. To make the slide cold, keep it inside the cryostat while you are building the ice mound and doing the sectioning. A warm slide will melt the ribbon immediately and you can lose your slices.

The icy ribbon can be moved to the center of the slide if done quickly before it melts. Then you can add a drop of water and coverslip as you would for any slide.

The cryostat can be adjusted for the thickness of the sections. The necessary thickness depends on the thickness of the specimen (leaf, stem; see Figure 115). Capsules are a bit more difficult once they form an internal air chamber because the air will be trapped inside. If this becomes a problem, you might try adding a bit of wetting solution inside the capsule before sectioning. Be careful that the wetting agent does not get on the ice mount because the water drops will run off before they can freeze. (We haven't really tried this, so we don't know if it will work.)

Figure 115. *Polytrichum juniperinum* leaf section using a cryostat. Photo by John Hribljan.

Adam Hoelzer (Bryonet 5 December 2013) likewise uses a cryostat. He reports that the slices are not as thin as one can achieve with paraffin, but they are definitely adequate. Rather than using pure water, he uses the mounting medium provided by the manufacturer of the cryostat – a medium that consists mostly of polyvinyl alcohol. This is the typical medium used by hospitals that use cryostats for histology.

Stems and Small Leaves

Mosses lack lignified vascular tissue in their stems, but they may have vascular elements called **hydroids** (water-conducting elements) and **leptoids** (photosynthate-conducting elements). Additionally, the center of the stem may contain small, thick-walled cells that serve as strengthening tissue (Figure 116), but that does not seem to have any conduction function. None of these structures can be seen without sectioning the stem. Furthermore, it is difficult to section small leaves by themselves, so they are best sectioned on an intact stem or branch. This is the method that works for me (Glime):

1. Place a wet moss stem on a **dry slide**.
2. Put a **drop of water** on one side of the slide, away from the stem.
3. While viewing through a dissecting microscope, use a **sharp razor blade** to cut as close to the end of the stem as possible. Use a fingernail or finger of one hand to guide (the one holding the stem) and steady the hand holding the blade. Alternatively, you might find it easier to press down on the stem with a pair of curved forceps instead of holding it with your finger.
4. **Discard** your first cut.
5. **Cut 8-10 very thin sections** and dip your razor blade in the drop of water to free them.
6. Examine the sections with the dissecting microscope to see if any of them are **lying in cross section**, indicating they are thin enough.
7. If there are satisfactory sections, put a **coverslip** on the slide and examine the stems under low and high power on the **compound microscope**.
8. Use a microscope with **plane polarized light** to see cells with phenolic compounds in the stem.

Figure 116. Stem cross section of the moss *Molendia sendtneriana* showing central strand. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University, with permission.

Lamellae

This sectioning technique, including the figure, is modified from the protocol by Ken Adams (2018).

When examining *Polytrichum* / *Polytrichastrum* / *Pogonatum* that do not have leaf margins folded over the lamellae, to determine the species, it is difficult for many people to cut very thin transverse sections. The late Peter Wanstall provided a simple solution to the problem, but beginners nevertheless seem to have difficulty with it. Hence this short procedural account:

1. Put a drop of water on a clean slide, and have some water in a dish plus a coverglass close at hand.
2. Assuming most of you are right handed, pull off a bunch of freshly wetted expanded leaves by their laminas with your right thumb and forefinger, then carefully grip the transparent sheathing leaf bases with your left thumb and forefinger so that the laminas lay across the flesh of your forefinger, before you let go with the right hand, as being springy and being bent at right angles they will otherwise fly out of line.
3. Then dip your second right finger in the water and transfer a good sized drop into the groove between your thumb and forefinger.
4. Take the coverglass in your right hand, dip the edge in this droplet, and move it away from you, gently scraping it against several laminas at once, several times, until you can see that patches of the green of the lamellae have given way to the clear tissue of the leaf lamina.
5. Dozens of lamella fragments will now be collected in a film of water along the bottom edge of your coverglass – but you are unlikely to be able to see anything – just be reassured that they are there, and dip the edge in the droplet of water you have prepared on the slide.

6. Add a cover glass and examine with the 10x objective and you should see plenty of torn-off lamellae looking like bits of green brick wall lying on their sides.

Beginners are often bewildered by these and fail to see what has happened. Imagine they really are bits of brick wall on their side. Along what was the top of the wall will be an edge with a constant repeating pattern, while along the other long edge the tissue will be torn and ragged from where it was ripped off the lamina. Students with no prior experience of microscopy may not even realize that the walls may be upside down! The top row of cells are heavily cutinized to prevent water loss, and slightly larger than the rest of the lamella cells, so that when the leaf loses turgor in dry conditions and the lamina curves slightly upwards at the edges, the top row of cells of one lamella come in contact with the top rows of lamellae on either side, thus closing off the moisture saturated air cavities in between, effectively minimising drying out of the lamellae. Using this technique the morphology of the top row cells is observed from the side, as opposed to end on as would be seen in a transverse section of the leaf. Nevertheless, because *Polytrichum commune* has top row cells with four large rounded bosses at their corners, in both TS and from the side two rounded bosses will be seen topping each cell, whereas in *Polytrichastrum formosum* and *Polytrichastrum longisetum* the top surface will be gently undulating in side view.

Techniques for Special Structures

Clearing Spores

Tom Blockeel (Bryonet 24 January 2012) sought a method to make it easier to see the very dark or blackish spores of species like those of *Riccia* (Figure 117). The ornamentation of the spores can help in identification, but it is not possible to observe it clearly with transmitted light.

Wagner (Bryonet 24 January 2012) suggested using a combination of transmitted and reflected light. The reflected light can be a strong LED light from a bicycle headlamp. This, combined with stacked images, can provide excellent quality (Figure 118).

Figure 118. Spore of *Riccia sorocarpa* using both transmitted and reflected light plus stacking. Compare the clarity to that of the same species in Figure 117. Photo by David Wagner, with permission.

Marko Sabovljevic (Bryonet 24 January 2012) suggested using 5-10% **Clorox bleach** (NaOCl – 8% of active chlorine) for 1-3 minutes to clear the spores, a method also suggested by Richard Zander and Jörn Hentschel in the same Bryonet thread. Hentschel also suggested **calcium hypochlorite** ($\text{Ca}(\text{ClO})_2$), the C-Solution used by lichenologists for their spot test. Martin Godfrey (Bryonet 25 January 2012) uses **gum chloral** to clear dark, dense specimens and also make a permanent preparation. But Upton (1993) reports that gum-chloral slides deteriorate steadily with time and specimens become irretrievably lost. Several bryologists (Richard Zander, Rod Seppelt, Bryonet 24 January 2012) also suggested **lactic acid**, but it wasn't clear that they had actually tried it for black spores. Seppelt also suggested a strong detergent like **Tween 80** because it reduces the black pigment in some lichens. Tom Blockeel reported that the bleach "does the trick perfectly well!" (Bryonet 6 February 2012).

An excited Richard Zander sent me an email on 15 November 2020 to share a discovery! He had been trying to clear the spores of thalloid liverworts using either 100% Clorox or lactic acid with little success. Then, he mixed the two and tried the mix on the spores of *Ricciocarpus natans* (Figure 119). A few bubbles arose, and "the spores decolorized and turned a very light, translucent brown, with morphologic details perfectly visible." He also used 5% Clorox and lactic acid on spores of *Targionia* (first one, then the other), and the spores again retained a brownish color. But, sadly, David Wagner tried the mix of Clorox 1:5 dilution with a drop of vinegar on spores of *Riccia nigrella*; before he could wash them, the spores turned to mush!

Spore Clumping and Cohesion Problems

Spores in a drop of water will tend to clump, making observations difficult. A drop of Extran[®] in 5 ml of water will break these apart. It might be useful to keep a bottle of water with detergent for making slides where surface tension or cohesion among leaves create problems. A little experimentation will determine appropriate amounts of detergent for various brands.

Gum Chloral Recipe for Mounting

Martin Hausler (pers. comm. 18 July 2012) provided me with this method for chloral hydrate, with the recipe originally from Watson's British Mosses and Liverworts:

Distilled water 100 ml
Gum arabic 40 g
Glycerine 20 ml
Chloral hydrate 50 g

1. Dissolve the gum arabic first in cold water, which can take a day or so as it is best not to stir to avoid getting masses of air bubbles which take an age to come out.
2. When dissolved add the glycerine and chloral hydrate and heat until dissolved; filter hot if necessary.

3. Put a drop on a slide, then add your wet specimen to it.
4. Leave the slide horizontal for a few days for the gum to set - in this time any clearing will take place. It is great for things like *Fossombronina* spores (Figure 120). For whole mounts of perianths or similar structures, the clearing properties will show up lots of structure without the need to dissect.

Figure 120. *Fossombronina longiseta* spore proximal SEM. Photo courtesy of William T. Doyle.

5. Although not strictly necessary, you may want to seal your coverslips with a couple of coats of nail varnish as it stops the gum from drying out. Technically this is a temporary mount but some slides last over 30 years old and are fine. It does tend to shrink delicate specimens so when if you don't need its clearing properties, use glycerine jelly as per Richard Zander in "Genera of the Pottiaceae."

Rod Seppelt (Bryonet 14 November 1997) suggested staining spores with **malachite green**, **acid fuchsin**, and **orange G**, a method used for testing pollen (Alexander 1969). The viable pollen stains deep red-purple, whereas the aborted pollen stains green. This recipe uses **chloral hydrate**, a controlled substance in the US. The solution uses 10 ml ethanol; 1 ml 1% malachite green in 95% ethanol; 50 ml distilled water; 25 ml glycerol; 5 gm phenol; 5 gm chloral hydrate; 5 ml 1% acid fuchsin in water; 0.5 ml 1% orange G in water; and 1-4 ml glacial acetic acid (for very thin to very thick walls). This should work as well for bryophyte spores.

SEM

Scanning Electron Microscopy (SEM) can reveal details not visible with an ordinary light microscope. Miyoshi (1969) demonstrated the intricate detail of *Schistostega pennata* and *Hedwigia ciliata* by using the Scanning Electron Microscope (SEM), compared to images using the light microscope. The image in Figure 121 was taken using SEM photography and can be compared to that of the same species using ordinary light (Figure 117) or both transmitted and reflected light (Figure 118). The SEM

technique is somewhat complex and time-consuming and will not be covered at this time. Methods can be found in Hofmann *et al.* 1996, Zhang *et al.* 2007, and Srivastava *et al.* 2011, and many others.

Figure 121. *Riccia sorocarpa* distal spore wall SEM. Photo courtesy of William T. Doyle.

Vacuoles

Many bryologists seemed to consider that bryophytes did not have vacuoles, but it appears this is only true for some taxa (Rod Seppelt, Bryonet 14 November 1997; Jeff Bates, Bryonet 14 November 1997). It is interesting that Seppelt reports that vacuoles seem to be absent in most Antarctic mosses. This suggests that absence of vacuoles may be an adaptation to cold temperatures – an interesting correlation to examine.

One indicator that a cell has a vacuole is the position of the chloroplasts (Michael Christianson, Bryonet 14 November 1997). If they are crowded around the periphery of the cell, it is likely that a vacuole is occupying the center of the cell. In Figure 122, fluorescent microscopy demonstrates the position of the chloroplasts at the periphery of the leaf cells of *Funaria hygrometrica*, whereas in Figure 123 that is more difficult to see.

Figure 122. Leaf of *Funaria hygrometrica* showing chlorophyll fluorescence and demonstrating the clustering of chloroplasts at the cell margins. Such positioning indicates the presence of a vacuole. Photo by Janice Glime.

Liverworts and Oil Bodies

Oil bodies can be a problem because they disappear as the liverwort dries (Tom Thekathyl, pers comm. 27 August 2012; Wagner 2013), in some species disappearing within hours despite a moist state of hydration. David Wagner (Bryonet 5 September 2012) considers it a general rule that when cells with oil bodies die, the oil bodies dissipate. Liverworts on rotting logs (which are moisture sinks) never dry out in nature, but when they dry, they die. Unlike other bryophytes, they are not desiccation tolerant. *Calypogeia* (Figure 124-Figure 125) species must be examined for oil-body characters before they dry. Once dry, the oil bodies are gone forever and slow drying doesn't help. On the other hand, liverworts that grow in extreme environments, like *Marsupella* spp. (Figure 126) on rocks in alpine situations, are as desiccation tolerant as any bryophyte. If air dried, herbarium specimens will retain oil bodies for years because the cells are NOT dead. They live for years in a desiccated condition. To have any chance of seeing oil-bodies in dried specimens, they must be rehydrated slowly with plain water.

Sometimes Wagner has been surprised at getting good results. Also be aware that oil bodies can change character as they age after collecting. There's no substitute for immediate observation upon collections, although this period can be prolonged if they are stored in a refrigerator or cooler (Wagner 2013). On the other hand, extended periods in the dark will alter their appearance or cause them to disappear. There are some mysterious anomalies. *Scapania gymnostomophila* (Figure 127-Figure 128) has oil bodies that persist for decades, itself a distinctive taxonomic character.

Figure 126. *Marsupella emarginata* var. *pearsonii*. Alpine rock-dwelling members of this genus retain their oil bodies when they are dried. Photo by Michael Lüth, with permission.

Figure 127. *Scapania gymnostomophila* with gemmae. Photo by Štěpán Koval, with permission.

Figure 128. *Scapania gymnostomophila* leaf cells showing oil bodies. Photo by Hugues Tinguy, with permission.

Nevertheless, liverworts survive wetting and drying in nature. Rod Seppelt (Bryonet 27 August 2012) reported that Jeff Duckett told him that the liverworts must dry SLOWLY for the oil bodies to survive, but does this always work, or does the death of oil bodies explain why so many liverworts seem to require a moist environment?

Oil bodies are often essential for identification. Several methods of liverwort preservation have been suggested (Lehman & Schulz 1982; Ohta 1991). Lehmann and Schulz suggest a method of fixation that preserves the oil bodies, as do Müller-Stoll and Ahrens (1990). The latter researchers provide a method of staining oil bodies in live cells with diachromes and fluorochromes. If you can read the language, these may be helpful.

Peristome Teeth

Niels Klazenga (Bryonet 9 April 2014) reports the method he uses, taught to him by Dries Touw. He uses it to see teeth without having too many spores to interfere with the view. He cuts the capsule in half transversely so

that you have a top half and a bottom half. Then cut the top half in four parts longitudinally. Transfer the four parts to a different slide after removing the columella and washing off excess spores. On the new, clean slide put two parts with the inside up and two parts with the outside up, so that you can see both the inside and outside of the peristome. You can do the same thing for the bottom half to see stomata, but it is rare that you need to see the inside of the bottom. These parts tend to be a bit temperamental, so they don't always end up the way you want them. Rod Seppelt added that the peristomes of some mosses assume a very different shape when wet. Instead of being straight, they bend from near the base, so that the upper parts of the teeth become strongly reflexed, completely reversing their direction. "Trying to wedge the peristome under a coverglass before wetting is tricky and does test the patience."

Brent Mishler (Bryonet 9 April 2014) suggested that one should select a recently dehiscent capsule and make a longitudinal cut through the peristome (Figure 129-1&2), followed by a transverse cut slightly below the peristome insertion (Figure 129-3, 4, & 5). The endostome (attached to the spore sac) will then usually separate from the exostome with fine forceps (Figure 129-6, Figure 130-Figure 133). If a large number of spores obscure the peristomial structures, a drop of 95% ethanol added before adding water will usually disperse the spores; then excess spores can be scraped or wiped off before adding water. "Treatment with ethanol also causes the separation of the exostome and endostome, facilitating their dissection and observation. If no dehiscent capsules are available, peristome details often can be observed adequately (*i.e.* adequately for identification purposes) by removing the operculum from a nearly mature capsule by immersing the capsule in water, adding a cover slip, and boiling the slide gently over a heat source. This is usually sufficient to cause the operculum to dehisce."

To study peristomes in plane polarized light, the ventral and dorsal laminae of the teeth (not outer and inner peristomes) must be separated (Taylor 1959). Examination may even require viewing a cross section of a tooth.

1. Split capsule vertically with a razor blade.
2. Soak teeth in groups of 3-4 in 5% solution of pectinase for 24 hours.
3. Wash in 3 or more baths of distilled water.
4. Make gum syrup mountant
 - A: 40 g gum arabic
0.5 g phenol crystals
60 cc water
 - B: 52 parts cane sugar
30 parts water (by volume)
 - Combine 25 cc A, 15 cc B, and 2 g glycerin.
5. Cover a small area of a slide with a thin coating of the gum syrup mountant.
6. For peristomes, permit gum arabic to become almost dry.
7. Transfer teeth in groups of 3-4 to mountant, making sure some groups show the ventral and others dorsal surface.
8. If peristome teeth curl, they can be moistened slightly with a damp (not wet) fine water color brush (# 00000).

9. The gum arabic can be remoistened if needed, especially if used for leaves and other structures.
 10. The teeth can be flattened on the slide with a needle or the damp brush.
 11. Make sure the gum syrup is nearly hard, but soft enough to flow under pressure. This will take practice to prevent ripples from too much liquid, but must permit the teeth to pull apart.
 12. To make teeth very flat (desirable), cover part of slide lightly with light coating of paraffin wax or other substance to prevent the adhesive from sticking to it.
 13. Press the coated slide against the teeth until they are tightly pressed against the mountant.
 14. Permit the gum arabic mountant to harden.
 15. Remove uppermost surface of lamina on each set of teeth by gentle scraping, using a dull tool such as a discarded side-cutting dental tool.
 16. Remove the loosened particles with a dry brush.
 17. Lightly moisten the gum syrup to get a smooth surface and allow to dry.
 18. To make the slide permanent, add the desired finisher, such as gum-chloral.
- To View Teeth:**
19. Place the finished slide on the rotating stage of a polarizing microscope and turn stage to a position where light is extinguished when viewing slide.
 20. Insert gypsum tube into microscope tube and rotate stage clockwise.
 21. If tooth lamina becomes blue or green, chains run N-S when tooth is returned to this extinction position.
 22. If tooth lamina becomes yellow after rotation, search for a position at right angles and repeat the test.
 23. Be careful not to rotate counter-clockwise.
 24. If all chains are parallel, you will not find the bright color change, but usually at least some will show an acute angle between two sets of chains.

Figure 129. Cutting method for capsule to display peristome teeth on a slide. Drawings by Sean Edwards.

Javier Penalosa (Bryonet 12 April 2014) found that slightly boiling the slide makes the operculum pop off the capsule (see Figure 130, Figure 132). He was successful in using this technique to see peristomes of *Bryum* (Figure 130, Figure 132) and *Brachythecium* (Figure 133). Once the operculum is off, a drop of alcohol will disperse spores on the slide. This exposes the **nodose cilia** in *Brachythecium rutabulum* (Figure 133) and appendiculate cilia in *Brachythecium oedipodium*.

Summary

Bryophytes often need to be cleaned before they are mounted for observation. Methods for doing this include a special bryophyte washing machine, netting on an embroidery hoop, wash bottle, HCl, H₂O₂, and agitation. Dried bryophytes need to be rehydrated using a wetting agent such as water, soap, detergent, heated water, 2% KOH, Pohlstoffe (docusate sodium), or Agral 600. Some leaves need to be cleared before cell wall papillae and wall structure can be seen clearly, using reagents such as lactic acid, KOH, NaOH, or chloral hydrate. Some species require air drying or dehydration in ETOH to prepare them for making a slide.

Stains permit further clarification of structures such as pores and wall markings and permit determination of cell types. They can be as simple as food coloring or an array of chemical stains used singly or in combination. Identification of *Sphagnum* usually requires a stain to discern the leaf cell pores. Archegonia and spermatogenous cells can be stained with fast green. Fluorescent dyes coupled with a fluorescence microscope can reveal bulbils and determine if spores are viable. A pectinase preparation can be used to stain liverwort capsules.

Some bryophytes (esp. Pottiaceae) produce different colors in reaction to a mix of HCl, KOH, concentrated H₂NO₃, and H₂SO₄. Some *Sphagnum* subgenera respond to pH and have distinctive colors in NaHCO₃.

Removing leaves from stems is aided by a dissecting microscope and microforceps. Sharp razor blades can be used to make sections of leaves and stems. Cutting is best done under a dissecting microscope, with the method being largely a matter of preference, including chopping, wax mounts, pith sandwich, cutting block, and double slide sectioning. If you are lucky enough to have a cryostat, you can use it to make sections.

Some structures require special treatment, such as clearing spores, using SEM, seeing vacuoles, preserving and seeing oil bodies, and seeing details of peristome teeth.

Acknowledgments

Numerous discussions by Bryonettters have contributed heavily to this chapter. I appreciate the additional help from Richard Zander who answered my many questions quickly and thoroughly and alerted me to his websites. He also did further testing of the clearing technique. Isawo Kawai kindly sent me numerous pictures and information on his staining procedure. Ralf Wagner provided me with the instructions for the Etzold staining and W3A staining.

CHAPTER 2-2b

SPHAGNUM STAINING

Figure 1. *Sphagnum russowii*, a species for which pores are seen more easily when stained. Photo by Des Callaghan, with permission.

Following a discussion on Bryonet and the diminishing size of his trusty aniline pencil (Figure 2), Rudi Zielman set out to compare various stains used to make the pores of *Sphagnum* leaves and stems more visible. This subchapter is the result of that investigation. Another driver for this

investigation is the toxicity of aniline. Furthermore, newer versions of this pencil simply didn't work – they didn't color wet leaves (Figure 3-Figure 4). And an aniline solution did not color the leaves easily. Then the leaves lost their color when they were placed in water.

Figure 2. Aniline blue pencil used to stain *Sphagnum*. Photo by Rudi Zielman.

Figure 3. *Sphagnum obtusum* branch in water with aniline blue pencil scrapings. Photo by Rudi Zielman.

Figure 4. *Sphagnum obtusum* stained with an old aniline pencil. The branch was stained, leaves carefully removed, and placed on a slide in water. The pores became more visible, as seen in the area inside the ellipse. Photo by Rudi Zielman.

The dyes used are all dyes with a ring structure; especially with toluidine blue it is emphasized that it should be the toluidine blue-O, *i.e.* the methyl and amine groups in the ortho position. This is also true with safranin, and apparently is the case in all the stains described here and currently available for staining the moss. Methylene blue and safranin are sold at (web) stores that also sell microscopy equipment.

Toluidine blue is currently the most difficult to obtain; when Zielman collected all the materials about 8 years ago he was able to collect the needed materials from a web shop and a university lab; gentian violet was also a problem at that time, now to a lesser extent; one needs a doctor's prescription to get it from a pharmacist. It is used in the treatment of **thrush** (a fungal infection) in infants, and can apparently also be found at shops that focus on supplies for breastfeeding. An advantage is that all these dyes are, in contrast to aniline, non-toxic. A 10 ml ready-to-use solution costs approximately 15-20 euros. Methylene blue, toluidine blue-O, and gentian violet are also available as a powder (quite difficult); to use them one places a few grains (forceps tip) on a slide and dissolves this in water or ethanol. You can also use the powder to prepare a "stock solution" (additional recipes on the internet; several are listed here, but unfortunately no URL's or author names were available), but then some stirring and filtering facilities are required. For the staining effects it does not matter whether you use the solution or the powder, but the solution works more easily.

A word about safety: methylene blue is the most annoying of these four dyes tested here. It is non-toxic, but it can cause eye and skin irritations. All solutions contain alcohol and are therefore slightly irritating. Spilled dyes

can be easily removed with a tissue and some methylated alcohol.

Methods

The stains used are:

- No colorant (stain) applied
- Methylene Blue
- Toluidine Blue (actually toluidine chloride)
- Gentian Violet (also called crystal violet or methylrosaniline)
- Safranin

Methylene Blue from Powder

Prepare a saturated solution of methylene blue by adding 1.5 g powdered methylene blue to 100 mL 95% ethyl alcohol. Slowly add the alcohol to dissolve the powder. Add 30 mL saturated alcoholic solution of methylene blue to 100 mL distilled water and 0.1 mL 10% potassium hydroxide. Always make these in a 1% ETOH solution, a saturated solution in water.

Toluidine Blue-O from Powder

Dissolve the toluidine blue powder in distilled water (0.1 g of toluidine blue in 100 ml of distilled water). Check the pH of the solution, it is very important. The stock solution should be pH 2.3 (and less than 2.5), achieved with 5 ml 1% sodium chloride in 45 ml; mix well. The working solution should be pH 2.0-2.5. Make this solution fresh and discard after use.

Alternatively, mix powder to dissolve and adjust pH to 2.0-2.5 using glacial acetic acid or HCl.

Gentian Violet Powder

Dissolve 2 g of gentian violet powder dye in 20 ml of 95% ethanol (Histanol 95) and mix with 80 ml of 1% aqueous solution of ammonium oxalate. Dip the moss quickly and rinse in water (Figure 5).

Figure 5. *Sphagnum* stained with gentian violet. Photo by Don Avery, with permission.

Safranin-O

Mix 10 ml of basic solution with 90 ml of distilled/demineralized water.

Applying Stain

For each stain, a dry branch or stem piece is quickly dipped in a few drops of the stain, stirred and slightly pressed to make sure the stain is distributed everywhere. If you dip too briefly, the leaf parts (often the proximal half) may not be properly stained because the stain solution could not reach them. After dipping, the branches or stem pieces are rinsed in demineralized water. Do this carefully; *Sphagnum* mosses very easily lose leaves or become damaged. Just dip in water, replace drops, re-dip, until the water no longer colors. After that, the material is mounted on the slide.

Microscopic images in this subchapter were taken with a Leica DM E microscope with 40 X achromatic objective and trinocular head with a Leica 1 X photo lens on which a Nikon D5300 camera body was attached. The diaphragm opening of the microscope is equal for all photos; the exposure intensity is not. Because a microscopic image has no depth of field, stacking is needed. First focusing is done slightly above the leaf blade or section and then the fine adjustment knob is used manually through small steps to change the focal plane through the cell wall, going deeper and deeper. The recordings are then stacked with CombineZM and reworked (color levels automatically balanced, stack edges clipped) with GIMP 2.10. (It is also possible to have a camera that does automatic stacking and combining the images.) The resulting photos are composed of a variable number of individual photos, depending on visual evaluation (or the number provided by an automatic camera).

Results

In the overviews below we show a few species in which pores are important to observe. For each species in the images shown, the different stains were applied to adjacent branches of the same stem just below the capitulum. The order is always no coloring, methylene blue, toluidine blue-O, gentian violet, safranin. This sequence shows a fairly even gradient in the colors seen, from blue through purples to orange-red.

Sphagnum divinum (Figure 6-Figure 16)

First of all, *Sphagnum divinum*, where the width of pores in the proximal part of branch leaves and the thickness of the wall between **chlorocytes** (cells with chloroplasts) and **hyalocytes** (colorless cells) are important to observe. What you see in these images of *Sphagnum divinum* is that the pores in the hyalocytes are clearly visible and are less than half the width of the cell. The leaf cross section is less clear. This is caused by the sigmoid cell pattern; the wall between hyalocytes and chlorocytes is visible through many sections behind one another, and thus is often blurred in stained leaf transections, so it is recommended to inspect these in unstained condition.

Figure 15. *Sphagnum divinum* leaf stained with safranin. Photo by Rudi Zielman.

Figure 16. *Sphagnum divinum* leaf cross section, stained with safranin. Photo by Rudi Zielman.

***Sphagnum obtusum* (Figure 4, Figure 17-Figure 27)**

A true challenge with staining lies in making visible the very small and very unclear pores of *Sphagnum*

obtusum. The cell wall thinnings that matter most are primarily located proximally in the leaf at the lateral sides; this zone is therefore always pictured.

Figure 17. *Sphagnum obtusum*, a species with faint pores that require staining for observation. Photo by Michael Lüth, with permission.

It should be clear that all stains enhance the visibility of the structures in the branch leaf cells of *Sphagnum obtusum*, while without such staining the faint pores remain invisible. But again, the stained cross-sections of the branch leaves are more difficult to interpret than the unstained ones.

Figure 27. *Sphagnum obtusum* leaf cross section, stained with safranin. Photo by Rudi Zielman.

Sphagnum russowii (Figure 28-Figure 38)

In *Sphagnum russowii*, the **pseudopores** (thin spots in the cell wall) of the stem epidermis are of importance. The easiest way to prepare them is by holding a piece of stem with forceps and then cut the whole stem diagonally with a razor blade; sometimes it even works to get rid of the tissue

below that epidermis completely (e.g. in the gentian violet preparation in Figure 36). Hölzer (2010) also mentions the large pores on the ventral side of branch leaves as characteristic (Figure 29); figs 30, 32, 34, 36 show the same pore structure.

Figure 28. *Sphagnum russowii*, a species with pores that are more easily seen with staining. Photo by Hermann Schachner, through Creative Commons.

Figure 29 is the non-stained version of *Sphagnum russowii* leaf pores; this image comes close to what we see through the microscope. In all pictures of the stem epidermis (Figure 32, Figure 34, Figure 36, Figure 38), except the unstained (Figure 30), the faint pores are clearly visible. Also the large pores on the ventral side in the branch leaves are easily recognizable. Please realize that the white holes are a view where a pore on the ventral and dorsal side are aligned with each other!

Judgment Call

The staining of *Sphagnum* helps in making pores visible, as unstained gaps in stained walls, but is not always necessary. As an example, one can make a good judgment on *Sphagnum divinum* (Figure 6-Figure 16) and *Sphagnum centrale* (Figure 39-Figure 42) without staining. Differentiating these species depends on the thickening of the cell walls of chlorocysts as seen in section, most obvious on the adaxial (= ventral) leaf side. Staining can help in assessing this wall. In general, however, we recommend the location of chlorocytes to be assessed by unstained cross-sections.

Figure 39. *Sphagnum centrale*. Photo by Hermann Schachner, through Creative Commons.

Figure 40. *Sphagnum centrale* unstained leaf cross section showing the almost hidden chlorocytes and thicker walls on the adaxial side of the hyalocytes. Photo by Rudi Zielman.

Figure 42. *Sphagnum centrale* leaf cross section with toluidine stain, giving a slightly better view of the thicker adaxial walls of the hyaline cells than in the gentian violet stain. Photo by Rudi Zielman.

If a decision has to be made as to whether faint pores or pseudopores are at hand, staining must be used. The dye which is used is less important as long as it is a cationic dye as already noted by Daniels and Eddy (1990). If I (Zielman) had read this in 2012 more carefully... For the rest it is merely a matter of taste; Adam Hölzer (2010) only wants to use gentian violet; Lisa op den Kamp (Bryonet, October 2012) has a strong preference for safranin; this is also the stain that was used by Laine *et al.* (2009), whereas in Australia all staining of botanical tissue is standardly done with toluidine blue (Rod Seppelt, pers. comm.). In general methylene blue, that used to be widely used, is considered a staining which is uncomfortably harsh and dark. Because of this I am, for the ease of use and availability, using more and more safranin, after my first bottle of gentian violet was empty. But after completing the work for this article, I tend to use toluidine blue, although it is tricky to obtain, or gentian violet. All in all it remains a tad a matter of personal taste, so not a firm conclusion. But I am going to use stains more often again, for an easier assessment.

Summary

Sphagnum pores are usually difficult or impossible to distinguish in unstained material. Some stains in use in the last century are toxic. And some current ones are difficult to obtain. Among the ones tested here, safranin and methylene blue are both safe and available from internet sources, gentian violet or toluidine blue might be preferred if obtainable. Some of the staining solutions can be made from powders, but it is easier to just buy the solutions ready-made.

Acknowledgments

This chapter is based mostly on a publication in Dutch (Zielman 2020). We all owe Rudi Zielman a vote of thanks for documenting the differences among the available stains.

CHAPTER 2-3

LABORATORY TECHNIQUES:

MAKING OBSERVATIONS

Figure 1. *Plagiomnium rhynchophorum* peristome ready to perform its dispersal of spores. Photo by George Shepherd through Flickr.

Sporophytes

Stomata

One of the most difficult things to see on a moss is the stomata at the base of the capsule. Rod Seppelt (Bryonet 27 August 2012) suggests clearing the capsules with lactic acid to make them easier to see. This method works well also to make it easier to see cell walls, cell content, papillae, and exothecial cells, including those on liverworts as well as mosses. The material should first be wet on a microscope slide and covered with a coverslip. Then place a drop or two of lactic acid on the edge of the coverslip and allow it to diffuse into the mount. **Gently warm the slide over a spirit flame** (a gas flame is too hot); this mix boils very quickly. The lactic acid gets rid of most of the cytoplasmic contents, thus clearing the tissues. If you want to make the mount permanent, then you must be sure all the lactic acid has been removed by heating, then add a permanent mounting medium at the edge of the coverslip.

Opening Immature Capsules (Lauridsen 1972)

Removing an operculum while keeping the peristome intact is difficult to impossible. Lauridsen (1972) tested a method that "fools" the capsule into behaving as if it is ripe, releasing the operculum. This is done with alternate immersion in **KOH** and **NaOCl**. The amount of KOH and NaOCl varies with species and ripeness and needs to be tested each time. This is best accomplished by dousing the capsule first with a drop of NaOCl for a few seconds, then in a solution of KOH until the mouth of the capsule becomes reddish. This may take 10 sec – 3 minutes. Zander (1993) recommends 2% KOH for Pottiaceae.

Although the method did not work well with *Funaria hygrometrica* (Figure 2) (14% opened), it was more than 90% successful in *Bryum argenteum* (Figure 3), *B. intermedium* (Figure 4), *Distichium inclinatum* (Figure 5), *Mnium hornum* (Figure 6), and *Polytrichum commune* (Figure 7) (Lauridsen 1972). The biggest disadvantage of the method is that the peristome teeth and exothecial cells

both become reddish in KOH, and the coloration remains. If possible, some capsules should be kept intact with no chemicals to retain natural colors. The treatment and color changes should be noted on the packet so as not to confuse further researchers with the altered colors. These chemicals should be washed away before mounting the specimen in Hoyer's or returning them to the packet. KOH plus Hoyer's will present a white precipitate, and excess NaOCl will eventually discolor the capsules.

Figure 2. *Funaria hygrometrica* capsule, with a lid (operculum) that is hard to remove. Photo by George Shepherd, through Creative Commons.

Figure 3. *Bryum argenteum* capsules, with opercula easily removed with KOH. Photo by Dick Haaksma, with permission.

Figure 4. *Bryum intermedium* with capsules; the operculum in this species is easily removed with KOH. Photo by David T. Holyoak, with permission.

Figure 5. *Distichium inclinatum* with capsules; the operculum in this species is easily removed with KOH. Photo by Michael Lüth, with permission.

Figure 6. *Mnium hornum* with capsules; the operculum in this species is easily removed with KOH. Photo by J. C. Schou, with permission.

Figure 7. *Polytrichum commune* capsules; the operculum in this species is easily removed with KOH. Photo by David T. Holyoak, with permission.

Zander (1993), working with **Pottiaceae**, suggests that if the operculum does not come off, the slide can be heated with a butane cigarette lighter, taking care not to let the flame touch the glass. A coverslip will reduce evaporation. If the peristome has a habit of breaking at the base, soak the intact capsule in a mix of **KOH** and **Pohlstoffe** for 15-20 minutes, or longer. To avoid precipitation that occurs with Pohlstoffe in KOH, one alternative is to add 1-2 drops of concentrated (4 g in 20 cc water) stock solution of **sodium N-lauroylsarcosine** (Gardol) to the bottle of KOH instead.

Britton (1890) found that capsules did not retain their ability to expand when rewet after drying, so she suggested that they should be kept in a moist dish under cover until needed for observation.

Peristomes

Miller (1988) reminded us of both the beauty and interesting behavior of peristome teeth (Figure 1). He advised that to see the details of the peristome, split the newly opened capsule lengthwise. Mount half in water with the outside surface upward and the other half with the inside surface upward. Adjust the light on the microscope, using the **diaphragm**, to get the best view of the details.

Sean Edwards (pers. comm. 22 April 2014) excites his students by demonstrating what he calls the karate-chop method, using a **Polytrichum** peristome (Figure 8). Using this method, he distinguishes peristomes in three species of the **Polytrichaceae**.

Figure 8. **Polytrichum** epiphragm showing peristome teeth. Photo by George Shepherd Creative Commons.

To observe the hygroscopic movement of the teeth, Miller (1988) suggested removing the sporophyte with its seta intact. Thread the seta through a pinhole in a stiff piece of paper to position the capsule firmly in a vertical position. In some mosses, like **Mniaceae**, you can see movement of an exposed peristome (Figure 9) and spore dispersal by breathing on the dry peristome, providing a change in moisture. Observe the teeth at 40X and 100X while blowing moist breath across the teeth. This works best when a second person supplies the breath so that you can observe it with the microscope at the same time. This will only work well if the capsule is mature and the spores are still inside, but the peristome can still respond even if the spores are gone.

Figure 9. **Plagiomnium rhynchophorum** (Mniaceae) peristome – one that flexes in response to humidity in one's breath. Photo by George Shepherd, with permission.

I have had success in observing peristome movement with **Dicranella heteromalla** (Figure 10-Figure 11) by keeping the capsule and seta attached to the moss. The moss needs to be rehydrated by placing one or more drops of water on the leaves near the seta insertion. Exercise caution to avoid getting water on the seta or capsule. The nearby moisture first causes the seta (Figure 10) to gyrate, delighting the students; then the peristome teeth (Figure 11) begin to flex. Breathing on it might give the same result.

Figure 10. **Dicranella heteromalla** with capsules; setae in this species will gyrate in response to moisture changes. Photo by Bob Klips, with permission.

Anchoring Specimens in Clay

Conard developed a unique idea for examining peristomes and their activities. He suggested placing a bit of clay (any color) 5-8 mm across and 1-2 mm thick on a slide. A capsule, with its seta removed, can be placed in any desired position for observation with high power on a compound microscope. The right clay will remain soft, so the slide can be kept for several years and the capsule can still be repositioned. This can also be useful for demonstrating peristome movement to students and for other uses where positioning is important.

Counting Spores

Britton (1890) detailed a way to examine the capsule and its contents. She suggested that observing a dry capsule on a microscope slide under low power on a compound microscope (4x or 10x objective) could lead to the breaking of the annulus that holds the lid (operculum) to the capsule. If the annulus releases the lid, the dryness will cause capsule compression and spores will be pushed out. If there are still too many spores in the capsule, put a drop of water on one edge of the coverslip and draw it through with a piece of paper towel or blotter on the opposite edge. The spores will be drawn out as the water moves.

If this procedure is unsuccessful, you can encourage the spores to come out by holding the slide over the flame of an alcohol lamp until the water boils (Britton 1890). This drives the air out of the capsule and the spores with it. BE CAREFUL with this technique because if the slide gets too hot it can break, sometimes explosively. Withdraw the slide before the water dries up completely.

Most of the recent spore counting techniques have been copied from pollen counts. To obtain a sense of variability, one capsule is not enough, despite the large number of spores in most species. Fifteen is a reasonable number, but they should, if possible, be distributed among 15 clumps to minimize the bias of a single genotype. One drop of Extran® in 5 ml distilled water can prevent clumping. These can be spread in 5 ml water in a **Newbauer chamber** (used for counting platelets and red cells in blood). This chamber is designed for a thick crystal slide with the size of a glass slide (30 x 70 mm, but 4 mm thickness). The counting area is located in the center of the slide. Counting can be done at 100x, with further replication achieved by four counts per sample. The mean number of spores per sporangium is used. Size uses the greatest diameter and can be based on photomicrographs analyzed with ImageJ software (Rasband 1997-2002).

Spores can be difficult to observe because of their density. Miyoshi (1969) compared the visibility of the special surface ornamentation under light and SEM microscopy, demonstrating the superiority of SEM for this purpose. Other methods are covered in Chapter 2-2 of this volume.

David Wagner (Bryonet 22 January 2020) suggested a method that is used for pollen grains in anthers. The anther or capsule is wetted with a small amount of wetting agent. This keeps the spores in a clump instead of floating to the edges of the drop. Smash the capsule in a small drop of glycerine that will fit under the coverslip. Instead of a

normal coverslip, use a **reticle** (series of fine lines or fibers in eyepiece of optical device such as microscope, used as measuring scale or aid in describing location of objects) with a 1 cm grid marked in millimeters. A grid of this size will have one square visible under the 10X objective of a compound microscope. This magnification is high enough to count the spores one square at a time, from top right to lower left, 100 squares. It is tedious but gives a very accurate result with a single mount.

Efrain De Luna (Bryonet 22 January 2020) suggested that to avoid the tedious stem, you can use the NIH Image (ImageJ, free software) or purchase ImagePro (Media Cybernetics) to recognize such discrete objects as cells, spores, *etc.* and determine their size and counts with the software.

Tom Ottley (Bryonet 22 January 2020) suggested a more mathematical approach.

Wagner assumes that evolutionary selection would result in the maximum number of spores being packed into a capsule. Then one can measure the internal diameter of the capsule and the diameter of a spore. Capsule diameter, divided by spore diameter, cubed x 0.6 would give the number of spores. He then multiplies by 0.5 to compensate for other structures (such as the columella) taking up space. This should actually be calibrated for each species by comparing to actual counts, and spores would probably need to be at the same stage of development. Ottley also suggesting that weighing a few (~10) ripe capsules, then emptying the spores and reweighing the capsule could give you an estimate of the spore weight. You could calculate the weight from a measured diameter by assuming a density of 1. This requires a sensitive balance.

Nicholas McLetchie (Bryonet January 2020) suggests the alternative method of using a hemocytometer, following methods for counting blood cells.

One method for calibrating counts, used by palynologists, is to purchase a tablet with a known number of *Lycopodium* spores – usually with ~10,000 each (Bent Vad Odgaard, Bryonet 22 January 2020). One tablet is added to the solution containing the liverwort spores and a few drops of HCl are added to dissolve the calcium carbonate that holds the tablet together. Since you know the number of *Lycopodium* spores, and if you assume an equal and even dispersion of both kinds of spores, you can compare the counts of the two kinds of spores under the field of view and use the ratio to calculate the total number on the slide.

Adam Hölzer (Bryonet 22 January 2020) suggests putting spores of several capsules in a measured amount of water (50 or 100 ml) with some glycerin. You will need to test several amounts of glycerin to find the appropriate amount. Then shake the mix very well and quickly remove 1 or 0.5 ml to a slide before the spores can settle. These can then be counted by one of the above methods.

Surface ornamentation and shape are likewise important in examining spores (Kristian Peters, Bryonet 13 November 2019). Some of these ornamentations are important in dispersal and may differ between aquatic and terrestrial species.

Flotability can also be an indication of density. Misha Ignatov (Bryonet, 12 November 2019) reported that he had heard about one experiment where **Polytrichaceae** spores remain floating on the water surface despite various

attempts to sink them, but after adding TRIS (reducing surface tension) they all sank immediately. Thus, their density is slightly greater than 1. Using solutions of various density one might like find out spore density quite precisely, if necessary.

Spore diameter is provided in most descriptive bryophyte floras for each species (Misha Ignatov, Bryonet 12 November 2019). For a description of shape, size, and ornamentation of moss spores in Europe, see Boros and Járαι-Komlódi (1975).

Spore Dispersal

Place mosses or liverworts with mature capsules where the heat of a lamp is focused on them. Allow the bryophytes and their capsules to dry with the heat until the operculum comes off (mosses) or the capsule splits (liverworts). If it is a moss, the peristome teeth will begin to move as the capsule dries further and the seta may begin to gyrate. If it is a liverwort, the elaters will begin to twist, aiding in the dispersal of the spores.

This demonstration could be even more interesting by placing the capsule on an agar plate (see chapter on culturing) for the above procedure (we haven't tried this, so it might not work). Set the capsule into the agar so that it is upright. It might be necessary to put a narrow cellophane collar around it to keep the capsule from absorbing moisture from the agar. When spores disperse, they will land on the agar. The plate can then be covered to allow the spores to germinate.

Another method for determining dispersal distance is to place a capsule upright by one of the methods described earlier and place microscope slides coated in glycerine at designated distances from the capsule. The spores that are dispersed will be trapped by the glycerine and can be observed under the microscope. This could likewise be done with plates of agar. I would suggest the small Petri plates (35 or 50 mm) to save agar and space. This same technique will work in the field as well as in the lab. There will undoubtedly be contamination, but since the goal is only to locate spores and the distance travelled, contamination need not be a concern.

Living spores in the capsule or elsewhere can be distinguished from dead ones by several techniques. Fluorescence (see Chapt. 2-2 in this volume) will make living spores and living parts of spores visible when viewed using a UV light source. When using an ordinary light microscope, living spores can be distinguished using acetocarmine stain (Mogensen 1978). Living spores stain deep red, whereas dead spores do not stain at all.

Sperm

The first problem for observing sperm (Figure 12) is finding the antheridia at the right stage. By the time the male inflorescence is distinguishable, the sperm are likely to be dispersed (Jeff Duckett, Bryonet 11 January 2012). While many bryophytes are adapted to take advantage of spring rains for dispersal of sperm, we are learning that

mites and springtails can disperse them, and some bryophytes take advantage of autumn water. *Polytrichum* (Figure 13-Figure 14) typically disperses sperm in early spring, *Sphagnum* (Figure 15) in autumn (Jeff Duckett, Bryonet 11 January 2012). *Pellia* (Figure 16), which has the largest sperm, disperses in early summer. Reese (1955) suggests that sperm are best collected during a dry period because rain will cause them to disperse and you will miss them. Of course if you see new growth arising from the antheridial head, you have missed the dispersal event (Figure 13).

Figure 12. Stained bryophyte sperm. Image modified by Janice Glime.

Figure 15. *Sphagnum* antheridia; these release sperm in autumn. Photo courtesy of Yenhung Li.

Figure 16. *Pellia neesiana* antheridia; these release large sperm in early summer. Photo by Michael Lüth, with permission.

If you are lucky enough to find ripe antheridia, you may need special techniques to actually see the sperm. First, you will probably need to squash the antheridia to release the sperm, a feat you can accomplish by pressing lightly on the coverslip, preferably while observing the antheridia through the microscope so you don't overdo it.

Once you have freed the sperm, they may not be as easy to observe as you might expect. They are in constant motion, so it might help to add a bit of **methyl cellulose** to the medium to slow them down (Rod Seppelt, Bryonet 11 January 2012). Even so, they are transparent, eluding detailed observation. Use the diaphragm of your microscope (NOT the rheostat) to decrease the light and increase contrast.

Reese (1955) presented a method for observing sperm. He suggested clipping off the antheridial heads or branches with perigonia and inverting several in a drop of water on a slide. The source of water is important, with chlorine in tap water killing the sperm, and distilled water likewise having deleterious effects, perhaps causing the cells to take in water and explode. Reese suggests letting tap water sit overnight. The slides can be put aside in Petri dishes with damp filter paper until the water on the slide becomes milky, indicating that spermatozooids have been released. At this point, the antheridial parts should be removed, leaving only water and sperm on the slide. Set the slide somewhere to dry in preparation for staining. The dry sperm can be stained with a 1% aqueous solution of gentian violet. You can immerse the slides in the gentian violet or place a few drops of the stain on the slide. All that is needed is 30-60 seconds to stain the material. Then wash the slide with distilled water and de-stain it in 50% ethanol for 10-20 seconds. Wash it again in distilled water, allow it to dry, and mount it in your choice of mounting media.

To observe live antherozoids, Reese (1955) recommends smearing a small amount of fresh egg albumen on a slide and adding a drop of water with freshly discharged antherozoids. You can add a cover slip if you wish to observe. The albumin helps to slow down the movements of the antherozoids. Using darkfield illumination helps in observing these, or close the diaphragm down as far as it will go.

Des Callaghan has created a film that shows sperm in motion <<http://youtu.be/Jdh8flxvZgk>>. These were not stained, but instead used differential interference microscopy (DIC) to create the contrast needed for the sperm to be visible.

If you just want to find sperm, and possibly count them, you can probably succeed with Sperm VitalStain™. We have not tried this – it is designed for human sperm and it can distinguish between living and dead sperm. The stain contains both eosin and nigrosine. The eosin will be absorbed by the dead cells – those with a damaged plasma membrane – and will stain these cells red. Nigrosine is a counterstain that facilitates the visualization of the living (unstained) cells. Instructions are available on their web page.

Nelly Horst (pers. comm. 3 February 2013) reports that DAPI staining (available from chemical suppliers) works nicely as a stain (Figure 17).

Paraphyllia

Seeing these small structures can be challenging, even in large species. Rod Seppelt (Bryonet 26 October 2022) offers suggestions to make it somewhat easier: For **pseudoparaphyllia**, he finds that by using a pair of very fine forceps (e.g. Watchmakers No. 5, but they are about AU\$50 in Australia) it is possible to press slightly on the stem and at the same time clasp the base of a branch and tear/slice away the branch base. This will have a bit of the stem and, with any luck, the pseudoparaphyllia if they are present. It is a bit frustrating, however.

Axillary Hairs

Seppelt (Bryonet 26 October 2022) relates that early on he asked Bill Buck where to look for axillary hairs. The reply was to look at the very apex of the shoots. He may have been primarily referring to pleurocarps. But, in general terms, carefully remove a number of leaves, clear the leaves in lactic acid (gets rid of the cellular contents making cell details more easily visible), and then go hunting, examining the basal attachment part of the leaves. They are often very small, sometimes with 1-2 tinted (yellowish or brownish) basal shorter cells. Length varies and it is a moot point as to what constitutes a "mature" axillary hair. Seppelt has also found that axillary hairs are not always to be found in the shoot apices. In some *Fissidens* (Figure 18) species, for example, they can still be found in the axils of leaves several pairs of leaves below the shoot apex.

Figure 18. *Fissidens adianthoides*; in some species of *Fissidens* one can find axillary hairs at some distance below the apex. Photo by Hermann Schachner, through Creative Commons.

Jeff Duckett (Bryonet 27 October 2022) has found that the best way to see axillary hairs is to cut the stem apex longitudinally and squash it with the cut surfaces uppermost. This will make the hairs readily visible in the axils of the young leaves. These hairs are short-lived and thus one is unlikely to find them among older leaves.

Hedenäs (1989) examined the axillary hairs of 200 pleurocarpous moss species. He pulled the leaves off the terminal ~5 mm of the stems. He found that the branches usually have fewer and weaker axillary hairs. Hairs could often be found attached to the bases of detached leaves where stem portions remained, but in other cases it was necessary to squash the tips.

Leaf Movement

Beginning students are often in awe when they drop water onto a moss like *Hedwigia ciliata* (Figure 19-Figure 20). The leaves spread before their eyes like a well-orchestrated ballet. Place a moss branch on a glass slide or in a Syracuse watch glass and add water to one end. As students watch the leaves spread, this permits a good discussion on why. They can compare species and further investigate to try to determine why some spread more easily than others.

Hedwigia (Figure 19-Figure 20) is great for a spreader (Figure 20), *Mniaceae* for non-spreaders (Figure 21) (without special coaxing). They can compare this behavior to that of dry tracheophyte leaves. It is an interesting exercise to try to determine what mechanism causes the leaf spread. For example, in *Polytrichum* species (Figure 13), the large, non-chlorophyllous area at the base of the leaf (Figure 22-Figure 23) fills with water and forces the leaf out. One can compare a variety of species and examine the leaf structure to see what facilitates the movement. This simple exercise can lead to lots of questions and simple observations and experiments – role of temperature of the water, other liquids, leaf structure (alar cells, borders, costa), staining to track where the water goes, etc.

Water Movement

Water enters bryophytes in various ways. For the majority of bryophytes, entry is through the leaves and in at least some it occurs most easily at the tips of the stems. But for some it is able to enter through rhizoids, and others absorb water throughout the plant. Once water gains access, various structures can help to move the water more quickly. Hydroids in stems seem to function like tracheids and vessels, moving the water upward in the plant through elongate capillary spaces of the hydroid cells. Alar cells can facilitate entry of water at leaf bases and from there it might enter the costa, travelling more quickly through the elongate cells of the costa because it has fewer cell walls to cross. But water will also move across the leaf lamina from cell to cell. And in mosses like *Polytrichum* spp., there are leaf traces (Figure 24) that can facilitate movement of water from the stem into the leaf. There is little published data to demonstrate how each of these structures affects the speed of movement and how that differs among taxa. Of even greater interest is a comparison of these structures and their effects on water movement as it relates to habitat.

Water movement can be demonstrated with dyes placed at various positions on the moss (Figure 25). Dyes at the tip can demonstrate how far downward the stain is able to go in a period of time and how it gets there – central strand? stem cortex? leaves? external capillary spaces? Plants positioned with their rhizoids in a dye can demonstrate the ability of rhizoids to take up water and the ability of the plant to move it upward.

After the dye has been placed on the portion of the plant of interest, one can cut sections at intervals to look for the presence of the dye in various parts of the plant. Care must be taken to prevent external dye from reaching other tissues when the specimen is mounted on the slide, so it is best to apply the dye, permit it to enter the plant for the time desired, then thoroughly wash the outside of the plant until it no longer discolors the wash water.

intensities to see what that particular bryophyte responds to. Studies on bryophyte tropisms are limited (See Volume 1, Chapter 5-5), so new discoveries are almost certain.

Figure 27. *Fontinalis squamosa* rhizoids exhibiting negative phototropisms to light coming from the left. Photo by Janice Glime.

Tropisms

Most, perhaps all, mosses exhibit tropisms. But do any, or all, liverworts do the same? Tropisms can be exhibited by culturing spores and using gravity (in darkness) or light from one side to test for these two tropisms (Figure 26- Figure 27). But a simpler method is to use a plastic bag and arrange the bryophytes to change direction of gravity or light. If testing for effects of one of these, be sure that the other cannot have any effect. For gravitropism, the clump can be placed on its side and light excluded. For phototropism, the clump should remain in its normal upright position and light should come from one side (Figure 26). Figure 28 demonstrates a combination of light and gravity on mosses on agar plates to test which has the stronger effect. Once a phototropism has been observed, one can experiment with various colors of light and

Figure 28. Paper rolls used to test the combined effects of light and gravity on tropisms. Photo by Janice Glime.

Etiolation

Etiolation can be demonstrated by placing bryophytes in a sealed plastic bag and giving them almost no light, such as that in a desk drawer or cabinet with the door closed. Within a few days or a week your bryophyte is likely to become elongated and spindly. I (Glime) sometimes see this in my terrarium where mosses grow from spores and have less light intensity than outdoor light.

Splash Cup Dispersal

The distribution of gemmae from the gemma cup of *Marchantia* (Figure 29-Figure 30) can be shown, and this might be applied to other splash dispersal structures in bryophytes. The splashing is effected by dropping colored ink or food coloring from a titration column onto the splash cup. The liverwort should be surrounded by white paper. As the dye hits the splash cup from the titration column, it splatters around the splash cup and makes blue spots on the white paper. This is a minimal approximation of the ability of raindrops to splash the gemmae. The distance of the water dropping is much less than that of a real raindrop, hence not having the same impact and resulting in shorter splash distances. The person doing the "splashing" should wear an apron or other protection during this demonstration.

Determining Oicy

Determining whether sexual organs occur on one plant or on separate plants is not an easy task. As Roxanne Hastings (Bryonet 14 April 2014) asserts "In order to be certain one must tackle the problem with systematic thoroughness." Using more traditional methodology, Hastings states that you must ensure that your clump of mosses is complete, including all the basal attachments, in order to determine **cladautoicous** (with antheridia on separate branch of same plant) mosses. She recommends taking a large clump, soaking it, and spreading it out on a slide or Petri dish. Then carefully tweeze the stems apart and remove any stems that are not basally attached. (You can't tell if they are part of the same or different plant.) Such fragments are only useful if the plant is **gonioautoicous** (having male and female reproductive parts on the same branch).

Then the tedium begins. Take a single stem and use needle-nose forceps, starting at the base, to carefully pull back each and every leaf to examine carefully for reproductive structures. When you reach the stem tip, remove that stem from the clump and set it aside. Then repeat the process on the next stem and every stem/branch of the clump until both sexes are located or you are certain only one is present. Yes, it can take several hours to peruse only one clump! Unfortunately, finding only one sex by this method is not definitive. Male organs typically develop before female organs do, or you might just be unlucky in finding only one of the sexes on your branches. And beware of the dwarf males (see Chapter 3).

But there is another way. And it even works for plants that are not producing sexual material at the time. Using the rarely reproducing dioicous moss *Drepanocladus turgescens* (Figure 31), Hedenäs *et al.* (2016) developed a method using a female-targeting marker that was previously developed for *Pseudocalliergon trifarium* (syn. *D. trifarium*; Figure 32) and *D. lycopodioides* (Figure 33). When male and female portions of *D. turgescens* were sequenced and amplified, this method was successful in consistently revealing differences between males and females at five sequence positions. Alas, this method is likewise time-consuming and complicated, but it is reliable.

Brownian Movement

Motion within a cell can often surprise the observer, especially a beginner. If you see chloroplasts moving as a group in something approaching a circle, it is most likely **cytoplasmic streaming**. However, if the movement is more like a vibration, it is most likely Brownian movement. Molecules are in constant motion, and these bump structures like oil bodies, causing them to move. Smaller particles within the cell will most likely also be in motion, but are less obvious. Ken Adams (Bryonet 2 February 2012) explains that at the small dimensions of cells, the thermal collisions of molecules against oil bodies is unbalanced. Thus, in any instant the number of collisions on one side of the oil body exceeds that on the other side.

Jeff Duckett (Bryonet 2 February 2012) reminds us that cytoplasmic streaming is unlikely to cause motion of liverwort oil bodies because there is almost no cytoplasm surrounding them.

Plasmolysis

Cyndy Galloway (Bryonet) uses the moss *Physcomitrium* (Figure 34) to demonstrate plasmolysis to

students. A fairly strong salt solution causes the protoplasts to look like little basketballs. However, she said that adding water for deplasmolysis caused the cells to take in water too rapidly, causing them to burst. Perhaps that could be solved with some tinkering – a lower salt concentration, and replacement by water with some amount of salt that would be close to isotonic. *Fontinalis duriaei* (Figure 35) demonstrates plasmolysis caused by a copper solution (Figure 36). Observations on plasmolysis can be an assessment tool for contamination by heavy metals and will most likely be useful for other types of pollution as well.

Figure 34. *Physcomitrium sphaericum* leaf cells, a good species for demonstrating plasmolysis. Photo by Michael Lüth, with permission.

Nutrient Cycling

There is a very easy, inexpensive exercise that can be done to demonstrate the role of bryophytes in nutrient cycles. Unfortunately, I don't know who contributed this, so if it is yours, please let me know!

Half fill a series of clear plastic (polycarbonate) cups with water – rainwater or distilled water is best. Add **methylene blue** dropwise to sets of three cups, one drop, two drops, and three drops for each cup in the set. (A small bottle of a concentrated solution of methylene blue can be obtained at a tropical fish store. It is a cationic stain that every bryologist should have on the lab bench.) The number of sets is determined by the number of samples.

Into each set place a moss or liverwort sample. Divide each sample into three parts. Add nearly equal amounts to each of the three cups in the set. A set = 3 cups, one with 1 drop, one with 2 drops, and one with 3 drops of stain. Volume by sight will work, but weighing is better. The sample should be small enough to be completely immersed in the methylene blue solution; bring the level up to about three quarters. It is interesting to compare nutrient sequestering abilities of *Sphagnum* (Figure 37), *Eurhynchium* (Figure 38), and forest floor leaf litter, for example.

Figure 36. *Fontinalis duriaei* leaf. **Upper:** healthy leaf cells in water, demonstrating normal cell protoplasm arrangement. **Lower:** *Fontinalis duriaei* leaf cells in $100\ \mu\text{g L}^{-1}$ copper, showing plasmolysis of cell contents.

Leave the sets overnight. The solution with moss will be clear in all of the cups (usually) while the dicot leaves and leaf litter water will still be blue. The graduated series of stain concentration helps visualize the effectiveness of the various samples. If you add an aquatic plant, you might get different results, so habitat comparisons could be quite interesting.

This demonstration shows how cations are scavenged by the cryptogams. In nature they pick out the micronutrients from rainfall that provide nutrition for the ecosystem or move them in solutions from the soil, using capillary spaces. Others remove them from water in streams and lakes. In industrial applications bryophytes clean water by picking out toxic metal ions and other cationic pollutants. This simple experiment can demonstrate rate differences among mosses and give an indication of their ability to extract nutrients from their ecosystems.

Figure 37. *Sphagnum centrale* with leaf litter. Photo by Janice Glime.

Figure 38. *Eurhynchium oreganum*. Photo by Matt Goff, with permission.

Depending on the size of the cups, it may be necessary to start with a more dilute solution of stain than comes out of the bottle. Try adding lichens to the experiment for another comparison.

Measuring

Most of the material viewed using the microscope is too small to be measured with an ordinary ruler. Instead, we use a device called the **ocular (eye) micrometer** (reticule; Figure 39), which is a small disk that fits inside the eyepiece of the microscope. The disk has a tiny scale etched on it, and when we view a specimen, the image of the scale is superimposed on the object image.

The ocular micrometer scale is usually divided into units of 10 (Figure 39). To measure an object, simply count the number of units superimposed on the object. Thus the object shown in the margin is 10 **units** long.

Note that the measurement is reported in units, not microns or millimeters. We cannot assign a label to the units until the ocular micrometer has been **calibrated** (Figure 40-Figure 42). The scale needs to be calibrated with each objective on the microscope because the magnification of the scale never changes, whereas the magnification of the object does. An ocular micrometer placed in a 10X eyepiece is always magnified 10 times,

whereas an object under the objective is magnified by the power of the objective **and** the ocular.

To calibrate the ocular micrometer, you need to compare the scale with a scale of known dimensions that fits on the stage of the microscope (Figure 40-Figure 42). Remember that the stage is where all your organisms will sit on slides and perform for you (Figure 42). This special slide is known as a **stage micrometer**. It is a microscope slide with a tiny ruler etched on it. The marks on the ruler are exactly 0.01 mm apart (0.01 mm = 10 microns, μm).

Figure 39. Microscope ocular, showing where the ocular micrometer is inserted. Photo from Wikimedia Creative Commons.

Calibrate

1. Begin to calibrate the ocular micrometer by placing the stage micrometer on the stage and focusing on it with low power.
2. Move either the ocular or the stage micrometer until the two scales are superimposed.
3. Now move the stage micrometer laterally until the lines at one end coincide with each other. Call this point A.
4. Look for another line on the ocular micrometer that coincides with one on the stage micrometer. Call this point B.
5. Count the number of divisions on the ocular micrometer between points A and B.
6. Count the number of divisions on the stage micrometer between points A and B. Multiply this

number by 0.01 mm to find the actual length of these divisions.

7. To find out how many mm equals 1 unit on the ocular micrometer, divide the answer to line 6 by the number of ocular micrometer units (line 5). (stage number of divisions/ocular number of divisions):

$$\frac{\text{mm}}{\text{ocular unit}} = \frac{0.01(\# \text{ stage divisions})}{\# \text{ ocular divisions}}$$

For example, in Figure 40 below, the number of stage micrometer divisions between points A and B is 6. The number of ocular micrometer divisions in this distance is 3. Therefore, the mm/unit on the ocular micrometer is: $(6 \times 0.01 \text{ mm})/3 = 0.02 \text{ mm/unit}$ or $20 \mu\text{m}$.

Figure 40. Alignment of scale of ocular micrometer (reticule) with that of the stage micrometer as seen in the eyepiece of the microscope. Drawn by Shelly Meston.

Figure 41. View of an ocular micrometer (reticule) in the eyepiece of the microscope. Drawn by Janice Glime.

Figure 42. Reticule in position to measure width of midleaf of *Barbula convoluta*. Measured width is 28 units and must be calibrated against stage micrometer. Leaf image by Dale A. Zimmerman; reticule by Janice Glime.

An object under this ocular and this objective measuring 8 units would be 0.16 mm long. Calibrate your ocular micrometer for each objective on your microscope and record the conversions below to keep as a reference.

low power:	
# stage micrometer units	_____
# ocular micrometer units	_____
mm/unit	_____
medium power:	
# stage micrometer units	_____
# ocular micrometer units	_____
mm/unit	_____
high power:	
# stage micrometer units	_____
# ocular micrometer units	_____
mm/unit	_____
oil immersion:	
# stage micrometer units	_____
# ocular micrometer units	_____
mm/unit	_____

You should also include the scale when you make drawings. Follow the instructions above for calibrating an **ocular micrometer**, which is a small ruler that fits in the eyepiece of your microscope. Using this ruler, you can measure things you see under the microscope. If you do not have an ocular micrometer available, you can estimate the size of objects using only a **stage micrometer**. The stage micrometer is a special slide that has a tiny ruler etched on it. Place the stage micrometer on the stage of your microscope and focus on the ruler with low power. Each mark on the micrometer is 0.01 mm apart. Use the ruler to measure the diameter of your field of view. Do this for each power on your microscope and record the diameters in the blanks below. Be very careful when focusing under the higher power objectives because the stage micrometer is very expensive. Then, use this

information to estimate the size of objects seen under each power and to include a scale with each drawing you make.

field of view diameters:

low power _____
 medium power _____
 high power _____

Leaf Measurements

It is challenging to measure leaf cells because, unlike bricks, they are not rectangular. Rather, their sides are not parallel and their width and length change along the cell. In an attempt to solve this measurement problem, Ivanov and Ignatov (2011) developed a method to digitize the "cell net." Using this software, one can measure cell length, width, and area. They compared the published cell width for five moss species in five different publications (Table 1).

Table 1. Comparison of published cell width data for five pleurocarpous moss species in μm (from Ivanov & Ignatov 2011).

	Noguchi		Lawton		Ignatov & Ignatova
	1992	Smith 2004	1971	Limpricht 1885-1904	2004
<i>Ptilium crista-castrensis</i>	2	4-5	3-5	5	4-6
<i>Callicladium haldanianum</i>	4-4.5	-	5-7	6	5-8
<i>Calliergonella lindbergii</i>	3-4	5.0-6.5	4-7	6-7	5-7
<i>Isopterygiopsis muelleriana</i>	4-4.5	4-6	-	5-6	-
<i>Hylocomium splendens</i>	3-4	5-7	4-6	5	5-6

Later, Ivanov and Ignatov (2013) developed a 2-d digitization of plant cell aeration using polarized light microscopy. This microscopic image is photographed into a digital photo. Using *Plagiomnium elatum* (Figure 43-Figure 44) and *P. medium* (Figure 45-Figure 46), they digitized the cell arrangement of the oblique rows (Figure 44) on these unistratose leaf lamina. They proposed a "computer analytic method that allows transferring visible images into coordinates of intracell boundaries and their **vertices** (points where three or more cells contact), *i.e.*, into a digital cell net. After such a digitizing it is possible to estimate many geometrical parameters of cells and their complexes under relatively simple mathematic treatment." Chemical or physical coloring methods should be used to permit distinction between cell boundaries and intracellular space. In some cases, this might be done by fluorescence microscopy. The method is somewhat complex, so I refer the reader to the original paper as I have not tried it myself.

Leaf Angles

A simple ocular protractor can be constructed using an ocular micrometer (Christy 1987). These instructions are modified only slightly from their publication in The Bryological Times.

1. Using an index card or heavy paper, draw a circle with a diameter equal to that at the top of your microscope eyepiece.
2. Use a protractor and ruler to draw 10 radii in 20° increments in a 90° segment of the circle (Figure 47, **a**).
3. Cut out the circle from (1) and cut a rectangle ~3 x 10 cm from the same card or paper.
4. At the points where the 10° radii meet the edge of the circle, draw corresponding marks along one of the long edges of the rectangle (Figure 47, **b**). Do this along the entire edge of the rectangle to form a scale calibrated in 10° intervals. Discard the circle (or save it for making replacement **collars**).
5. On the rectangle, draw a smaller mark midway between each 10° mark. Midway in the scale, label one of the 10° marks "0," then count in each direction from 0 and mark off 45, 90, 135, and 180°. This makes a scale calibrated in 5° intervals (Figure 47, **c**).
6. Wrap the scale, calibrations on upper edge, around the side of the eyepiece tube, and using adhesive tape, secure the overlapping end to the other end to form a ring of paper around the eyepiece tube (Figure 47, **d**). This is the **collar**, for which the fit should be loose enough that it can be rotated on the tube, but tight enough for friction to hold it at any setting.
7. Put a V-shaped scratch or pencil mark, on the rim of the eyepiece, on a radius parallel to the scale line of the ocular micrometer to serve as an index mark (Figure 47, **e**).

Use of the Ocular Protractor

1. Rotate the eyepiece or move the microscope slide until one of the scale increment lines on the ocular

micrometer is parallel with one side of the angle to be measured. While holding the eyepiece stationary with one hand, rotate the collar with the other hand and set the zero point of the collar at the index mark on the rim of the eyepiece (Figure 47, **f**).

2. While holding the collar stationary with one hand, rotate the rim of the eyepiece with the other hand until the other side of the angle is parallel to one of the scale increment lines on the ocular micrometer (Figure 47, **g**). The degrees of the angle can then be read on the collar at the point directly below the index mark on the rim of the eyepiece.

Figure 48. *Polytrichum juniperinum* leaf cross section showing vertical lamellae and width of leaf lamina. Photo courtesy of John Hribljan.

Figure 47. Ocular protractor for measuring angles. Modified from Christy 1987.

Rigidity Index

To calculate the **rigidity index** of *Polytrichaceae* leaves, Sean Edwards (pers. comm. 22 April 2014) multiplies the mean height of leaf **lamellae** (thin sheet of cells standing up along costa of leaf; Figure 48) and divides by the mean width of the **lamina** (expanded portion or blade of leaf; Figure 48), both as mid-leaf number of cells. This permits you to quantify the rigidity of the leaves as a rigidity index. This can be used to characterize different species, even within environmental variation.

Making Drawings

Rod Seppelt (Bryonet 30 December 2022) reports that he was shown a way to use black and white prints to make line drawing images. First, go over the outlines with India ink. Then clear the print in potassium permanganate. This leaves you with the outlines on a white background. But Rod doesn't use this technique because he is able to make excellent drawings by hand.

Older bryologists will remember the camera lucida. This method uses a mirror attached to the ocular of the microscope. Hence, while looking through the microscope you can see the sheet of white paper at the same time and trace around what you see.

David H. Wagner (Bryonet 30 December 2022) has posted a youtube video <<https://www.youtube.com/watch?v=pXbVEVnSX4c&t=28s>> to demonstrate using photographs to make pen and ind drawings. The method is useful for both macro- and microphotographs.

Summary

Bryophytes have a number of interesting performances, and these can be enhanced by clearing tissues with lactic acid. Capsules can be opened with KOH and NaOCl or heating the slide, depending on the species. To see peristomes under the compound microscope, the capsule should be split. Teeth on whole capsules are best viewed if positioned carefully so they are vertical. Clay can serve as an anchor. Moisture modification can cause the teeth to flex. Spore dispersal can be demonstrated on an agar plate.

Observation of sperm requires a knowledge of the delicate timing. Sperm can be slowed in methyl cellulose and the diaphragm should be adjusted to increase contrast. Other options are DIC microscopy or use of a vital stain such as Sperm VitalStain™.

Adding water to dry leaves can cause leaf movements. placing the base of a plant in dye can demonstrate the movement of solutions in the capillary spaces. Tropisms can be demonstrated on agar plates or other positioning. Etiolation is easily demonstrated in low light.

Dispersal can be demonstrated in splash cups using food coloring. Brownian movement in cells is easily

observed in live leaves. Adding a salt solution to the edge of the coverslip can demonstrate plasmolysis.

Nutrient cycling can be demonstrated by the ability of bryophytes to clear a dye solution in a small cup.

Measurements are important for identification and making descriptions. These will require an ocular micrometer and stage micrometer. These must be calibrated for each microscope and user. Measuring leaf angles may require making your own simple equipment.

Acknowledgments

I thank all the Bryonettors who have shared their excitement and discovery with the rest of us. Please continue to contribute your wonderful stories and demonstrations that excite your students.

CHAPTER 2-4

LABORATORY TECHNIQUES:

PRESERVATION AND

PERMANENT MOUNTS

Figure 1. Stained permanent mount of *Sphagnum* capsule from Triarch. Photo by Janice Glime.

Permanent and Semi-Permanent Slides: Mounting Media – Mountants

There are lots of considerations in making permanent mounts – ease of use, availability of ingredients, drying time, clearing effect (Angela Newton, Bryonet 16 February 2011). Most people would like their permanent mounts to be durable, surviving being "tossed around." Each mounting medium seems to have its problems, satisfying some, but not all the criteria (Holzinger 1900; Yuncker 1921; Jennings 1935; Iwatsuki 1955; Bowers 1964; Wilberforce 1970; Zander 1983, 1993; Frahm 1990). Nevertheless, as seen in the professionally prepared slide in and available at <http://digitalcommons.mtu.edu/bryophyte-ecology/>., details can become more visible with staining and made to last.

Traditionally, mounting was accomplished with balsam mounts (Jennings 1935) or a synthetic resin like Permunt, but slides made with these had to be stored horizontally or the mountant would drift to one slide, carrying the specimen(s) with it. The balsam procedure is time-consuming, requiring dehydration of the specimen in an alcohol series until it is ready to accept an organic

solvent such as **xylene** that will mix with the resin. This means that the **mountant** cannot simply be added to a slide once one determines that the mount is suitable for preservation. Furthermore, xylene is highly toxic. MSDS guidelines recommend protection with goggles, respirator, lab coat, and gloves to avoid potential toxicity to "blood, kidneys, liver, mucous membranes, bone marrow, or central nervous system (CNS). Repeated or prolonged exposure to the substance can produce target organs damage."

Des Callaghan (Bryonet 14 December 2018) notes that delicate species with thin cell walls do not preserve well in most mountants. The cell walls collapse in glycerine jelly. A detailed but time-consuming method for mounting delicate liverworts is provided by David Copestake (2015).

Rod Seppelt (Bryonet September 2017) advises making the mountant more viscous by varying the percentages of the glycerol-water mix or the Karo syrup-water mix.

Glycerine to Gum Arabic

Sayre (1941) suggested a gum arabic **mountant** (mounting medium) for bryophytes. At the time, this was a new approach that was superior to glycerine, although Wagner finds that the glycerine mounts of thin sections can

be made overnight and will last for decades if handled carefully. Sayre reports that a combination of glycerine and gum arabic can last for more than a year:

1. Mix 20 g gum arabic in 60 cc distilled water.
2. Let stand covered several hours.
3. Filter through coarse paper.
4. Add 10 cc glycerine and 4 cc formalin (more glycerine may be needed in a dry climate).
5. Place specimen in drop of mix (mountant).
6. Allow to dry for 24 hours in flat position at room temperature.
7. Store flat.
8. Store the mountant in bottle with pipette stopper.

Hoyer's Solution

Hoyer's Solution, also known as gum chloral, was one of the earliest mountants in widespread use for bryophytes (Anderson 1954; Conard & Redfearn 1979; Schofield 1985):

distilled water	50 cc
gum arabic (USP flake)	30 g
chloral hydrate	200 g
glycerine	20 cc

Schofield (1985) recommended allowing the solution to stand for several hours to reduce the number of bubbles; a magnetic mixer can help in this regard as well. Store in air-tight bottles.

Anderson (1954) reported that it was suitable for all mosses he tried (he did not study liverworts) except **Mniaceae** (Figure 3) and **Tortella** (Figure 2). In the latter mosses, **Hoyer's solution** caused cell shrinkage and distortion in some species. Lightowers (1980) expressed frustration at the cell distortion. Anderson did report that both H. L. Blomquist and R. M. Schuster used Hoyer's solution for **liverworts** and that these had held up well, as did **Sphagnum** (Figure 4). Schofield (1985) likewise recommended Hoyer's, stating that it results in distortion in leaves of some bryophytes, but it is suitable for most. Hoyer's solution has the added advantage of being an effective clearing agent, so it is helpful for such structures as peristome teeth, capsule exothecial cells, and dense papillae (Anderson 1954). It has the added advantage of not needing **luting** (sealing edges with something like nail polish) (Zander 1993) although unsealed slides will dry out or crystallize much faster than sealed slides.

Figure 2. *Tortella tortuosa*, a genus in which cell shrinkage occurs in some species when placed in Hoyer's solution. Photo by Des Callaghan.

Figure 3. *Mnium spinosum* leaf cells. Cells of members of this family (Mniaceae) exhibit cell shrinkage and distortion in Hoyer's solution. Photo by Ralf Wagner <www.dr-ralf-wagner.de>.

Water Glass Alternative (WGG) for Hoyer's Solution plus Glycerin

This chapter was posted for less than a week when Richard Zander posted this alternative (Zander 2013). He touts it as a way to avoid the "tedium of heating slides to melt glycerin jelly." It does not solidify as quickly as glycerin jelly, and its longevity is not known but may be at least as long as a glycerin mount. Even if it crystallizes around the edges, it will still render the bryophyte acceptable.

- 2 parts water glass solution (sodium silicate solution 40-42 Be)
- 1 part glycerin (glycerol) mixed with a little water to help it dissolve in the water glass

1. Mix and stir well.

- Put in capped squeeze bottle or dropper bottle (not a glass-stoppered bottle).
- Soak specimen in water or 2% KOH solution or water or aerosol solution.
- If cells are large and thin-walled and apt to collapse, add a drop of pure glycerin and heat to force glycerin into the cells, but this is usually unnecessary even for species with moderately large laminal cells.
- Add a few drops of WGG over the moist specimen and add cover glass.

In addition to the slow drying time, the basic pH may cause some interesting color reactions similar to those when using KOH. On the other hand, its high index of refraction and tinting of leaf cells may make stains unnecessary for *Sphagnum* leaves. If stains are needed, they must be basic with this mountant.

Modified Hoyer's for Chromosomes

Concerned about the distortion effects on *Mnium* (Figure 3) and *Tortella* (Figure 2, Figure 5), Bowers (1964) developed a technique to give better results for making chromosome preparations.

- First place the material in concentrated HCl, water, and stain (1:3:3).
- Mix the modified Hoyer's medium:

gum arabic (U.S.P. flake)	20 g
distilled water	60 cc
chloral hydrate	5 g
glycerine	10 cc
- Mix in above order at room temperature. The solution may need to stand for several hours for bubbles to dissipate. It should be clear and with no precipitate. Store in glass, air-tight bottle.
- Add stain to Hoyer's medium (1:1) and place drop on slide.
- Transfer plant material to the medium-stain mixture.
- Macerate by tapping.
- Add coverslip.
- Smear with pressure from a finger.
- For recently fixed (aceto-alcohol 30:70) or fresh material, use one part aceto-orcein to one part medium. For material stored for a long time, aceto-carmin gives better results.

Figure 5. *Tortella rigens* leaf cells, member of a genus in which cells of some species collapse in Hoyer's solution. Photo by Kristian Peters.

Gum Chloral Solution

This solution can serve both as a clearing agent and for making permanent mounts. This recipe has the same ingredients as Hoyer's solution, but in different proportions. The following recipe is from Watson, courtesy of Martin Godfrey:

distilled water	100 ml
gum arabic	40 gm
glycerine	20 ml
chloral hydrate	50 g

- Dissolve gum arabic first in cold water for 1-2 days.
- Do not stir – you will get masses of air bubbles.
- When dissolved, add glycerine and chloral hydrate and heat until dissolved.
- Filter hot if necessary.
- Put drop on a slide and add wet specimen to it.
- Leave slide horizontal for 2-3 days for gum to set and clear.

Godfrey (Bryonet) reports that gum chloral is great for things like *Fossombronia* spores (Figure 6). For structures like perianths, the clearing properties will make the interior structures visible without the need to dissect. The slide can be sealed with a few coats of nail polish to stop the gum from drying out, permitting it to last more than 30 years. Beware, however, that delicate specimens may shrink. If these don't need to be cleared, you can use glycerine jelly, as suggested by Richard Zander. And this actually causes little distortion (Zander 1997).

Figure 6. *Fossombronia* spores and elaters. Gum chloral works well as a mountant for these spores. Photo by Tom Thekathyl.

David Long (Bryonet 11 October 2009) reminds us that Hoyer's solution is especially good for liverworts because it can both clear the tissue and preserve it. However, it can cause health issues. Long-term use of **chloral hydrate**, a constituent of Hoyer's solution, can cause addiction, rashes, gastric discomfort, and severe renal, heart, and liver failure (Gelder *et al.* 2005). It should not be used for classroom studies.

Its reputation as a health hazard has made Hoyer's solution difficult to obtain. David Wagner (Bryonet 31 May 2010) tells us that "the primary deterrent to availability of Hoyer's Solution for use as a clearing agent is that it is a controlled substance. In the USA it is a

Schedule IV drug, classed with barbiturates, tranquilizers and sedatives. A prescription is necessary to obtain it. It is/was known by the street name 'Mickey Finn,' a knockout or date rape drug. It has been used (and misused) as a sedative and sleep-inducing agent for over a century and a half; its hypnotic effects seem to be a reason for its abuse as a recreational drug."

A recent product might have some value as a substitute, but its track record is unknown (Villani *et al.* 2013). This product, Visikol™, is made with polychlorinated alcohol and is considered a replacement for chloral hydrate as a clearing agent. It already contains glycerol and works successfully for flowering plant tissues, clearing them in 20-30 minutes, although the authors warn that larger samples may require up to three days. It also works for insects, fungi, and protists, but its usefulness for bryophytes and its effect on bryophyte tissue shrinkage and effectiveness over time remain to be tested.

But it has problems as a mountant as well. It can badly distort specimens by drying them, clear them so much they are nearly invisible, or suffer crystallization (Wagner, Bryonet 31 May 2010). Considering the relative safety issues and undesirable traits of Hoyer's solution, glycerine jelly is a much wiser choice for a mountant.

The distortion problem can be mostly eliminated by soaking the plants thoroughly and adding a little heat to eliminate trapped air (Angela Newton, Bryonet 25 June 1999). Flowers (1973) suggests using a warm coverslip to reduce the bubbles. Then, once the specimen is in the glycerine, it is necessary to wait until the tissues relax before putting on a coverslip (Angela Newton, Bryonet 25 June 1999). An additional problem is the invasion of bubbles from the edges of the coverslip. Interestingly, round coverslips seem to reduce this invasion, but sealing the edges may be a better plan. One can also refill the coverslip during the first few weeks to reduce this problem.

Jonathan Sleath (Bryonet 24 June 1999) agrees with Newton. He has used Hoyer's solution (or gum chloral) successfully for a number of years, following the recipe given in Smith (1978). "The slides have kept well, and could probably be made permanent by sealing the edges of the coverslip with clear nail polish. The material does distort a little at first as water is drawn out by osmosis, but once equilibrium is reached the cell walls seem to regain their normal shape. Of course the cell contents are lost, but the clearing properties of the solution can be quite useful." Despite all the concern over health issues, Sleath reports that chloral hydrate, the major constituent of Hoyer's solution, is still occasionally used in pediatric practice in the United Kingdom because it is so safe. Chloral hydrate is not a controlled substance in the United Kingdom at this time (Wikipedia, 2013). When he makes a permanent mount, he seals the coverslip on all four sides, unlike the corner technique of Wagner.

Allan Fife (Bryonet 24 June 1999) suggested that soaking dissected bryophyte tissue overnight in **90% lactic acid** will largely prevent the cell wall collapse that is a common feature of Hoyer's mounts, particularly of thinner-walled cells. But, that does not remove its dangers from its chloral hydrate. The Oxford MSDS gives the ORL-RAT LD50 480 mg kg⁻¹. (ORL=Oral, RAT=rat, LD50=the dosage that killed 50% of the rats). So, if you weigh 70 kg, you would need to ingest 33.6 grams of chloral hydrate to

have a 50% probability of death (assuming you were a rat). According to Anderson's recipe there are 0.2 grams of chloral hydrate per ml of Hoyer's Solution. Therefore if you imbibed ca. 160 ml of Hoyer's Solution you would have a high likelihood of not seeing the next sunrise. The Oxford MSDS recommends safety glasses and ventilation when handling chloral hydrate. It is listed as a skin, eye, and respiratory irritant. You should also wear gloves and take care when using Hoyer's, and make a point of rinsing your hands after using it.

Belen Albertos (Bryonet 25 June 1999) reported that his lab uses **Kaiser's glycerol gelatin** to make permanent slides for microscopy. This is available in Europe, Asia, South America, and Australia from Merck, ready to use. Interestingly, it is not available through this supplier in Canada or the United States, although it is available in Mexico. To use it, you need to warm a portion of the solution to about 40°C. Once your slide is prepared as a water mount, place a drop of the warm solution on the edge of the coverslip. If there is excess liquid, pull the glycerol under the coverslip by placing the edge of a paper towel on the opposite edge of the coverslip. Albertos suggests placing the slide on a slope to let the glycerine run down and displace the water, but the paper towel method is probably the most effective. When solution completely covers the material, place the slide on a level surface to cool. The coverslip will keep the specimen in position during storage, but there might be a slight loss of color. Albertos reports that slides made in this way are still in good condition after five years. However, he warned that a colleague found that liverworts get altered quickly.

Lightowers (1981) suggested a modification of gum chloral to preserve the shape of cells:

1. Presoak the specimen in an aqueous solution of 50% polyethylene glycol (PEG) 400 grade for about 12 hours (until thoroughly penetrated). 50-100% glycerol or 100% lactic acid are somewhat less effective.
2. Remove from solution after soaking and blot thoroughly with tissue paper. Too much PEG reacts with gum arabic to make an opaque precipitate. Too much glycerol slows the setting time. Excess lactic acid crystallizes upon drying.
3. Place specimen in drop of mountant on slide & dissect as needed.
4. Tease out bubbles and cover with coverslip.

Glycerine, Glycerol, and Glycerine Jelly

Hoyer's solution has been used for many decades as a mountant, but its toxicity (chloral hydrate) has decreased its availability and popularity. Furthermore, with Hoyer's solution, slides remain sticky and are easily smeared. Glycerine seems to be a viable alternative.

Glycerol is made from glycerine (=glycerin). Glycerine is the solid state, whereas glycerol is the liquid state. The formula is the same. Several Bryonetters have recommended this alternative (Ida Bruggeman, Cyndy Galloway, Martin Godfrey, Paul Davison, David Wagner, Richard Zander).

In 1900(!), Holzinger suggested mounting bryophytes in **glycerine jelly**. He improved upon the method of using mounts in jelly between mica sheets (replaced now by

coverslips) by using two thicknesses of paper – one ordinary writing paper, one cardboard that is slightly heavier than postal card paper (poster paper?).

1. Cut these into strips the length of a microscope slide and slightly wider.
2. Fasten at one end with paste to keep them from slipping.
3. Lay glycerine jelly mount in center of paper slide.
4. Cut through both thicknesses with sharp pointed pen-knife.
5. Cover inside of cardboard with paste.
6. Lay jelly mountant down over it.
7. Press down the thin paper, being careful not to misplace anything.
8. The two thicknesses of paper form a frame for the mount with margin of white paper to put data about the specimen.

Ida Bruggeman, Bryonet, reports that specimens in Hoyer's mounting medium will dry out after a while, losing contrast and making many details invisible. In comparison, many of her glycerine gelatin slides, sealed with nail polish, have lasted more than ten years, but they, too, dry out or get fungal infections after 15-30 years.

Glycerine appears to be the simplest and safest method of making permanent slides. Once you are through observing anything that might move and are ready to make it permanent, you can simply add a drop of glycerine at the edge of the coverslip (David Wagner, Bryonet 12 February 2001). It can be drawn under the coverslip by placing a bit of paper towel on the opposite edge of the coverslip and letting capillary action pull the excess water away. If the slide is left in the open for several days, water will evaporate and the glycerine will penetrate the specimen. Once the specimen is impregnated with glycerine, affix the coverslip by placing a drop of clear nail polish at the corners of the coverslip. Wagner recommends NOT trying to seal all the sides with nail polish because they seem to leak, but the ones affixed at the corners can last 20 years or more. Centering the coverslip will minimize the leakage of glycerine from the slide. You can clean the coverslip when needed on this more-or-less permanent mount by using alcohol on a cotton swab. Unfortunately, the oil bodies will not preserve.

It takes practice to determine how much glycerine to use. The needed amount varies with the thickness of the specimen, with a thin mount of leaf sections typically requiring only a single drop. More glycerine can be added, but as the slide dries, air may be drawn under the coverslip, trapping bubbles when more is added. If you add too much, you can blot it with thin strips (5 x 20 mm) of tissue paper, toilet paper, or paper towel. This process should be repeated until the glycerine barely starts to draw back from the edge of the coverslip.

Some bryophytes will shrink and curl when the glycerine is added. This is an indication that the change has been too quick. Dilute the glycerine and add it more slowly, allowing some of the liquid to evaporate, then adding more.

Glycerine quickly follows capillary spaces. While this is an advantage for drawing it under the coverslip, it is likewise a danger for drawing it out. If the slide contacts another slide next to the coverslip, the glycerine will creep

to the edge of the slide, then follow the capillary spaces between the slides, ultimately travelling in the capillary spaces under the slides. Within a few days to weeks, all the glycerine will have followed this capillary route and will vacate the coverslip space. To help prevent this, be sure the coverslip is perfectly centered on the slide before you add nail polish. Wagner finds that it is best to add the nail polish right after the glycerine has been applied and before it is set aside for drying.

In 1997, Zander retracted his earlier advice (Zander 1983) on the use of lactophenol gel made with methyl cellulose. While this seemed to be a good alternative for clearing without collapsing the cell wall structure, making nice mounts, it dried out within six months, making the mounts unusable (Zander, pers. comm. 19 July 2012). Zander (2007) contends that the perfect mounting medium still does not exist, despite the many presented by past bryologists (Davis 1909; Sayre 1941; Anderson 1954; Bowers 1964; Wilberforce 1970; Lightowlers 1981; Zander 1983; Frahm 1990). He (Zander 1997, 2007) recommends mounting in **glycerine jelly** (= a mixture of glycerine and gelatin that is used in histology for mounting specimens). This glycerine jelly medium sets fast, is safe for delicate tissues, preserves the color responses of cell walls to potassium hydroxide, has a high index of refraction, has a long life, and the ingredients are safe and inexpensive. Its slow evaporation rate makes it virtually permanent with **luting** (sealing with a paste, nail polish, or other sealant around the coverslip).

Glycerine jelly requires a longer procedure because it must be melted before it can be used. But melting degrades the gelatin so it does not set, so it must be melted just before it is used. If the slide gets too hot, it will destroy delicate organs such as axillary hairs. Coloration from KOH tests will disappear in a few days. And, the glycerine will evaporate over a period of years. Evaporation can be retarded by storing the slides in a closed container, but that presents an additional nuisance.

Glycerine Jelly Preparation (Zander 2003)

Richard Zander (2003) has suggested using glycerine jelly instead.

1. Take 2 packets (7 g each) of gelatin (Knox brand works fine).
2. Mix in 50 ml cold water to hydrate.
3. Heat but don't boil, while still stirring, until the liquid is clear or at least there is no undissolved gelatin.
4. Swirl it to dissolve all gelatin.
5. Add glycerine to make 200 ml.
6. [Optional: Add a crystal of thymol to keep down bacteria and fungi.]
7. Heat for about an hour until everything dissolves and the liquid is clear.
8. Pour on a clean PVC (polyvinyl chloride) pan with a flat bottom to make a thin layer.
9. Leave uncovered or cover with cloth to prevent dust overnight to several days to allow most of the water to evaporate.
10. Peel off the thin, flat sheet of glycerine jelly.
11. Roll into a kind of jelly roll.
12. Slice the roll crosswise into neat, tight curlicues or helices about 0.5 cm wide.

13. Store in a plastic box.
14. Pinch off a small piece when wanted.
15. If there are bubbles, reheat in a beaker (water bath is helpful) and let stand as liquid. Do not keep hot for a very long time, as heat denatures the gelatin.
16. The glycerine jelly will be hard to remove from the plate unless the water portion has evaporated. It is best to evaporate the water portion with heat since glycerine absorbs water, to some extent, from the air.

Using Glycerine Jelly

1. Place bryophyte material in a drop of water on a slide and soak it.
2. If the water is not absorbed readily, heat the slide slightly with a butane cigarette lighter, or start with warmed (not boiling) water.
3. Make desired sections and arrange the material on the slide.
4. Pinch off a bit of the glycerine jelly and place on slide and heat the slide evenly. (Heating one spot can break the slide.)
5. Arrange the material and add a coverslip.
6. The jelly hardens in a minute and may be mailed after cooling.
7. If clearing is needed, first dip the moist plant in lactic acid for a minute or so, or heat in pure lactic acid before preparing the glycerine jelly mount.
8. The jelly can be kept liquid for a short time on a hot plate, but prolonged heat turns the jelly brown and the gelatin breaks down so that it won't harden.
9. NOTE: Glycerine will eventually dissolve calcium carbonate.

Making Semi-permanent Mount

1. From wet mount, blot specimen to remove excess water.
2. Add small drop or drops of glycerol to slide with specimen.
3. Heat with lighter under slide till boiling (this pumps up the tissues after an initial collapse).
4. Do dissections if needed.
5. Add piece of glycerine jelly and heat until melted (try to avoid boiling a second time).
6. [Try transferring boiled specimen atop solid piece of glycerine jelly on clean slide, then heat just to melting; this helps minimize bubbles and helps minimize mess.]
7. Arrange specimen quickly and if needed cover with a coverslip.
8. Add label on left side and store slide flat in air-tight box.

Dave Wagner has been mounting liverworts on his slides in just glycerin for years, and seems to have much success. However, Des Callaghan (Bryonet 25 November 2013) found that some bryophyte species, such as *Thuidium* (Figure 7), do not reach "full turgor" and remain somewhat dehydrated in glycerol plus alcohol (the alcohol evaporates, leaving the glycerol).

Richard Zander (Bryonet 6 December 2013) suggests heating the slide of water-mount cells in added glycerol on a hot plate or coffee cup warmer. Cells of such sensitive species as *Tortula hoppeana* (Figure 8) expand to full

turgor and stay that way. He also recommends using a 1 to 1 mixture of glycerol and Elmer's Clear School Glue (apparently a thick polyvinyl alcohol solution). The index of refraction remains high. When the water in the glue is evaporated it makes a semi-solid mount. If the cells collapse, heat on a hot plate or cup warmer as with pure glycerol. Make sure the glue and glycerol are well mixed or the slide will seem to "weep" glycerol.

Clearing

If you need a more transparent specimen, you can clear it first by using a mixture (1:1) of glycerol and lactic acid [see step 7 in "Using Glycerine Jelly" above (Zander 1997)]. You can make mounts more quickly by adding glycerine jelly directly to a blotted wet mount and heating to boiling (bubbles may be troublesome). Dip the moist plant in lactic acid for a minute or so (or heat in the pure acid) before preparing the glycerine jelly mount.

Alternatively, you can keep a small hot plate near your microscope. Set a microscope slide with the wetted plant (or sectioned material) in a little water (or a mixture of water and a little glycerine) and a cube of glycerine jelly on the hot plate. After a moment or two, the glycerine jelly melts and some of the extra water evaporates. Remove the slide, arrange the material, and put a coverslip on it. The hot plate can be one of those coffee warmers you can pick up in a flea market cheaply. This eliminates heating a cube of glycerine jelly on a slide, which can break the slide if it is not heated evenly with the cigarette lighter or other point-source heat source. You can rig it so that the hot plate warms up whenever the microscope light is on.

Zander (1997) adds that glycerine will eventually dissolve calcium carbonate. Also, if you make the glycerine jelly with a high concentration of gelatin, then if you work on your specimen in a water/glycerine mixture (which slows sections from flying around when you make them), any added glycerine jelly will not be too dilute (when mixed with the pure glycerine on the slide) to harden.

For **Mniaceae** (Figure 9) and other large-celled bryophytes, you may need modifications. Richard Zander (Bryonet 9 November 2009) suggests that you strip leaves in water or Pohlstoffe solution or 2% KOH, then add 2 tiny drops of pure glycerine to the water or solution mount. Make cross sections and arrange leaves nicely in the unmixed water/glycerine mount, add a fingernail-sized clod of glycerine jelly, heat with one of those butane lighters with the nice torch flame, taking care to heat the slide fairly evenly so it does not break. Heat until the glycerine jelly just melts, or before it is completely melted, rearrange the leaves and whatever else is on the slide before placing a coverslip on it. After it cools it should be solid and ready to mail or bang around the lab without drying. Don't use 2% KOH with liverworts as the leaf cell walls are attacked.

Figure 9. *Plagiomnium cuspidatum* dry, a moss that repels water instead of absorbing it. Photo from Dale A. Zimmerman Herbarium, Western New Mexico University.

Dan Marsh (Bryonet) similarly suggests Frahm's (1990) Solution, 1:1:1 glycerine, water, mucilage (the brown glue-type from school supply sections of stores). For study of variation in *Sphaerocarpos* spores (Figure 10), this solution served not only as a satisfactory mounting medium but also cleared the spores quite nicely.

Figure 10. *Sphaerocarpos michelii* spore, a structure that clears well in Frahm's solution of glycerine, water, and mucilage in equal parts. Photo by Dick Haaksma, with permission.

DMHF (5,5-dimethyl Hydantoin Formaldehyde)

In his search for a better mountant, Zander (2007) uncovered 5,5-dimethyl hydantoin formaldehyde (DMHF), discussed by Steedman (1958). It is a water-soluble resin generally used in such products as cosmetics, adhesives, coatings, inks, and textiles. Although a similar chemical is used to gradually release the carcinogenic formaldehyde, DMHF releases little or none. Zander found the solution easy to use with tested species of *Tortula* (Figure 11) and *Mnium* (Figure 3) but, when hardened, the mountant resulted in somewhat collapsed laminal cells and a low index of refraction. Although DMHF would indeed make permanent mounts of bryophytes that are less collapsed than, e.g., acrylic solutions, the low index of refraction makes it difficult to examine anatomical details such as laminal papillae. When mixed with glycerine, visibility improves but the material will not set well.

Figure 11. *Tortula subulata* leaf lamina cells, member of a genus wherein mountants may collapse the laminal cells. Photo by Kristian Peters.

PVA

Zander (2007) credits Howard Webb with alerting him to polyvinyl alcohol with glycerol (PVAG) and polyvinyl alcohol with glycerol and borax (PVAGB) media (Salmon 1954; Dioni 2007; Webb 2007). However, Anderson (1954) cautions against use of PVA (polyvinyl alcohol) as a mountant because after a few months the plants begin to shrink and distort, ultimately becoming unrecognizable. The addition of glycerol and borax had the potential to prevent those problems.

If in fact PVA is an acceptable medium, it is easy to obtain. It is the primary ingredient of transparent glues and glue gels, and one could experiment with these as well. Carolina Biological Supply has a powdered form that can be made into a thick syrup by heating it for a long time in water. Zander points out that when used alone the PVA causes the same problems as in Anderson's warning, those also known for acrylic resins and DMHF, where cell walls collapse and the index of refraction is low. Zander reports that the addition of glycerine gives the mountant a high index of refraction, but the resulting hardened medium is cloudy. The addition of borax does not help, nor does decreasing the water. He couldn't recommend it.

Elmer's glue consists of PVA, water, ethanol, and acetate. It can serve as a mounting medium, as shown by David Meagher (Figure 12).

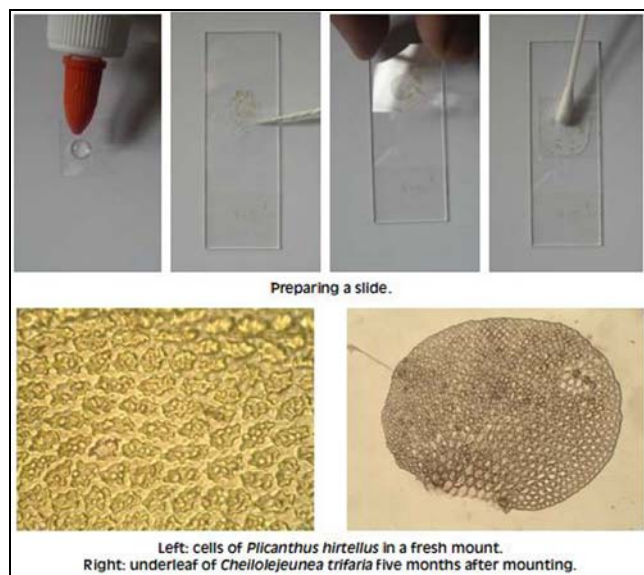

Figure 12. Meagher permanent mounting methods using glue. Photos by David Meagher, with permission.

Karo Syrup

A cheap and readily available mountant is Karo Syrup. This is the mountant of choice at the State Herbarium of South Australia. Graham Bell (pers. comm.) reports that it works better than other media in that dry climate. He adds phenol (2-3 %) to the dilute Karo mix to prevent fungal and bacterial contaminants. Standard dilutions of the Karo syrup are 20, 50, and 80%. It is often necessary to start with a lower concentration, let the slide dry for a day or two, then backfill it with more Karo solution at a higher concentration. Some of the slides made in this manner are more than 70 years old and still useable. Some stains seem

to present problems, but once the slides stabilize they remain in good condition.

Polyvinyl Lactophenol

This mountant has the advantage that it need not be luted (Zander 1993) because it actually sets, which Hoyer's does not (Fisk 1991). However, cells collapse in it. Zander (1983b) suggests instead a lactophenol gel because it usually does not collapse the cells. It also has a high index of refraction. However, Rod Seppelt (Bryonet 12 February 2001) warns that heating solutions with **phenol** needs to be done with care. The MSDS data sheet considers it to be very hazardous when in contact with skin or eyes and dangerous if ingested or inhaled. It can cause corneal damage or blindness if it contacts the eye and can cause blistering of the skin. Severe over-exposure can cause lung damage, choking, unconsciousness, or even death. Use a hood if available and avoid breathing the fumes:

lactic acid (=2-hydroxypropanoic acid)	20 cc
phenol, crystal (=carbolic acid)	15 g
distilled water	15 cc
methyl cellulose powder	6 g
(=cellulose methyl ether, of viscosity 25 cP in 2% solution of lowest viscosity available)	
ethylene glycol (=1,2-ethanediol)	35 cc

Procedure:

1. Mix phenol with lactic acid, dissolving with gentle heat.
2. Add water and stir.
3. Heat to just boiling (**use fume hood**).
4. Add methyl cellulose powder and stir vigorously into hot solution to dissolve (reheat if necessary).
5. Add ethylene glycol last.
6. Pour into glass cylinder and let stand to allow bubbles and undissolved material to rise.
7. Allow to settle for a day or two, then remove any floating particles.
8. Pour clear liquid into storage bottle.
9. Use small bottle with applicator wand in lid or plastic squeeze bottle with fairly wide opening (4 mm) to place drop or two on slide.
10. If specimen is incrustated with carbonates, first soak them in drop or two of dilute HCl to prevent bubble formation in lactophenol gel.
11. Specimens previously soaked in KOH should be neutralized with drop or two of dilute HCl before mounting in lactophenol gel.
12. Moist plants may form a precipitate in the lactophenol gel, but it will dissolve with stirring.
13. Arrange the plants and leaves on a **clean** slide while the gel is still liquid.
14. Add coverslip to preserve for 1-2 months.
15. For semi-permanent slides, it is best to seal the mount with a **lutant** like clear fingernail polish. Nail polish does not adhere well to glass, so varnish might be substituted. Some bryologists (e.g. Watson 1963) prefer **circular coverslips** because their lack of corners makes them adhere better.

16. For a more permanent lutant you can use one of the following:
 - poly (ethyl methacrylate) with butyl benzyl phthalate as plasticizer (Krystalon® Harleco, Gibbstown, NY 08027 USA) (an artificial balsam)
 - polyurethane gloss finish (used for wood floors) – keep slide out of light
17. Apply lutants liberally to make a good seal, but avoid having a ridge that might interfere with changing objectives on the microscope.
18. Keep lutants in a balsam bottle or small disposable applicator bottle; keep more than half full to help exclude air.
19. Keep disposable wipers on hand to keep tools and hands clean from the reagents.
20. A fan may be needed to carry away vapors.

Aquamount Improved

Matt von Konrat (Bryonet 25 June 1999) suggests Aquamount Improved, from BDH Laboratory, an improvement over Aquamount that contained phenol. This solution comes ready to use and is relatively cheap. It avoids the problems of tissue shrinkage.

Kleermount, Xylene solution #2

Kleermount (Figure 13), suggested by Volkmann-Kohlmeyer and Kohlmeyer (Kohlmeyer & Kohlmeyer 1972; Volkmann-Kohlmeyer 1996) for fungi, works well for bryophytes as well (Martin Wigginton, Bryonet). Kleermount is available from Carolina Biological Supply Company, 2700 York Road, Burlington, NC 27215-3398. International orders: (+1) 910-584-0381; FAX (+1) 910-584-3399). They provide a Material Safety Data Sheet (MSDS) for the solution, which warns that it is harmful by inhalation, possibly causing irritation to the respiratory tract. Prolonged exposure may result in an allergic reaction; it can cause eye and skin irritation. If ingested it may cause gastrointestinal discomfort. It is also a fire hazard: closed containers of Kleermount Xylene solution exposed to heat may explode. In short, its use requires caution and common sense.

Serge Hoste (Bryonet 24 June 1999) adds that Kleermount causes serious plasmolysis in *Plagiomnium* (Figure 14), *Funaria* (Figure 15), *Amblystegium* (Figure 16), and others. He advocates "using a medium with the highest water content possible. A gelatine-glycerol-water and PVA-glycerol-water, with a few drops of thymol added as fungicide, is claimed to keep for more than 20 years and conserve color to a much larger extent than with the use of chloral hydrate. Good sealing around the edges of the cover slide is paramount but can easily be obtained by applying two (or more) generous coatings of clear nail varnish around the edges of the cover glass."

Fluoromount-G

Bernard Goffinet (Bryonet 12 February 2012) recommends Fluoromount-G. This mountant is available from Fisher (OB100-01, 25 ml for 25\$ before discount, good for "500 slides"). It is toxic and should be handled with care. The MSDS data sheet states that it is potentially harmful if ingested and warns "Do not get on skin, in eyes, or on clothing. Potential skin and eye irritant." It has the advantage that it does not bleach the leaves, nor alter them in any way (at least within the two weeks following its use). It is water soluble, so it can be used for mounting wet specimens.

Gray-Wess Mountant

Uwe Schwarz (Bryonet 12 February 2012) suggests Gray-Wess as an alternative mountant:

polyvinylalcohol	2 g
glycerine	5 ml
lactic acid	5 ml
water	10 ml

Mix everything together and heat it in a test tube in hot water until the liquid becomes clear. If the specimen has calcareous incrustations, you should skip the lactic acid because it will cause a lot of bubbles.

Double-Coverslip Method

Martin Wigginton (Bryonet) suggested the double-coverslip method (Figure 18), published for fungi (Figure 17) by Volkmann-Kohlmeyer and Kohlmeyer (1972; 1996), but originally introduced by Diehl in 1929. Although this method was developed for preserving fungal spores, it works well for bryophytes. The method is more time-consuming than just using fingernail polish, but the results are much more permanent. This method should be used by anybody who needs to prepare voucher specimens, and it should always be used for preserving type material where slides are needed.

Figure 17. Ascospores of a fungus, using a double coverslip, with appendages perfectly preserved after 29 years. Photographed using Nomarski interference contrast and quartz filter. Photo from-Kohlmeyer & Kohlmeyer 1996.

Tocci noted that shellac was used in the 1800's and lasts about 100 years. One can also use Paraloid B-72 in acetone. But she also recommends the double cover slip method that is popular for mounting fungi (Kohlmeyer & Kohlmeyer 1972), and that can be used with glycerine. It permits observation of living material that can subsequently be made into a permanent mount.

Double Coverslip Method of Kohlmeyer and Kohlmeyer:

Place a 25 x 25 mm coverslip on a clean 76 x 26 mm glass slide, sealed to it with two drops of distilled water.

Place a larger drop of distilled water in the center of the cover glass. Add the specimen to the drop.

Use the smaller coverslip (18 x 18 mm) to cover the drop with the specimen, permitting immediate viewing of the living material with a compound microscope. Immersion oil can be used if necessary, but it is messy and must be cleaned off, endangering what has been accomplished. It is better to save it until the slide has been sealed and dried.

After making all the observations, measurements, and photographs you need for now, add a droplet of concentrated glycerine to the water at one or two sides of the small coverslip to prevent drying out. The slide must be stored horizontally in a dustproof container for a few days to allow the water to evaporate. Excessive water plus glycerine can be removed from the edges of the larger coverslip easily with filter paper – or if needed, add more glycerine.

Seal the mount with a thin ring of clear fingernail polish. It is best to repeat this step after an hour to be sure the glycerine is perfectly sealed.

When the nail polish is fully dried, remove the large cover glass from the slide using a needle. Place a drop of mounting medium on the small cover glass. It will take some experimentation to get the right amount.

Turn over the preparation and place it on the slide, gluing it to the slide.

The drop of mounting medium flattens out, but this will happen more readily if a small weight is put on top, *e.g.* some of the larger nuts from a nut and bolt set. These are small, so a supply can easily be kept in the lab. The medium will ooze out and surround the edges of the small cover glass, permanently sealing in the small cover glass and nail polish. Any excess medium squeezed out at the sides can be taken off with a needle syringe. The preparation must be stored horizontally until the medium is hardened, but it can be used after a day, should further microscopy be necessary. The sealing procedures are best done under a hood to avoid breathing the toxic fumes of the medium.

Figure 18. Double-cover slip slide showing smaller top coverslip (arrow) and nail polish seal. Note the blank label on the right. Paper labels can easily come off, so using a slide with frosted glass on one end may be a preferred solution. Labelling should be done with waterproof ink and a Rapidograph pen. Photo modified from Volkmann-Kohlmeyer and Kohlmeyer 1996.

Since this slide and specimen can be used again and again, it is wise to check it for visual clarity of important structures before beginning the sealing process. Be sure

that both sides of the leaf can be seen, that at least one leaf base can be seen clearly, and that papillae, if present, can be seen. The latter often requires showing a bent surface of a leaf. Once the process is complete and thoroughly dry, the slide can be placed in a minipacket for protection and stored in the packet with the specimen. This will serve the added advantage of preserving more of the specimen because it won't be necessary to use more material to make more slides.

The method requires two coverslips of different sizes, a large one (25 x 25 mm) and a smaller one (18 x 18 mm). The large coverslip is attached to a clean slide (76 x 26 mm) by using two droplets of distilled water (to avoid mineral deposits). A somewhat larger drop of water is placed on the coverslip and the specimen added. The smaller coverslip is then used to cover the specimen and water.

This method seems to lack a preservative, so one might want to follow the advice of Norbert Stapper (Bryonet 13 February 2001) and add camphor or phenol. We don't know their long-term effects on the slides, but see the warnings of health risks of phenol discussed above.

Lutants – Sealing Slides

Once the mounting medium is reasonably dry, it is usually necessary to seal the coverslip (Diehl 1929). The medium remains somewhat fluid, so the coverslip is essentially floating. David Wagner (Bryonet 31 May 2010) recommends painting with a **lutant** of clear fingernail polish on the two sides of the coverslip parallel with the length of the slides. He cautions against enclosing the coverslip completely because it may become necessary to add more glycerine later. Glycerine at the edges may prevent the nail polish from sticking, in which case the slide may need to be cleaned. Excess liquid should be drawn off first with a paper towel at the edge of the coverslip. You should finish the cleaning of the remaining residue with alcohol or a wetting agent on a cotton swab. It is a good idea to check to be sure that the specimen(s) remains in a suitable position before affixing it permanently. The polish should be spread well away from the edge of the coverslip to give the polish more adherence outside the influence of the glycerine.

In addition to keeping the specimen moist, a coverslip that is tacked down is much easier to clean. Dust will easily accumulate over time and glycerine may invade the surface from a neighboring slide. Wagner advises cleaning lengthwise with a cotton swab moistened with alcohol, being careful to avoid the open edges of the mount so the alcohol is not drawn under the coverslip.

Nail polish has been criticized as not being permanent, but permanent slides need to be sealed with a **lutant** (sealer). Richard Zander (Bryonet 12 December 2018) recommends a 70:30 mixture of clear glue (*e.g.* Elmer's) and glycerin. The glue is a polyvinyl alcohol and lasts a long time. Since lutants usually don't last more than a decade, it is necessary to make sure you can easily soak the slide and remount the specimen. The polyvinyl alcohol is suitable for this purpose because it is soluble in water.

But David Wagner argues that Sally Hansen's "Hard as Nails" clear fingernail polish will last more than 40 years as a lutant, with pure glycerine as a **mountant**

(mounting medium). Instead of ringing the cover glass, he uses it to tack the cover slip in place. This permits the cover slips to be cleared of dust in later years without disturbing the mount. The mountant of glycerine is placed at the edge of the water mount over night so that the glycerine can slowly replace the water. Once the mountant has permeated the mount, the cover glass can be tacked in place with the nail polish.

Reviving Dried Slides

All is not lost if your slides dry out. Glycerine mounts can be revitalized by adding water with a good wetting agent around the open edges of the coverslip (David Wagner, Bryonet 31 May 2010). This will gradually loosen the coverslip so it can be removed carefully with your needle-point forceps. Nail polish usually comes off with the coverslip and can easily be broken off. Polish left on the slide can be scraped away. Make sure the material you need is still on the slide before placing a new coverslip. Otherwise, if important specimens are stuck to the removed coverslip, it is best to re-use that coverslip. Flood the surface of the mount area with your wetting agent mix and gently lower the coverslip as you would with a fresh mount. Add glycerine to the edge of the coverslip and let it sit to dry and infiltrate the specimen. Continue processing it as you would a new mount.

Cleaning Slides

Des Callaghan (Bryonet 11 December 2013) has a great way to clean your dirty slides, whether for re-use or

permanent slides that have become smeared. Rub them with a paste-type cleaner between your fingertips. Callaghan uses the UK brand Astonish; a tub will last a lifetime. The paste washes off easily and leaves the glass surface spotless.

Labels

Stick-on labels are available, but these eventually come off. A more permanent solution is to use a slide with an etched area for writing (Chris Cargill, Bryonet 11 December 2013). There is nothing to come off, and Cargill says that permanent markers do not wash off with water and if stored in the dark do not fade appreciably. Non-permanent ink does come off. One can also use a diamond-tipped pen to inscribe the slide permanently. This can be done with an accession number, but the accession list could get misplaced, so it is better to put all information on the slide.

David Wagner (Bryonet 10 December 2013) has used Scotch brand Magic Mending Tape for years, long enough to consider it of archival quality (good for at least a couple of decades). It is quick, easy, and reversible (Figure 19):

1. Strip off a 2 inch (5 cm) length of 3/4 inch (~2 cm) wide tape and tape the slide to the work bench. This holds the slide tightly in place so that writing very small is possible.
2. Write specimen information on the tape. I always use a pencil because there's no wait for ink to dry. Erasable, too. This is the stage to add glycerine to the edges of the coverslip for a semipermanent mount.
3. Cut the edge cleanly with a razor blade.

Figure 19. Application of Scotch Magic Tape labels. Photo by David Wagner.

Jan-Peter Frahm (Bryonet 11 December 2013) suggests another alternative for quick, long lasting labels using a computer and Brother P-Touch labelling machine connected through a USB port (Figure 20). This printer

also works as a printer for MS Word so that one can make a template in Word. The labels are superior because they are plastified and do not flake off as is often the case with other labels. The print is superior to handwriting for legibility.

Figure 20. Slide label made using Brother P-Touch labelling machine. Photo by Jan-Peter Frahm.

Des Callaghan (Bryonet 11 December 2013) suggests using a laser printer, then cutting labels to size and attach them with PVA glue or double-sided sticky tape (Figure 21). The labels can be sprayed with hair lacquer **before** sticking them to the slide to protect them from abrasion.

Figure 21. Slide labels using a laser printer, PVA glue, and hair lacquer. Photo by Des Callaghan.

Richard Zander (Bryonet 11 December 2013) considers all commercial slide labels to be inadequate, coming off the slide within a few decades. He feels all slides should be kept for students to use in the future. This is especially important for rare collections with little material. Zander cuts rectangular labels from buffered paper and stores a supply in a box. When needed, they are glued on a slide with Elmer's white glue (polyvinyl acetate – "a superb glass adhesive"). This can also be used to re-attach labels that fall off. The glue is kept half cm deep in a balsam applicator bottle so that no glue collects around the edges of the top and is has a glass applicator rod in it. The glue should be slightly diluted with water and the lid of the balsam bottle should be coated with mineral oil on the ground glass to make a better seal. Only a tiny drop of glue should be rubbed on the back of label and label pressed on the slide. Information is added to the label with permanent, non-fading ink, but print carefully so it can be read by people whose first language uses a different alphabet.

Slide Storage

Mounting media of "permanent slides" tend to settle if the slide is placed on its side. Hence, horizontal storage is usually essential. Richard Zander (11 September 1998) makes "trays" using corrugated cardboard. Strips of cardboard are glued across the tops and sides, and one down the middle. This provides the right space to keep slides lined up and the height keeps the next "tray" from making contact with the slide. He recommends gluing a small tag on the bottom edge of the "tray" that tells the contents of that group of slides.

Wagner stores his slides on trays the size of plant press boards or herbarium sheets so they fit on shelves of a standard herbarium cabinet. Three rows can be placed from end to end. Its durability was tested when he dropped a tray of slides in a parking lot. The tray was sandwiched between cardboard press boards so when the bundle hit the pavement upside down, only one slide was thrown out and broken. The rest survived unscathed even though tumbled.

Storage trays need not be made of expensive material. Some bryologists use cardboard trays, although they may suffer loss of rigidity if they get wet. Wagner is currently using foam core board. It helps to line the bottom with blotting paper or similar absorbent material to help absorb any glycerine that travels there by capillarity. It also helps to super glue borders and dividers that are 1.8 cm wide by .4-.5 cm thick as a means of keeping the slides in place.

Preserving Bryophyte Plants for Dioramas

The following advice for preparing dioramas is from Roxanne Hastings and Donna Cherniawsky, Curators of Botany, Royal Alberta Museum, Canada. The recipe came from a display tech, Ludo Bogart, long since retired and where he got it from nobody knows, including him.

Field Collections

1. It is critical that you get the plants into the tank as fresh as possible... especially with vascular plants, less important for bryophytes and lichens but absolutely critical for gymnosperms. Large plastic bags work well (museum specimen bags of heavy poly count – not Safeway Ziploc) or sheets; wrap the plants into them in the field and put them into the largest thermos tubs available, with ice packs. For conifer shrubs and long branches, you can wrap them in plastic and put them on top of blocks of dry ice to get them back home from the field. You have maybe two days at most to get the plants from field and into the vat. Having walk-in refrigeration at both a field station and at the museum will go an awful long way to the success of preservation. Putting the plants into Tupperware-like containers and storing them in refrigeration will buy you several days time. Getting conifers in the tank the same day you get back from the field, no matter how late, is important. The other material, if stored in refrigeration, can wait a day or two.
2. Hastings and Donna Cherniawsky would go into an area and spend the first few days just scouting the sites and tagging all the spots where they wanted to collect. And then in the last 2-3 days they went back to all the sites and collected the stuff in a mad rush.
3. What works superbly for collecting sheets of mosses is large plastic under-the-bed storage trays with snap-on lids. The depth is about perfect for the height of mosses and the trays can be easily stacked on top of one another, which makes transport in the back of a van or minibus that much easier. Also get a number of smaller plastic containers to pick up smaller samples of evergreen shrubs and specific mosses that you can weave into your display when you build your diorama. These will make for a more realistic forest floor, and having the specimens in separate tubs

makes it easier to find them when you are building your display. Tupperware will become your friend for this project.

4. Collect at least twice as much as you think you are going to need for the display. Some specimens will just fall apart in the processing or will just not look as good as you thought they would when you saw them in the field. Having more diversity available will help you create better displays. Any extra material will find a happy home in a teaching collection. People absolutely love handling specimens that they can see on display in your gallery and they make for gorgeous open house/public appreciation days material.

Preservation Protocol (From Roxanne Hastings, pers. comm. 11 October 2012)

1. Assemble the equipment:
 stainless steel tank with a lid
 perforated stainless steel paddle or spoon
 stainless steel wire mesh
 roll of stainless steel wire
 fume hood
 source of hot tap water
 sink hose
 big funnel
2. Assemble personal safety equipment:
 Wrap around eye goggles
 Nose and mouth mask – medical or industrial
 Long rubber gloves
 Rubber boots – safety toes if working with barrels of liquids
 Knee length lab coats
 Breathing mask is good idea if working with industrial volumes

NB you must wear proper safety equipment. Acetone and alcohol are dangerous. At the minimum you need safety goggles for your eyes and you should have an eye rinse station in the area and wear elbow length rubber gloves. With big tanks you need rubber boots, maybe even safety toes depending if you have to roll drums yourself. Breathing masks are advised for big jobs. You must work in a ventilated room and the tank must be used under a fume hood. The process sounds a lot worse than what it is. It becomes routine. But you must pay attention to safety. Cover your eyes and cover your mouth and nose. There will be splashing and it will hit you in the face. A trip to an industrial safety supply shop will easily resolve your concerns.

3. Prepare the preservative:
 1 part Acetone
 1 part Isopropyl Alcohol at 70%
 2 part Glycerine

The acetone evaporates the water in the plants, whereas the alcohol and glycerine enter. The alcohol preserves the plants and the glycerine gives them their lifelike feel and luster. Acetone can remove chlorophyll color and cause some species to become black or grey. Fortunately, mosses and lichens usually came out unscathed and required no touch up. To ensure accurate color rendition, take photographs

in the field with color charts and also write down the color numbers so you can match the colors later. You can use standard paint chips available free at paint shops to match colors.

4. These fluids are all **thoroughly** mixed together at once. This takes some effort because they have significant density differences. For large batches, you can use perforated steel shelves built so that they can be put into a large tank on a ledge built all around the inside face of the tank at half height. This allows two layers of specimens without them all piling up in the bottom of the tank.
5. Moss specimens will easily fall apart in a big tank so it helps to wrap the sheets of mosses in stainless steel mesh - what concrete people use to provide structure for a sidewalk when they pour concrete into it. You will need a strong set of metal clippers to cut the mesh and a long roll of wire to stitch the mesh together once you have wrapped your specimens. The mesh is reusable. Wear leather work gloves because the wire mesh is really sharp once it is cut.
6. If you are doing a big job and need to order your chemicals by the drum, then you will need a stainless steel hand pump to get the fluid from the barrel into the tank. You must ground the pump with a wire to prevent friction sparking when you pump. Plastic pumps won't spark but they are useless for pumping viscous liquids like glycerine and will melt in Acetone. And obviously you cannot use electric pumps. If you are doing a smaller job you can buy the supplies by the liter and just dump it into the tank. Then you won't have sparking issues.
7. It takes a lot of stirring; a perforated stainless steel spoon or paddle works best. Plastic will eventually melt in the acetone and is not strong enough to stir glycerine. The perforations provide better mixing and glides more easily through the glycerine.
8. Put your specimens into the tank and keep pushing them down. They will float for a few hours to a few days while they absorb the fluid and the air gets beat out of them. Gently stir them until they settle. In a big tank you may have to come back the next day and gently stir them again. Let them sit for a few weeks. Mosses go through the process in a matter of weeks. Small trees or branches in the order of a meter or so long will take a few months.
9. Put a lid on the tank; it should also be stainless steel. You **MUST** do this in a fume hood. Smaller tanks can be put in a lab fume hood.
10. Then you have to fish them out. A 3 m long stainless steel rod with a hook on it to grab the mesh works well. Large plants will be really, really heavy! Lift them out and let them drain into the tank. Then you have to rinse them, still in the screens, with very hot tap water. Rinse them until the water runs clear and not brown. Don't let this water go down a drain! Rinse them back into your now empty chemical drums. You can use a big plastic funnel with screens in it; put the funnel over the drums and rinse into that.
11. Once the plants are drained, open up the screens and lay out the specimens **in the fume hood** to dry. This will take at least a week. Keep checking.

12. Now your plants are ready to process. They will be lustrous and flexible with various amounts of fading that may require some airbrushing – or not. Some specimens still look very good after 40 years. Specimens that were processed in 2008 were still in perfect condition in 2012 and you could still smell the aroma of the sap of the pine trees. All the pines still have their needles and are flexible (2012). You can use leftovers for hands-on teaching with school kids and the public; they are still perfectly life like, in fact they are tougher because they are a tiny bit like rubber cement.

Preserving Liverworts

Despite Rob Gradstein's claim that thallose liverworts can be dried like mosses (see chapter on Field Taxonomy and Collecting Methods in this volume), Wagner considers preservation in liquid a necessity for examination of morphological characters. He recommends using rubber-topped vials used for drawing blood and reports that some are 20 years old, but have not lost any appreciable amount of liquid.

Susan Moyle Studlar (Bryonet 20 September 1999) has observed that some of the thallose liverworts retain their green color and are easy to work with after air drying in a plant press. She has had success with this treatment of species of *Conocephalum* (Figure 24), *Pellia* (Figure 23), and *Pallavicinia* (Figure 22).

Figure 22. *Pallavicinia lyellii*, a liverwort that can be preserved by drying. Photo by Jan-Peter Frahm.

Jesús Muñoz (Bryonet 19 February 1999) suggests two formulas for preserving liverworts:

10:1:1:8 96% ethanol : glutaraldehyde : glycerol : water
or
1:1:18 glutaraldehyde : glacial propionic acid : 70% ethanol

Muñoz reports that you can use formaldehyde instead of glutaraldehyde, but that glutaraldehyde gives better results. The bottles must close tightly or the ethanol evaporates. Unfortunately, the mixtures degrade chlorophyll and lipids, so although morphology and anatomy remain as in live plants, oil-bodies and natural color disappear. As suggested in the chapter on Field Taxonomy and Collecting Methods in this volume, it is a good idea also to keep a herbarium sample cross-referenced

to the liquid sample so that there is still material for DNA or chemical analysis.

Figure 23. *Pellia endiviifolia* near Swallow Falls, Wales. This liverwort can be preserved by drying. Photo by Janice Glime.

Figure 24. *Conocephalum conicum*, a liverwort that can be preserved by drying. Photo by Dick Haaksma.

David Wagner (Bryonet 19 September 1999) agrees that these two formulas work well. He advises against Pohlstoffe for thallose liverworts and compares working with the revived specimens to working with boiled lettuce. Even leafy liverworts do not fare well in Pohlstoffe because the oil bodies disintegrate in that and other wetting agents. The oil bodies sometimes survive drying if water, but no wetting agent, is added to rehydrate them. Wagner uses FAA (formalin-acetic acid-alcohol), which is similar to the suggestions of Muñoz except for the presence of 5% acetic acid and lack of glycerine. But Wagner points out that the

glycerine is important to keep the tissues soft if they accidentally dry out. The downside of glycerine is that it can interfere with the embedding process if one wants to prepare the specimen for microtome sectioning.

David Wagner (Bryonet 5 November 2022) uses a 50:50 mix of denatured alcohol and distilled white vinegar as a liquid preservative. The denatured alcohol is available at hardware stores in the paint section where paint thinners, paint strippers, solvents, *etc.* are found. A common one has the brand name Klean Strip and actually has a high percentage of methanol, which is why it is a good glass cleaner and marine stove fuel. Of course, it is really poisonous if consumed. The vinegar is 5% acetic acid, from a grocery store; it helps preserve proteinaceous cell structure. The advantage of this method is that it is cheap and readily available to most people. Wagner used this method to preserve *Riella americana* with sporophytes (Figure 25).

Figure 25. *Riella americana* with sporophytes, preserved with methanol and vinegar. Photo by David Wagner, with permission.

Michael Christianson (Bryonet 19 September 1999) raised the possibility of using **lyophilization** (freeze-drying), suggesting it should keep such important organelles as chlorophyll and oil bodies intact. If the material is put into ampoules after lyophilization, these could be sealed. If the ampoule is further treated by replacing the air with nitrogen, Christianson predicts that DNA would be preserved for decades.

One of the problems in preservation is that such specimens require maintenance about once a year to replace the liquid that has evaporated from them. Angela Newton (Bryonet 20 September 1999) suggested that this labor can be greatly reduced by placing a group of vials in a larger jar that can easily be topped off. Furthermore, it will provide a head of liquid that will last much longer than that of a small vial. This also helps to reduce swirling motion that can damage small specimens during the refill process.

Kronstedt and Echlin (1982) suggested freeze-drying the thallose liverwort *Ricciocarpos natans* (Figure 26) instead of acetone or ethanol dehydration in preparation for critical point drying for scanning electron microscopy because freeze-drying causes less cell collapse.

Figure 26. *Ricciocarpos natans* thallus, one whose cells collapse in acetone or ethanol. Photo by Ralf Wagner <www.dr-ralf-wagner.de>.

Summary

Permanent slides usually require use of a mounting medium. Ideally, these must dry quickly, be effective in clearing, be durable, and be easily available. Older mounts used glycerine, other mountants include gum arabic, Hoyer's solution, gum chloral, DMHF (5,5-dimethyl Hydantoin Formaldehyde), PVA, Polyvinyl Lactophenol, Aquamount, Kleermount, Fluoromount-G, Gray-Wess Mountant. Slides can also be sealed with a lutant like fingernail polish, including those using the double-coverslip method. Most of these methods permit repair when the slide dries out too much. Storage usually must be flat to prevent movement of the mountant and specimen.

Caution is needed in selecting a mountant. Chloral hydrate (in Hoyer's solution) is toxic, and some mountants distort the cells or cause plasmolysis.

A mix of glycerol and lactic acid can be used to clear specimens. Liverworts may require special preservation, but some thallose specimen can simply be dried.

CHAPTER 3-1

HERBARIUM METHODS AND EXCHANGES

Figure 1. Benito Tan and herbarium cabinets for bryophytes at the Hattori Botanical Laboratory in Nichinan, Japan. Photo by Janice Glime.

Folding Packets

The standard for bryophyte storage is to put them in packets. These are made from a sheet of white paper, preferably acid-free, 100% cotton to reduce decomposition of brittle paper. Some herbaria use brown packets made from shelf liners or grocery bags (*e.g.* Kraft paper), and use of these is somewhat common in the field. Those are not quite as easy to read, but they do last well. Wagner uses 3" margins for the packets, but Glime finds that 1-1.5" margins work well. The size depends in part on the size of the herbarium box or drawer used to hold the packets. Having an exact size isn't critical, so after a little practice it probably won't be necessary to measure. If the housing for the packets permits larger sizes, larger packets may be desirable for some large taxa. Note that the outside (last) fold should be a little shorter than the others (Schofield 1985). This permits more space for the bryophyte and makes it clear which side is to be opened.

At CAS, curators use Strathmore ultimate white 100% pure cotton 24 lb watermarked paper, available in reams of 500 sheets, CODE 318003 (US standard size 8.5 x 11 in) (Jim Shevock, Bryonet 8 April 2015). CAS also uses Strathmore 25 percent cotton fiber paper for printing of herbarium labels and to process additional labels for specimen exchange. Both are acid free and of archival quality and print well on photocopiers. Karen Golinski (Bryonet 8 April 2015) similarly uses 100% cotton, acid free, Avon Brilliant White, wove finish, 24 basis <<http://www.neenahpaper.com/finepaper/morebrands/cottonpapers/classiccottonpapers/productdetail?color=Avon+Brilliant+White&finish=Wove>>. Mary Zimmerman (Bryonet 8 April 2015) uses Byron Weston Linen Record Ledger Paper from Talas: 100% cotton ('linen' is just the slight texture on the paper) and it has the year of manufacture watermarked into the sheets

<http://apps.bnt.com/ecom/catalog/product_specific.cfm?ClientID=15&ProductID=24235>

Bryophyte specimens should be placed into the packets. An 8 1/2 x 11" (21.6 x 28 cm) sheet of paper, or size close to that such as the standard European size, should be folded in thirds like a business letter (Figure 2). After the first fold, the two open ends are folded inward. It is an important consideration that the first fold is up, then the sides are folded in before the top is folded down. This folding is less likely to lose specimens and fits more neatly

into the box or drawer than those where sides are folded last. And it is the only folding system that works well when the packet is glued to a herbarium sheet. The typical resulting packet is 4x6" (10x15 cm), a convenient size for storage in shoe boxes. These packets may be stored in boxes as packets or glued to a herbarium sheet, with the packet glued across the middle section of the back so the opening flap faces you like the flap of a pocket. See storage below.

Left to right: 1. Mark 3" (7.6 cm) in from top of 8.5x11" (21.6x25.4 cm) sheet. 2. Mark 3" in from other side at top. 3. Mark 3" from top using 3" card template. 4. Fold bottom up to mark 3" down side. [Change 3" on sides to 1.5" 3.8 cm) if you desire.]

Left to right: 5. Fold left edge to mark 3" (7.6 cm) from left. 6. Fold right edge to mark on right. 7. Fold top flap down.

Left to right: 8. Crease well. Packet is complete. 9. Packet with preprinted label data.

Figure 2. Steps for folding herbarium packets. Colors were used to make it easier to see the folds in these images. Photos by David Wagner.

Packet Machine

Miller (1988) offers an alternative way to expedite making packets. He uses a file folder to make a **packet machine**. We have modified it here to make the same type of packet as the one shown in Figure 2 and to maintain packet size close to 4x6" (10x15 cm) with maximum space on the flap for the label [3.5" (8.9 cm)] (Figure 3-Figure 13) (Schofield 1985).

Figure 3. Cut the tabs from the folder to leave all edges straight and square. Then carefully measure 3.75" (9.5 cm) wide on one end of the opened folder, parallel to the folder fold. Score this line with a ball point pen and ruler to make it easy to fold. Photo by Janice Glime.

Figure 4. On the opposite end prepare a similar pocket; measure 1.25" (3.2 cm) from that end, score, and fold both ends to make pockets. Photo by Janice Glime.

Figure 5. Line up the pocket creases carefully and press them with a spoon or your fingernail. Photo by Janice Glime.

Figure 6. Staple or tape the ends so that it forms a pocket. Once stapled, this packet machine is ready to prepare packets. Photo by Janice Glime.

Figure 7. The machine is now complete with staples. For the first fold, 2-3 sheets can be folded together. Place one end of the 8.5" (21.6 cm) wide paper in the 3.75" (8.9 cm) pocket and fold it over the pocket. An old stainless steel spoon under the thumb or just the thumbnail helps to get a good crease on the packet. Photo by Janice Glime.

Figure 8. Separate the sheets and place one side that is perpendicular to the fold into the 1.25" (3.2 cm) pocket. Photo by Janice Glime.

Figure 9. Fold the packet over the pocket and crease. Photo by Janice Glimme.

Figure 10. Repeat the operation on the other side of the packet. Photo by Janice Glimme.

Figure 11. After you fold this side of the packet, you have an envelope and only the top flap needs to be folded down. Photo by Janice Glimme.

Figure 12. Place the bottom folded edge of the packet into the 3.75" (9.5 cm) pocket of the folder and fold the exposed part of the sheet over the pocket just above the pocket top edge so that when folded the dimensions are 3.75x6" (9.5x15 cm) with the last flap being 3.5" (8.9 cm). You won't be able to fold along the edge of the folder pocket this time, but must fold just above it. Photo by Janice Glimme.

Figure 13. Now it is ready to use. The label should be placed on the top flap. Photo by Janice Glimme.

Followers

David Wagner (pers. comm. 2009) has found a way to keep folded packets neatly stacked, in order, under constant but light pressure. This also works for sorting, since specimens can be added anywhere in the row with ease and it will expand readily to fit. The trick is to use a cylinder (can of beans in this case) in a tray that is propped up to provide an incline for the can to roll against the packets (Figure 14).

Figure 14. Packets held in place with food can in inclined box. Photo by David Wagner.

Card files (4x6" card size \approx 10x15 cm) have a movable back on the drawers that can be adjusted to hold the packets upright. Shoe boxes can be packed with wadded paper in back to keep packets upright.

Herbarium Sheets

Jerry Jenkins (Bryonet 31 January 3013) reports getting good herbarium paper from Herbarium Supply <http://www.herbariumsupply.com/nu_listCategoriesAndProducts.asp?idCategory=31> in Bozeman, Montana.

Herbarium Labels

Rob Gradstein (pers. comm. 26 July 2012) states that "labels should be a little smaller than herbarium packets and glued on the outer surface (top, not bottom!) of the packet." But we agree with Schuster (1966) that the label should be printed directly on the front flap of the packet. This saves time, and glued-on labels have a tendency to come loose from packets after time in storage. This can result in loss of data, or worse, incorrect information when the label is matched to the wrong specimen. (Glime inherited a herbarium where loose and lost labels were a serious problem.) If the specimen needs to be put in a new packet, the label can always be cut from the original packet and glued to it or stored inside if a new label is printed on the packet. In either case, the label should be on the opening face of the packet.

Label data should include **name of the species** (if known), the **author** of the scientific name, **altitude**, **habitat**, **substrate**, **date** of collection (with month written out), and **location** (country, state, county, distance to nearest town), **GPS** coordinates, name of **collector**, **collection number**, **determiner** (name of person identifying or verifying identification). Persons adding identifications or verifications to specimens often precede their names with an **exclamation mark (!)** to indicate determined by. Additional information may include name of associated species, color, height of plant, abundance or other information not evident from the pressed specimen. For liverworts, it should include descriptions of the oil bodies because these will disappear upon drying.

The family name is less commonly used for bryophyte labels because the family concept is less stable than in flowering plants and there are fewer families and genera. Specimens are usually stored alphabetically by genus (see Herbarium Arrangement below).

The label will usually also include the name of the **herbarium** and the **accession number** for that herbarium. The herbarium name aids in getting loans back to the rightful owner.

A sample herbarium label is shown in Figure 15. Note that the **date is written out in full** to avoid confusion among different country annotations, and a detailed collection location is included.

CRYPTOGAMIC HERBARIUM OF MICHIGAN TECHNOLOGICAL UNIVERSITY	
FAMILY: Fontinalaceae	
SPECIES: <i>Fontinalis duriaei</i> Schimp.	
DATE: 1 May 1969	
LOCATION: USA, New Hampshire, Grafton Co., 1 km. north of Plymouth in woods on left of Texas Hill Rd.	
45°8'N, 71°40'W, R21, T15, sec 6	ELEV. 300 m
HABITAT: on granite rock in mountain stream in <i>Tsuga canadensis</i> woods	
NOTES: few dark capsules with ends abraded away; plants dark green with little algal growth	
COLLECTED BY: Janice Glime	COLLECTION NUMBER: 281
DETERMINED BY: Janice Glime	! Winona Welch
ACCESSION NUMBER: 12896	

Figure 15. Sample herbarium label from Michigan Technological University. Designed by Janice Glime.

Multiple Species

Bryophytes often grow intermixed (Figure 16). Here need of ecologists and taxonomists/systematists differ. For ecological studies, the associations contribute important information. I (Glime) am reminded of a letter I received from Sin Hattori, along with his careful notes on the species in a set of collections of *Frullania*. Most of the collections contained multiple species. He encouraged me to "do something" with the information of the mixes – so I did (Li *et al.* 1989; Glime *et al.* 1990).

On the other hand, when Niels Klazenga (Bryonet 15 July 2013) collected bryophytes in Borneo in 1997, he grabbed what he could – as told to by his PhD supervisor, hence including many mixed collections. Curation officers at the museum spent ten years cleaning up the mess.

Figure 16. At least 3 species are tucked in between lobes of *Conocephalum conicum*. When mixes like these are in collections it is best to make a minipacket if the mixed-in species are important. In any case, they should be noted on the label. Photo by Janice Glime.

Jean Faubert (Bryonet 15 July 2013) disagrees. Rather, he admonishes not to try to make single species collections. Grab the lot, put it in the bag and DO identify everything you see in it when back in the lab. Sure enough, that is when the goodies show up. He declares that most of his lifetime big finds were made that way. Philip E. Hyatt (Bryonet 15 July 2013) agrees and adds that since most info is slowly going on line, someone who is desperate to find a specimen won't have too much problem running it down in the future like we might have had to do with mixed collections in the past. In 1990, if you were not in a herbarium you probably didn't know the specimen existed. Life changes.

In habitats like the Sahara Desert or epiphylls, species are often not separable. Tamás Pócs (Bryonet 14 December 2015) makes a packet with one good specimen of the mix, then makes as many copies of the label as the number of species present. Packets with just labels (no specimens) or just labels are filed by each species, with the appropriate species for that location underlined.

As Philip Hyatt suggested, the herbarium in Trondheim is databasing every species (present in the same packet) as a separate record. They have a way to track which of the species is the 'main' species in the packet, *i.e.* in what cabinet the specimen is stored. This is more practical for the data users (and less practical for the herbarium curators), and curation of synonyms is easier this way, too.

The practices and reasons are varied, as demonstrated by a Bryonet discussion in mid July 2013. There are certainly pros and cons for both approaches. Separating the species is likely to lose the growth habit. Parts may be broken and underground structures lost. One loses the information gained by determining which species form associations and how reliable those associations are. Baranabas Malombe (Bryonet 15 July 2013) also considers it important to collect and retain all the species in the collections to demonstrate the diversity of the site.

If it is desirable to have archival specimens of more than one species, then removal to a separate packet is necessary. If only one species is of interest, it is safest to make minipackets to represent the accompanying species and to include their names in the notes on the packet label, or at least indicate that it is mixed with other species. Keep in mind that beginners may use this collection to learn species. Rod Seppelt (Bryonet 16 July 2013) agrees. "While it may be desirable to have monospecific collections, in practice it is rarely possible." For example, Seppelt states "I have been looking at *Fissidens* (collected by the late Ilma Stone); the label clearly indicates that the packet also contains fruiting material of two, sometimes three, additional *Fissidens*. It would be impossible to separate these into separate collections and still have a meaningful herbarium voucher." As Seppelt points out, "if all threads/plants of a particularly species are removed from a mixed collection, what can be important information about associated taxa is lost."

While it is desirable to separate species into separate packets, exemplars of intermixed species can be housed in minipackets within the herbarium packet. When accompanying species are removed to separate packets, the collection numbers should be retained, but individualized by adding a letter at the end of the collection number. The

parent packet should retain the letter **a**, alerting the researcher that there are other packets. If the other taxa have been identified, they should be listed in the notes along with their collection number and letters.

David Wagner suggests a way to have all the specimens catalogued in the herbarium: Make duplicate labels and file the duplicates for the subordinate species in their appropriate places, but indicate the specimen label where the actual specimens are located. This does cause problems when the systematics are updated, but can be helpful in locating the smaller associates.

Alas, in large herbaria, as noted by Ambrose Baker (Bryonet 16 July 2013), 1 specimen = 1 species at 1 location at 1 collection date. This is also true for higher plants, but it is easier to do for them. As stated by Niels Klazenga (Bryonet 15 July 2013), "mixed collections are not okay." But Jon Shaw (Bryonet 15 July 2013) disagrees.

My (Glime) own solution to the mixed collection is to make minipackets in which a bit of each minor species is placed. A sample of the dominant species can also be placed in a minipacket to assure the right specimen/species is examined. If the community is important, only samples of each species are removed, but if the specimen is important for taxonomic purposes, I might attempt to remove all the minor associates. Blanka Shaw, herbarium curator at Duke, likewise treats the plants that are mixed together and a separation is not an option by making small fragment packets with a few plants of each named species separated from the rest. "If you spend the extra time to name more than one taxon in the packet, definitely do make a fragment packet. There is nothing more frustrating than having a specimen with a rare liverwort in it, that is present in few stems only, and there's no way to find it out among all the other dried species that look identical in the dissecting scope." Blanka Shaw further distinguishes between plants associated in the same microhabitat in the field and those associated in the collection/packer.

Blanka Shaw (Bryonet 15 July 2013) does issue a warning about only listing the species on the same packet as associated species. These species might not be searchable in some databases. The bryophyte portal <<http://bryophyteportal.org/portal/index.php>> currently doesn't enable one to search the associatedTaxa field. However, the field is available there for this purpose, and you can get at the data by downloading the result of your search. In the Duke database, there are about 5,000 specimens with the associatedTaxa field filled in (out of ca. 160,000 records). But this information is rarely used – she has never considered it when preparing species lists. When a species name is updated, the name(s) in the associatedTaxa field does not get updated automatically (=you have to search for every synonym). So, it is not very practical for the data users. Hence, David Wagner's method of making a separate label to be filed as if it were a herbarium packet would put it into the database and enter it in both the search and nomenclatural updates.

Dorothy J. Allard (Bryonet 15 July 2013) suggests the following from the perspective of a bryophyte collector and curator:

- If you have enough material, split all of it into separate packets and establish one collection for each species. Then in an "associated taxa" field, indicate which other

species are present. Separating material can sometimes be difficult and destructive.

- If it is easy and non-destructive you can separate the material into individual packets. Information on the associated taxa is still useful to express on the label.
- If you don't have enough material, label the specimen with a single species and include information about the other species in the packet in an associated species field. If possible include one smaller packet inside for each of the associated species with its own label.

It is not unusual for one of the minor species to be the one of interest. Dorothy J. Allard (Bryonet 15 July 2013) reports that sometimes she collects a specimen because of a small and interesting liverwort, for example, embedded within a clump of *Brachythecium*. In this case she labels the specimen with the name of the liverwort and indicates that it is within a matrix of the *Brachythecium* in a habitat field, but she also lists the *Brachythecium* in an associated taxa field. In essence she treats the *Brachythecium* as the liverwort's substrate.

Ken Kellman (Bryonet 15 December 2015) separates a collection out when the identification is made. Each will become a separate collection with a suffix like a,b,c etc. On the front of the label, you can then put "growing with *Tortula muralis*, *Didymodon fallax*...) and this information is included on all the separated packets. But he only does this if there is some special reason to separate the collection: 1) the separated plant needs to be documented for a study; 2) the separated plant is rare or disjunctive etc. It would take so much time to separate out all collections that you have to prioritize. In any event, he tries to put all species found in a collection on the label so future workers can read what he was seeing.

Genevieve Lewis-Gentry (Bryonet 14 December 2015) and coworkers use three different options for a mixed collection:

1. Put a separate barcode for each different biological organism on the single packet. Use this to track name changes/annotations for each.
2. Use a single barcode that corresponds to the packet. Add many biological organisms to this one identifier.
3. Only use a single barcode, pretend it is a simple specimen, and note all the other species in a remarks field. (This is exclusively what was done with older systems, but this is never done now.)

Their database and workflow centers around barcodes. Everything has to have at least 1 to go into their computer. Their system is flexible so that depending on the situation they can choose to either put many barcodes on a single packet/sheet/slide/etc. or to put a single barcode with the packet etc. and tell the computer that this preparation has multiple organisms they would like to track separately.

As Claudio Delgadillo-Moya (Bryonet 15 July 2013) summed it up, "What and how you collect mosses and other small plants depends on where you live, the purpose of your research, or what you want the herbarium for."

Annotations

Sometimes labels are filled with information and little room remains for further annotation. A common practice is to glue one end of a slip of paper to the edge of the packet

label for name changes, verifications, or other notes. However, this slip of paper can easily come loose, so several options are used. One is to glue the packet to a larger card and attaching the paper, fully glued, to that. This seems to defeat some of the advantages of the packets and can create storage problems, unless the packets are in palm folders, but packets could get tangled with each other, causing glue to come loose. Another alternative is to place the annotations in a waxed envelope and to place that inside the packet. (Putting it in without protection could result in smudging or mold.) The disadvantage is that one must open the packet to know that something has been added. If the addition is extensive, one could place a note on the outside label instructing one to see inside.

At the University of Colorado Museum, William Weber reports that annotations are placed on the back of the packet (with packets stored in boxes or palm packets, not on herbarium sheets).

NEVER DISCARD THE ORIGINAL LABEL. Handwritten and even typed labels must be interpreted, and sometimes that interpretation is in error. Keeping the original label permits researchers to check for possible alternative interpretations. And there is always the possibility of transcription error.

Multiple Access

Guido van Reenen (Bryonet 15 December 2015) has refined his relational database to overcome the problems mentioned above. In his database structure the specimen information is basically stored in two tables, an 'Observation' table and a 'Collection' table. In the 'Observation' table the information of the specimen is stored (taxon name, determiner, date, substrate, phenology, if there is a microscope slide and/or a photo, etc.). If the specimen is also collected (that is not necessarily the case) a link is established to the 'Collection' table. In database jargon: the 'Observation' table has a many-to-one relation to the 'Collection' table. In other words a collection can contain one or more specimen.

In the case of multiple specimen in a collection, van Reenen defines one specimen as the 'main' specimen. Mostly this is the most abundant specimen in the collection. Under this specimen the collection is stored in the herbarium. The herbarium label also lists the names of the other specimens in the collection. He also uses the method of placing cards in the herbarium to reference to the physical collection, but that takes too much time and requires a lot of discipline, especially after a name change. And it is not necessary anymore because all the information is now in the database. He does most of the queries in the 'Observations' table, because all other tables in the database are linked to this table and it gives him all the information I need, including herbarium information.

Van Reenen also maintains a 'Taxa' table with information on the name, if it is a synonym, if it contains synonyms, place in the taxonomic hierarchy, etc., a 'Location' table, a 'Persons' table and a 'Relevé' table, to name the most important. The last one gives some headaches as well, because when collecting in a 400 m² relevé, often one species was collected more than once. And a percentage cover should only be attached to every unique species in the relevé.

The printing of the herbarium labels is done from the 'Collections' table (Figure 17). The collection is stored in the herbarium under *Fissidens ornatus*.

BRYOPHYTES OF COLOMBIA	
Collected by G.B.A. van Reenen & C. Schulte Fischedick	
No. 04366	15 August 1981
<i>Fissidens ornatus</i> Herzog	
+ <i>Fissidens flexinervis</i> Mitt.	
+ <i>Fissidens intermedius</i> Müll. Hal.	
Identified by R.A. Pursell, 1988.

Storage

Cabinets

Herbarium cabinets are the standard method for storage of preserved plant material. For most tracheophyte specimens, pest control is essential and it is important that the cabinets be sealed or nearly so to keep specimens dry and to discourage pests. Bryophytes, on the other hand, are usually not bothered by pests, so in less humid climates, less expensive storage cabinets are acceptable.

But cabinets require lots of space, so many larger herbaria with larger budgets have converted to compactors (Figure 18) that are used for both bryophytes and other plants. Although these can be a nuisance at times, they are great space savers and also make it somewhat easier to control humidity and pests because access is reduced.

Packet Storage

Nearly everyone stores bryophytes in packets, but some herbaria glue the packet to a standard size herbarium sheet. This has the advantage that the herbarium can use the same storage method for the bryophytes as they use for tracheophytes. But the packets take much more room this way, and a herbarium sheet is difficult or impossible to put under the microscope for closer inspection. It also makes your working space more crowded. My biggest concern is that the large format forces me to remove the specimen to observe it under the microscope, and when comparing several specimens, it is easy to mix them up, returning specimens to the wrong packet. Single packets can be placed under the microscope without removing the bryophyte from the packet.

Dale Kruse conducted a survey of bryonnet members in 2008 and got a mixed response. Susana Rams Sánchez has worked with specimens at MA, MUB, BM, E, S, MO and others. She finds the method at MO (Missouri Botanical Garden) to work the best, *i.e.*, packets. Others using packets included Noris Salazar Allen (Herbarium, University of Panama), Chris Cargill (Canberra), Stephen Rae (MUSCI Natural Resource Assessment). Rudolf Schuster (1966) considered packets in shoe boxes, trays, or drawers to be "much better" than pasting the packets to herbarium sheets. He also recommended that if the packet must be affixed to a herbarium sheet, it should be stapled

rather than glued so that it can be removed without destroying the packet.

Figure 18. Herbarium compactor at Missouri Botanical Garden showing cabinet with open door. Labels on the ends denote the contents of that section. Photo by Paul J. Morris through Flickr Creative Commons.

Cargill (Canberra) reports that one can prevent specimens from falling to the bottom of the packets by storing the specimens in polypropylene archival bags. In some cases they are also wrapped in Kimwipes® before placing them in the bag.

Kerry Barringer (Brooklyn Botanic Garden) reported that they were changing their method from packets on sheets to packets in cardboard boxes (51 x 16.5 x 6.3 cm). The boxes are open and two will fit lengthwise on a standard herbarium cabinet shelf. They made new packets and photocopied disintegrating old ones to store inside the packet.

Those who disliked the placement of packets onto herbarium sheets cited concerns such as glue yellowing the packet, glue coming loose, packets getting caught and being torn off, glue catching dirt, difficulty in removing packets from the sheet (resulting in loss of specimens), greater cost for sending loans, more storage space required. To this list, one must consider where the packet is to be placed on the sheet. If it is placed in the lower right corner, where a label would normally go, then the stack becomes very lopsided. If packets are arranged at random on different sheets, then it makes sorting through the sheets to find a particular specimen a more difficult job. Placement of more than one packet on a sheet brings its own problems – renaming some, but not all, specimens; shipping for loans or

verification of identification, and still has the problem of locating the labels when sorting through to find something.

David Long (Royal Botanic Garden, Edinburgh), a proponent of herbarium sheets, cited advantages of gluing packets to herbarium sheets: being able to use standard herbarium cabinets, species covers, and genus covers; specimens do not get lost as easily as those in loose packets; it is easier to flick through sheets to find individual specimens (if packets are in a standard position and only one per sheet); hunting for specimens requires less handling and thus less chance for damage; specimens are kept horizontal so that soil does not collect at the bottom of the packet and damage specimens; specimens are better protected when sent on loan; there is greater ease to arrange packets geographically by sheets (this could also be accomplished in a palm folder); types can have the traditional red folder and be easier to spot; useful literature can be placed in the folder with them (Bryonet July 2008).

Bill Buck (New York Botanical Garden) further supports the use of packets glued onto herbarium sheets. The greater protection of the specimen seems to be a primary concern for supporters of this method, including problems with settling in vertical packets and provision for extra padding without tight packing. The herbarium sheet also will accommodate large packets for such taxa as *Spiridens* (Figure 19) and *Polytrichum*; when just packets are used, large specimens must either be cut into sections or stored elsewhere. And packets, due to their small size, are more easily lost, especially when sent out on loan. Catherine La Farge England (Bryonet 18 July 2008) reports the same reasoning for the University of Alberta Herbarium, an approach established by Dale Vitt.

Type Specimens

Colored folders are traditionally used for tracheophytes to indicate special collections. Red is standard for type specimens, whereas blue or other color may be used to indicate a particular geographic area. The same system can be used if bryophytes are stored on herbarium sheets and provides one of the arguments in favor of this method. A red felt pen run across the top of a packet will serve the same purpose (Figure 20-Figure 21), or a red herbarium folder can be cut to fit around the packet (Figure 22).

Figure 19. *Spiridens flagellosus*, a large epiphytic moss. Photo by John Game through Flickr Creative Commons.

Figure 20. Type specimen packet (red top) among other packets. The red top is made by a red felt pen. Photo by Janice Glime.

Figure 21. Close view of type specimen packet among other packets. The red top is made by a red felt pen. Photo by Janice Glime.

When a palm folder is used, a felt pen can be used to make a colored dot on the folder to indicate the presence of a type specimen (Figure 25).

Figure 22. Sample type specimen folder for bryophyte packet. Photo by Janice Glime.

When slides are made of the type specimen, it is important to retain the slide with its specimen (Singh Deo & Majumdar 2020). These can be mounted in a permanent medium, or allowed to dry on the slide. For the latter, in particular, the slide should be placed in a small packet to prevent loss of the specimen. These latter ones can be rewet to position the specimen as needed.

It might be tempting to keep a "**kleptotype**" (stolen specimen or part of specimen of type) when working with type specimens, but this should never be done. With other herbarium specimens, it should be done only with permission of the owner/curator (Katagiri & Majumdar (2020). In the International Code of Nomenclature for Algae, Fungi and Plants, Rec. 7A.1 (Turland *et al.* 2018), it is strongly recommended that the material on which the name of a taxon is based, especially the holotype, be scrupulously conserved. Nevertheless, the Code does not explicitly prohibit the taking of fragments of a type specimen. Katagiri and Majumdar have proposed the following language be added to the Code:

"8A.n. The unauthorized division of a type specimen should be prevented to avoid a loss of the type specimen. Such action most likely complicates the work of future generations and the resulting reduced collections may give a misleading concept of the species. When found, such "kleptotype" specimens should not be destroyed but preserved as duplicates. Formal notification of the existence and location of these specimens should also be published."

Storage Containers

For those using 4x6 (10x15 cm) packets, a 4x6 card file cabinet can be used to hold the packets. It has a pull-out drawer that can be removed and a movable back that can hold the packets up even when the drawer is not full.

Brian Eversham uses plastic boxes that can hold a double row if the packets are folded small enough (Figure 23). I use shoe boxes because they are free at the local shoe stores and keep the packets covered, avoiding excess dust. It is easy to attach a label to the end of the box to indicate the part of the alphabet contained therein. I try to leave enough room for half as many more packets to be added, *i.e.*, 2/3 full.

Figure 23. Herbarium drawer with packets. Photo by Brian Eversham.

Packets on herbarium sheets can be stored in a standard herbarium cabinet, and that seems to be the main asset for those who prefer them. The boxes or drawers, however, can also be stored in a herbarium cabinet and require much less space than a packet plus herbarium sheet.

Bryophytes are seldom eaten by pests in a herbarium, unlike tracheophytes, so most bryologists store them without mothballs or other deterrents.

Palm Folders

Palm folders were originally constructed to handle large or thick tracheophyte specimens like palms, hence the name. Palm folders can hold 10-20 packets, or even more, depending on the size and thickness of the packets. Those using packets placed in palm folders (Bryonet July 2012) included Jaakko Hyvönen (Plant Biology, Helsinki), Dan Norris (Berkeley University Herbarium), Xiaolan He-Nygren (Helsinki), and Jim Shevock (California Academy of Sciences). This method permits the packets to lie flat, overcoming the crushing problem and the problem of having specimens collect at the bottom of the packet in a pile of soil.

Dan Norris (Bryonet July 2012) cites the flexibility offered by palm folders for having different sizes of packets to accommodate large specimens. The folders are 30.5 mm x 56 mm and have additional flaps on each side, top, and bottom (Figure 24). The large size of the folder, like the large herbarium sheet, can accommodate large specimens like *Spiridens* (Figure 19) or *Dawsonia*.

Palm folders can be stacked so that 6-7 will fit on one standard herbarium shelf (Figure 25). The folders will allow specimens up to 27 mm thick. This permits a collection of various sizes to remain together. Jim Shevock points out that a further advantage is that the 27 mm thickness permits labelling the end of the folder (Figure 25), making it easier to find the right folder.

Figure 24. Herbarium palm folders showing arrangement of packets with a variety of labels, some as part of the packet, others glued on. Note the map on one of the labels indicating its location in the state of Nevada. Photo by Jim Shevock.

Susana Rams Sánchez warns against making species sheets with more than one packet glued to them. These will soon be a problem as identifications change with revisions. And when specimens are sent for loan, all the packets must be shipped, making them unavailable at the home herbarium and increasing shipping costs.

Figure 25. Herbarium cabinet with palm folders. Photo by Jim Shevock.

Storage Boxes from Genus Covers

If you are familiar with large herbaria, you are familiar with the heavy poster board or Manila folder quality of genus covers used for storing tracheophytes. Davison (2002) suggests using these for making storage boxes for bryophyte packets. These are similar to the palm folders, but the ones Davison has designed are the width of a "standard" packet and are not covered. The following instructions (Figure 26-Figure 28) are only slightly modified from his:

The finished box occupies the full length of a standard herbarium cabinet. Two boxes fit side by side on the shelf. The boxes can hold 40-130 upright specimens, depending on the size of the specimens. Be sure to measure the shelf size of your cabinet before making the boxes because the cabinet sizes can vary somewhat.

Figure 26. To make boxes, use scissors, razor knife, or paper cutter to remove 4.2 cm from long side of a 43x61 cm genus cover. Save trim as template for trimming additional genus covers. Score with hard metal edge such as door key and fold/unfold along indicated lines. Scoring controls exact line of fold. Rub smooth, hard object down folded edge to make creases sharp. To save measuring scoring lines, create template strips from cardboard or genus covers to guide scoring tool.

Figure 27. To form corners of box, push slightly inward at arrows and align edge **a** with edge **b**. Hold edges **a** and **b** firmly together and crease from inside. The corner crease will find itself as you align, meet, and hold edge **a** to **b**. Press firmly while creasing. Fold/unfold all four corners.

Figure 28. Once all folds have been made, shape the box and adhere each end with tape, glue, or staples. Davison uses clear 2" (5 cm) wide commercial-grade box packing tape and cover the entire outer face of each end. The tape provides a tear-resistant surface for taping and removing labels that identify the box contents. If handled carefully, as specimens should be, the boxes are adequately sturdy. Placing cardboard inside the upright ends strengthens the boxes but is not required.

Size 3 ($4 \frac{3}{4} \times 3 \frac{3}{8} \times \frac{7}{8}$): ~pricing range \$0.72 to \$0.88

Size 4 ($7 \frac{5}{16} \times 4 \frac{15}{16} \times \frac{7}{8}$): ~pricing range \$0.93 to \$1.19

Size 5 ($9 \frac{5}{8} \times 6 \frac{7}{8} \times \frac{7}{8}$): ~pricing range \$1.59 to \$1.91

Specially Made Storage Boxes

Jay Cordeiro of the Northeast Natural History & Supply Co. supplies herbarium drawers and trays to your specifications (Figure 29-Figure 34). Specimen drawers and unit trays are designed for curation, storage, rehousing, and display. They can be used for shells, minerals, skeletal material, feathers, eggs, skins, anthropological objects, fossils, glass vials, and memorabilia, as well as bryophytes. Archival trays are custom manufactured to any dimension; they are rigid, unbuffered, and acid-free with neutral pH. Trays are constructed of white corrugated cardboard, come free-assembled (not flat and self-folding), are overwrapped, and nested for maximum storage efficiency. Archival drawers are available in standard sizes to fit typical Cornell, California Academy, and National Museum of Natural History style storage cabinets. Trays can be lined with plastazote or ethafoam, unbleached cotton, or polyester batting for use with delicate specimens. Lids are optionally available for better protection from ambient environmental damage and for use in layered storage. The trays are sturdy and affordable.

The company does not have an online catalog because their product is custom designed. The trays and drawers can be purchased in sets of 100 or more. Sample sizes and prices include:

Size 1 ($2 \frac{3}{8} \times 1 \frac{5}{8} \times \frac{7}{8}$): ~pricing range \$0.50 to \$0.63

Size 2 ($2 \frac{3}{8} \times 3 \frac{5}{16} \times \frac{7}{8}$): ~pricing range \$0.62 to \$0.76

Preservation

Most specimens will keep well in packets if they are not packed together too tightly. If a specimen has fragile parts sticking out, it helps to pack crumpled tissue paper around the specimen. An alternative is to cut out space for the specimen in a piece of styrofoam or corrugated cardboard of appropriate thickness and dimensions. However, if the specimen falls out of the styrofoam, it may suffer even greater damage than with no packing, so it might be necessary to staple or tape a minipacket in the cut out space. Small jewelry boxes can sometimes be useful.

Glime once stored *Splachnum ampullaceum* in a plastic film can.

Preservatives should be avoided so the material can be used later for DNA or chemical analysis. If preservation is necessary for maintaining the morphology of a liverwort, maintain some of the specimens in preservative and others dried, and in some cases (flat thallose species), like *Conocephalum* (Figure 35), pressed. Rob Gradstein (pers. comm. 26 July 2012) suggests using FAA (feryl-acetic-alcohol). This preservative served Barbara Crandall-Stotler for her morphological work and Rudy Schuster for making the drawings used in his liverwort volumes.

Figure 35. *Conocephalum conicum*, a mostly flat thallose liverwort that preserves better if it is pressed. Photo by Robert Klips.

Gradstein (pers. comm. 26 July 2012) also suggests that dry, shrunken herbarium material of thallose liverworts can be rehydrated and stained with methylene blue (see Rico 2011), a method that works well for him in studying *Riccardia* (Figure 42). Rico developed this method of rehydrating the moss in a solution of sodium hypochlorite (commercial bleach) diluted to 20% in distilled water. This restores the form of the liverwort and the structure of the cells. The cells are cleared, making observation easier.

Species like *Riccia fluitans* (Figure 36) can be teased apart and floated onto a 3x5 (7.6x12.7 cm) card. The algae on these aquatic plants will serve as a glue to make them adhere to the card. Once affixed, they will retain their shape and remain flat.

Figure 36. Floating form of *Riccia fluitans*, a species that can be floated on a card before putting it in a packet. Algae help to glue it to the card. Photo by Janice Glime.

Since leafy liverworts will lose their oil bodies upon drying, one should preserve them by a photograph that shows details of the oil bodies. In addition, describe the oil bodies in detail.

Cool Preservation

Bryophytes prosper in cool temperatures, so it is not surprising that cooling them during drying can improve the quality of the specimen over air-drying. Victor Ardiles H. (Bryonet 25 September 2013) reports that both gametophytes and sporophytes look better when fresh samples, still in their paper bags, are placed in a freezer for 15 days at 7°C, 37% Relative humidity. The method discourages fungal growth and retains colors, leaf details, structure of thallose and leafy liverworts, bottle liverworts, and hornworts. The low temperature slows the dehydration of the tissues, a more natural approach.

Minute Species and Special Structures

The really tiny species can present special problems because they are easily lost among the soil in the packet. Several methods can help to make these locatable in the future. One popular method is to remove some of the specimens from the soil and place them in a minipacket (Rothero & Blackstock 2005) or small envelope without the soil. Another possibility, suggested by Richard Zander (pers. comm. 1 August 2012) is to glue the plants (without soil) to a white card with a polyvinyl-alcohol-based glue. That glue is water soluble, so the specimens can be soaked loose.

In some cases, only a few plants may have capsules, antheridia, archegonia, or propagules. To help avoid loss of these important structures, make a small packet or use a small envelope to store these within the species packet (Rothero & Blackstock 2005). Microscope slides can also be put in a small packet and stored within the species packet. They may survive better in a waxed paper envelope because the slide can be sticky and the paper may stick to the slide. The waxy surface can reduce this but won't necessarily eliminate it.

Herbarium Arrangement

There are two choices in widespread use in the arrangement of bryophyte herbaria – systematically or alphabetically. They each have their advantages and disadvantages, so one needs to choose based on resources and needs. The majority of those who commented on this to Dale Kruse in his survey preferred a strictly alphabetical system.

The systematic arrangement provides groupings that make it easier for someone making a systematic study. All members of a family would be grouped together. This method is further divided into choices – systematic or alphabetical arrangement of genera. Richard Zander (Bryonet 13 November 2008) considers this family grouping with alphabetical arrangement of genera to be "a nice compromise." Rod Seppelt (Australian Antarctic Division) practices a further compromise to group genera into the family, but to arrange the families alphabetically. This solves the problem of trying to linearize the non-linear systematics of families. One could also arrange the species systematically, but that does not seem to be a common practice.

The disadvantage of systematic arrangements is that our knowledge of bryophyte systematics is constantly changing. The publication of Shaw and Goffinet (2000) moved a lot of genera to other families and split some families. Because of the instability of our understanding of the systematics, the cabinets would require an updated list of the locations of each genus and family. Flora North America is making further changes. As we gather more molecular information we keep moving things. Hence, this arrangement can be expensive because it would require constant monitoring and rearrangement whenever a taxon has been moved or redefined.

The alphabetical arrangement is more practical. In some cases, the packets are arranged in families with an alphabetical arrangement of families. In other herbaria, the genera are arranged alphabetically with no family groupings. The latter arrangement is the most stable arrangement.

Jim Shevock reports that the University of California herbarium files their bryophytes alphabetically by genus (Figure 25). My own experience is that most bryological herbaria use that method because it is easier and less expensive to maintain. Missouri Botanical Garden uses family groupings. At the California Academy of Sciences the genera are filed by family, but the genera and species are filed alphabetically within the family, and the families are arranged alphabetically.

I like the advice of Jaakko Hyvönen (Bryonet July 2008) regarding phylogenetic vs alphabetical: we are...still too far away from the classification that would enable arrangement accordingly. Alphabets have been pretty stable for quite some time and this makes it easy for ALL people (most of whom are NOT bryologists) to locate specimens in collections. On the long run one would be able to save a LOT of precious volunteer, student *etc.* herbarium time by adopting this simple system. At the same time, need for rearrangement is minimized.

Guide Cards

A practical way to help the user is to provide guide cards. William Weber (University of Colorado Museum) uses blue cards for Colorado material and yellow for other areas. A salmon guide card indicates the genus, yellow the species. Alternatively, one could color code the top of the packets with a felt pen. Note that red is reserved for type specimens.

When a herbarium is rearranged or names change, guide cards can be placed where the alternative name would occur, directing the user to the location of that group. This can be useful if staff lack the time to rearrange the collection. A guide card can be placed where the new name should be, directing users to the name on the packets.

Herbarium Care

Soil

More information is retained if the substrate is collected with the specimen. However, this brings its own problems. It can be bulky, bring plant pests, and prevent you from taking or sending specimens across borders. But Brent Mishler (Bryonet 2 March 2021) warns us that if it is removed, rhizoids, tubers, and other underground structures can be damaged or removed. Furthermore, the soil helps to keep the clump intact. Hence, for taxonomic and

ecological purposes, it is best not to remove soil in contact with rhizoids or stems. Mishler recommends using window screening to gently rub away excess soil.

Wet soil is likely to cling to the clump, but dry soil may have dried to fine parts like glue. Sometimes a gentle washing by dipping the bases of the clumps in water can help to remove water with minimal damage to the underground parts, but caution is needed. Heavy soil clumps can pull on the rhizoids and break them loose.

Chris Cargill (Bryonet, 2 March 2021) faces similar problems at the Australian National Herbarium (CANB), especially with specimens like *Riccia* (Figure 37) and hornworts that typically have soil attached. The soil detaches over time as researchers access the collections, often just by disturbing the packet without removing anything. To improve maintenance of the collection integrity, they wrap terricolous collections carefully in archival tissue paper, sometimes on a piece of card for rigidity, and then place the whole wrapped specimen into an archival quality polypropylene bag. This reduces the movement of the specimens and inside the packet and therefore any rubbing from loose soil or small pebbles. They place any loose soil in a separate small archival plastic ziplock bag and place it with the specimen.

Figure 37. *Riccia* showing rhizoids clinging to soil. Photo by Bernd Haynold, through Creative Commons.

Ken Kellman (Bryonet, 2 March 2021) agrees with the importance of keeping soil. If there is a lot of powdery soil, wrap the sample in a smaller packet inside your herbarium packet. Fragment packets work well. That tends to minimize the inevitable settling of the soil.

Richard Zander (Bryonet, 2 March 2021) finds that, within limits, the more soil the better:

1. Rhizoidal gemmae, fallen calyptrae, and other plant parts may be found in the debris
2. Other organisms are present in the packet, and I think maybe in the future the best place to search for new taxa or significant species will be among soil in packets already in the herbaria.

Brent Mishler (Bryonet, 2 March 2021) raised an additional concern. The specimens may be used later for extracting DNA [or heavy metals in soil vs bryophytes], so washing can give false results. Initial wetting can cause a

lot of damage and loss of cellular contents. This is particularly true if they dry out again before being able to repair the damage. Hence, if specimens must be cleaned, Mishler recommends doing it dry.

Brent Mishler, Bryonet 2 March 2021

Pest Control

Pests can be a problem in a herbarium, and methods to eliminate or minimize them can be detrimental to future studies that rely on untreated material for historical pollution studies or DNA testing. In November of 2010 there was a discussion on bryonet-L regarding means of eliminating pests without compromising future studies.

Historically, most bryophyte herbaria have not treated for pests with the same care as that used for vascular plants. For example, beetles can be real pests among tracheophytes and some algae, but are usually not rampant among bryophytes. The popular belief that nothing eats them let of a somewhat false confidence in storing the with no pesticide treatments. However, if you have ever tried to import them into a country, you know that the border quarantine agents are concerned about pests in the soil, and this alone should suggest that the bryophytes may introduce pests into the herbarium. Scattered publications, and especially more recent ones, as cited in the interactions volume on this website, demonstrate that our assumption that nothing eats bryophytes was incorrect.

Agral 600

As mentioned in the Laboratory Techniques subchapter on Slide Preparation and Stains, Tom Thekathiyil (Bryonet 12 May 2010) submerses the bryophytes in **Agral 600** (horticultural wetting agent). It kills the animal life that often accompanies the bryophytes but does not seem to affect the plants.

Moth Balls (Naphthalene)

For tracheophytes, the standard treatment has been to put **moth balls** in the cabinets. These have contained such compounds as **naphthalene** (highly flammable and carcinogenic), **1,4-dichlorobenzene**, or **camphor**. These all have strong odors that are very offensive to some people, especially when they work for many hours in that environment.

Rod Seppelt (Bryonet 26 November 2010) reports using fumigation with *Pyrethrum* in a spray. The plant that produces the Pyrethrin[™], however, is known to cause human health problems among long-term growers of the plant.

Microwave Oven

A more recent method for killing bryophyte inhabitants has been to put them in the microwave oven, but such treatment renders the bryophytes unusable for future DNA studies due to the ability of the gamma rays to alter the DNA. Lars Hedenäs (Bryonet 30 November 2010) reports that the Swedish Museum of Natural History would never send material to another herbarium if there is the danger that the material on loan would be subjected to microwaves. The risk of destroying DNA would "seriously reduce its value for future research."

Wagner finds that the microwave is not effective, largely because of the uneven distribution of microwaves inside the oven. The oven has the further problem of being

too small unless you purchase a commercial grade oven. Wagner had a friend who trapped a fly inside his otherwise empty microwave, turned it on for 60 seconds, and when he opened it the fly flew out. It had survived by cowering in a safe corner. Some herbarium material absorbed microwaves and overheated. Wagner has even had charred herbarium specimens, and blackened paper under them, that resulted from too long a treatment.

Bromomethane (Methyl Bromide)

Juan Larraín (Bryonet 13 April 2016) raised concerns that Chile requires that all specimens with soil, including bryophytes, must be treated with bromomethane before entering the country. While this may be a good means to prevent the introduction of agricultural pests, Rod Seppelt (Bryonet 13 April 2016) warns that it should not be used on specimens to be used for molecular work. Rather, he recommends freezing.

Freezing

It appears that the safest and most common method in current use is freezing. And this is standard practice in many herbaria (Figure 38). In this method, one recommendation is to freeze the packets for 24-48 hours; the process should be repeated annually to maintain the pest-free environment (Denis Oliver, Bryonet 26 November 2010). Rod Seppelt (Bryonet 26 November 2010) recommended three days at -18°C for material collected in the region or -18°C for seven days if it has come from a different biogeographic region or outside the country. He later modified this (Bryonet 6 February 2012), based on a response from the herbarium in Auckland, New Zealand. They found that a more effective treatment was to use cycles of room temperature to -15°C over a few days. It is kinder to the bryophytes and more effective against insects. At Christchurch (CHR), freezing is for 7 days at -20°C (Allan Fife, Bryonet 15 August 2002).

At the University of Alberta Herbarium (ALTA) specimens are frozen at -20°C (Catherine La Farge England, Bryonet 15 August 2002). The specimens are stacked as single sheets or only a few sheets overnight; larger stacks are stored at that temperature for four days to be sure the center gets cold enough. The specimens are sealed in poly freezer bags in the freezer and kept in them until they reach room temperature afterwards, for up to a day for larger stacks. A similar procedure is followed at the New York Botanical Garden (NYBG) and Missouri Botanical Garden (Marshall Crosby, Bryonet 15 August 2002), where freezing is for 3-4 days (Barbara Thiers, Bryonet 15 August 2002).

At the Helsinki Herbarium (H), all loans are frozen for at least a week before putting them in herbarium cabinets (Johannes Enroth, Bryonet 15 August 2002). The same procedure is followed at the British Museum (Brian O'Shea, Bryonet 15 August 2002). At the Chicago Field Museum (Matt von Konrat, Bryonet 15 August 2002), new specimens and loans are frozen unless they are to be used for DNA analysis or study of oil bodies in liverworts. The concern is more for the protection of other plants and fungi in the herbarium since bryophytes are seldom eaten by herbarium pests. Fungi are particularly vulnerable.

Figure 38. New specimens are being placed into the freezer at Beaty Biodiversity Museum in Vancouver, BC, Canada. Photo by Derek Tan, copyright Beaty Biodiversity Museum

Lloyd Stark (Bryonet 15 August 2002) warns that freezing as described above may be too effective, killing the bryophytes as well as the pests. In regeneration tests on specimens from UC, MO, and Cal Acad, mosses were not able to regenerate, but members of Pottiaceae that had not been frozen were able to regenerate several years later. At the University of Nevada Herbarium (UNLV), the dry climate makes freezing unnecessary. David Wagner agrees that low humidity is almost as effective as low temperature for controlling typical herbarium pests.

Rod Seppelt (Bryonet 16 August 2002) reports the additional precaution of freezing specimens that have been taken out of the herbarium cabinets for more than a few hours. If the specimens are kept in the herbarium facility, overnight freezing is usually adequate. If they reside anywhere else while outside the cabinets, they are frozen for several days.

At the Provincial Museum of Alberta (PMAE), the procedure is even more extreme. They do a quick freeze to -70°C for small accessions (fewer than 50 specimens). For larger collections they fumigate. Roxanne Hastings (Bryonet 16 August 2002) reports that creatures are killed within 24 hours at the very low temperature and have no chance to acclimate to it.

Herbarium personnel have done some experimenting, although it may not appear in the literature. John Braggins reported to Rod Seppelt (Bryonet 26 November 2010) that **multiple freezing events** were more effective than a single event. He found at AK that silverfish could be killed with a number of cycles, from room temperature down to -6°C or -10°C and back to room temperature. That procedure was more effective than just one cycle to -10°C . Freezing overnight is most likely useless. After all, these organisms survive such cycles in nature in many parts of the world. Rod Seppelt (Bryonet 6 February 2012) also reported that he had greater success with several low temperature (-1°C)/warm temperature cycles for several days. The multiple freezing event treatment seems to be gaining popularity, and many of the herbaria cited above may already be using it.

Domestic freezers vary in their temperatures, but generally only go down to about -15°C , and depending on their arrangement may have zones that are warmer or slightly colder.

Jeff Duckett (Bryonet 26 November 2010) points out that one advantage to freezing the bryophytes is that it does not **always** kill the bryophytes, despite killing their inhabitants. These are plants that can spend the winter, often for three months, under snow, or in many cases exposed with no snow above below freezing temperatures. In the polar regions they survive in areas that may be snow-free for some time at very low temperatures. Yet these species survive. Such is probably not the case for tropical bryophytes.

Adequate freezing facilities are not available in many herbarium locations. David Wagner (Bryonet 16 August 2002) suggests that baking or poisoning, coupled with closely contained quarantining may be necessary instead, particularly in the tropics. An alternative in temperate climates is an air-conditioning system that chills the air before heating it, thus dehumidifying it. Keeping vulnerable specimens, especially fungi, away from the bryophytes solves a lot of the problems, especially if low humidity can be maintained.

The downside to all this pest control is that the specimens are no longer suitable for longevity tests on spores or plant tissues and might not be usable for DNA testing. The **specimen label should indicate treatments** such as these to protect against faulty conclusions by people using the specimens for physiological purposes or DNA analysis.

Eva Krab (Bryonet 3 February 2012) found that a number of approaches did not work. After a number of failed attempts, she took the approach of flushing the moss cores [*Sphagnum fuscum* (Figure 39) and *Hylocomium splendens* (Figure 40)] in a gas-closed chamber with 100% CO₂ for 12 hours, then leaving the cores at room temperature for 24 hrs (so that eggs would hatch) before freezing them at -20°C. But even after 3 rounds of all those treatments – and still no success – the springtails were still active! (It worked a lot better in the *Hylocomium* cores than in the *Sphagnum* cores.) The mosses actually survived these treatments surprisingly well. These were subarctic springtails, so maybe temperate springtails might be more sensitive to the freezing part of the cycle.

Figure 39. *Sphagnum fuscum*, a hummock moss that survives cryopreservation with a pretreatment in 100% CO₂ to eliminate pests. Photo by Michael Lüth.

I like the suggestion from Javier Martínez-Abaigar (Bryonet 3 February 2012). He suggested using a Berlese

funnel (Figure 41) to chase the springtails out of the moss, then returning them to their natural habitat.

Figure 40. *Hylocomium splendens*, a moss that survives cryopreservation with a pretreatment in 100% CO₂ to eliminate pests, but invertebrates do not survive as well as those on *Sphagnum*. Photo by Janice Glime.

Insect Traps

Some passive means include insect traps, apparently somewhat standard procedure in large herbaria, but these are ineffective against eggs that may be dormant for long periods, causing new outbreaks when new material is introduced. What traps adults may not work for larvae that sit and chew on bryophytes and packets for weeks or months.

Drowning

Eleanor Edge (Bryonet 2 February 2012) found that washing the collections with a surfactant before drying them increases the effectiveness in killing them. She reports that springtails usually have a very hydrophobic cuticle and thus tend to float. Forced immersion in water will reduce their populations. If bryophytes are the only concern, some of the predatory mites will eat the springtails but not the bryophytes.

Steam Sterilization

Soil can be sterilized with steam. While this will most likely kill the pests, it will likewise kill the bryophytes. Rod Seppelt (Bryonet 16 December 2009) reported that Alison Downing found that some bryophyte spores, such as the thick-walled spores of *Riccia* species, survive standard autoclaving of soil.

UV radiation can be used to sterilize the air and even for a short distance (a few cm) into water (Javier Martínez-Abaigar, Bryonet 16 December 2009). However, soil shields it, so it is not an effective tool for sterilizing soil adhering to bryophytes, and most likely will not kill invertebrates hiding among the bryophytes.

Moisture Control

Moisture is another challenge in some herbaria, especially in the tropics. Fungi may appear as tiny hairs projecting upward or as a mass of hairs forming a mat. In worse cases they may form spores that spread easily to

other specimens and that are not healthy to breathe. Roxy Hastings (Bryonet 26 November 2010) found that fungi could be a problem at relative humidities above 40%.

Dehumidifier

Use of a dehumidifier may be sufficient in some cases to prevent the growth of fungi and bacteria, but it adds to the operating expenses and may be insufficient in large herbaria in very humid climates.

Figure 41. Berlese funnel showing its parts. A = liquid for trapping insects (not needed if you want to keep them alive). B = air space above liquid in jar or bottle. C = lid with hole for funnel end. D = open funnel area with screen or wider mesh on top. E = area of funnel where sample is placed. F = space above funnel to avoid scorching bryophyte sample. G = light/heat source that causes invertebrate inhabitants to go downward to escape. Drawing from Creative Commons.

Silica Gel

Modest problems can be controlled with silica gel packs, available from herbarium suppliers (Roxy Hastings, Bryonet 26 November 2010). They are available from "Herbarium Supplies" to maintain various humidity levels in the range of 25-40%. These packs can be "recharged" by putting them in an oven to dry and usually provide a color indicator of their state of moisture.

Herbarium Cabinet Materials

If you choose to make your own cabinet for herbarium specimens, be aware that particle board can contain formaldehyde in the glue, presenting a long-term health risk (Rod Seppelt, Bryonet 26 November 2010). Herbarium cabinets are usually made of metal with a somewhat spongy material around the door to seal it. A good cabinet will not allow pests to gain entry unless they travel with the herbarium specimen.

Sending Specimens for Identification

Understanding accepted courtesy and rules for sending bryophyte specimens can make it easier for one to get much needed help. These guidelines should keep you out of trouble and avoid misunderstandings:

1. Assign each of your collections a unique collection number. Many bryologists pre-number collection bags and keep a life list of numbers to avoid ambiguity.
2. When mailing a specimen for identification, keep part of the sample yourself and be sure it has the same collection number on both yours and the identifier's packets. This will permit correspondence with the least ambiguity.
3. Be prepared to donate the collection to the person doing the identification (Loeske 1925; Raup 1926; Zander 1993). This is a courtesy for the time that person spends helping you. Be aware that some recipients will assume that the specimen is now theirs.
4. Make it clear who will be considered author(s) of any scientific publications resulting from the identification. If possible, offer to make the determiner a co-author. If there is a reason you can't do this, explain why you must be the only author. Establishing this at the onset can avoid awkward misunderstandings.
5. Include details of name of collector, collection number, date, substrate, habitat, and location on the packets, including latitude, longitude, and more precise coordinates, including GPS if possible.
6. Include on the packet label any notes that might be important. Information included in an accompanying letter will usually not be added to the label by others.
7. Check and follow the import/export laws regarding herbarium specimens in both yours and the receiving

countries. Usually it is sufficient to label a package as "herbarium specimens, no commercial value," but some countries have very rigorous import standards to protect against introducing soil organisms and disease, and more recently, against collections of rare or endangered species. For example, specimens entering Australia and New Zealand require paperwork in advance and treatment protocols (Rod Seppelt, Bryonet 12 July 2012). The sender or recipient may have to pay inspection and/or fumigation costs, the alternative being destruction of the specimens. And in some countries you could get the recipient in trouble because the necessary paperwork is lacking. A Google search for **plant import regulations** and the name of the country can be a good start.

8. Remove as much soil as possible.
9. Be sure the specimen is dry and in paper, not plastic, to avoid mold.
10. Get permission from the recipient before sending the specimen. Otherwise, you might never see your specimen or any identification again.
11. Provide a clear address and email address for providing you with the names of bryophytes identified.
12. If you have a target deadline, be sure you discuss that with the person identifying before you send the specimens.
13. Try not to send more than three specimens at a time so the task will not seem so daunting to the recipient (Zander 1993).
14. Don't include more than one species in a packet if you can avoid it. If not, tease out the individual species and put some branches of them in small packets within the larger one, giving each the same collection number but a unique letter to distinguish it (and keep duplicates of the individuals). It is important to maintain the growth form to help in identification.
15. If you are borrowing samples for DNA analysis or other destructive purpose, be sure the person/institution loaning them understands that, and be sure that at least some material is left for verification by anyone later. Actual plants from which DNA analysis is made should be maintained in minipackets (triangular packets) and kept both in the original voucher specimen packet, entered in the herbarium database, and linked to the voucher specimen in Genbank (Brent Mishler, Bryonet 20 January 2023).
16. Include in your packet a carefully prepared slide with a semi-permanent or permanent mount of the specimen of interest, including stem leaves, branch leaves from the middle of the branch, a short branch from which the middle leaves have been removed, and if available, a peristome (Holzinger 1900). It is also very helpful to provide a permanent mount slide of leaf cross sections. These inclusions will save

considerable time for the identifier and make it more likely that you will get your identifications in a timely manner. These should be protected in a small envelope within the packet.

17. Karen Golinski (Bryonet 12 July 2012) suggests providing a spreadsheet with the collection numbers and collection information with space for adding the name. This makes it easy for the identifier to provide you the names and makes it easier for that person (or you) to add the information to a herbarium database.
18. Make an attempt to identify your specimens before you send them to experts. Not only will you learn more this way, but it makes the task less daunting for those helping you. And some bryologists will take the time to tell you where you went wrong in those that are identified incorrectly. David Wagner (Bryonet 12 July 2012) states "First, for anybody sending specimens to an expert you have not had communication with before, send only one or two specimens with your best guess as to identification. This is far more likely to get a prompt response. As soon as somebody sends me a box with a dozen or more specimens, it gets put on a shelf as a 'when I get time to do it' task. This shelf has accumulated specimens for many years with most boxes advancing only very slowly to the top of priority tasks. Send me one specimen and I'll look at it and respond within 24 hours. Offering to pay helps to advance priority ranking, of course." Wagner also points out that your identifications will give the expert some idea of your level of expertise.
19. Make use of the internet to see if your identification matches the images there. But of course be aware that some ID's shown there may be wrong.
20. If you took pictures of the bryophytes and their habitats, send the best of these to the person doing identification (Figure 42-Figure 44). Field growth habit can help in the identification, and if the pictures are good, they are an additional way of saying thank you to the one helping you. Photographs of microscopic characters are even better.

Figure 42. *Riccardia cf. elata*, posted to Bryonet by Zhang Li for help in identification. With only this view, Bryonetters suggested the fern *Hymenophyllum*. A view showing its habitat and growth habit might have helped. Cellular structure and other microscopic views are needed. Photo by Zhang Li.

Figure 43. *Riccardia cf. elata*, posted later to Bryonet by Zhang Li for help in identification. With the addition of this view, Bryonetters could be more certain the species was one of *Riccardia*. Photo by Zhang Li.

Figure 44. *Riccardia cf. elata* microscopic view posted to Bryonet by Zhang Li for further help in identification. This view enabled Bryonetters to be certain the species was not a fern, but rather one of the liverwort *Riccardia*. Note the oil bodies. The suggestions were narrowed to *Riccardia elata* or *R. prehensilis*. Photo by Zhang Li.

References

Current Names

The choice of references depends on your geographic location, so it would most likely be of little help for us to make suggestions. Old references can be useful if you check the names in TROPICOS <<http://www.tropicos.org/>> for nomenclatural changes. If you can't locate them there, Google might help, or The Plant List <<http://www.theplantlist.org/tpl/record/tro-35156923>>. Be careful of your spelling – these lists don't find similar spellings. They don't care about capitalization. For liverworts and hornworts, the best source currently is Söderström *et al.* (2016).

Bryologists will always disagree among themselves about generic placement using the Linnean naming system. This generates healthy discussion about relationships, but creates problems for a herbarium and the ability to relocate a specimen. It is best for a herbarium to choose a published classification system and be consistent in its use. If a different system is chosen, then the entire collection should be updated. This might be at the generic or family level, not necessarily at the level of the entire herbarium. But it

should not be store partly by phylogeny and partly by alphabet at the same hierarchical level.

Easy sources for names, authors, synonyms, and currently accepted legitimate names are Söderström *et al.* (2016), TROPICOS <<http://www.tropicos.org/>>, a service of the Missouri Botanical Garden, and The Plant List <<http://www.theplantlist.org/>>, a collaboration between the Royal Botanic Gardens, Kew, and the Missouri Botanical Garden. I (Glime) don't like the higher level classification used by the Missouri Botanical Garden (it puts the bryophytes in the class Equisetopsida to use classification levels considered commensurate with those of animals). At least I don't have to look at them in the Kew list!

Indexing

Wagner recommends indexing your taxonomic reference books. He found the books more inviting when they were easier to use, and found that the accuracy of his work definitely increased as a result. With bryophytes he indexes the major genera. Figure 45 shows an indexed copy of Paton's "The Liverwort Flora of the British Isles." Figure 46 shows the thumb tabs in greater detail and Figure 47 shows the method for cutting them. An index card serves as template for the area to be cut out. A cutting mat is placed ON TOP of the page to be indexed. Wagner uses a #11 scalpel blade to cut through forty pages (twenty sheets of paper). The important part is to plan which pages will be indexed. It is easy to want to do too many and run out of space on the outer margin of the book.

Figure 45. Index tab indentations in The Liverwort Flora of the British Isles. Photo by David Wagner from Bryological Times #136 (2012).

Figure 46. Close view of index tab indentations in The Liverwort Flora of the British Isles. Photo by David Wagner from Bryological Times #136 (2012).

Figure 47. Tools for cutting indentations in page edges. Photo by David Wagner from Bryological Times #136 (2012).

The second type of index Wagner uses is an invention that began with an address book. The index is printed on only one side of the paper and stapled on the right side. This might seem counterintuitive because most booklets have the binding on the left side when it is face up. However, because our writing is from left to right, it means the words to be indexed will appear lined up on the left side of a sheet. (This might need to be reversed for some Asian countries.) By staggering the sheets and trimming on the left, any item is quickly found. There are two examples here. The first (Figure 48) shows an index to the five most common references Wagner uses for liverworts, directing one to the pages for species of liverworts found in Oregon. The species are designated by six letter codes. This index is kept with the appropriate books on the workbench or book shelf.

Figure 48. Excel file printout of six-letter liverwort codes, showing reference where it can be found and page. Photo by David Wagner from Bryological Times #136 (2012).

The second example of this kind of index is an older one, made in 1998 when Wagner was doing extensive cryptogam inventories in southwestern Oregon. It has all the mosses and liverworts known from the entire state, almost 700 names (Figure 49). It is useful to check spelling or authority of a name when typing memos, labels, or annotating. Again, the names are designated by six letter codes manufactured for rapid data entry both in the field

and when databasing. By using small type all 678 names fit onto 14 pages.

Figure 49. List of all bryophytes found by David Wagner in Oregon, used to check spelling and supply authors. Photo by David Wagner from Bryological Times #136 (2012).

Herbarium Label Programs

There are several programs on the internet, *e.g.* <http://www.flmnh.ufl.edu/herbarium/pl/>, to help make it easier for you to produce labels and make a herbarium database. If you can use Access, UC Davis has a free Herbarium Management System to download <http://herbarium.ucdavis.edu/database.html> that allows you to print up labels from Access data (Stephen Lodder, Bryonet 12 July 2012).

Specify 6 is another free herbarium program <http://specifysoftware.org/>, funded by the U.S. National Science Foundation. This program can handle specimen data for computerizing collections, tracking specimen and tissue management transactions, and moving species data to the internet. It runs on Windows, Mac OS X, and Linux operating systems.

One consideration for computer programs is that their database is compatible with other programs in widespread use. Current efforts to create a national database of US holdings are underway, supported by government funding. Part of this effort includes converting the many individual databases into a single one that is accessible online. This will permit researchers to find the location of needed specimens and to determine the contact person(s) for loans.

Shipping Live Bryophytes

Bryophytes don't like to be wet and hot at the same time, and this can be exacerbated by also being dark. Such conditions are ideal for fungi to grow, and once a fungus attacks the bryophytes, they most likely won't recover. Hence, shipping live bryophytes can be a major challenge. To reduce these ideal fungal conditions, whenever possible pack some of those frozen picnic cooler gels with your bryophytes to keep them cool and use an insulated container, or insulate one with something like crumpled paper or styrofoam peanuts. If the bryophyte is drought tolerant, send it dry. If you are shipping aquatic

bryophytes, seal them with clean water in plastic bags and keep them cool. Use a rapid shipping method to ensure the best results. Don't provide nutrients as they will encourage growth of algae, fungi, and bacteria on the surface. I have had some success packing aquatic mosses with wet paper towels or newspaper, but heat will quickly spoil all your efforts.

Your first concern may be to keep the bryophytes alive, but getting them across the border might be even more challenging. Even within the same country, it might be necessary to have a **nursery license** to ship plants across state borders. For example, in North Carolina, the Department of Agriculture and Consumer Services requires a nursery license for shipping within the US (Annie Martin, Bryonet 8 December 2010). All live plants and bryophytes need to be inspected for nematodes, insects, or diseases in advance. A certificate documenting certification must be included in any shipment of live plants (bryophytes). For international shipments, at least from the USA, a local inspector must examine each and every shipment that leaves the country. Shipping overseas is a laborious process and shipping is costly.

Sharing Images

Many herbaria have web pages where they provide images of bryophytes. If you choose to set up your own web page, a few guidelines will make it more useful.

Make it clear what you consider fair use. If you prefer restricted use or permission, provide contact information for those seeking permission and make clear what information you will need to give that permission (*e.g.*, intended use, size and resolution, whether it will be modified, attribution, web address). When I (Glime) request images for this book, I state that the image is for an online book on Bryophyte Ecology <www.bryoecol.mtu.edu>, sponsored with no financial support by the International Association of Bryologists and the Department of Biological Sciences of Michigan Technological University. I clearly state that I will give credit for the image and ask if there is additional attribution they would like included besides the name of the photographer.

Sending large images by email can really slow down the system at both ends, so you might want to share images with specific individuals through a free downloadable program called DropBox <www.dropbox.com>. There are also a number of websites where you can post images that are available to everyone, or by becoming a "friend" for that group, much like FaceBook. If you give full permission for use, provide the attribution information you would like the user to include.

BE SURE OF IDENTIFICATION! It is okay to post species where your identification is doubtful, but be clear that it is doubtful, or ask for help when you post the picture.

Don't post pictures taken by anyone else without getting their permission and all the information discussed above.

Some posters restrict the resolution and size of the images they post to avoid having them used commercially for profit as posters, calendars, or advertisements. Many posters give permission for educational use, but not for other purposes. If you have no plans of publishing your

pictures, or using them for profit, why not give permission for all but commercial use? This book is built on the willingness of people to share. And the less time one must spend hunting for a contact person to gain permission, the more time can be spent on creating and sharing the final product.

Herbaria

There are numerous herbaria around the world, and many of them are able to loan specimens to other herbaria. When requesting specimens, it is important to state the use you will make of them and anticipated return date. If you need them for DNA or chemical analysis, or any other destructive sampling, be sure the loaning herbarium understands that. NEVER use type specimens for destructive sampling. And likewise, avoid using voucher specimens unless the destruction is necessary to verify identification or compare then and now. Try not to use the entire specimen.

Index

Herbariorum <<http://www.nybg.org/bsci/ih/ih.html>> provides a list of the registered herbaria of the world. The index lists 1610 herbaria in 117 countries. The site permits searching by institution, city, state, acronym, staff member, correspondent, and research specialty.

Herbarium Specimen Mapping

Some herbaria include a dot map on the herbarium label (Figure 50). Phytogeographers need to understand plant distributions, and floras typically include the distributions of the species. The size of the map depends on the level of detail needed for that herbarium or project. For instance, specimens collected for the BBS vice county records will have a dot in the county of collection.

Figure 50. Dot map for Michigan, USA, indicating location of a specimen in one county. From Voss 1996.

Computers have brought us mapping programs that greatly facilitate these tasks. Brent D. Mishler (Bryonet 13 July 2008) has alerted us about the free program BerkeleyMapper <<http://berkeleymapper.berkeley.edu/>>. This program uses Google maps and places GIS-based points on the maps.

The best way to look at a map is to run the query first at <http://ucjeps.berkeley.edu/bryolab/UC_bryophytes.html>. For example:

1. Search for Scientific name *Mnium* (or any other)
2. Submit query
3. Select on the return page the link: "Map the results using BerkeleyMapper (192 records with coordinates [those with a light green checkbox])"

Live Collections

Maintenance of live collections requires a solid background in the ecological and physiological needs of the species to be cultured. These details will be covered elsewhere in this volume. In the present chapter, we wish to caution you that cultured species may not look like the same species in the field. For genes to be expressed, the right nutrients must be present for development. Hence, caution should be used in using cultured bryophytes for taxonomic identifications. Nevertheless, live cultures are one way to maintain rare species on the verge of extinction.

An alternative to living, growing cultures, is cryopreservation. Michael Christianson (Bryonet 10 June 1999) reported that he had taken over the culture collection established by Malcolm Sargent and that he had begun using cryopreservation of the species, including successful cryopreservation of liverworts.

Cryopreservation

Before we have scratched the surface of the complexity of evolution and biogeographic pathways, many plants and animals are disappearing from the planet forever. We have struggled with our fossil record to make sense of the small samplings we have through time and we do not want to compound our struggle for understanding by losing the species we have today. Nature does not preserve species as fossils on a regular basis, so to ensure these disappearing taxa remain available for study, we as scientists must help out.

We have known for a very long time that most bryophytes have the ability to survive being frozen (Gubin *et al.* 2003), so our knowledge about cryopreservation for this group of animals already has a sound scientific basis. Some of the early studies on cryopreservation for scientific purposes have included bryophytes (Sugawara *et al.* 1980). But several bryologists led the way toward building a collection of cryopreserved endangered and rare bryophyte species (Burch & Wilkinson 2002; Burch 2003; Burch & Ramsay 2003).

Developing such a collection requires considerable testing to be assured that most of the cultures will survive and begin growth again. However, this method for conservation has advantages over the traditional live culture methods. It requires much less maintenance time once the species has been cryopreserved, and it is less

likely to get contaminated while frozen. Furthermore, cultured bryophytes tend to lose vigor over time and both their physical and physiological characters may change in the unnatural conditions of culture, making them look like a different species (Christianson 1998).

As in standard culture, it is desirable to obtain a pure culture free of algal and fungal contaminants. Burch and Ramsay (2003) and Christianson (1998) suggest eliminating algae by growing protonemata **in** (not on) a medium where they will grow toward the light. The photosynthetic ends of these protonemata will emerge from the medium free of algae.

Dehydration prior to freezing will minimize the formation of ice crystals that damage cells. Desiccation-tolerant species are able to survive the prolonged dehydration that makes this successful, but desiccation-intolerant species may not (Burch 2003). Survival of these intolerant species is more likely to be successful if the growth medium is supplemented with abscisic acid (ABA) and sucrose (see volume 1 for a discussion of desiccation tolerance in bryophytes) (Christianson 1998; Burch 2003; Burch & Ramsay 2003). Exact levels needed will require experimentation, with needs differing by species.

Preparation of the bryophytes can be important to their survival, and as you might expect, the ones from wet habitats lack desiccation tolerance, making them more difficult to preserve through cryopreservation (Burch 2003). Christianson (1998) found that only 3-4 days in a medium supplemented with 10^{-5} M ABA and 100 mM proline prepared the mosses *Ceratodon purpureus* (Figure 51), *Funaria hygrometrica* (Figure 52), *Physcomitrella patens* (Figure 53), and two species of *Sphagnum* (Figure 39) to survive at least one year in cryopreservation at -80°C .

Figure 52. *Funaria hygrometrica*, a disturbed habitat soil moss that survives when treated with ABA and proline prior to cryopreservation. Photo by Janice Glime.

Figure 53. *Physcomitrella patens*, a disturbed habitat soil moss that survives when treated with ABA and proline prior to cryopreservation. Photo by Janice Glime.

In a study of a desiccation-tolerant, a non-desiccation tolerant, and an intermediate-tolerant bryophyte, Burch verified this expectation (Figure 54Figure 57). Burch tested a protocol in which the moss protonemata were cultured on sucrose-free 1/2 strength MS medium (Murashige & Skoog 1962), pH 5.8, solidified with 3.5 g L^{-1} Gelrite®. These were cultured in 5 cm Petri plates sealed with Micropore® tape and maintained at $20 \pm 2^\circ\text{C}$ with 16:8 hour light:dark cycle. Light was provided by Growlux® and cool white fluorescent tubes ($22\text{--}29 \mu\text{mol m}^{-2} \text{ s}^{-1}$). After sufficient cultured material developed, the protonemata were air dried for 18 days with half the cultures encapsulated and half not. The **encapsulation** process started with a double thickness sterile filter paper cut into $0.5 \times 1.5 \text{ cm}$ strips placed into sucrose-free 1/2 MS, 3% sodium alginate (from Sigma) encapsulation medium. This medium was solidified using 100 mM calcium chloride solution. The two pieces of filter paper were separated so that one side was coated in alginate. 2-4 mm diameter circles of protonemata were embedded in the alginate, re-immersed in 3% sodium alginate, and set again using 100 mM calcium chloride solution (Wilkinson *et al.* 1998). Each strip of filter paper had only one sample protonemata, and each strip was placed separately in a 5 cm Petri plate. An equal number of samples was cultured the same way, but without the encapsulation procedure. When these were transferred onto fresh control media, and little

difference was visible between the cultures. After 18 days of dehydration in empty Petri plates sealed with Micropore® tape, they were again tested for viability. The three species exhibited 100% survival of the desiccation-tolerant species, 40% for the intermediate species, and 0% survival for the desiccation-intolerant species. After 18 days, one strip was placed in each cryovial and immersed directly into liquid nitrogen, cooling rapidly to -196°C . After 20 hours of cryopreservation, the protonemata were warmed rapidly by immersing the vials in a 40°C water bath for two minutes. The thawed samples were transferred once again to 12 MS medium and returned to the original cultural conditions. This procedure indicated that encapsulation did little to affect the survival of cryopreservation in these species. Hence, Burch concluded that for desiccation-tolerant species, pretreatment may be unnecessary.

Figure 56. *Cyclodictyon laetevirens*, a bryophyte that lacks desiccation tolerance and that has no survival following dehydration and freezing. Photo by Sean Edwards.

Figure 57. Comparison the effects of encapsulation in alginate on survival in a desiccation-tolerant (*Bryum rubens*), an intermediate-tolerant (*Ditrichum cornubicum*), and an intolerant (*Cyclodictyon laetevirens*) bryophyte species. Bars with the same letter are not significantly different from each other ($\alpha = 0.05$). Redrawn from Burch 2003.

Pence (1998) developed a protocol similar to that of Burch (2003), testing three liverworts and one moss. The thallose aquatic *Riccia fluitans* (Figure 36) was sensitive to desiccation and required either abscisic acid (ABA) pretreatment or encapsulation in alginate beads with 0.75 M sucrose to achieve 100% survival of drying. ABA had little effect on the leafy liverwort *Plagiochila* sp. (Figure 58); it survived with simply drying, encapsulation, and liquid N exposure. The thallose liverwort *Marchantia polymorpha* (Figure 59) required both ABA and encapsulation. Hence, ABA was needed as pretreatment for both thallose species to avoid total mortality upon drying. Rowntree and Ramsay (2009) reported that pretreatment methods, including ABA and encapsulation, were successful for 22 species of bryophytes having a broad range of moisture and other ecological requirements. Some species had 100% survival, and overall regeneration rates were more than 68% for all species tested.

Figure 58. *Plagiochila asplenoides*, member of a genus for which ABA had little effect on survival of cryopreservation. Photo by Dick Haaksma.

Duckett *et al.* (2004) suggest ways of streamlining the cryogenic process. Spores, gemmae, and vegetative fragments can be surface sterilized and grown in Petri plates on media with inorganic salts. Phytogel or Gelrite are preferable to most traditional agars because these are often toxic due to impurities. And some bryophytes benefit from dilution of nutrients. Spore availability can be extended by storing ripe capsules at 4°C. Temperatures >25°C can cause excess respiration and reduce the health of the propagule/culture; light intensity should be much lower than that in nature to prolong the culture viability.

Figure 59. *Marchantia polymorpha*, a thallose liverwort species that requires both ABA and encapsulation before cryopreservation. Photo by Jan-Peter Frahm.

Bryophytes such as *Ditrichum plumbicola* that produce specialized propagules may be easier to preserve through desiccation and cryopreservation (Rowntree *et al.* 2007). Some species cultured in preparation for cryopreservation will produce protonemal gemmae hitherto unknown in nature (*Ditrichum cornubicum*, *Saelania glaucescens*, *Seligeria camiolica*, and *Zygodon gracilis*) (Duckett *et al.* 2004). Protonemal gemmae suspensions are an ideal way to re-introduce these species to the natural environment.

Ditrichum plumbicola protonemata exhibited unexpectedly low survival of cryopreservation (Rowntree *et al.* 2007). Rowntree *et al.* (2007) found that pretreatment of *Ditrichum plumbicola* protonemata with ABA and sucrose caused protonemal growth to be arrested and propagules induced. Most protonemal cells died, but those that survived were characterized by thick, deeply pigmented walls, numerous small vacuoles, and lipid droplets in their cytoplasm. The protonemal propagules were highly

desiccation- and cryopreservation-tolerant, behaving like the desiccation tolerant rhizoids in the natural environment where they are induced by extreme conditions.

Not all mosses need to be cultured as protonemata to preserve well. Schulte and Reski (2004) used fresh plants to preserve 140,000 mutants by cryopreservation (Figure 60-Figure 61). They used a combination of several of the pre-treatment techniques described above, but with some additions. They used a complete Knop medium (Egener *et al.* 2002), amended with 920 mg L⁻¹ ammonium tartrate, 87 g L⁻¹ mannitol (Grimsley & Withers 1983), 10 µM ABA dissolved in DMSO (dimethyl sulfoxide), and 100 mM proline (Christianson 1998). The liquid medium was filter sterilized; the solid medium was supplemented with 1.2% (w/v) agar. Macro- and microelements, FeSO₄ x 7H₂O, glucose, and mannitol were autoclaved. The other supplements were filter-sterilized with a 0.22 µm millipore filter and added to the medium after it was autoclaved. The medium pH was adjusted to 5.8 before autoclaving and before filter sterilizing.

When You Depart – Willing Your Herbarium

Your personal herbarium is valuable, but non-botanists might not recognize its value (Miller 1988). Therefore, it is wise to be sure you have either included it in your will or your heirs understand its value and where it should go. Since herbaria will not always be willing to accept collections, it is wise to make arrangements with the receiving herbarium so you know they will accept your specimens. It is the responsibility of the receiving herbarium to let the bryological community know that they have received your herbarium. If your herbarium is a personal herbarium and is duplicated elsewhere, consider giving it to an exchange program or to a struggling bryologist where the herbarium is inadequate. And be sure provisions are made for return of any specimens you might have on loan.

Exchange Programs

Several of the bryological societies sponsor bryophyte exchange programs. For example, the ABLS (American Bryological and Lichenological Society) program has separate liverwort and moss exchanges. To join the program, one needs to send several species with five duplicates to the current appropriate director of exchange. For each specimen you send, you can select a species from the next exchange list. Hence, if you send six species with five specimens of each, you are eligible to receive 30 specimens from among the forthcoming lists. Specimens contributed must be of adequate size, typically palm size, but this depends on the abundance and size of the species. Sending rare species for exchange should be avoided. The packets must have complete label information, as discussed earlier in this chapter.

Borrowing Specimens

Funk (2007), US National Herbarium, has provided a good introduction into the many uses of a herbarium <<http://www.virtualherbarium.org/vh/100UsesASPT.html>>. Top among these uses for ecologists is to compare your specimens with those of others to verify your identification.

If you are not near with a large herbarium, it may be necessary to borrow specimens to verify your identifications. There is an etiquette for borrowing and asking in the right way is more likely to get you the specimens you need. Visit the New York Botanical Garden website for instructions on how to borrow specimens <<http://sciweb.nybg.org/science2/herb/tips.asp.html>>.

Type Specimens

You should only borrow type specimens when non-types will not do. This would include revisions of a genus or species when you must verify the original description. Type specimens must be handled with utmost care and returned to the loaning herbarium quickly. This method of verification may change somewhat as our use of molecular identification becomes more common and a larger database is available.

The first problem in borrowing a type specimen is to locate it. Generally there are multiple paratypes placed in multiple herbaria, but there is only one holotype. The location of the holotype can be determined by checking the Index

Herbariorum <<http://sciweb.nybg.org/science2/hcol/bryotypes/index.asp.html>>. Index Herbariorum provides the physical location of a herbarium, its web address, holdings (number and type of specimens), history, staff, areas of expertise of associated staff, and contact information. Only permanent collections with active management and accessibility to scientists are included.

When using Index Herbariorum, you can locate herbarium personnel by entering the person's name on the **Text Search** page. For example, when I entered "Deguchi," it provided me Person: Hironori Deguchi; Herbarium Acronym: HIRO; Institution: Hiroshima University; Location: Japan, Hiroshima; Research Pursuits: Taxonomy; morphology; and ecology of bryophytes.

To locate a herbarium where a type specimen is housed, one can use the Virtual Herbarium for Bryophytes and visit the **Type Specimen Catalog**.

Always return type specimens as quickly as possible by a method that insures they won't get lost.

Summary

Most bryophytes are stored in packets folded in thirds of a standard sheet of 100% rag paper. It is easy to make your own packet folding machine. Labels can be designed on a word processor or produced by a herbarium label program. Labels need to include **name of species**, **author** of the scientific name, **altitude**, **habitat**, **substrate**, **date** of collection, **location** (country, state, county, distance to nearest town), **GPS** coordinates, name of **collector**, **collection number**, and **determiner** (name of person identifying or verifying identification). Once they are placed into the herbarium collection, an accession number should be added. Packets with multiple species should indicate so; methods of storing and labelling depend on the purpose of the collection. Storage cabinets need to protect from pests but usually do not require moth balls. Keeping specimens dry is most important.

Herbaria have preferences for specimen storage, including boxes, drawers, folders, and herbarium sheets. Cool preservation works best, but is expensive. Minute species and special structures may require liquid preservation or minipackets. Arrangement in the herbarium may be alphabetical (for ease of filing) or phylogenetic (useful for systematic studies). Type specimens are usually indicated by red folders, but other marks of red can be used.

Killing inhabitants and soil pathogens is necessary for new collections, whether fresh from the field or obtained from another herbarium. This can be accomplished by Agral 600, moth balls, microwave, freezing, steam, insect traps, moisture control, or drowning.

A herbarium should be equipped with both dissecting and compound microscopes and equipment named in Chapter 2-1. Its workspace should include

good taxonomic references, and it helps to add indexing tabs. A computer station is useful for entering data, using online keys, updating nomenclature, making dot maps, and finding images, as well as making herbarium labels.

When shipping specimens to other countries, be sure you know and comply with pertaining laws. Most prohibit soil. Be sure the recipient knows they are coming, and whenever possible, ship to a herbarium where the recipient can receive them. There are many acts of courtesy that can help when you ask others to identify your specimens. Posting pictures online to ask for identification help should include as much information as possible, show habit, plant, leaf, and cross sections, and be kept small so as not to clog inboxes or be slow in loading. Be sure you have permission to post pictures that are not yours.

Living culture can maintain rare species and permit testing without decimating the extant populations. Cryopreservation can also maintain the genome for later study and cultivation.

Exchange programs are available through some of the societies, e.g. the American Bryological Society, where members of the program can exchange specimens with others in the group to build the diversity in a herbarium.

Herbaria can borrow specimens from each other, but loans to individuals might be refused. Type specimens are more likely to be carefully protected, so you might have to travel to the host herbarium.

Acknowledgments

Dale Kruse kindly sent me a printout of all the emails he received on Bryonet and offline regarding herbarium practices.

CHAPTER 1-1

AQUATIC AND WET ANTHOCEROTOPHYTA

Figure 1. *Phymatoceros bulbiculosus* with capsules, a species that can occur in European streams and rivers. Photo by Ken Kellman, through Creative Commons.

Nomenclature for this chapter is based primarily on Söderström *et al.* (2016). In addition, Lars Söderström provided me with correct names for species that I could not link to the names on that list. TROPICOS also permitted me to link names by tracking the basionym. I have ignored varieties, forms, and subspecies unless I could verify a current name for them. These unverifiable taxa have been included in the species. Listed synonyms are those I encountered in the aquatic literature and are not complete with all possible synonyms.

To develop this list, I used my own bibliography, collected over the past 56 years, and Google Scholar. These papers soon led me to others. I do not pretend that this is complete. It concentrates on streams, but includes lakes and other wetlands. It deliberately ignores bogs and mostly ignores fens, but nevertheless includes a few of these species because they were found in a wetland study. Bogs and poor fens have been treated in whole books and provide an extensive literature; fens seem somewhat less studied. They would require considerably more review and time. Thus I felt that less-reviewed topics, particularly the aquatic habitats with which I am most familiar, should be

given priority. Nevertheless, some of the citations took me into that literature.

Many of the species on this list are not typical wetland or aquatic species. They were, however, found in a wetland or aquatic study. Their relative frequency can be suggested based on the number of references cited.

The **Anthocerotophyta** (hornworts) is a small group when compared to the other two bryophyte phyla. Few of these occur in wet habitats, although some have been reported from mountain streams. Four of the five families have appeared among the studies cited herein.

Anthocerotaceae

Most systematic treatments include only *Anthoceros* and *Folioceros* in this family, but a number of studies use the name *Aspiromitus*, a genus that is considered a synonym of *Anthoceros* by Söderström *et al.* (2016), but some species have not been studied sufficiently to determine their affinities. These are listed here in *Aspiromitus* until their affinities are better understood.

Anthoceros (Figure 2, Figure 5, Figure 6, Figure 7)

The genus *Anthoceros* (Figure 2, Figure 5, Figure 6, Figure 7) occurs mostly on **arable** (suitable or used for growing crops) fields (Porley 2020). My own limited experience suggests that it is a non-competitor that benefits from the disturbance and reduction of "weeds" as competitors in such situations. It is perhaps these same factors that permit it to occasionally live in wet habitats.

***Anthoceros agrestis* (Figure 2)**

(syn. = *Anthoceros punctatus* var. *cavernosus*)

Distribution

Anthoceros agrestis (Figure 2) occurs primarily in the temperate zone in central Europe, ranging in northern and eastern Europe as well (Paton 1979), but is rather rare in the Mediterranean-Atlantic parts (www.iucnredlist.org). It grows in arable fields and gardens, or in ditches in open habitats or woodlands (www.iucnredlist.org).

Figure 2. *Anthoceros agrestis* with capsules in an area that becomes muddy. Photo by Michael Lüth, with permission.

Aquatic and Wet Habitats

The only wetland/aquatic study that I found including this species reported it in mountainous streams on Madeira Island, Portugal (Luis *et al.* 2015). *Anthoceros agrestis* (Figure 2) is not uncommon, but difficult to find, because both the thallus and sporophytes are short-lived, and tend to occupy ephemeral habitats, such as the still-wet soils of receding rivers and lakes in the spring. In New Brunswick, Canada, it is found on wet soil and humus in boggy habitats (Haughian 2019). Kresáňová (2002) reported it from Slovakia, where it has been under-recorded. Paton (1979) considered it to have a more restricted distribution and ecology than that of *Anthoceros punctatus* (Figure 6-Figure 7).

Reproduction

Anthoceros agrestis (Figure 2) is **monoicous** (having male and female reproductive organs on same plant) (Paton (1979). The antheridia may number up to 45 in a chamber. Archegonia are embedded in the thallus and the egg is enclosed within that thallus. Szövényi *et al.* (2015) demonstrated its advantages as a model organism,

demonstrating that the plants grew faster when provided with continuous light than when given long-day photoperiods when the light was at or below $300 \mu\text{E m}^{-2} \text{s}^{-1}$. In the British Isles, it is a summer annual. Sporophytes (Figure 2) mature July to December. Colonies of *Nostoc* sp. (Figure 4) occur in mucilage cavities scattered in the ventral tissue.

Figure 3. *Anthoceros* thallus cs showing large parenchyma cells and pore with *Nostoc*. Photo from Botany Website, UBC, with permission.

Figure 4. *Nostoc* from *Anthoceros agrestis*. Photo by Ralf Wagner <www.dr-ralf-wagner.de>, with permission.

Biochemistry

Several biochemical studies have used this hornwort as a model organism. These have revealed alkaloids, a number of glutamic acids (Trennheuser *et al.* 1994), and cinnamic acid (accumulated as rosmarinic acid) (Peterson 2003). Soriano *et al.* (2018) considered that rosmarinic acid might aid in UV filtering, but none of the variables they measured seemed to respond significantly to the UV exposures used in the experiments. However, all of them had an increasing trend under the combination of PAR UV-A UV-B radiation.

***Anthoceros caucasicus* (Figure 5)**

Distribution

Anthoceros caucasicus (Figure 5) is European (GBIF 2019), occurring mostly in Macaronesia, with a few localities in the Azores, Portugal, Italy, southern Spain, and the Caucasus (During *et al.* 1996). The only wetland study in which I found this species is that of Luis *et al.* (2015) in mountainous streams on Madeira Island, Portugal. In a broader search on the species, I found that in 1994, it was discovered along a rivulet in The Netherlands (During *et al.* 1996).

Reproduction

It is **dioicous** (having separate male and female plants) in The Netherlands, but **monoicous** elsewhere (During *et al.* 1996). These plants in The Netherlands apparently originated from the large spores that were buried when the site was covered by sand 35 years earlier. The land was unfertilized at the time of discovery. Its general habitat includes rural mosaics with forest, hedges, pastures, and crops, as well as sublittoral sediment (GBIF (2019). In addition, GBIF (2019) reports it from sublittoral sediment, in addition to its presence in rural mosaic habits of woods, hedges, pastures, and cropland.

Figure 5. *Anthoceros caucasicus*, a stream that sometimes includes streams and rivulets among its habitats. Photo by Rosalina Gabriel, with permission.

***Anthoceros punctatus* (Figure 6-Figure 7)**

Distribution

Anthoceros punctatus (Figure 6-Figure 7) occurs in Europe, Asia, and North and South America (MBG 2020).

Aquatic and Wet Habitats

Anthoceros punctatus (Figure 6-Figure 7) presents near absence in wetland studies; like the previous species, only one of the wetland studies I have reviewed reports this species, likewise from mountainous streams on Madeira Island, Portugal (Luis *et al.* 2015). By contrast, Wagner (2011) reports that in Oregon, USA, it occurs mostly on recently disturbed soil in urban areas and is not common away from towns.

Figure 6. *Anthoceros punctatus* with sporophytes, in Madeira, Portugal. Photo by Michael Lüth, with permission.

Figure 7. *Anthoceros punctatus* with maturing sporophytes beginning to dehisce. Photo by Malcolm Storey, with online permission.

Role

A well-known symbiosis occurs between members of the **Anthocerotophyta** and **Cyanobacteria**. Campbell and Meeks (1989) found that all *Nostoc* (Figure 4) species that

were able to become symbionts in association with *Anthoceros punctatus* (Figure 6) formed **hormogonial filaments** (gliding filaments; Figure 8) in great frequency in its presence. The production of hormogonia was induced when *A. punctatus* grew in nitrogen-limited culture conditions. These symbiotic filaments lacked **heterocysts** (Figure 6), were mobile, and were comprised of "distinctly" smaller cells than those of "vegetative" filaments. These small cells were the result of continued cell division without biomass increase. During this time of rapid division, nitrogen fixation disappeared and CO₂ fixation decreased by 30%, accompanied by a 40% reduction in NH₄⁺ assimilation. These, however, returned to normal rates within 72 to 96 hours after hormogonia induction. Likewise, the hormogonia reverted to their vegetative growth state and differentiated heterocysts. One mutant was able to form chill-resistant akinetes.

Figure 8. *Nostoc punctiforme*, a *Cyanobacterium* that can be a symbiont in cells of *Anthoceros punctatus*. The colorless round cell at the lower left is a **heterocyst**. Photo from UTEX, through Creative Commons.

Wong and Meeks (2002) examined the ability of non-heterocystic strains of the *Cyanobacterium Nostoc punctiforme* (Figure 8) to form a symbiotic relationship with *Anthoceros punctatus*. With ammonium deprivation, vegetative cells of another *N. punctiforme* mutant randomly lysed, thus forming short filaments (**hormogonia**). These mutants were equally able to infect the hornwort compared to the wild type, but the association did not support the growth of the hornwort.

Fungal Interactions

The symbioses of this species are of interest regarding both its ecology and its evolution. When spores of the *Glomales* fungus *Claroideoglomus claroideum* (syn. = *Glomus claroideum*) (*Basidiomycota*; Figure 9) contact the thalli of *Anthoceros punctatus* (Figure 6-Figure 7), they develop hyphae that appear within the thallus as branched hyphae (Schüßler 2000). By 45 days in culture, these have formed arbuscules and vesicles. This is the first record of an identified Glomalean arbuscular mycorrhiza-like symbiosis with a bryophyte.

Figure 9. *Claroideoglomus claroideum*, an endophytic fungus that can occur within cells of *Anthoceros punctatus*. Photo by V. A. Silvani, M. Pèrgola, and S. Fracchia, through Creative Commons.

Aspiromitus (Figure 10)

Most of the members of the genus *Aspiromitus* (Figure 10) have been included in the genus *Anthoceros* (Figure 2, Figure 5, Figure 6, Figure 7) (Söderström *et al.* 2016). The four listed here have not yet been transferred or synonymized and must therefore still be treated in the genus *Aspiromitus*. Their apparent limited distribution has left them as neglected taxa. All of them are reported in only one paper on wetlands, that by Ruttner (1955).

Aspiromitus asper

Aspiromitus asper can occur in wetland areas in the tropics (Ruttner 1955). It is reported from Java (Söderström *et al.* 2010). I have been unable to find additional information on its distribution or ecology.

Aspiromitus bullosus

Aspiromitus bullosus can occur in wetlands in the tropics (Ruttner 1955). It likewise has been reported from Java (Söderström *et al.* 2010)

Aspiromitus lobatus (Figure 10)

For *Aspiromitus lobatus* (Figure 10) Ruttner (1955) gave the most information, indicating that it occurs above water level, in water spray in the tropics. Söderström *et al.* (2010) reported the species from Java.

Figure 10. *Aspiromitus lobatus*, a species that can grow in waterfall spray in the tropics. Photo through Creative Commons.

Aspiromitus squamulosus

Ruttner (1955) indicated that *Aspiromitus squamulosus* occurs over water in the tropics. Information on this species is so scarce that I am unable to determine where it is known to occur.

***Folioceros* (Figure 11, Figure 12)**

Folioceros (Figure 11, Figure 12) is a tropical and subtropical genus in and near Asia, where it grows on moist rocks, in fallow fields, and near waterfalls (Wikipedia 2019).

***Folioceros fuciformis* (Figure 11)**

(syn. = *Aspiromitus falsinervius*)

Folioceros fuciformis (Figure 11) is often reported in checklists from various tropical locations and countries in Asia (TROPICOS 2020a), but its habitat is not included.

Figure 11. Wet *Folioceros fuciformis* with capsules, a species that lives in the zone above the water level in the tropics. Photo by Li Zhang, with permission.

Aquatic and Wet Habitats

The only wetland record I could find was that of Ruttner (1955), indicating that it occurs up to about 30 cm above water level in the tropics. The only labels in the online Consortium of North American Bryophyte Herbaria are from Hawaii, Micronesia (on steep clay and sand bank, associated with *Philonotis revoluta* and *Selaginella* sp.), Guam (abundant on moist clay bank), and India (in dense jungle beside a stream on a moist cliff and in wet soil of marshy area in jungle).

***Folioceros glandulosus* (Figure 12)**

(syn. = *Aspiromitus glandulosus*)

Folioceros glandulosus (Figure 12) is known from waterfalls in the Asian tropics (Ruttner 1955; TROPICOS 2020b). Like *Folioceros fuciformis* (Figure 11), little information seems to be published about it.

Figure 12. *Folioceros* cf. *glandulosus*, a species that occurs in waterfalls of the Asian tropics. Photo by Li Zhang, with permission.

Dendrocerotaceae

***Megaceros* (Figure 13)**

Of the nine species of *Megaceros* (Figure 13) listed by Söderström *et al.* (2016), only two occurred in the wetland studies I reviewed. Both are primarily tropical.

***Megaceros flagellaris* (Figure 13)**

(syn. = *Megaceros salakensis*)

Distribution

Megaceros flagellaris (Figure 13) is widely distributed in the Eastern Hemisphere, especially the tropics, including Angola, China, Japan, India, Sri Lanka, Thailand, Philippines, Borneo, Indonesia, Papua New Guinea, New Caledonia, Samoa, Society Islands, Tahiti, Hawaii, Vanuatu, Australia, New Zealand, and Tanzania (Chantanaorrapint 2014; Ruklani *et al.* 2016).

Figure 13. *Megaceros flagellaris* with sporophytes, a species of waterfalls and permanently wet habitats, among others. Photo by Scott Zona, through Creative Commons.

Aquatic and Wet Habitats

Ruttner (1955) reported *Megaceros flagellaris* (Figure 13) from waterfalls in the tropics. Cargill *et al.* (2013) considered its typical habitat to be shaded soil, over pebbles, rocks, and boulders, on fallen logs, and at the bases of tree ferns. It is usually in permanently wet habitats such as streambanks or in creeks and streams. In Thailand, Chantanaorrapint (2014) found it on wet rocks and tree logs in shady areas inside the forest. Ruklani *et al.* (2016) found this species on wet rocks and tree logs, in shady areas inside the forest of Sri Lanka.

Reproduction

The species is **monoicous** (Chantanaorrapint 2014). Desirò *et al.* (2013) did not find any colonization of this species by fungi, although some other **Anthocerotophyta** are known to serve as suitable substrates.

Megaceros tjibodensis

The only wetland or aquatic report for *Megaceros tjibodensis* is in the listing of Ruttner (1955) for the tropics. None of the online label publications by the Consortium of North American Bryophyte Herbaria includes habitat information except an occasional mention of forest. From these labels, we learn that the species occurs in montane forest in Micronesia and *Myristica* forest of the Caroline Islands. Other locations include Indonesia and Java.

Phymatocerotaceae

Phymatoceros (Figure 1, Figure 14-Figure 16)

Phymatoceros (Figure 1, Figure 14-Figure 16) is the only genus in this family (Söderström *et al.* 2016) and only one of its two species occurred in the aquatic/wetland studies reviewed here.

Phymatoceros bulbiculosus (Figure 1, Figure 14)

(syn. = *Phaeoceros bulbiculosus*)

Distribution

Proskauer (1957) reports *Phymatoceros bulbiculosus* (Figure 1, Figure 14) as widespread in the Mediterranean region of Europe and Africa, and it is also present in North and South America.

Aquatic and Wetland Habitats

Phymatoceros bulbiculosus (Figure 1, Figure 14) is the only member of this small family of two species (Söderström 2016) that seems to be reported from any wetland or aquatic habitat. Ferreira *et al.* (2008) reported it from rivers. Luis *et al.* (2015) found it in mountain streams on Madeira Island, Portugal.

Distribution and Wet Habitats

It occurs on shaded soils in slow-to-dry or summer-dry habitats (Doyle & Stotler 2006). These include hillsides, creek banks, road and trail banks, and margins of sloping meadows. Kresáňová (2002) reported the species as *agricolous* in Slovakia, but protected (red-listed), suggesting that it might be under-recorded.

Figure 14. *Phymatoceros bulbiculosus*, a species that can occur in rivers and mountain streams. Photo by David Wagner, with permission.

Reproduction

The species is **ephemeral** (short-lived), appearing in open sites during the rainy season and producing abundant tubers (Figure 15-Figure 16) (Stotler *et al.* 2005) that presumably permit its survival when in a dormant state resulting from insufficient water.

This perennial species is distinguished from the other species of *Phymatoceros* by the presence of stalked tubers on the ventral thallus surface (Figure 15-Figure 16) (Doyle & Stotler 2006). In some cases, the population consists entirely of only males or only females, persisting through these tubers.

Figure 15. *Phymatoceros bulbiculosus* showing numerous ventral tubers. Photo by Donna Pomeroy, through Creative Commons.

Figure 16. *Phymatoceros bulbiculosus* with young tubers. Photo by David Wagner, with permission.

Notothyladaceae

Phaeoceros (Figure 18-Figure 21)

This genus has 34 species recognized by Söderström *et al.* (2016). Of these, only two have been reported among the aquatic/wetland species reported here.

Ridgeway (1967a) described the *Nostoc* (Figure 17) relationship in the genus *Phaeoceros*. The *Nostoc* enters the thalloid cavities and produces typical globose **endophytic** (occurring within plant tissues) colonies. In this event, or when the *Nostoc* is cultured on a nitrogen-free substrate, but in intimate contact with the *Phaeoceros* thalli, **chlorosis** (abnormal reduction of green color in plant tissues) did not occur to the degree that it occurred in control cultures. Ridgeway considered this evidence that the *Nostoc* fixed nitrogen that was available to the hornworts. He also suggested that *Nostoc* might benefit if it could catabolize the carbohydrate components of the mucilaginous thalloid cavity.

Figure 17. *Nostoc* (brown) in hornwort. Note the strings of round cells that form the hormogonia. Photo by Chris Lobban, with permission.

Phaeoceros carolinianus (Figure 18)

(syn. = *Anthoceros carolinianus*, *Anthoceros laevis* var. *carolinianus*, *Phaeoceros laevis* var. *carolinianus*)

Phaeoceros carolinianus (Figure 18) is a worldwide, ubiquitous species (Campbell & Outred 1995; Cargill & Fuhrer 2008). It was reported in only one wetland aquatic study included here; Ferreira *et al.* (2008) reported it from rivers. It is known in Australia from banks of waterways, as well as more terrestrial locations. This is the most common of the *Phaeoceros* species in New Zealand (Campbell & Outred 1995).

Figure 18. *Phaeoceros carolinianus* with capsules, a species for which wet habitats include rivers and stream banks. Photo by Hermann Schachner, through Creative Commons.

Reproduction

This is a **monoicous** species (Cargill & Fuhrer 2008). Penjor *et al.* (2016) reported that no tubers were present on this species at Coi Suthep, Chiang Mai, Thailand, despite their widespread occurrence among hornworts as a means of surviving unfavorable conditions. They suggested that the habitat might not be suitable for their formation. The **antheridia** (Figure 19) follow the typical pattern of green when young, turning yellow-orange at maturity. This color change results from the loss of green chlorophyll due to conversion of chloroplasts to chromoplasts in the antheridial cells. The genus is characterized by yellow spores with spines (Figure 20). In their study in Thailand, Penjor *et al.* (2016) found that the sporophyte tissue can continue spore production throughout the growing season.

Figure 19. *Phaeoceros* antheridia in their yellow-orange mature stage. Photo by George Shepherd, through Creative Commons.

Figure 20. *Phaeoceros carolinianus* spores SEM. Photo by Christine Cargill, through Creative Commons.

Phaeoceros laevis (Figure 21)

Distribution

(syn. = *Anthoceros laevis*)

Phaeoceros laevis (Figure 21) is cosmopolitan, occurring in North America, South America, Europe, and Asia, but avoiding more northern locations above 60° N latitude (Schuster 1992). It has been reported from South Island, New Zealand, but the Southern Hemisphere records should be viewed with caution, as they are probably all misidentified *Phaeoceros carolinianus* (Figure 18) (Cargill & Fuhrer 2008).

Aquatic and Wet Habitats

Phaeoceros laevis (Figure 21) occurs on moist rock surfaces or springy banks of ravines in Connecticut, USA (Nichols 1916). Watson (1919) reported that it occurs on ground associated with fast water. In South Island, New Zealand, plants so-named are positively correlated with bankfull discharge in 48 streams (Suran & Duncan 1999). It survives in steep streams in the high rainfall area of South Island, New Zealand (Lepp 2012). For *Phaeoceros laevis* there was little or no difference in drag forces between bare rocks and hornwort-bearing rocks (Lepp 2012). *Phaeoceros laevis* can be found in rivers (Ferreira *et al.* 2008); and occurs in mountainous streams in Madeira Island, Portugal (Luis *et al.* 2015).

Figure 21. *Phaeoceros laevis* with sporophytes, a Northern Hemisphere hornwort that occurs in rivers, streams, and on wet soil. Photo by David Holyoak, with permission.

This species is common in areas that have abundant moisture, including moist soil in fields, sides of ditches and streams, and is sometimes even submerged (Isaac 1941).

Reproduction

One of the earliest reports of *Phaeoceros laevis* (Figure 21) is that it can be **aposporous** (producing $2n$ gametophytes from sporophyte tissue with no meiosis) (Lang 1901). It is dioicous (Cargill & Fuhrer 2008) and behaves as a short-day plant for antheridial initiation, but requires no critical temperature for initiation (Ridgeway 1967b). It grows well and forms gametangia at both 10°C and 21°C under **short-day** (occurring only after being exposed to light periods shorter than a critical length, as in early spring or fall) conditions, whereas liverworts and mosses in the same experiment were more specific in their requirements (Benson-Evans 1964).

Fungal Interactions

In addition to *Nostoc* (Figure 17) symbionts, Ligrone (1988) identified an aseptate fungus living as an endophyte in *Phaeoceros laevis* (Figure 21). This fungus forms **extracellular** (on outside of cell) thick-walled hyphae, **intercellular** (between cells) thin-walled hyphae, and **intracellular** (within cells) **arbuscules** (treelike growth of filaments in certain mycorrhizal fungi). **Vesicles** (swollen end cells, thought to be storage organs for food reserves in fungi) can be formed by either inter or intracellular hyphae that swell. These are common in summer. The fungus colonizes the host parenchyma, but is absent at the growing apices and epidermal cells. The infected cells of the hornwort increase their cytoplasmic contents while the chloroplast loses starch and its **pyrenoid** (protein body in chloroplasts of algae and hornworts, involved in carbon fixation and starch formation and storage). The arbuscule forms numerous convoluted branches intermingled with the **arbuscular hyphae** (Figure 22-Figure 23). Eventually the arbuscule degenerates, leaving intracellular clumps of collapsed hyphae. These hornwort cells can become re-infected. Ligrone and Lopes (1989) reported that in some strains of this hornwort **sessile** (unstaked) or shortly stalked tubers can form near the growing points or on the ventral surface.

Summary

Four families of hornworts have members that are associated with aquatic or wetland habitats. These representatives are rarely submersed. Some have Cyanobacteria partners that aid by producing usable nitrogen through nitrogen fixation. Others have associated fungi, but their role requires further investigation.

Anthoceros agrestis, *Anthoceros caucasicus*, *Anthoceros punctatus*, *Megaceros flagellaris*, *Phymatoceros bulbiculosus*, and *Phaeoceros laevis* occur in streams, especially mountain streams.

Acknowledgments

I appreciate Lars Söderström, who helped me find the current acceptable names for a number of older taxa. Thank you to all those who have put their images in Creative Commons or given me permission to use them. Llo Stark has contributed by noting minor errors in the chapter.

CHAPTER 1-2

AQUATIC AND WET MARCHANTIOPHYTA, CLASS JUNGERMANNIOPSIDA, ORDER JUNGERMANNIALES: CEPHALOZIINEAE 1

Figure 1. Alpine tundra lake, late snowbeds, and small streams where some members of the **Cephaloziineae** may take advantage of the longer availability of moisture. Photo courtesy of Bob Janke.

Nomenclature for the liverwort subchapters is based on Söderström *et al.* (2016). In addition, Lars Söderström provided me with correct names for species that I could not link to the names on that list. TROPICOS also permitted me to link names by tracking the basionym. I have ignored varieties, forms, and subspecies unless I could verify a current name for them. These unverifiable taxa have been included in the species.

As in the subchapter on **Anthocerotophyta**, I used my own bibliography, collected over the past 56 years, and Google Scholar. These papers soon led me to others. I searched in Google Scholar for additional information on the species in that constructed list. I do not pretend that this is complete. It concentrates on streams, but includes lakes and other wetlands. It deliberately ignores bogs and mostly ignores fens, but nevertheless includes a few of these species because they were found in one or more other wetland studies. Bogs and poor fens have been treated in

whole books and provide an extensive literature; fens seem somewhat less studied. They would require considerably more review and time. Thus I felt that less-reviewed topics, particularly the stream habitats with which I am most familiar, should be given priority.
